ABSTRACT BOOK

SETAC EUROPE 33RD ANNUAL MEETING

30 APRIL–4 MAY 2023 | DUBLIN, IRELAND + ONLINE

"DATA-DRIVEN ENVIRONMENTAL DECISION-MAKING"

Abstract Book

SETAC Europe 33rd Annual Meeting

Table of Contents

This book compiles the abstracts from the 33rd annual meeting of the Society of Environmental Toxicology and Chemistry – Europe (SETAC Europe), conducted from 30 April–4 May 2023 in Dublin, Ireland, and online.

The abstracts are reproduced as submitted by the author and accepted by the scientific Committee. They appear in order of abstract code and alphabetical order per presentation type. The poster spotlight abstracts are included in the list of poster abstracts. The presenting author of each abstract is highlighted in bold.

The information in this abstract book reflects the status of the abstracts as was on 14 April.

No part of this publication may be reproduced, stored in a retrieval system, or transmitted in any form or by any means, electronic, electrostatic, magnetic tape, mechanical, photocopying, recording, or otherwise, without permission in writing from the copyright holder. SETAC Europe's consent does not extend to copying for general distribution, for promotion, for creating new works, or for resale. Specific permission must be obtained in writing from SETAC for such copying. Direct all inquiries to SETAC Europe.

Society of Environmental Toxicology and Chemistry Europe (SETAC Europe)

About SETAC

In the 1970s, no forum existed for interdisciplinary communication among environmental scientists, biologists, chemists, toxicologists, managers, engineers or others interested in environmental issues. The Society of Environmental Toxicology and Chemistry (SETAC) was founded in North America in 1979 to fill the void and quickly saw dynamic growth in the Society's membership, meeting attendance and publications.

A unique strength of SETAC is its commitment to balance the scientific interests of government, academia and business. The Society by-laws mandate equal representation from these three sectors for officers of the World Council and Geographic Unit Boards of Directors and Councils, and in the composition of committees and other society activities. The proportion of members from each of the three sectors has remained nearly equal over the years.

The Society is concerned about global environmental issues. Its members are committed to Environmental Quality Through Science®, timely and effective communication of research, and interactions among professionals so that enhanced knowledge and increased personal exchanges occur. Therefore, SETAC publishes two globally esteemed scientific journals and convenes annual meetings around the world, showcasing cutting-edge science in poster and platform presentations. Because of its multidisciplinary approach, the scope of the science of SETAC is broader in concept and application than that of many other societies.

SETAC's growth is reflected in the founding of Geographic Units around the world. SETAC Europe was established in 1989 as an independent organisation, followed by SETAC Asia-Pacific in 1997 and SETAC Latin America in 1999. In 2002, the four existing organisations joined together under the governance of the SETAC World Council. SETAC Africa is the most recent Geographic Unit, which was adopted in 2012. As evidence of international acceptance of the SETAC model and of the great interest at the local level, regional chapters and branches have emerged in a number of countries.

SETAC publishes two journals, *Environmental Toxicology and Chemistry* (ET&C) and *Integrated Environmental Assessment and Management* (IEAM). ET&C is dedicated to furthering scientific knowledge and disseminating information on environmental toxicology and chemistry, including the application of these sciences to risk assessment. Integrated Environmental Assessment and Management focuses on the application of science in environmental decision-making, regulation and management, including aspects of policy and law, and the development of scientifically sound approaches to environmental problem solving. Together, these journals provide a forum for professionals in academia, business, government and other segments of society involved in the use, protection and management of the environment for the enhancement of ecological health and human welfare.

SETAC books provide timely in-depth reviews and critical appraisals on scientific subjects relevant to understanding a wide range of contemporary topics pertaining to the environment. These include any aspect of environmental chemistry, toxicology, risk assessment, risk management or environmental policy.

SETAC has two administrative offices, in Pensacola, Florida, USA, established in 1992, and in Brussels, Belgium, established in 1993.

Track 1: Environmental and Human Toxicology: From Molecules to Organisms, From Omics to in Vivo

1.01.A Alternative Approaches to Animal Testing for Ecotoxicity Assessments: Exploring Approaches and Avenues for the Future

1.01.A.T-01 EcoToxChip Test System: A Toxicogenomic New Approach Method (NAM) for Chemical Prioritization and Environmental Management

Nil Basu[1]*, Markus Hecker*[2]*, Doug Crump*[3]*, Jessica Head*[4]*, Natacha S Hogan*[2]*, Jianguo Xia*[1]*, Gordon Hickey*[1] *and Steven Maguire*[5]*, (1)McGill University, Canada, (2)Toxicology Centre, University of Saskatchewan, Canada, (3)Ecotoxicology and Wildlife Health Division, Environment and Climate Change Canada, National Wildlife Research Centre, Ottawa, Canada, (4)Faculty of Agricultural and Environmental Sciences, McGill University, Canada, (5)University of Sydney, Australia*

In response to regulatory and stakeholder calls for New Approach Methods (NAMs), since 2016 our team has set forth to develop, test, validate, and commercialize toxicogenomic solutions (i.e., EcoToxChips, and a data evaluation tool, EcoToxXplorer.ca) for the characterization, prioritization, and management of environmental chemicals and complex mixtures of regulatory concern. EcoToxChips have been developed for common models (fathead minnow, Japanese quail, *Xenopus laevis*) and native species (rainbow trout, Northern leopard frog, double-crested cormorant). EcoToxChips are now being tested according to a validation plan that has been reviewed by regulatory partners in Environment and Climate Change Canada. To date, more than 1,800 EcoToxChips have been analyzed and in this presentation we will summarize key findings from our case studies. In brief, case studies to date consist of 28 distinct chemicals as well as four complex environmental samples. Two of the chemicals are being tested in a dose-response manner in three independent laboratories. In addition, four of the chemicals are tested in multiple species (species read-across), and four chemicals are being tested both *in vivo* and *in vitro*. For most test chemicals, dose-response (i.e., to derive transcriptomics points of departures) and RNA-seq data (i.e., to evaluate cross-platform comparisons) are available. Exposure studies are complete for 22/28 chemicals and all four complex environmental samples. Notably, 10 of the 28 chemicals are of regulatory interest. The interpretation of EcoToxChip results is facilitated through a user-friendly and intuitive cloud-based tool (EcoToxXplorer.ca) that continues to evolve based on feedback. EcoToxXplorer now integrates with information from the AOPwiki and includes EcoToxModule gene sets designed for interpretation of toxicogenomics data. Taken together, these diverse studies demonstrate how the EcoToxChip Test System can serve as a toxicogenomic New Approach Method that is accessible, standardized, and user-validated. Importantly, many partners have regulatory interests, and so the case studies are helping us to purposefully design the Test System to be one that can be used quantitatively as a decision support tool in regulatory applications including chemical prioritization and guideline development.

1.01.A.T-02 Transcriptomic Profile of Protein-Coding Genes Across Multiple Life Stages of Six Ecologically Relevant Vertebrate Species

Krittika Mittal[1]*, Jessica Ewald*[2]*, Doug Crump*[3]*, Jessica Head*[4]*, Natacha S Hogan*[5]*, Markus Hecker*[5]*, Jianguo Xia*[2] *and Nil Basu*[2]*, (1)Natural Resource Sciences, McGill University, Canada, (2)McGill University, Canada, (3)Ecotoxicology and Wildlife Health Division, Environment and Climate Change Canada, National Wildlife Research Centre, Ottawa, Canada, (4)Faculty of Agricultural and Environmental Sciences, McGill University, Canada, (5)Toxicology Centre, University of Saskatchewan, Canada*

As part of the EcoToxChip project, 49 distinct exposure studies were conducted on three lab model species (Japanese quail, fathead minnow, African clawed frog) and three ecologically relevant species (double crested cormorant, rainbow trout, northern leopard frog), at multiple life stages (embryo, adult), exposed to eight chemicals of environmental concern (ethinyl estradiol-EE2, hexabromocyclododecane-HBCD, lead-Pb, selenomethionine-SeMe, 17β trenbolone-TB, chlorpyrifos-CPF, fluoxetine-FLX, and benzo[*a*]pyrene-BaP. Whole transcriptome analyses were conducted on these samples resulting in a rich RNA-seq dataset covering various species, life stages, and chemicals, which is one of the largest purposeful complications of RNA-seq data within ecotoxicology. Recently, a unified bioinformatics platform of relevance to ecotoxicology, EcoOmicsAnalyst and ExpressAnalyst, was developed to facilitate RNA-seq analysis of nonmodel species lacking a reference transcriptome. The platform uses the Seq2Fun algorithm to map RNA-seq reads from eukaryotic species to an ortholog database comprised of protein sequences from >600 eukaryotic species (EcoOmicsDB) with a translated search. The availability of these tools presents a unique opportunity to examine the EcoToxChip RNA-seq dataset for cross-species comparisons. Accordingly, the objectives were to A) demonstrate the utility of EcoOmicsAnalyst for comparative transcriptomic analysis across multiple datasets, and present a single repository for the EcoToxChip RNAseq dataset, B) conduct integrative analysis of the baseline transcriptomic profile across all species and life stages, and C) look at differential gene expression across all species-life stage-chemical combinations. From the preliminary PCA of the transcriptomic profile, the first principal component captured variability across the tissue types, the second captured variability across the species families, and subsequent principal components captured variability within the species, and effects of chemical exposure. Exposure to TB and HBCD resulted in the fewest number and to EE2 resulted in the greatest number of differentially expressed genes across species. This work shows the potential of the EcoOmicsAnalyst and Seq2Fun platform to facilitate fast and simple analysis of RNA-seq datasets from nonmodel organisms with unannotated genomes and conduct comparative transcriptomic analysis across various species and life stages for cross-species extrapolation.

1.01.A.T-03 Development of a Novel Computational Pipeline to Identify Biomarkers of Reproductive Toxicity in Fish

Roman Li[1,2]*, Vid Modic Modic*[3]*, Ziva Ramsak*[3]*, Stephan Fischer*[2]*, Kristin Schirmer*[1] *and Anze Zupanic*[4]*, (1)Environmental*

Toxicology, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Dübendorf, Switzerland, (2)aQuaTox-Solutions GmbH, Switzerland, (3)National Institute of Biology (NIB), Slovenia, (4)Department of Biotechnology and Systems Biology, National Institute of Biology (NIB), Slovenia
Environmental Risk Assessment (ERA) often relies on exposures of live animal to chemicals of concern and the subsequent measurement of adverse outcomes. For example, *in vivo* fish tests are an integral part of chemical regulatory assessment. These assays are necessary to reduce the potential environmental impact of chemicals, but raise ethical concerns, are resource intensive, and offer little mechanistic insight. In the framework of the NC3Rs CRACK IT Challenge "SAFE", which targets to replace *in vivo* fish studies in environmental risk assessment, we aim to develop *in vitro* assays based on cultured fish cells, focusing particularly on reproductive toxicity.
As a first step toward the development of such *in vitro* assays, which should be robust, sensitive, and scalable, we identified a panel of biomarkers rooted in a holistic understanding of reproductive toxicity in fish. To do this, we set out to develop three complementary methods to identify biomarkers that are based on mechanistic information, have shown robust regulation by environmentally relevant chemicals, and can be measured by established and scalable methods. (1) We built a computable Adverse Outcome Pathway (AOP) network to anchor our biomarker selection to mechanistic information and to move beyond individual signalling pathways to systems level analysis. (2) We integrated data from several bioinformatics databases into a fish-specific protein-protein interaction network to expand our selection into poorly studied territory. (3) We collated published transcriptomic datasets reporting reproductive adverse outcomes in fish to identify the most consistently regulated genes.
With this strategy, we identified 382 unique biomarkers. To demonstrate the effectiveness of our strategy, we measured the expression of 36 of these genes in the rainbow trout liver cell line (RTL-W1) exposed to endocrine disruptors. We detected the expression of 30 of those genes and 27 of those showed chemical regulation, i.e., 90% hit rate for genes that were expressed. With these promising preliminary results, we are now poised to measure the concentration-response of all newly identified biomarkers to a panel of chemicals in fish cell lines and create a computational pipeline to extrapolate *in vitro* responses to *in vivo* outcomes.

1.01.A.T-04 Time-Resolved Acute Toxicity Testing With Fish Cells Under Flow Conditions in the RainbowFlow CHIP Biosensor

***Jenny Maner**[1,2], Carolin Drieschner[3], René Schönenberger[2], Christian Ebi[4], Philippe Renaud[5] and Kristin Schirmer[1,4,6], (1)Environmental Systems Science, ETH Zürich, Zürich, Switzerland, (2)Environmental Toxicology, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Dübendorf, Switzerland, (3)HSE AG, Switzerland, (4)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Dübendorf, Switzerland, (5)EPFL, Switzerland, (6)School of Architecture, Civil and Environmental Engineering, EPFL, Lausanne, Switzerland*
Research into alternatives to animal experiments for aquatic toxicity testing has produced a number of powerful tools, one of which is the use of permanent cell lines. They have been shown to accurately and reproducibly predict acute toxicity to fish. However, most *in vitro* assays using cell lines are carried out under static exposure conditions and assess cell viability only at a single time point, after chemical exposure. Thus, no information is gained on how toxicity develops over time. In the RainbowFlow CHIP project, we use two epithelial cell lines from rainbow trout (*Oncorhynchus mykiss*) for time-resolved acute toxicity investigation under flow conditions. To this end, we use Electric Cell-substrate Impedance Sensing (ECIS); cells are seeded on an electronic chip, and their adherence creates a resistance to an applied electric current. This resistance reflects the health status of the cells. A decrease in resistance is an indicator for loss of cell viability as can be elicited, for example, by exposure to chemicals. This is a fast and noninvasive method for cell viability assessment, which can easily be automated. As a consequence, cell viability can be monitored in real-time during chemical exposure. Flow conditions are achieved in a microfluidic setup, whereby cells are exposed in a channel through which medium is pumped at a defined rate. The fluid flow creates a shear stress, which is a physiological stimulus to epithelial cells neglected in static setups. The use of multichannel ECIS chips enables the testing of several chemical concentrations in parallel. We show the wide applicability of the system on the basis of model compounds with different physicochemical properties and toxic modes of action. Our results indicate that the two cell lines give similar results for the same chemicals, while different chemicals show different toxicity profiles over time. This proof-of-concept study shows the applicability of the biosensor for concentration dependent toxicity testing under flow conditions and highlights the importance of the additional dimension of time. An extension of this setup for the application to on-line effluent monitoring in the field is also currently being implemented.

1.01.P-Tu001 The 'Omics of Fish Epidermal Mucus

***Denina B.D. Simmons**[1], Urvi Pajankar[1], Ameila Del Vecchio[2], Raina Hubley[1], Gerald Erick Porche Jr[1], Kylee Ronnenberg[1] and Theresa Warriner[1], (1)Ontario Tech University, Canada, (2)Faculty of Science, Ontario Tech University, Canada*
Fish epidermal mucus is a dynamic biofluid that covers the integument, protecting the fish from potential threats such as injury and pathogens. Epidermal mucus can be sampled from fish in a nonlethal and relatively noninvasive manner, which could be a valuable refinement for studies on aquatic vertebrates in the lab and in the natural environment. We aimed to develop methods to identify and measure proteins and metabolites in fish epidermal mucus, for low-impact monitoring of threatened and/or protected wild fish populations. We used liquid-chromatography high resolution tandem mass spectrometry to identify and measure proteins and metabolites in mucus samples from rainbow trout to determine the most effective sampling and sample preparation methods. We then used the optimal method to measure more proteins and metabolites in mucus samples from other rainbow trout and fathead minnows to better understand mucus 'omics as a tool for ecotoxicological monitoring studies. We measured >5000 proteins in fish mucus and found that there was minimal influence from temporal variation of proteins and metabolites. However, we did find that proteins were sensitive to contaminant exposure and also environmental stress, where >1500 proteins were significantly affected by nickel. Specifically, proteins involved in immune responses, inflammation, and also the lateral line and

sensing were altered. These results suggest that mucus could be a good indicator for stress, immunological, and behavioural responses.

1.01.P-Tu002 Ecotoxicogenomic Profiles of Thyroid Disruption in Zebrafish Embryos

*Antonia Bruder[1], Steve Uwa Ayobahan Dr.[2], Fabian Essfeld[1], Julia Alvincz[1], Christoph Schaefers[3] and **Sebastian Eilebrecht**[4], (1)Fraunhofer Attract Eco'n'OMICs, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany, (2)Attract Eco'n'OMICs, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany, (3)Ecotoxicology, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany, (4)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany*

Active ingredients of pesticides, biocides, but also industrial chemicals can have adverse effects on environmental organisms, which can threaten populations and have far-reaching consequences for the ecosystem. To avoid such effects, European legislation requires chemical manufacturers to provide data for environmental risk assessment of active substances in order to be registered. Current environmental risk assessment of endocrine disruptors targeting thyroid hormone-related physiological processes requires large numbers of amphibians, which is expensive in terms of both resources and animal consumption. Consequently, alternative approaches to screening compounds are needed, and cost-effective, reliable biomarkers must be identified. ’Omics methods are attractive for collecting consistent high-content data and identifying chemical modes of action for prioritizing risk assessment. In the context of identifying screening-compatible biomarkers for thyroid MoAs, we analyzed early molecular signatures induced by the deiodinase inhibitor iopanoic acid and the thyroid peroxidase inhibitor methimazole in zebrafish embryos. Freshly fertilized zebrafish eggs were exposed to a range of concentrations of the two test compounds according to the Fish Embryo Toxicity Test using lethality, hatching rate, and swim bladder size as endpoints. For transcriptome analysis by RNA sequencing followed by differential gene expression analysis with DESeq2, total RNA was extracted after 96 hpf. Both substances induced a statistically significant decrease in swim bladder width, which is consistent with previous literature. The transcriptomic approach aims to identify candidate biomarkers that can identify and differentiate the mode of action of thyroid hormone disruption. Future screening approaches developed based on such data will allow prescriptive hazard assessment of substances and thus ab initio development of more environmentally friendly substances with less negative impact on the aquatic environment.

1.01.P-Tu003 Toward a High-Throughput New Approach Method for Acute Fish Toxicity: Painting the Rainbow (Trout)

***Jo Nyffeler**[1,2,3], Felix Harris[4,5], Steven Lasee[3,5], Brett R Blackwell[5], Jonathan Haselman[5], John Nichols[5], Daniel L. Villeneuve[5] and Joshua Harrill[5], (1)Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany, (2)Department of Cell Toxicology, Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany, (3)ORISE participant at US Environmental Protection Agency, (4)ORAU student services contractor at US Environmental Protection Agency, (5)US Environmental Protection Agency*

An *in vitro* method (OECD TG 249) using rainbow trout (*Oncorhynchus mykiss*) gill cells (RTgill-W1) in a plate-reader based viability assay (CV-PR) has been developed as a potential alternative to acute fish toxicity tests. We miniaturized this existing New Approach Method (NAM) from 24-well to 384-well format and added two previously established image-based assays: image-based cell viability (CV-IB) and high-throughput phenotypic profiling (HTPP, ‘Cell Painting’). We then tested 233 unique chemicals with the aim to compare the results from this NAM to existing *in vitro* and *in vivo* data.
Cells were seeded at 22,500 cells/well and exposed to the test chemicals for 24 h in a minimal medium. Chemicals were tested at eight concentrations (0.05–100 µM) in four independent cultures. The three assays resulted in six endpoints. The lowest potency value was considered as the *in vitro* potency.
Existing *in vitro* data from RTgill-W1 cells were collected for 51 chemicals. The fraction of chemical freely available in the culture wells was estimated using three different models (Armitage 2019, Armitage 2021, Fischer 2017). *In vivo* biotransformation was accounted for with the Arnot 2008 model. Existing *in vivo* mortality data for rainbow trout and fathead minnow (*Pimephales promelas*) was gathered from the ECOTOX Knowledgebase (~11,000 records).
Only 26/51 chemicals were active in literature *in vitro* studies and in the present study, with 14 and 24 chemicals having potency estimates within one and two orders of magnitude, respectively. The overall root mean squared error (RMSE) was 1.2 (on a log10 mg/L scale).
Overall, 78 chemicals had all the required information for modelling and at least three ECOTOX records. Of those, 45 were active in our NAM. The Armitage 2021 model resulted in the best prediction relative to the existing *in vivo* effects data, with a RMSE of 1.4, and 24 and 39 chemicals had potency estimates within one and two orders of magnitude of the *in vivo* value, respectively.
By miniaturizing the existing assay, we were able to generate *in vitro* data for >200 chemicals, compared to data for ~100 chemicals obtained previously. Ongoing efforts include the analytical measurement of the free chemical concentration for 12 exemplary chemicals to better understand which *in vitro* disposition model is the most accurate compared to empirical measurements. In the future, we aim to leverage the HTPP data to identify putative modes-of-action.
This work does not reflect USEPA policy.

1.01.B Alternative Approaches to Animal Testing for Ecotoxicity Assessments: Exploring Approaches and Avenues for the Future

1.01.B.T-01 Grouping Chemicals Into Mode of Action (MoA) Classes - A Semi-Automated (Neuro)Developmental Toxicity Assay Using Zebrafish Embryos

***Riccardo Massei, Dr**[1], Nico Grasse[1] and Stefan Scholz[2], (1)Helmholtz Center for Environmental Research (UFZ), Leipzig,* *Germany, (2)Chemicals in the Environment Research Section, Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany*

The major goal of chemical risk assessment is to identify the potential adverse health or environmental effect of chemicals. In this context, animal testing played a central role in predicting the effect of hazardous chemicals on human health. Although it has been widely used to predict adverse effects in humans, animal testing using adult animals has started to raise many ethical and economic concerns. The project PrecisionTox aims at identifying hazards of chemicals using a suite of nonmammalian alternative model organism and in vitro tests, including the zebrafish embryo test. Embryos of the zebrafish (*Danio rerio*) represent a valid alternative to standard animal testing and align with the 3Rs concept. Furthermore, it is an ideal test system to support high throughput chemical screening. Therefore, the main goal of the present study is to apply a previously developed semiautomated high content workflow to assess the adverse effect of 250 chemicals using automated imaging and behaviour tracking for the assessment of developmental (neuro)toxicity. Fertilized zebrafish eggs were exposed in 96-well plates for 96 hours to chemicals covering a wide spectrum of mode of actions.

(Neuro)developmental toxicity was assessed by monitoring mortality, motor behaviour, and morphological changes in a fully automated approach. Preliminary clustering results for six acrylamides and seven imidazoles . Hierarchical clustering and heatmap analysis confirmed specific effect patterns in zebrafish embryos. Acrylamides showed higher lethality and a clear effect on all motor behaviour endpoints with respect to imidazoles. Imidazoles caused cardiotoxicity as a consequence of a general decrease of the heart rate. While imidazoles were decreasing pigmentation, yolk, and the pericardial size, acrylamides were increasing the body curvature and decreasing eye area, body length, and otolith development. Furthermore, it was still possible to observe differences within the group class. Our preliminary results with imidazoles and acrylamides support that a semiautomated (neuro)developmental toxicity assay with zebrafish can highlight distinct effect patterns. Subsequent assessment of a total of 250 chemicals aims at combining the data of various model organisms including OMIC data.

1.01.B.T-02 A High-Throughput Analytical Workflow to Assess Specific Toxicokinetic Behaviour of Xenobiotics in Zebrafish Embryos

***Nico Grasse**[1], Riccardo Massei, Dr[2], Stefan Scholz[3], Qiuguo Fu[4] and Thorsten Reemtsma[5], (1)Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany, (2)University of Antwerp, Belgium, (3)Chemicals in the Environment Research Section, Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany, (4)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Dübendorf, Switzerland, (5)Department of Analytical Chemistry, Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany*

Modern toxicology with the integration of 3Rs calls for new developments or adaptations for *in vitro* and *in vivo* models for better evaluating and predicting chemical toxicity. For this purpose, nonsentient organism (NSO) model species, high-throughput generation of toxicological data, and powerful computational modelling approaches are used to understand which chemicals are toxic and why. Currently, the zebrafish embryo (*Danio rerio*) has been actively explored to establish such predictive models and understand the mechanistic effects of chemicals. The precision of models largely depends on the high content and relevance of the collected toxicological data. In this context, zebrafish embryos can be applied in high-throughput studies providing lethal and sublethal effects or behavioural change due to their small size and transparency. Additionally, toxicokinetic information is essential and highly relevant to estimate the specificity of effects caused by chemical substances. To identify compound classes and class-representative compounds that lead to specific toxicokinetic behaviour in the NSO-based model, we exposed zebrafish embryos to 250 compounds and determined their internal concentrations and biotransformation using an LC-MS/MS-based high-throughput analytical workflow. Preliminary results on the internal concentrations of 30 chemicals in the zebrafish embryo were compared to the predicted internal concentration by partition models between water and the embryos. We further determined the internal concentration-based toxicokinetics for compounds significantly deviating from the model and identified transformation products.

1.01.B.T-03 Predicting Ecotoxicity Across Taxa Through Machine Learning

***Christoph Schuer**[1], Lilian Gasser[2], Fernando Perez-Cruz[2], Kristin Schirmer[1] and Marco Baity-Jesi[3], (1)Environmental Toxicology, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Dübendorf, Switzerland, (2)Swiss Data Science Center, Switzerland, (3)Siam, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Dübendorf, Switzerland*

New approach methods, such as machine learning, have promising potential when applied to animal testing for ecotoxicology. Most of the available literature focuses on the classification of chemicals into toxicity classes (e.g., toxic/nontoxic). This is opposed to regression modelling, which predicts actual toxicity values (e.g., LC50/EC50), which is closer to the outcome of ecotoxicological experiments. Comparing the performance of models across available studies to predict toxicity values is difficult because model performance is highly dependent on the data set and the applied train-test-split. Ideally, data sets would cover a broad range of species and chemicals, but in reality, they are usually limited to single or few species and/or a limited chemical space. The applied train-test-splits have to ensure that a chemical and/or a species is only present in either the train or the test split to avoid information leakage. To motivate machine learning experts without a strong biological background to work on ecotoxicological challenges we provide our clean and well-characterized data set as a potential benchmark. The data set is comprised of effect values (EC50/LC50) for acute mortality ($\leq$ 96 h) in three taxonomic groups: fish, crustaceans, and algae. We describe feature curation and data set assembly and give insights into our modelling approach, a greedy forward feature-selection approach based on Gaussian process (GP) regression. The greedy approach proved superior to models using all available features at once, like least absolute shrinkage and selection operator (LASSO) and GP regression. In other words, a selected subset of features led to better performances than using all available features. We compared four molecular representations (three binary fingerprints and the mol2vec embedding). For all representations, the correlation coefficient R^2 from the predictions of the greedy approach exceeded 0.60 compared to LASSO and GP regression, which reached an R^2 of 0.50 and 0.55-0.59, respectively. Additionally, we compare our model performances to the state of the art by applying the most prevalent models from literature to our data set. To complete the benchmark data set, we propose a number of prediction challenges that could help answer pressing questions from our field. These range from predictions limited to single species that are dominant in our data set, to predictions inside and across taxonomic groups, to predictions on the whole data set.

1.01.B.T-04 Ongoing Status of the Regulatory Acceptance of New Approach Methodologies in the EU

Leonie Mueller[1] *and Francois Busquet*[2]*, (1)Altertox, Germany, (2)Altertox, Belgium*

Research on Approach Methodologies (NAMs) has created a sizable toolbox of methods available for regulatory use. With the ban of animal experiments for the cosmetics regulation and Article 13 in REACH to test animals as a last resort, the European regulatory landscape has created a strong incentive for the application of NAMs. Additionally, phasing out animal experiments aligns with the opinion of the general public and has almost unanimous support of the European Parliament as demonstrated in the 2021 Motion for Resolution. However, regulatory application of NAMs remains very limited so far, caused by various roadblocks. Changing them requires joint efforts across the sectors of academia, industry, and government. Main roadblocks were analysed and three areas were identified: (1) NAMs for regulatory science need to be fit for purpose, but often NAMs do not fit well in regulatory testing requirements. Cooperation in the developmental phase, with good communication between developers and users will increase the likelihood of NAMs to be accepted for regulatory purposes. There is a need to establish interfaces between the different sectors that enable and foster cooperation. (2) The acceptance of NAMs by regulators highly depends on the validation and robustness of the methods, which represents a time and cost intensive process. Different strategies have been suggested to overcome this bottleneck. Validation oftentimes falls short in publicly funded research projects, which can be overcome by the adoption of funding schemes. Furthermore, cooperation with industry would help overcome the underfunding of validation. A close cooperation between developers and industry can guide selection of the most promising methods for regulatory application for in-house validation studies. (3) In most cases, NAMs do not represent 1:1 replacements of animal tests. Their application in regulatory science will most likely be realized through weight of evidence approaches or Integrated Approaches for Testing and Assessment (IATA). There currently exist various suggestions from ecotoxicology and toxicology on how to integrate these approaches. Here, two things should be kept in mind: (a) the developed approaches need to align to the regulatory context and regulators should be included in their development and (b) the fields of ecotoxicology and toxicology should align their efforts during the development of the approaches and agree on basic structures for decision and language.

1.01.P-Tu004 Development of Freshwater Planaria as a Risk Assessment Tool

Lucia Rejo[1]*, Thomas Verrier*[2]*, Judith Lorin*[2]*, Jean-Michel Malgouyres*[3]*, Thierry Montaut*[4] *and Caroline Vignet*[3]*, (1)Biology, INU Champollion, University of Albi, France, (2)BTSB, (3)Centre Universitaire Jean-François Champollion, Albi France, (4)INU Champollion, University of Albi, France*

In ecotoxicology, the adoption of the 3Rs rule—reduce, refine, replace—aiming to limit the use of vertebrate animals in scientific research, has precipitated the development of new models using invertebrate organisms for bioassays. Their relatively high sensitivity to pollutants makes them promising screening tools for predicting toxicity in mammals.

Freshwater planaria, an invertebrate flatworm, have been shown to be a promising alternative model to assess chemicals that may end up in the aquatic environment. They are distributed worldwide, and easy to collect and to maintain in the lab. Their small size allows medium to high-throughput *in vivo* screening of toxicity. Planaria can enable the evaluation of toxicity of chemicals on many levels: 1) they are nontarget organism; 2) almost all species are endemic to their geographical location; 3) they are good indicators of chemical risk on the aquatic ecosystem; 4) their nervous system shares the same neuronal subpopulations and neurotransmitters as the mammalian brain, making them potential screening tools for predicting pollutant toxicity for mammals. As in mammals, their central nervous system controls motor coordination and behaviour.

Planaria have been shown to exhibit specific behavioural patterns in response to neuroactive molecules, active ingredients of drugs or pesticides, whose neuronal targets are known. Many neuroactive molecules have been tested and have induced various stereotypic behaviours in planaria (Buttarelli et al. 2000). A stereotype is a behaviour that is observed when a planarian is exposed to a specific molecule.

However, stereotypes are currently characterised manually. Automating the identification of these stereotypies would allow the rapid screening of the effects of numerous molecules whose mode of action is not yet known. Thus, the aim of this study is to automate the assessment of planarian stereotypes using Deep Learning.

At the end of the labelling process, we obtained images classified into six categories: Wildtype, C-shape, Screw-like, Snake-like, Contracted, and Bridge-like.

Once the model is trained, the stereotype with the highest probability is the final result displayed**.** As an output we have a simple-to-use web interface which is: the stereotype with the highest probability, a bar chart with the probabilities of the stereotypes associated with the image, a summary table with the name of the images and the predicted stereotypes, downloadable in .csv format.

1.01.P-Tu005 Sleeping with the Fishes: Haloperidol and β-Cyclodextrin Effects on Mobility of Planaria

Manel Habel[1]*, Vitaliy Khutoryanskiy*[2] *and Adrian Williams*[2]*, (1)University of Reading, United Kingdom, (2)Pharmacy, University of Reading, United Kingdom*

The use of animal models in experimental research has helped to uncover many fundamental principles and supported development of applications relevant to biological research, medical sciences, and toxicology among other fields. The historical reliance of the pharmaceutical industry on animal testing has been under increasing scrutiny due to ethical and scientific reasons,

leading to the development of new alternative approaches based on the “3 Rs principles.” This framework encourages the Reduction of the number of animals used, the Refinement of methods employed, and the Replacement of animal use by nonanimal methods when possible, or by substituting one animal model with another from a less-sentient species lower on the phylogenetic scale, including invertebrates. Consequently, we have explored the use of pond worms, Planaria species, to replace higher-order animals in toxicology screening.
An important characteristic of planaria which has led to their increasing use in neurotoxicology research is the similarity of their central nervous system to that of vertebrates. In fact, despite their simplicity, planaria display cephalisation and possess numerous mammalian-like neurotransmitters including glutamate, dopamine, and serotonin. The aims of our current study were to investigate the pharmacological effects of haloperidol (a dopamine 2 receptor antagonist) on planaria, and to assess cyclodextrin's (CD) ability to potentiate the drug's delivery through the planarian membrane.
Quantitative assessment of haloperidol and CD's effects was achieved using a planarian locomotor velocity assay. First introduced by Raffa's research group, this method is a surrogate to techniques employed for the quantification of rodent behaviours. Following exposure of planaria to each tested solution, the organisms showed haloperidol-induced cataleptic effects which have previously been reported in studies using higher-order animals such as mice and rats, thus demonstrating the utility of the planarian model. Interestingly, whilst cyclodextrins have been reported to act as membrane disruptors or penetration enhancers in various biological membranes, here the cyclic sugar reduced the efficacy of the haloperidol and the planaria remained mobile. This is probably due to the formation of a complex between the drug and the CD which effectively prevents the drug from exerting its somnoletic effects.

1.01.P-Tu006 Approaches to Reduce Vertebrate Use in Environmental Risk Assessment ***Emma Danby*[1]**, *David Mayfield*[2] *and Francis Crawley*[1], *(1)Labcorp Early Development, United Kingdom, (2)Labcorp*
Environmental Risk Assessments (ERA), whether it be for crop protection products, industrial chemicals, or pharmaceuticals, can lead to large testing programs and potentially high vertebrate usage. Both fish acute and chronic testing is often required as well as bioaccumulation or biomagnification testing being triggered as part of the Persistent, Bioaccumulative and Toxicity (PBT) assessment. Just these studies can use in excess of a thousand fish depending on study design and replication. When endocrine disruption endpoint testing is also required this figure can increase exponentially.
Whilst this testing is essential to ensure environmental protection, Labcorp have been working on strategies to provide the data required to fulfil the needs of an ERA whilst minimizing animal use. Here we discuss some of the strategies available to us and how we can potentially fulfil an ERA using hundreds less fish.
Such strategies include using the threshold or limit test approaches wherever possible to reduce numbers significantly. Additionally, we are validating in vitro alternative assays for the fish bioaccumulation testing as well as the fish acute test. Another approach we are taking is to use our regulatory expertise to write waivers resulting in not needing the testing at all and we will give examples of successful waivers written saving time, money, and animals.

1.01.P Alternative Approaches to Animal Testing for Ecotoxicity Assessments: Exploring Approaches and Avenues for the Future

1.01.P-Tu007 Aquatic Risk Assessment of Plant Protection Products in the Future – Still Protective Without Acute Fish Toxicity Testing?
Elena Adams, *Sarah Hartmann, Daniel Faber, Yvonne Wolf, Markus Ebeling and Eric Bruns, Environmental Safety, Bayer AG - Crop Science Division, Germany*
In July 2022, there were 451 active substances (a.s.) approved for use in plant protection products (PPPs) in the EU. The current risk assessment (RA) of PPPs for the aquatic environment is based on the evaluation of the toxicity to various taxonomic groups including acute and chronic vertebrate studies with fish. Despite the fact that there are alternative, nonvertebrate methods available which are based on fish embryos and cell lines (OECD TG No. 236 and 249), according to the Commission Regulations (EU) No 283/2013 and No 284/2013, there is still the requirement to perform acute fish toxicity studies for the authorization of PPPs. We critically reviewed the current approach to find out if the aquatic Tier 1 RA is still protective even without fish acute testing as it can be usually covered by the RA of other aquatic taxonomic groups. Therefore, we firstly investigated whether acute fish toxicity endpoints are drivers for the aquatic RA of PPPs by calculating and comparing the regulatory acceptable concentration (RAC) for each aquatic taxonomic group. In a second step, we applied RA refinements (geomean approach or reduced assessment factor) and finally, considered the availability of chronic fish studies and whether the endpoint leading to the lowest RAC is not unbound. For this, we examined all currently in the EU approved a.s. with a published EFSA Conclusion except for natural substances and substances without a reliable database. This led to 228 a.s., 77 fungicides, 22 insecticides, 54 herbicides, nine multitarget pesticides, 19 plant growth regulators, and eight others. For 23 a.s., the lowest RAC was found for fish acute toxicity which equals to ~10% of all investigated substances. However, after refinements using geomeans and assessment factor adaptions, only 15 substances were still driven by the acute fish toxicity. From these, 14 substances did either show an unbound acute fish toxicity endpoint, no available chronic endpoints for fish, or an endpoint from a formulation exhibiting a higher toxicity compared to the a.s. endpoint was used in the RA. Only for one out of 228 substances (0.44%, fungicide) the RAC can be considered as driven by the acute fish endpoint. Based on this evaluation it can be stated that there is huge potential to minimize vertebrate testing and that the aquatic RA for PPPs could be performed without acute fish toxicity studies and still assure protectivity for the aquatic environment including fish.

1.01.P-Tu008 Replacing Animal-Derived Components in *in Vitro* Test Guidelines OECD 455 and 487
***Inska Reichstein**[1], Maria Koenig[2], Niklas Wojtysiak[2], Beate Escher[2], Luise Henneberger[3], Peter Behnisch[4], Harrie Besselink[4], Beat Thalmann[5], Sarah Hörchner[6], Julien Colas[1], Ralph Borgardt[1], Henner Hollert[7] and Andreas Schiwy[1], (1)Evolutionary Ecology and Environmental Toxicology, Goethe University Frankfurt, Frankfurt am Main, Germany, (2)Department of Cell Toxicology, Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany, (3)Cell Toxicology, Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany, (4)BioDetection Systems BV (BDS), Netherlands, (5)Scinora GmbH, Germany, (6)Aquatic Ecotoxicology, Goethe University Frankfurt, Frankfurt am Main, Germany, (7)Evolutionary Ecology & Environmental Toxicology, Goethe University Frankfurt, Frankfurt am Main, Germany*
The next step to advance *in vitro* (eco-)toxicology is the replacement of animal-derived components like fetal bovine serum (FBS) and rat liver homogenates (S9) in effect-based methods. The substitution of these animal-derived products is advantageous as these components can impact bioassay quality due to inherent product variability.
In a proof-of-concept study, the adaptation of the cell-based *in vitro* OECD test guidelines (TG) 487 (micronucleus test for evaluation of genotoxicity) and 455 (detection of estrogen receptor agonists/antagonists) were evaluated for an animal-component-free methodology. The human cell lines A549 (for OECD TG 487) and ERα-CALUX® (for OECD TG 455) were investigated for growth in a chemically defined medium (CDM) without FBS and for the implementation of metabolism via the biotechnological metabolisation system ewoS9R and induced rat liver S9 for comparison. Both cell lines were successfully cultivated in CDM, but with increased doubling time. The adaptation of the ERα-CALUX® cells could be reproduced within two laboratories.
In a next step, both TGs were conducted with ewoS9R and rat S9 in both CDM and FBS-containing medium. For this, benzo[*a*]pyrene (B[a]P) was used as model compound as it shows increased genotoxicity and endocrine activity after metabolization. The biotechnological ewoS9R showed potential to replace rat liver S9 in OECD TG 487 in FBS-medium with A549 cells. However, a micronucleus assay in CDM could not be conducted as the cells could not be distributed homogenously, and the formation of cell aggregates made the detection of micronuclei impossible. The OECD TG 455 for endocrine activity assessment could be adapted to CDM and an increase of estrogenic activity of B[a]P could be determined with the addition of ewoS9R or rat S9. However, in the CDM-variant of the OECD 455, the response intensity of the cells and the sensitivity of the assay was reduced.
All in all, promising results were obtained for adaptation of *in vitro* assays to CDM. The application of CDM in OECD relevant TGs has the potential to reduce the use of FBS in cell cultures in the future, thus improving the reproducibility, quality, and informative value of the bioassay results. Furthermore, it can reduce the ethical concerns of using animal components for *in vitro* assays and strengthen those methods as an alternative to animal experiments.

1.01.P-Tu009 Novel Approaches to Assessing Interspecies Variation in Sensitivity to Polycyclic Aromatic Hydrocarbons
***Justin Dubiel**[1], Derek Green[2], Andreas Eriksson[3], Yamin Raza[1], Hunter Johnson[1], Zhe Xia[4], Gregg Tomy[4], Jon Doering[5] and Steve Wiseman[1], (1)University of Lethbridge, Canada, (2)University of Saskatchewan, Canada, (3)University of Jyväskylä, Finland, (4)University of Manitoba, Canada, (5)Louisiana State University*
Polycyclic aromatic hydrocarbons (PAHs) are naturally occurring chemicals that are ubiquitous in the environment. Polycyclic aromatic hydrocarbons can become alkylated, and the alkyl PAHs are more abundant in certain environmental matrices. Some PAHs can exert toxicity to fishes by activation of the aryl hydrocarbon receptor (AhR). Although there is evidence that alkylation could increase potency of PAHs, these effects are not well characterized. Additionally, most research has focused on a small number of species of fishes, which likely does not capture interspecies variation in sensitivity, as has been demonstrated for other classes of AhR agonists. However, toxicity testing across numerous species is impractical due to limitations in time, cost, and challenges associated with certain species. The goals of this research were to investigate effects of alkylation on potency of PAHs that are agonists of the AhR, and to assess sensitivity of phylogenetically diverse fishes to AhR receptor activation. As a step toward characterizing how alkylation affects potency of PAHs, zebrafish (*Danio rerio*) embryos were exposed to benz[*a*]anthracene and three alkyl homologues via microinjection to assess lethality. Alkylation had position-dependent effects on potency. The most potent alkyl PAH, 8-methylbenz[*a*]anthracene, was 5.6-fold more potent than benz[*a*]anthracene, 7,12-dimethylbenz[*a*]anthracene was 1.4-fold more potent, and 4-methylbenz[*a*]anthracene was equally potent. Next, the potency for activation of the zebrafish AhR2 was quantified using a standardized *in vitro* AhR transactivation assay. These assays yielded relative potencies similar to those observed *in vivo*. To assess interspecies differences in sensitivity, the AhR transactivation assay was performed for each of the four PAHS in eight additional phylogenetically diverse species of fishes. Results showed chemical-specific ranges in sensitivity, with White sucker (*Catostomus commersonii*) being the most sensitive and Northern pike (*Esox lucius*) being the least sensitive to each PAH. The range of sensitivity to AhR activation was 73-fold by benz[*a*]anthracene, 123-fold by 4-methylbenz[*a*]anthracene, 417-fold by 8-methylbenz[*a*]anthracene, and 17-fold by 7,12-dimethylbenz[*a*]anthracene. Due to the abundance of PAHs in the environment and differences in sensitivity across species, developing molecular tools to assess these toxicities more pragmatically could be essential for more objective ecological risk assessment of these chemicals.

1.01.P-Tu010 How Can We Achieve Fish Free Fish Testing in Environmental Risk Assessment?
***Daniel Faber**[1], Yvonne Wolf[1], Eric Bruns[1], Tobias Pamminger[2], Sebastian Schmidt[2], Thorsten Leicher[2], Zhenglei Gao[2], Michael Boeckers[2] and Xin Li[2], (1)Environmental Safety, Bayer AG - Crop Science Division, Germany, (2)Bayer AG - Crop Science Division, Germany*
In general, to register plant protection products (EU regulation 284/2013) and active substances (EU regulation 283/2013) an environmental risk assessment (ERA) is performed on a set of different *in vivo* studies. To assess the effect on aquatic vertebrates (fish) the acute (OECD 203) and chronic toxicity (OECD 210, if DegT90 > 1day) are routinely performed, which results in a

substantial number of fish being used for testing globally each year. In the EU these data requirements are currently strictly enforced even in cases where such tests will likely not provide additional information (e.g., acute fish toxicity is rarely the most sensitive endpoint driving the ERA; see poster abstract of Adams et al.). To reduce unnecessary suffering of fish (3R principle) several nonanimal testing methods (e.g., FET OECD 236, Fish-gill cell lines OECD 249 and QSARs) have been developed over the past years. Each of those NAMs is capable of predicting some adverse effect in fish, yet a 1:1 replacement for all relevant endpoints–especially for chronic fish testing–is very unlikely and not aimed. Therefore, we aim to combine multiple complementary NAMs into a robust workstream within a digital framework to 1) reliably predict all regulatory relevant aspects of fish toxicity testing and 2) minimize potential NAM specific blind spots in the testing strategy. As a first step it is planned that this approach will be used to design tailor-made regulatory studies for fish that meet both the current regulatory data requirements and avoid unnecessary suffering of fish (e.g., limit tests if feasible, defined concentration range in full dose-response study). By combining those different NAMs the regulatory endpoint will be predicted and besides that, the available data will be used to gather a detailed understanding of the toxic dynamics. Ultimately, we strive for a fully NAM based fish free fish testing strategy for the registration of plant protection products. These efforts are in line with the principles of the 3R (refine, reduce, replace) and the ongoing debate to reduce vertebrate testing for regulatory purposes and wherever scientifically justified possible.

1.01.P-Tu011 Comparative Study on the Intrinsic Clearances of Pharmaceuticals in Rainbow Trout (*Oncorhynchus mykiss*) Subcellular S9 Fractions and 3D Primary Hepatocyte Cultures

***Tea Pihlaja*[1,2]**, *Päivi Järvinen[1] and Tiina Sikanen[1,2], (1)University of Helsinki, Finland, (2)University of Helsinki, Helsinki Institute of Sustainability Science (HELSUS), Finland*

Pharmaceuticals are ubiquitous in the aquatic environment. Many of these compounds are relatively lipophilic (high logK_{OW}) and predicted to bioaccumulate in fish. Although there are several in silico methods available for nonanimal assessment of bioconcentration factors (BCF), these predictions are sometimes contradictory to *in vivo* BCF data (e.g., OECD305), because of their limited capability to account for the impact of hepatic metabolism of pharmaceuticals. In 2018, the OECD launched new guidelines for determination of *in vitro* intrinsic clearances (CL_{int}) using cryopreserved rainbow trout (*Oncorhynchus mykiss*) hepatocytes (RTHEP, OECD319A) or liver S9 subcellular fractions (RT-S9, OECD319B), to facilitate extrapolation of in vivo CL_{int} and its incorporation into in silico BCF models.

In this study, we compared the intrinsic clearances of five pharmaceuticals (clozapine, levomepromazine, naproxen, quetiapine, and sertraline) determined in RT-S9 assays (OECD319B) with those determined in 3D cultures of primary RTHEP (custom culture protocol). These pharmaceuticals (all log K_{OW}>3) were selected because of their contradictory predicted vs. in vivo BCF data for fish (clozapine, sertraline) or their extensive metabolism in human (levomepromazine, naproxen, quetiapine). The hepatocytes were cultured as scaffold-free 3D spheroids (~65 mm, ca. 50 cells/spheroid) on Aggrewell plates (Stemcell Technologies), because this increased the cellular enzyme activities (7-ethoxyresorufin deethylation, EROD) about four-fold compared with suspension cultures (such as OECD319A). In addition to EROD activity, the maturation of the 3D RTHEP cultures was evaluated based on spheroid morphology. The pharmaceuticals' intrinsic clearances were determined on Day 8. In this study, both RT-S9 fractions (pool of five female and two male fish) and cryopreserved RTHEP (pool of six female fish) were of commercial origin (Primacyt Cell Culture Technology GmbH). The intrinsic clearances of pharmaceuticals in RT-S9 and 3D RTHEP incubations were determined by substrate depletion approach over 3-4 h incubation time and, when metabolized, the kinetic constants were derived as instructed in OECD319A/B. The *in vitro* CL_{int} values were then extrapolated to *in vivo* estimates and further to S9-BCF and HEP-BCF according to OECD280 guideline. The extrapolated S9-BCF and HEP-BCF were compared with calculated logK_{ow} based BCF and, where available, with *in vivo* BCF.

1.01.P-Tu012 Understanding of Phase Distribution of Ionic Liquids in *in vitro* Cell-Based Systems

***Eunhye Bae, M.Sc.*[1]**, *Stephan Beil[1], Beate Escher[2], Stefan Stolte[1] and Marta Markiewicz[1], (1)Institute of Water Chemistry, Technical University Dresden, Germany, (2)Department of Cell Toxicology, Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany*

The freely dissolved concentration (C_{free}) in *in vitro* cell-based system is important as it is not only the dose available for uptake and thus driving effects, but it is also used for quantitative *in vitro-in vivo* extrapolation. Mathematic models have been developed to predict *in vitro* C_{free} using partition coefficients between system compartments, but they have not been validated for permanently charged ionic compounds. We aimed to investigate factors influencing the *in vitro* distribution of ionic liquids in cell-based assays to parametrise a mass balance model for prediction of C_{free}. The effects of plastic sorption on concentration stability were evaluated in serum-free medium and medium containing 10% fetal bovine serum (FBS) for ionic liquids with increasing length of the alkyl side chain. The liposome-water partition coefficients ($K_{lip/w}$) and serum albumin-water partition coefficients ($K_{SA/w}$) were experimentally quantified by using a solid supported membrane. Three different modelling approaches to predict $K_{lip/w}$ were compared: correlation with a HPLC-retention factor (log k'), polyparameter linear free energy relationship (pp-LFER) and COSMOmic. A WCX 96-well microelution solid-phase extraction (SPE) was applied to isolate the freely dissolved ionic liquids from proteins and lipids and thus bound compounds and the quantified C_{free} was compared with the predicted C_{free} by the mass balance model. The sorption on plastic plates reduced C_{free} in the serum-free medium for compounds with an alkyl chain length of ≥12 carbons while medium concentrations remained constant in the medium containing FBS. These results proved that protein containing medium compensates for chemical depletion by a multiwell plate, allowing avoidance of concentration loss to the plastic plate of *in vitro* system. As expected, the lipid and serum affinity were enhanced by increasing the side chain length but the investigated chemicals generally showed stronger affinity to lipid than proteins. All modelling approaches for $K_{lip/w}$ prediction showed a good linearity (R^2=0.95 for COSMOmic, 0.86 for pp-LFER and 0.91 for correlation with log k', respectively), but the accuracy was the best by COSMOmic. The mass balance model performed well in predicting the concentration bound to protein and lipid phase for chemicals of low to medium hydrophobicity (within a factor of 10), but it underestimated C_{free} by up to three orders of magnitude concerning the most hydrophobic chemicals.

1.01.P-Tu013 Use of Japanese Quail EcoToxChips to Derive Transcriptomic Points of Departure for Chlorpyrifos in a Multilab Early-Life Stage Ring Test

Emily Boulanger[1], *Natalie K. Karouna-Renier*[2], *Elizabeth Brandt*[2], *Tasnia Sharin*[3], *Markus Hecker*[4], *Natacha S Hogan*[4], *Nil Basu*[1], *Doug Crump*[5] *and Jessica Head*[1], *(1)Faculty of Agricultural and Environmental Sciences, McGill University, Canada, (2)US Geological Survey, (3)Ecotoxicology and Wildlife Health Division, Environment and Climate Change Canada, Ottawa, Canada, (4)Toxicology Centre, University of Saskatchewan, Canada, (5)Ecotoxicology and Wildlife Health Division, Environment and Climate Change Canada, National Wildlife Research Centre, Ottawa, Canada*

The field of toxicity testing is increasingly moving toward New Approach Methods (NAMs) that are considered to be more cost-effective, ethical, and efficient. Here, we evaluate the combined use of two NAMs: 1) an early-life stage avian embryo test, and 2) transcriptomic dose-response analysis (TDRA) using a targeted qPCR array (EcoToxChip). Repeatability of results was assessed based on a ring test involving three independent laboratories (McGill University, Environment and Climate Change Canada [ECCC] and U.S. Geological Survey Eastern Ecological Science Center [USGS]). Exposures were conducted according to an avian egg injection protocol that we have proposed for standardization. Briefly, fertilized, unincubated Japanese quail (*Coturnix japonica*) eggs were exposed via air cell injection to DMSO (solvent control) or seven concentrations (0.04-40 µg/g egg nominal) of chlorpyrifos (CPF) on embryonic day 0 (ED0) (10 eggs per dose group). Eggs were incubated at 37.5 ± 0.5 °C and 60 ± 5% humidity until mid-incubation (i.e., ED9). Liver samples from five viable embryos were harvested per dose group at ED9 for hepatic gene expression analysis using the 384-gene Japanese Quail EcoToxChip. Standard operating procedures, reagents, chlorpyrifos dosing solutions, and dose-response analysis methods using EcoToxXplorer (www.ecotoxxplorer.ca) were common between the three laboratories. The strain of quail used and the qPCR instrumentation differed. Preliminary results from two labs point to a large difference in the number of genes for which benchmark doses (BMDs) could be derived (39 *vs* 70). Despite this difference, transcriptomic points of departure for the first mode (tPODmode) were similar (20.3 µg/g *vs* 16.8 µg/g) and corresponded to the tPODmode previously calculated from RNASeq data (21.6 µg/g). All tPODs were below our previously published organismal level LOAEL of 41.1 µg/g for chlorpyrifos in Japanese quail embryos. Overall, our results suggest that performing TDRA on a reduced gene set (i.e., 384-gene EcoToxChips) in an alternative avian testing model is a valid approach that can produce repeatable tPODs, which are protective of adverse apical outcomes.

1.01.P-Tu014 Deriving Fish and Daphnia Toxicity QSARs for Anionic Surfactants by Using Experimental and Computational Membrane-Water Partition Coefficients

Andrea Gredelj[1], *Elin Barrett*[1], *Jayne Roberts*[1], *Eoin Kearney*[2], *Alexandre Teixeira*[1], *Nicola Haywood*[1], *Geoffrey Hodges*[1] *and Mark Miller*[2], *(1)Unilever - Safety and Environmental Assurance Centre (SEAC), United Kingdom, (2)Department of Chemistry, Durham University, United Kingdom*

Quantitative Structure-Activity Relationships (QSARs) can be used in the environmental risk assessment (ERA) of chemicals to provide a viable alternative to toxicity testing. Anionic surfactants are one of the most widely used surfactant types in the home and personal care industry. The aquatic toxicity of surfactants is generally recognized as being driven by narcosis which is characterised by the adsorption and penetration of the molecule into cell membranes where it can disrupt vital cell mechanisms e.g., energy metabolism and nutrient/oxygen transport across the membrane. Chemical hydrophobicity, usually described with the octanol-water partition coefficient (K_{ow}), is a common proxy for predicting the (aquatic) toxicity of chemicals. However, using K_{ow} is not appropriate for surfactants, not only due to difficulties in its experimental determination but also due to limitations in its applicability for, particularly ionic, surfactants. Biological membranes are ordered and anisotropic tri-dimensional structures, contrary to octanol being homogenous isotropic media. Membrane-water partition coefficient (K_{mw}) has been previously demonstrated as a suitable alternative to K_{ow} that provides a more biologically relevant descriptor.

For some strongly sorbing surfactants or surfactants with very long chains, where water solubility can be a limiting factor, experimental determination of K_{mw} can be difficult. To overcome this, and in cases where data on shorter pure homologues are available, computational methods can allow for the extrapolation of K_{mw} to longer chain lengths. Here, we will demonstrate that the measured values of K_{mw} can be successfully inter- and extrapolated using a computational predictive method for the homologue series of several subgroups of anionic surfactants. For this purpose, we are using a previously developed coarse-grained simulation method, based on molecular dynamics.

This poster will show how both measured data and simulation methods can be integrated for deriving K_{mw} values and used further in developing QSARs for predicting the acute toxicity of anionic surfactants to aquatic species. Furthermore, it will emphasize the scientific and regulatory potential of using the well-known *in silico* methods with more biologically relevant predictors in avoiding unnecessary fish testing for describing the (eco)toxicity of groups of chemicals with already well-researched mechanisms of toxicity.

1.01.P-Tu015 Effects of the Marine-Derived Anticancer Drug Prodigiosin on Zebrafish: Integration of i*n vitro* and *in vivo* Outcomes

Fabianne Ribeiro[1], *Ives Charlie-Silva*[2], *Roberto Martins*[3], *Simone Teixeira*[2], *Paula Jimenez*[4], *João Agostinho Machado Neto*[2], *Glaucia M. Machado-Santelli Dr*[2], *Leticia Lotufo*[2], *Amadeu M.V.M. Soares*[5], *Susana Loureiro*[3] *and* ***Maria D Pavlaki***[5], *(1)Department of Biology & CESAM - University of Aveiro, Aveiro, Portugal, (2)University of São Paulo (USP), Brazil, (3)CESAM & Department of Biology, University of Aveiro, Aveiro, Portugal, (4)Departamento de Ciências do Mar, Instituto do Mar, Universidade Federa de São Paulo, Brazil, (5)University of Aveiro & Centre for Environmental and Marine Studies*

(CESAM), Aveiro, Portugal
Chemotherapy is the most common treatment against cancer, where anticancer agents (AAs) are designed to kill fast-growing tumour cells by interfering with the cellular reproduction mechanism. However, they act in both healthy and cancerous cells. Prodigiosin (PG) is a microbial marine-derived anticancer drug with significant therapeutic potential against cancer due to its efficacy in treating cancer cell lines. The environmental consequences arising from the presence of PG, especially in the aquatic environment, are still unknown. In this regard, this study aimed at assessing the *in vitro* effects of PG on ZFL cell lines, linking it with the *in vivo* effects observed in zebrafish (*Danio rerio*) as an *in vivo* model. The main goal is to predict the environmental hazard of this new substance and validate the implementation of *in vitro* approaches in the environmental hazard assessment of AAs. For the *in vitro* assessment, cell viability and morphology were evaluated. For the *in vivo* assessment, endpoints measured in zebrafish embryos and larvae were hatching, mortality, developmental malformations, heartbeat, and locomotion. Prodigiosin was cytotoxic to ZFL cells, presenting an IC50 value of 68.43 mg L^{-1} after 72 h of incubation. Cell viability was significantly reduced by 47.5% and 45.2% at 81 and 162 mg L^{-1}, respectively after 24 h, while no significant effects were observed at 16 and 32 mg L^{-1}. Prodigiosin led to changes in cell morphology, mainly at higher concentrations. Treated cells were fusiform, seeming to modify their attachment to substrate and microtubule organization. Regarding *in vivo* effects, PG induced mortality in *D. rerio* in a dose-dependent manner, with a LC50-96 h of 4 mg L^{-1}. Heart rate and larvae size were also affected, along with swimming behaviour alterations. Most observed embryo malformations were edema, scoliosis, and failure to absorb the yolk sac, at concentrations above 124 µg L^{-1}. Our data revealed that *in vitro* was, as expected, a more sensitive approach to assessing the effects of AAs in our model species. It also showed the specific cellular mode of action of PG such as cell morphology alterations and microtubule organization, with possible consequences for cell division, which can be integrated to understand *in vivo* observed effects, such as developmental malformations in zebrafish.

1.01.P-Tu016 Effects of Chromomycin A2 on Zebrafish and ZFL Cell Lines: Integrating *in vitro* and *in vivo* Approaches
Fabianne Ribeiro[1], Ives Charlie-Silva[2], Roberto Martins[3], Simone Teixeira[2], Leticia Lotufo[2], Glaucia M. Machado-Santelli Dr[2], Susana Loureiro[3], Amadeu M.V.M. Soares[4] and ***Maria D Pavlaki**[4]*, (1)Department of Biology & CESAM - University of Aveiro, Aveiro, Portugal, (2)University of São Paulo (USP), Brazil, (3)CESAM & Department of Biology, University of Aveiro, Aveiro, Portugal, (4)University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Aveiro, Portugal*
Cancer is still one of the most lethal diseases worldwide. Given the variety of forms cancer manifests in humans, the search for new molecules with anticancer activity, the antineoplastic drugs (AAs), is a constant process. In such a context, particular attention has been devoted to natural AAs molecules. Chromomycins comprise a group of antibiotics produced by *Streptomyces* spp., which has antitumour activity. Chromomycin A2 (CA2) was first isolated in 1957 and has been proven efficient in inducing autophagy in melanoma cell lines. Like other AAs, the mode of action of CA2 encompasses DNA intercalation and nonspecific cytotoxicity. This feature places the AAs in the spotlight of emergent environmental contaminants of concern, which require an assessment of the hazard that they may represent for the environment. This study assessed both *in vitro* and *in vivo* toxicity of CA2 to ZFL cell lines and zebrafish embryos, respectively. For the *in vitro* assessment, cell viability, enzyme activity, and cell morphology were evaluated. For the *in vivo* toxicity assessment, endpoints measured in zebrafish embryos and larvae were hatching, mortality, developmental malformations, heartbeat, locomotion, and markers related to oxidative stress and neurotransmission impairment. Results from the *in vitro* exposure showed that the 72-h IC50 for cell growth inhibition was 0.23 mg L^{-1}, while at 6 mg L^{-1}, CA2 impaired cell viability by 50% after 24 h. The catalase (CAT) and acetylcholinesterase (AChE) activities were significantly inhibited at all tested concentrations after 24 h of exposure. The activity of glutathione reductase (GR) and Glutathione-S-Transferase (GST) in ZFL cells was not affected by CA2 exposure. CA2 induced alterations in ZFL cells morphology as observed in immunofluorescence preparations. However, the *in vivo* effects were less pronounced, and mortality was not observed at concentrations up to 2 mg L^{-1}, nor were any alterations in larvae's locomotion. The heart rate of ZF embryos was decreased at 500 mg L^{-1}. GST was at all tested concentrations, GR activity increased at 1 and 2 mg L^{-1}, while AChE increased at 2 mg L^{-1}, which may signalise an irreversible impairment of both neurotransmission and antioxidant enzymatic activity. *In vivo* CAT activity was not impaired by CA2 exposure. Overall, CA2 was more toxic to ZFL than to zebrafish embryos. These results are compatible with CA2's highly cytotoxic and nonselective nature.

1.01.P-Tu017 'Omics-Based Fingerprinting of Androgen Disruption in Zebrafish Embryos
***Steve Uwa Ayobahan Dr.**[1]*, Jannis Strompen[1], Christoph Schaefers[2], Elke Eilebrecht[3] and Sebastian Eilebrecht[3], (1)Fraunhofer Attract Eco'n'OMICs, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany, (2)Ecotoxicology, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany, (3)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany*
Endocrine disruptors (EDCs), which are capable of disrupting an organisms endocrine system, are undeniably an increasing concern owing to their developmental and reproductive health impact both in human and the environment. Screening for EDC properties, particularly of active ingredients of pesticides, biocides, or complex mixtures of contaminants, involves a diverse range of species and endpoints that are costly in terms of both resources and animal use. To this end, we applied transcriptomics to identify molecular signatures of androgen hormone signalling interference that underpin physiological effects in zebrafish (*Danio rerio*) embryos. In this study, zebrafish embryos were exposed to different sublethal concentrations of the androgenic steroid trenbolone and the antiandrogenic herbicide linuron as model substances to detect enhanced and suppressed androgen hormone signaling pathways in a modified zebrafish embryo toxicity test (zFET). In comparison to the control group, no significant effects were observed for survival or hatching rate. Application of transcriptomics identified genes involved in androgen synthesis, sexual dimorphism, spermiogenesis, and cholesterol synthesis, such as *star*, *cyp7a1*, *cyp17a1*, *dhcr7*, *srd5a2a*, and *hsd11b2*, to be significantly regulated by trenbolone exposure. Both Linuron and Trenbolone significantly targeted

genes involved in the biosynthesis of steroid hormones, essential for sexual development. This study demonstrates that zebrafish embryos are a suitable vertebrate model not only to identify potential hazards associated with exposure to chemicals that directly affect androgen synthesis, but also to investigate potential endocrine disrupting effects of compounds. Evaluation of the molecular biomarkers identified here in zebrafish embryo-based preregulatory bioassays will aid in the identification of ED hazards of compounds, which may significantly reduce animal testing in higher tier studies.

1.01.P-Tu018 First Steps to Expand the Model *Parhyale hawaiensis* to Evaluate Genetic Damage in Germ Cells

***Marina Tenório Botelho**, Amanda dos Santos and Gisela Umbuzeiro, School of Technology – State University of Campinas, Brazil*

Developing new model organisms for tropical estuarine ecosystems is necessary because this area is particularly vulnerable to anthropogenic influence and climate change. Amphipods have good potential as models because they connect benthic food webs to higher trophic levels and are easily cultivated in the laboratory. The amphipod *Parhyale hawaiensis* has a circumtropical distribution and have been considered an important model for evolutionary development, regeneration, sensory biology, chronobiology, bioprocessing, and more recently ecotoxicology. Protocols to evaluate acute toxicity, genotoxicity, gene expression, regeneration, and to measure internal concentrations of toxicants are already available. We aim to expand the use of *P. hawaiensis* developing assays to evaluate the adverse effects of environmental contaminants in germ cells. But oogenesis and spermatogenesis have not been yet described for this species. To describe these processes, organisms in amplexus with females in the last part of their reproductive cycle (hatched juveniles in the brood pouch) were separated and observed daily until neonates were found and a new batch of oocytes was observed in the marsupium, marking the start of a new reproductive cycle. Then, males and females were separated and the organisms were observed daily until they completed the reproductive cycle (around 13 days). For females, embryo number and stage were evaluated, and for males, sperm cells were counted. We observed that neonates took between 13 to 14 days to be born at 24±2ºC and females had 9.2±4.2 embryos. Sperm count was expressed in number of spermatozoids per male weight. In general, sperm counts seem to increase until the 6^{th} day after female fecundation and then the number becomes stable. The maximum observed value was achieved on the 6^{th} day, reaching 811±529 sperm cells/male weight (mg). Our next step will be to evaluate DNA damage in germ cells using comet assay after *in vivo* exposure to reference compounds. In the future, we aim to perform experiments exposing not only males, but also females and/or both before copulation to evaluate possible alterations in embryo number, stage development, and abnormalities.

1.01.P-Tu019 Speeding up Eco'n'OMICs – High Throughput Hazard Assessment by Multiplexed Bead-Based Analysis of Molecular Biomarkers

***Fabian Essfeld**, Julia Alvincz, Hannes Armin Reinwald, Fatma Marghany, Steve Uwa Ayobahan and Sebastian Eilebrecht, Fraunhofer Attract Eco'n'OMICs, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany*

The Fraunhofer Attract project Eco'n'OMICs aims at the 'omics-based identification of molecular biomarkers in different ecotoxicological model organisms, which will enable assessment of the hazard potential of substances more rapidly than conventional tests, while providing qualitative information on the compound's mode of action. For this, ecotoxicological experiments with model organisms such as zebrafish embryos are performed with low, sublethal effect concentrations of well-characterized reference substances. Afterwards, total RNA or protein is extracted for differential gene expression analysis using RNA sequencing or LC-MS-based proteomics, in order to identify potential biomarkers. Recent proof-of-concept studies were promising, but results require further validation. Since using RT-qPCR as the standard method for gene biomarker assessment would be extremely labor- and cost-intensive for a higher number of samples and targets, the Eco'n'OMICs project aims at using a bead-based multiplexing method enabling to quantify up to 80 targets for up to 48 samples at once. To increase testing throughput, the exposure experiments are currently transferred from petri dishes to 96-deep-well-plates. The combination of automated pipetting and automated extraction of RNA allows the processing of 96 RNA samples simultaneously. Roughly estimated, this will result in time savings for the individual steps of testing and assessment: Firstly, in comparison to the regular approach it is possible to perform about five times more exposure experiments in the same amount of time. Secondly, the automated extraction of RNA from 96 samples takes only about two hours while the manual extraction takes at least two days. Thirdly, the protocol for bead-based multiplexed gene expression analysis takes about three days, much of which is incubation time. Assuming four 96-well-plates being processed daily using RT-qPCR, this would take 20 days, not including the necessary controls. Taken together, this approach can save a tremendous amount of time, while also avoiding errors and increasing reproducibility thanks to automation.

1.01.P-Tu020 Developmental Effects of Nanoparticles in *Schmidtea mediterranea*

***Julie Tytgat**[1], Nathalie Leynen[2], Frank G.A.J. Van Belleghem[3], Nelly Saenen[2], Karolien Bijnens[2] and Karen Smeets[2], (1)Biology-Biodiversity and Toxicology, Hasselt University, Belgium, (2)Biology - Geology, Hasselt University, Belgium, (3)Department of Environmental Sciences, Open University, Netherlands*

The rapid growth of nanotechnology, and the use of nanomaterials in personal care products, food, or other applications, leads to increasing amounts of nanoparticles (NPs) in the environment, where they form a potential risk for living organisms. Although the hazardous effects of several of these particles were identified, in-depth knowledge of the underlying modes of action and their relationship to the physicochemical properties of the particles is still lacking in current risk assessment strategies. Especially for developing organisms, large knowledge gaps exist.

In our study, the regenerative capacity of the freshwater planarian *Schmidtea mediterranea* was used as a proxy to study developmental effects. A large amount of pluripotent adult stem cells allows *S. mediterranea* to regenerate all body tissues, including the nervous system. This makes it possible to study developmental and neurotoxicity *in vivo* in line with the 3R principles and REACH regulations. *S. mediterranea* was exposed to polyvinylpyrrolidone-coated and noncoated silver nanoparticles ((PVP)-Ag-NPs) of 20 nm; titanium dioxide nanoparticles (TiO2-NPs) of 21 nm; and polystyrene micro- and nanoparticles (PS-MNPs) of 49 nm, 215 nm, 1 µm, and 2 µm. The physicochemical properties of the particles were characterized using transmission electron microscopy (TEM) and dynamic light scattering (DLS).

Particle uptake was confirmed for all particles using confocal microscopy and TEM, but their composition and size affected the toxicokinetic profile. All particle types— (PVP)-Ag-NPs, TiO2-NPs, and PS-MNPs— impaired (neuro)regeneration. PS-MNPs had a size and concentration-dependent effect on (neuro)regeneration, regardless of their size with the highest concentration, causing the most pronounced effects. PVP-coating strongly influenced the adverse outcomes of the silver NPs, which again emphasizes the role of the physicochemical characteristics in particle-induced toxicity. Further particle-specific effects were increased mucus production after exposure to TiO2-NPs which serves as a defence mechanism. In summary, our study shows general and particle-specific effects of (PVP)-Ag-NPs, TiO2-NPs, and PS-MNPs, and indicates the importance of including physicochemical properties in hazard and risk characterization. In addition, the stronger effects on developing organisms cannot be overlooked, and investigating different physiological stages is the way forward in future risk assessment strategies.

1.01.P-Tu021 Transcriptomic Points of Departure for Japanese Quail Exposed to Six Pesticides Using the EcoToxChip Test Method

***Nil Basu**[1], Yanan Zhang[1], Aimen Akbar[1], Ke Xu[1], Emily Boulanger[2] and Jessica Head[2], (1)McGill University, Canada, (2)Faculty of Agricultural and Environmental Sciences, McGill University, Canada*

Under the banner of New Approach Methods (NAMs) transcriptomics dose-response analysis (TDRA) has emerged as a promising approach for integrating toxicogenomics data into risk assessments. Here we combine an early life stage (alternative to animal) avian embryo test and a targeted qPCR array (EcoToxChip; n = 384 genes of relevance to environmental toxicology) to determine if 1) transcriptomics points of departures (tPOD) can be derived from this test system; and 2) the tPOD values are protective of levels associated with adverse outcomes. Fertilized, unincubated Japanese quail (JQ) eggs were injected with graded concentrations (100, 32, 10, 3.2, 1, 0.32, 0.1 µg/g egg plus DMSO control) of six pesticides: ethoprophos, carbofuran, trichlorfon, permethrin, glufosinate ammonium, and chlorpyrifos. Phenotypic endpoints including mortality, infertility, embryo mass, and deformity (presence of fatty liver) were assessed at embryonic day 9. Gene level BMDs (benchmark dose) were derived for each chemical. While there were relatively few gene-level BMDs (<25 per chemical), they were lower than levels associated with adverse outcomes. Further, for all test chemicals, investigation of gene- and pathway-level results concurred with expected mechanisms of action. Finally, two of the chemicals were repeated and yielded similar results, thus giving confidence to the test method. In conclusion, the EcoToxChip Test Method can yield gene level BMD values that are protective of levels associated with adverse outcomes, and also give insights into mechanisms of action. However, derivation of tPODs may be challenging with the reduced gene set provided by EcoToxChip thus necessitating more work in this area.

1.01.P-Tu022 Fluid Shear Stress Affects the Metabolic and Toxicological Response of the Rainbow Trout Gill Cell Line RTGill-W1

*Penny Fenton[1], Christer Hogstrand[2] and **Nicolas Bury**[1], (1)Ocean and Earth Science, University of Southampton, United Kingdom, (2)King's College London, United Kingdom*

The Rainbow trout gill cell-line (RTgill-W1) is of growing importance as a tool in chemical risk and has been accepted by the Organization for Economic Co-operation and Development (OECD 249 Test Guidelines) as a replacement for fish in acute toxicity tests. In these tests cells are exposed under static conditions. In contrast, *in vivo*, water moves over fish gills generating fluid shear stress (FSS) that alters cell physiology and response to toxicants. The current study uses a specialized 3D printed chamber designed to house inserts and allows for the flow (0.2 dynes cm^2) of water over the cells. This system was used to assess RTGill-W1 cell responses to FSS in the absence and presence of copper over 24 h. In response to FSS RT-gill W1 cells remained attached to the inserts showed no changes in morphology or transepithelial resistance (TER). Fluid shear stress caused increased gene expression of mechanosensitive channel peizo1 and the Cu-transporter atp7a, elevated reactive oxygen species generation, and increased expression of superoxidase dismutase. Cell metabolism was unaffected by Cu (0.163 µM to 2.6 µM Cu) under static conditions but significantly reduced by FSS + Cu above 0.325µM. Differential expression of metallothionein (mt) a and b was observed with increased expression of mta under static conditions and mtb under FSS on exposure to copper. These findings highlight toxicologically relevant mechanosensory responses by RTGill-W1 to flowing water that may influence toxicological responses.

1.01.P-Tu023 Acute Toxicity Study of 3,5-Dichloroaniline Using RTgill-W1, Fish Cell Line

***Jigarkumar Rameshbhai Rana**[1], Pritee Singh[2], Brijendra Kurmi[2] and Nadeem Ahmad Khan[2], (1)Ecotoxicology, Jai Research Foundation, India, (2)Jai Research Foundation (JRF) Global, India*

Fish cell line assay is an *in vitro* method to predict the acute toxicity of various chemicals which is an attractive alternative assay to the fish acute toxicity test (OECD TG 203). The rainbow trout (*Oncorhynchus mykiss*) cell line assay with RTgill-W1 cells has been used to predict the toxicity *in vitro*. In the current research, we are presenting results of 18 research trials performed at Jai Research Foundation for standardization of assay. In this experiment, confluent monolayers of the RTgill-W1 cell line were exposed in a completely defined, protein-free exposure medium, L-15/ex, at a range of 3.13 to 100 mg/L for 24 h in 24-well tissue culture plates with positive control substance, 3,5 dichloroaniline (DCA) recommended in OECD TG 249. Cell viability after exposure were analysed by three fluorescent indicator dyes, measured on the same set of cells, and compared to unexposed cells, which served as control. Combining the cell viability measurements and the measured chemical exposure concentrations, effective concentrations impacting 50% of the gill cells (EC50 value) were calculated based on concentration-response modelling. In this experiment, we were able to standardize the assay according to preset quality criteria. The variation of raw fluorescence data of the two cell-free control wells (one carrying L-15/ex and the other carrying L-15/ex with the highest test chemical concentration, 100 mg/L) were found to be below 20%. The cell viability of the solvent control within the range of 10% compared to negative control, which is within the range of natural background variability. The mean nominal EC50 values for the DCA was found to be 36.8–55.3 mg/L, 16.7–103.3 mg/L, and 19.9–69.6 mg/L for AlamarBlue™, CFDA-AM, and Neutral Red, respectively, which is within two-and-a-half standard deviations (SD) from the EC50 values recommended in OECD TG 249 for the test to be valid. This result is within the range given in the OECD TG 249. This study therefore underlines the robustness of the RTgill-W1 cell line assay and its accurate performance.

1.01.P-Tu024 Using Automated Size Measurement Software as a Possible New Approach Methodology to Support Adverse Outcome Pathway
Maria Christou[1]*, Maria T. Hultman*[2]*, Camila Esguerra*[3]*, Adam Lillicrap*[2] *and You Song*[2]*, (1)Norwegian Insitute for Water Research, Norway, (2)Norwegian Institute for Water Research (NIVA), Norway, (3)Center for Molecular Medicine, University of Oslo, Norway*
Oxidative phosphorylation (OXPHOS) is the main metabolic pathway, taking place in the mitochondria, that produces energy in the form of ATP. Chemicals that act as mitochondria uncouplers can disrupt the OXPHOS process and can lead to adverse outcomes of regulatory concern such as growth inhibition. Chemical regulatory frameworks (e.g., REACH), aim to reduce traditional animal toxicity tests in favor of alternative testing methods, for hazard assessment of chemicals. Under the adverse pathway (AOP) concept, an AOP has been published linking the uncoupling of OXPHOS to growth inhibition, via a reduction of ATP pool and cell proliferation (OECD project #1.92, AOPWiki, AOP #263). This study aims to utilize new approach methodologies to investigate the sublethal effects of mitochondrial uncouplers on the growth as well as developmental inhibition of zebrafish (*Danio rerio*) larvae. Zebrafish embryos were exposed to different concentrations of the known mitochondria uncoupler carbonyl cyanide 3-chlorophenylhydrazone (CCCP) until 96 hours postfertilization. At the end of the exposure period, lateral images of zebrafish larvae were taken. The FishInspector software (version 1.69) will be utilised to automatically annotate features on the acquired pictures of zebrafish larvae. Subsequently information will be extracted on the effects of exposure to CCCP in different structures of zebrafish larvae such as length and size of the yolk sac area, the pericardium, otoliths, and eye as well as otolith to eye distance, among others. The results will be used to expand the current adverse outcome of AOP263, providing information on the effects of mitochondrial uncouplers on multiple structures of zebrafish larvae as well as to construct a quantitative AOP (qAOP) based on AOP263.

1.01.P-Tu025 Risk Assessment for Amphibia in the EU – How Much Additional Animal Testing Is Adequate?
Heino Christl*, Eva Gryglewicz and Anja Russ, Tier3 Solutions GmbH, Germany*
Based on publications on effects of agrochemicals on amphibia, in the EFSA opinion paper on amphibia and reptiles recommendations are made how to test aquatic and terrestrial stages. While the body burden concept allows to compare different ways of exposure and to predict toxic effects also across different stages, even within aquatic stages (comparing the sensitivity of tadpoles and fish), fairly inconsistent endpoints are listed in Appendix K of the supporting document Ortiz-Santaliestra et al. 2017. Based on this dataset, the EFSA Panel proposed to apply an additional assessment factor of "at least 100" if acute fish-endpoints were used as a surrogate for acute amphibia endpoints in the risk assessment for aquatic stages. The dataset Appendix K can however be improved, if matching fish endpoints (of the very formulation used in the amphibian test) are used for the evaluation. These acute fish endpoints are available for virtually every formulation as it is a core data requirement. When updating the database accordingly, only very few cases remained with fish less sensitive than amphibia, and only these would justify such a high additional AF (100) to bridge between fish and amphibian LC50-endpoints. If this additional AF were included in any future Guidance Document, this would result in a very conservative risk assessment, and so trigger many additional experiments on amphibia. This is even clearly encouraged by EFSA (to generate more experimental data with amphibia), until there was more evidence available. However, based on the revision of the existing data (by formulation) we conclude that there is already extensive evidence, suggesting that acute risk to amphibians can be reliably predicted, and hence additional acute animal tests are largely dispensable. Also, an additional assessment factor of 100 to bridge between fish and aquatic amphibia stages should be dispensable.

1.01.P-Tu026 Characterization of Hepatic 3D Spheroids Using Multiphoton Fluorescence Microscopy and 'Omics
Prem Chand[1]*, Tania Gomes*[2]*, You Song*[2]*, Awadhesh Jha*[3] *and Maria T. Hultman*[2]*, (1)Ecotoxicology and Risk Assessment, Norwegian Institute for Water Research (NIVA), Norway, (2)Norwegian Institute for Water Research (NIVA), Norway, (3)Plymouth University, United Kingdom*
Due to current regulatory legislation mandate for hazard assessment of a large number of chemicals, testing for toxicity and bioconcentration has become more crucial. As a result, the attempts to develop nonanimal and alternative bioassays, with a focus on the use of cells to replace *in vivo* fish toxicity tests, have increased, with focus on fish. The SPHERTOX project is assessing the rainbow trout (RT) hepatic three-dimensional (3D) spheroids model's suitability as an alternative chronic toxicity- and bioconcentration method with enhanced comparability to *in vivo* test systems in fish. The hepatic 3D RT spheroid system is a novel cell model, requiring comprehensive morphological and physiological characterization. We therefore investigated the

uptake, disposition, and toxicity of chemicals in spheroids by using a high-resolution multiphoton fluorescence microscopy (MFM). Multiphoton fluorescence microscopy was used to visualize cellular and subcellular responses during exposure to sublethal concentrations of copper sulphate, 17 β-ethinylestradiol, pyrene, 3,4-dichloroaniline, and carbonyl cyanide m-chlorophenyl hydrazone. More specifically, biomarkers for morphology, area, diameter, sphericity, actin synthesis, cytoskeleton, lipid membranes integrity, bile canaliculi structures, DNA/nucleus staining, viability, metabolic activity, and oxidative stress were assessed. Our findings suggest that the 3D spheroids maintain their morphological and physiological integrity, as well as viability for longer than five weeks postisolation, with no signs of hypoxia at the core. Furthermore, transcriptomics and metabolomics are being explored to unravel the spheroids' physiological complexity and potential use in chemical toxicity studies. The morphology and physiological responses of RT hepatic spheroids observed suggest that this model has significant potential as a future toxicity screening tool for different chemicals.

1.01.P-Tu027 Development of a Modular, Cell Line-Based Framework for the Animal-Free Prediction of Chemical Toxicity to Fish

***Stephan Fischer**[1], Roman Li[2], Vid Modic Modic[3], Ziva Ramsak[3], Kristin Schirmer[2] and Anze Zupanic[4], (1)aQuaTox-Solutions GmbH, Switzerland, (2)Environmental Toxicology, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Dübendorf, Switzerland, (3)National Institute of Biology (NIB), Slovenia, (4)Department of Biotechnology and Systems Biology, National Institute of Biology (NIB), Slovenia*

Environmental risk assessments are performed to protect our natural environment while maximising benefits that chemicals offer to all aspects of life. Traditionally, these assessments are animal-centric, e.g., fish are used and sacrificed in toxicity studies to identify adverse outcomes elicited by chemicals. These procedures raise ethical concerns but, additionally, are too slow and insufficiently informative to keep up with the rapidly growing need to test chemicals for potential harm. Alternatives to these tests are therefore urgently needed. Our vision is to build an alternative fish framework, which combines permanent fish cell cultures and computational models, to allow accurate predictions of chemical impact without the need for animal experimentation. Pursuing this vision, we have previously demonstrated that it is possible to use cell lines from Rainbow trout (*Oncorhynchus mykiss*) to predict the impact of chemicals on fish survival and growth. As part of the CRACK IT Challenge – SAFE: Innovative Safety Assessment of Fish adverse Effects – funded by the NC3Rs (UK), we now propose to expand these concepts to allow predictions on reproductive toxicity. In a first project phase, we have developed a novel multistage computational pipeline that allowed identification of key molecular players and processes in fish reproductive toxicity. We will now exploit the identified key players and processes to develop scalable biomarker response assays in fish cell lines originating from liver, testis, and ovaries. Upon establishing routine culture of these cells, we will explore them for their constitutive biomarker response levels and then monitor regulation of the biomarkers upon exposure to known reproductive toxicants, negative control chemicals, and chemicals for which reproductive toxicity is thus far ambiguous or unexplored. We will complement gene expression analyses by monitoring cellular biomarkers and processes for comprehensive toxicological profiling. We will then incorporate these responses into a computational scheme to translate the cell-based information into an outcome for fish. A comprehensive set of historical *in vivo* data will serve as a benchmark for reproductive toxicity predictions. We will provide wide access to the knowledge gained and services and products developed to ensure maximal benefits to the 3Rs.

1.01.P-Tu028 Extrapolation of *in vitro* Bioactivity Data to Points of Departure (PODs) Using an *in vitro* Mass Balance Model (IV-MBM V2.0)

*James M Armitage[1], **Alessandro Sangion**[2] and Jon A. Arnot[2], (1)AES Armitage Environmental Sciences, Inc, Canada, (2)Arnot Research and Consulting Inc. (ARC), Canada*

In vitro bioactivity and toxicity data are increasingly being generated to facilitate chemical assessment activities. One prominent example is the estimation of Administered Equivalent Doses (AEDs). Administered Equivalent Doses are typically calculated as the ratio of an *in vitro* Point of Departure (POD, e.g., EC_X, µM) and the predicted steady-state blood or plasma concentration (C_{SS}, µM) corresponding to an oral dose of 1 mg/kg/d (i.e., AED = $EC_X/C_{SS} \cdot$ 1 mg/kg/d). A key underlying assumption inherent to the calculation of AEDs following this approach is that the *in vitro* POD and steady-state blood or plasma concentration are directly comparable exposure metrics (e.g., identical freely dissolved concentrations). This assumption can be problematic for several reasons stemming from the fact that *in vitro* PODs are almost always reported on a nominal concentration basis. Because the composition of assay medium can be very different from the composition of plasma and blood and other losses can occur in vitro (e.g., volatilization), there may be substantial errors and uncertainties between in vitro PODs and expected C_{SS} with respect to exposure. To assess the potential bias in AED calculations that do not explicitly address bioavailability and in vitro disposition, we applied an *in vitro* mass balance model (IV-MBM v2.0) to a set of neutral organic chemicals spanning a wide range of partitioning properties. The model was parameterized to represent *in vitro* test systems with different exposure conditions particularly with respect to the volume fraction of fetal bovine serum (FBS) added. An alternative IV POD denoted the "equivalent blood concentration" was calculated using the model and compared to EC_X. For semivolatile hydrophobic chemicals, the difference between the AEDs calculated using nominal EC_Xs and *in vitro* PODs estimated using IV-MBM v2.0 can approach two orders of magnitude. There can also be large differences for volatile chemicals due to excessive losses from the *in vitro* test system. On the other hand, differences between AEDs calculated using nominal EC_Xs and *in vitro* PODs estimated using IV-MBM v2.0 are relatively small for more hydrophilic chemicals (i.e., less than a factor of two). The model application demonstrates the importance of considering *in vitro* disposition and bioavailability issues when extrapolating *in vitro* bioactivity data to AEDs and then comparing them to traditional *in vivo* PODs and exposure estimates for risk and safety evaluations.

1.01.P-Tu029 Evaluation of Fish Keratocyte Explant Culture as Environmental Immunotoxicity Screening Assay

Serena George[1] *and Gavin Dehnert*[2]*, (1)University of Wisconsin, Madison, (2)VCGRE, University of Wisconsin, Madison*

2,4-Dichlorphenoxyacetic acid (2,4-D) is the active ingredient in many selective herbicides worldwide that can enter aquatic ecosystems through terrestrial runoff and direct application. 2,4-D is commonly used to control invasive aquatic plants; however, 2,4-D exposure has been associated with sublethal impacts on nontarget organisms, such as fish. Limited research on the impacts of 2,4-D exposure on teleost immune function has been conducted, and the development of a high throughput, *in vitro* assay to screen 2,4-D, and other environmental toxicants, for immune impacts would be highly valuable to the field of aquatic toxicology. Keratocyte cells are one component of fish epidermis that are integral for barrier function, compartmentalization of immune cells, and, in some cases, phagocytic activity. Fish keratocyte explant cultures have been demonstrated to serve as a rapid and low-cost cutaneous wound healing model system which allows for *in vitro* study of cell differentiation, replication, and migration. However, this assay's feasibility and utility as an environmental toxicant screening tool is unknown. To validate this assay, 240 scales were nonlethally extracted from 20 adult male fathead minnows (*Pimephales promelas*), incubated in culture medium for 24 hours, and photographed under a microscope at regular intervals. Using Image J, cell sheet area and leading-edge distance were measured–normalized and not normalized to scale area, scale perimeter, and border length–to determine the most consistent measure of cell growth. Cell sheet area at 6 hours was the most variable measurement, while leading-edge distance at 6 and 24 hours was the most consistent. Next, to model herbicide exposure in freshwater fish, scales were placed in culture medium with different concentrations of 2,4-D ranging from 0.04 to 20,480 ppm (15 concentrations; four replicates per concentration; 12 scales per replicate). Ongoing research will compare *in vitro* results to *in vivo* wound healing experiments to test the applicability of this *in vitro* assay to environmentally relevant *in vivo* scenarios. This comparison will evaluate the potential for keratocyte explant cultures to serve as a valid screening tool for toxicological effects on cutaneous wound healing and may be applied to other environmental toxicants and fish species in the future.

1.01.P-Tu030 Development of a Nonanimal Integrated Approach to Testing and Assessment for Acute Aquatic Toxicity Hazard Classification and Labelling

Donna S. Macmillan[1]*, Pravin Ambure*[2]*, James Dawick*[3]*, Nicolas Fabre*[4]*, Geoffrey Hodges*[5]*, Sophie Loisel-Joubert*[4]*, Blanca Serrano Ramon*[6]*, Eva Serrano-Candelas*[2] *and Ricky Stackhouse*[7]*, (1)HSI, (2)ProtoQSAR, Spain, (3)Innospec Limited, United Kingdom, (4)L'Oréal Research & Innovation, France, (5)Unilever - Safety and Environmental Assurance Centre (SEAC), United Kingdom, (6)ECETOC, Brussels, Belgium, (7)Sasol, Houston, Texas*

Aquatic toxicity is an ecotoxicological endpoint which provides important information about a chemical's potential to elicit adverse effect(s) on aquatic organisms. Within regulatory toxicology, three trophic levels are typically considered as a proxy of the ecosystem: fish (representing vertebrates/apical consumers), daphnia (representing invertebrates/primary consumers), and algae (representing producers/plants). Acute aquatic toxicity effects are typically studied using one or more OECD guideline standardised tests including the Fish Acute Toxicity Test (OECD 203); the Fish Embryo Acute Toxicity Test (OECD 236) and the Fish Cell Line Acute Toxicity - The RTgill-W1 cell line assay (OECD 249). For animal welfare reasons there have been significant efforts in recent years to reduce or eliminate the number of vertebrates, namely fish, used in ecotoxicological regulatory assessment, for example, by applying the 3Rs principle and replacing *in vivo* tests with *in vitro* assays, such as the RTgill-W1 assay, or by developing Integrated Approaches to Testing and Assessment (IATA) for a given chemical. To build upon this body of work, a modular nonanimal IATA has been created, using the following components: *in silico* predictions, RTgill-W1 assay results, physicochemical parameters, and data concerning the mode/mechanism of action (MoA).

Four peer-reviewed publications were used to compile a curated, high-quality dataset of existing *in vivo* and *in vitro* data and good correlation between *in vivo* and *in vitro* data was observed. The *in vivo* data were used to develop a multiclass quantitative structure activity relationship (QSAR) model and the *in vitro* data used to support the development of other relevant modules. The IATA is designed to provide a categorical output suitable for use within the EU Classification, Labelling and Packaging (CLP) and United Nations Globally Harmonized System of Classification and Labelling (UN GHS) frameworks. Case studies and considerations with respect to species relevance and applicability domain will be discussed within.

1.01.P-Tu031 Can Healthy Stem Cells Replace Animal Testing in Assays Addressing Molecular Initiating Events *in vitro*?

Hans Thomas Allner[1]*, Petra Stahlschmidt-Allner*[1]*, Rebecca Prause*[2]*, Alexander Froschauer*[2]*, Kurt Pfannkuche*[3] *and Bernhard Allner*[1]*, (1)GOBIO-GmbH, Aarbergen, Germany, (2)Environmental Monitoring and Endocrinology, Technical University Dresden, Dresden, Germany, (3)Center for Physiology and Pathophysiology, University of Cologne, Germany*

The concern of endocrine disruption due to exposure of xenobiotics has triggered the implementation of effect-based substance testing in the field of environmental legislation. These methods (OECD 229, 230, 234, MEOGRT) use fish as a vertebrate model to measure both molecular initiating events (MIE) such as the activation of the oestrogen receptor and the late effects of exposure such as reduced fertility and fitness as proof of the adverse outcome. The benefit of testing strategies requiring both the MIE, e.g., vitellogenin (VTG) and the corresponding adverse outcome pathway (AOP) (e.g., fertility, condition of offspring) for individual test compounds is questionable.

Based on comparative AOP research on laboratory model fish and riverine/marine species that both present longer life spans, more elaborated capacities for tissue regeneration and repeated gonadal recrudescence, we identified a cell type which seems to be crucial for the healthy seasonal development of the gonads and for tissue regeneration. By a targeted process we could isolate nontumour derived self-renewing cell lines from *Cyprinus carpio* brain. A constitutive Histone 2B-GFP fusion-protein expressing transgenic variant of this cell line was used in transplantation experiments, showing the labelled cells behave like gonad regenerating cells identified *in vivo*. Based on transcriptome data the cells correspond to mesenchymal stem cells of mammals and express the genes of the estrogen pathway. The available H2B GFP transgenic variant is accepted for micronucleus-based genotoxicity assessment as a surrogate for OECD 487 and enables recording of estrogen induced growth promotion. A battery of transgenic variants reporting different modes of action is under development.

Regarding estrogen endocrine disruption a transgenic variant transactivating an estrogen response element controlled NLS-GFP fusion protein is promising. With this construct it is possible to visualize estrogen receptor activation at the single cell level.

The technique enables monitoring the exogenous activation of intrinsic estrogen receptor by means of high throughput live cell imaging. In contrast to cancer cell or yeast-based transactivation assays there is no need to determine the expression of the transgene, e.g., recording catalytic activity of a transactivated enzyme after cell fracturing.

Based on the comprehensive characterisation of the cell lines, we consider them to be perfectly suited to represent MIE and thus contribute to the replacement of animal experiments.

1.01.V Alternative Approaches to Animal Testing for Ecotoxicity Assessments: Exploring Approaches and Avenues for the Future

1.01.V-01 Reducing the Number of Controls in Fish Early Life Stage Toxicity Tests
John W. Green[1], *Christopher Fassbender*[2,3], *David A Dreier*[4], *Daniel Faber*[5], *John Handley*[6], *Thomas Hutchinson*[7], *Lennart Weltje*[8] *and Gilly Stoddart*[9], *(1)Ecostatistical Consulting, JohnWGreen-ecostats.com, (2)PETA International Science Consortium Ltd., (3)PETA Science Consortium International e.V., Germany, (4)Syngenta, (5)Environmental Safety, Bayer AG - Crop Science Division, Germany, (6)JH Consulting, United Kingdom, (7)R&D Global Safety Assurance, Reckitt, United Kingdom, (8)Ecotoxicology, BASF SE, Germany, (9)Science, PETA Science Consortium International e.V., United Kingdom*
This project is investigating whether it is possible to use only a solvent control and omit a water control in case a solvent is necessary in Fish Early Life Stage toxicity (FELS; OECD TG 210) tests. The use of only one control would reduce the number of fish used in tests when solvents are required.

Extensive statistical computer simulations have been conducted to investigate the statistical power of the FELS study to determine NOEC and EC_x values based on one control or pooled controls. The computer simulations covered the observed range of variability in each endpoint observed in each species of fish, the level of variance heterogeneity or overdispersion, the effect of mortality on sublethal responses, and monotonic and nonmonotonic concentration-responses including flat and shallow trends as well as hormesis and quantified the effects of these data characteristics. The study demonstrated the benefits of model averaging on EC_x estimation over model selection but also explored model selection criteria both for its own uses and to improve model averaging.

Furthermore, control and concentration-response data from FELS tests have been collected for analysis of the effect of the control choice on NOEC and EC_x values. Simulated and collected test data were used to determine whether, for one or more required endpoints, there are systematic differences between the two controls. For each endpoint, the distributions of control data (means, between-, and within-replicate variances) for water, solvent, and pooled controls were investigated. Fish Early Life Stage concentration-response data were used to investigate the treatment effect (NOEC, EC_x regressions) when using the water, solvent, or pooled controls.

The analyses indicate that, when the solvent dimethylformamide is used, Fathead Minnow (*Pimephales promelas*) EC_{10} point estimates for length and weight based on the solvent only are more accurate (i.e., in agreement with the real EC_{10}) than those based on either the water control only or the pooled control and that there was a greater ability to fit models for EC_x estimation with the solvent control versus the water control. Use of the solvent control maintains 80% power to detect 10% effects with lower false positive rates than other control choices. Results for survival, abnormalities, and time to hatch or swim-up will also be reported.

1.01.V-02 Zebrafish Cell Lines to Assess the Cytotoxic Effect of Single and Joint Exposures of Antineoplastic Agents
Magda Carvalho Henriques[1], *Ives Charlie-Silva*[2], *Simone Teixeira*[2], *Leticia Lotufo*[2], *Margarida Fardilha*[3], *Susana Loureiro*[4] *and Maria D Pavlaki*[5], *(1)iBiMED - Institute of Biomedicine, University of Aveiro, Aveiro, Portugal, (2)University of São Paulo (USP), Brazil, (3)Department of Medical Sciences, University of Aveiro, Aveiro, Portugal, (4)CESAM & Department of Biology, University of Aveiro, Aveiro, Portugal, (5)University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Aveiro, Portugal*
Over the years, the global average age of the human population has increased. The ageing process is a high-risk factor for the most frequent diseases (e.g., cardiovascular diseases and cancer), leading to an increase in pharmaceuticals' consumption worldwide. Antineoplastic agents (AAs), whether individually or in combination, are widely used in developed countries for cancer treatments. Subsequently, AAs have been quantified in environmental samples, mainly due to their poor removal by wastewater treatment plants, thus expecting the effects to the environmental health to be adverse, even at very low doses.

In this study, to understand the potential cytotoxic effects of AAs, the single and joint effects of three AAs with different mechanisms of action (trabectedin, doxorubicin, and oxaliplatin) were evaluated. For that, the zebrafish liver (ZFL) cell line was used as a model to test the hypothesis that AAs exhibit an unspecified cytotoxicity even at low doses. Cells were incubated using a wide range of increasing concentrations of AAs along with the control treatments for 72 h. The viability of cells exposed was determined by a fluorometric assay using resazurin (commercially available as PrestoBlue®), and morphological changes were observed and assessed by microscopy. Then, the IC50 values calculated for each AA were transformed into Toxic Units (TU) and a full factorial design was used to predict their joint toxicity pattern. The MIXTOX model was used to predict their joint toxicity using as starting point the reference models of Concentration Addition and Independent Action. Our results showed that the exposure to the three AAs in single exposures induced a reduction in ZFL cells viability in a concentration- and time-dependent manner, and it was observed that the most toxic was trabectedin followed by doxorubicin and oxaliplatin. Moreover, at morphological level, treated cells showed relevant alterations. Regarding the joint exposures, our results indicate significant interactions between the tested AAs. Since little is known on the effect of AAs on aquatic organisms, our results demonstrate that ZFL cells provide a relevant and sensitive tool to screen the toxicity of environmental pollutants in the frame of hazard assessment, highlighting the importance of investigating the potential of cell lines to serve as proxy to *in vivo* for the single and joint toxicity assessment of AAs.

1.02 Applications of Computational Toxicology in Environmental Risk Assessment

1.02.P-Mo001 Expanding SeqAPASS Capabilities to Protein Structural Comparisons Across Species

Carlie LaLone[1], *Maxwell Botz*[2], *Peter Schumann*[3], *Wilson Melendez*[4], *Audrey Wilkinson*[4] *and Cody Simmons*[4], *(1)Office of Research and Development, Great Lakes Toxicology and Ecology Division, US Environmental Protection Agency, (2)Oak Ridge Institute for Science and Education, Duluth, Minnesota, (3)School of Freshwater Science, University of Wisconsin, Milwaukee, (4)General Dynamics Information Technology, Research Triangle Park, North Carolina*

The availability of protein structures has expanded significantly with advances in artificial intelligence. Specifically, AlphaFold (https://alphafold.ebi.ac.uk/) and MetaAI ESM Metagenomic Atlas (https://esmatlas.com/), which house the structures for hundreds of millions of AI predicted proteins from the diversity of species. The Protein Data Bank (PDB; https://www.rcsb.org/) contains empirically derived protein structures and other approaches, such as Iterative Threading ASSEmbly Refinement (I-TASSER; (https://zhanggroup.org/I-TASSER/), that provide means for additional protein structure predictions. With these advances in predicting protein structures comes the opportunity to enhance the ability to compare species at the molecular level. Such comparisons lead to understanding similarities and differences across species that can improve understanding of chemical-protein interactions and conserved biological pathways. Protein sequence comparisons for conservation across species have been used as the primary evaluation in the Sequence Alignment to Predict Across Species Susceptibility (SeqAPASS; https://seqapass.epa.gov/seqapass/) tool for predictions of chemical susceptibility and pathway conservation. However, the intent of the SeqAPASS developers is to take advantage of all existing protein information as it becomes available and tools become more amenable to automation for predicting cross-species susceptibility. Therefore, SeqAPASS version 7.0 includes new features integrated in the interface to generate and capture protein structural models from the sequences aligned in Level 1 (primary amino acid sequence alignment), compare protein structures across species for an additional line of evidence toward protein conservation, and provide users with the protein structures for more advanced molecular docking, virtual screening, and possibly molecular dynamic simulation. Moving beyond protein sequence-based predictions to structure using the SeqAPASS web-based pipeline has led to enhanced understanding of the likelihood for chemical interactions, allowing advanced users the ability to examine binding affinities. This presentation will describe the new features of SeqAPASS v7.0 and demonstrate the utility of the enhanced features. *The contents of this abstract neither constitute nor necessarily reflect USEPA policy.*

1.02.P-Mo002 Exploring the Potential of *in silico* Machine Learning Tools for the Prediction of Acute *Daphnia magna* Nanotoxicity

Surendra Balraadjsing, *Willie Peijnenburg and Martina G. Vijver, Leiden University, Leiden, Netherlands*

Engineered nanomaterials (ENMs) are ubiquitous nowadays, finding their application in different fields of technology and various consumer products. Virtually any chemical can be manipulated at the nano-scale to display unique characteristics which makes them appealing over larger sized materials. As the production and development of ENMs have increased considerably over time, so too have concerns regarding their adverse effects and environmental impacts. It is unfeasible to assess the risks associated with every single ENM through *in vivo* or *in vitro* experiments. As an alternative, *in silico* methods can be employed to evaluate ENMs. To perform such an evaluation, we collected data from databases and literature to create classification models based on machine learning algorithms in accordance with the principles laid out by the OECD for the creation of QSARs. The aim was to investigate the performance of various machine learning algorithms toward predicting a well-defined *in vivo* toxicity endpoint (*Daphnia magna* immobilization) and also to identify which features are important drivers of *D. magna in vivo* nanotoxicity. Results indicated highly comparable model performance between all algorithms and predictive performance exceeding ~0.7 for all evaluated metrics (e.g., accuracy, sensitivity, specificity, balanced accuracy, Matthews correlation coefficient, area under the receiver operator characteristic curve). The random forest, artificial neural network, and k-nearest neighbor models displayed the best performance but this was only marginally better compared to the other models. Furthermore, the variable importance analysis indicated that molecular descriptors and physicochemical properties were generally important within most models, while features related to the exposure conditions produced slightly conflicting results. Lastly, results also indicate that reliable and robust machine learning models can be generated for *in vivo* endpoints with smaller datasets.

1.02.P-Mo003 Predictive Modelling of the Maternal Transfer of Organic Pollutants to Next Generations in Reptile Species

*Cynthia C. Munoz[1], **Peter Vermeiren**[1,2] and Sandrine Charles[3], (1)Radboud University, Netherlands, (2)Department of Natural Sciences and Environmental Health, University of South-Eastern Norway, Norway, (3)UMR CNRS 5558, University Claude Bernard Lyon 1, Villeurbanne, France*

Maternal transfer of pollutants between mothers and their offspring presents one of the first exposure routes for newborn organisms before they themselves come into contact with the external environment, and this during sensitive early life stages where many fundamental development and organization processes take place. To support exposure assessment of early life stages, we aimed to develop a predictive model regarding the maternal transfer of organic pollutants that is applicable across reptile species. We developed a Bayesian orthogonal regression model to characterize the relationship between pollutant concentrations in mother and offspring tissues as dependent variables which are both measured quantities. The model explicitly accounts for uncertainty in measured variables by applying a Gaussian error distribution on both variables and constraining their range in relation to the population mean. Parameter estimation using Bayesian inference allowed the full parameter uncertainty to be propagated into the probabilistic model predictions. To support model development, we conducted a systematic search regarding measurements of organic pollutants in coupled samples from mother and offspring tissues. Subsequent data curation, including homogenization, standardization, and integration, resulted in a large, compiled database containing heterogeneous records from diverse species, diverse tissues, and diverse chemicals (including legacy POP such as PCB and OCP as well as newer compounds such as plasticizers). Alternative model formulations and extensions were developed to identify the most parsimonious model that can capture the influence of the diversity in species and chemical structures within the database, as well as account for the large proportion of censored data (records where measured concentrations were below the detection limits of the analytical instruments). Model goodness of fit was evaluated against the WAIC criterion and predictive performance assessed via cross-validation. The resulting model allows scientists and decision-makers to quantitatively link internal body burdens of mothers to subsequent generations in reptile species, a group which is underrepresented in ecotoxicology and chemical risk assessment.

1.02.T-01 MechoA+: A Significant Update to the MechoA Classification Scheme

***Gaspard Levet**[1], Franklin Bauer[1], James Firman[2], Jayne Roberts[3], Steve Gutsell[3], Bruno Campos[3], Mark A. Bonnell[4], Paul Thomas[1], Mark Cronin[5] and Geoffrey Hodges[3], (1)KREATiS, France, (2)School of Pharmacy and Biomolecular Sciences, Liverpool John Moores University, United Kingdom, (3)Unilever - Safety and Environmental Assurance Centre (SEAC), United Kingdom, (4)Environment and Climate Change Canada, Canada, (5)Liverpool John Moores University, United Kingdom*

Knowledge of the mechanisms by which substances induce adverse effects is key to understanding, predicting, and limiting the impact of chemicals on humans and ecosystems. This is often based on the adverse outcome pathway blueprint of molecular initiating events (MIE) and some subsequent key events for a wide domain of species. Different schemes for attributing mode and mechanism of toxic action to chemicals have been developed historically but the most recent are the MechoA (Mechanisms of Toxic Action) and Sapounidou schemes. The improvement and subsequent merger of both schemes were carried out by KREATiS in collaboration with Liverpool John Moores University and supported by Unilever giving rise to a new scheme called MechoA+. This new tool was developed by a team of chemists, biologists and (eco)toxicologists using a holistic approach. It considers the mechanisms and effects observed in different species and experimental conditions to validate or invalidate the proposed MechoA subclass. Furthermore, protein orthology databases were used and the number of alerts covered by the scheme doubled. Thus, the spectrum of application of the model is greatly extended compared to previous schemes. It now covers many regulatory endpoints in toxicology and ecotoxicology. To boost its usage for regulatory purposes, including QSAR building and read-across, it will be made freely accessible in the OECD QSAR Toolbox as the “MechoA+” profiler, as is already the case for the current version, the iSafeRat® MechoA profiler. Another more advanced version of MechoA+, named MechoA Premium, available in iSafeRat® Desktop, is under development by KREATiS, and will be frequently updated to integrate new knowledge. These new advances will pave the way toward a broader and more versatile tool for regulatory use or in other areas such as R&D molecular design and eco-conception.

1.02.T-02 Explainable Deep Learning to Predict Bioaccumulation in Fish

***Sebastian Schmidt**[1], Linlin Zhao[2], Henry Heberle[2] and Floriane Montanari[2], (1)Bayer AG - Crop Science Division, Germany, (2)Bayer AG - Crop Science Division, Eritrea*

The rapid evolution of machine learning and explainable artificial intelligence (XAI) methods opened up new opportunities for predictive modelling in the context of molecular design and safety assessments. We explored explainable deep learning methods to predict bioaccumulation in fish from molecular structures. Bioaccumulation is an important parameter in the environmental risk assessment of chemicals and new alternative methods are required to reduce vertebrate testing. Despite limited numbers of tested molecules and the complexity of biological systems, artificial intelligence can be useful, especially in combination with human expert mechanistic knowledge.

We developed a new multitask deep learning model for the bioconcentration factor (BCF). The model is based on a continuous data-driven representation of chemical space that operates on simplified molecular-input line-entry system (SMILES) strings. In addition to BCF data, we utilized a large dataset for lipophilicity (logD) to improve model performance and extend the applicability domain. Our model is more accurate than previously published models (RMSE of 0.59 log units on an independent test set) and generalizes well to unknown regions of the chemical space. It is purely data-driven and therefore independent from expert-crafted rules or the definition of functional groups.

Moreover, we developed an explainability approach that provides valuable feedback to the user by highlighting the most influential parts of the molecule (SMILES characters). This additional explainability layer helped during model development, can foster acceptance of the predictions by allowing users to explore the inner workings of the model, supports the design of safe molecules, and can improve mechanistic understanding of the processes involved in bioaccumulation.

Overall, with its accuracy, the broad applicability, its ability to generalize, and the explainability aspects, our model satisfies the criteria for many use cases and could be considered an alternative for animal testing.

1.02.T-03 EAS-E Suite for Chemical Safety and Sustainability

***Jon A. Arnot*[1]**, *Alessandro Sangion[1], Li Li[2], James M Armitage[3], Liisa Toose[1], Trevor N. Brown[1] and Lauren Hughes[1], (1)Arnot Research and Consulting Inc. (ARC), Canada, (2)School of Public Health, University of Nevada, Reno, (3)AES Armitage Environmental Sciences, Inc, Canada*

Thousands of new and existing chemicals require environmental risk assessment and the necessary information is quite limited or nonexistent for most chemicals. The freely accessible on-line Exposure And Safety Estimation (EAS-E) Suite platform includes curated, measured physical-chemical properties, environmental biodegradation half-lives, biotransformation half-lives, and production volumes for thousands of chemicals, quantitative structure activity relationships (QSARs) for predicting chemical information (if measured data are unavailable), and tools to aid chemical assessment decision-making. The EAS-E Suite includes various multimedia mass-balance environmental fate, bioaccumulation, and exposure models for a wide range of ecological receptors (plants, invertebrates, fish, birds, and mammals) as well as humans. The EAS-E Suite also includes the CiP-CAFÉ model for estimating life cycle chemical mode-of-entry and emission rates. The PROduction-To-EXposure High Throughput (PROTEX-HT) model combines CiP-CAFÉ and the RAIDAR, and RAIDAR-ICE models for simulating aggregate exposures to representative ecological receptors and humans in a one health approach for environmental risk assessment. Using only chemical structure as an input parameter, the EAS-E Suite also provides information for Persistence, Bioaccumulation, and Mobility assessments. The recently added internal Threshold for Toxicological Concern (iTTC) provides conservative safety-based screening information for existing chemicals as well as prospectively for new chemicals that have not yet entered the market. The objective of this study is to highlight the role EAS-E Suite can play in screening and prioritizing thousands of chemicals for hazard and risk assessment. The case study comprises a range of chemistries including flame retardants, plasticizers, biocides, personal care products, industrial chemicals, and chemical intermediates. The chemicals are compared for P_{OV}, maximum BMFs (from aquatic and air-breathing organisms), and maximum exposures (mmol/kg-ww) in a range of ecological receptors, and safety. P_{OV} ranges from about 10 h to 1,000,000 h. The maximum BMFs (i.e., fish, mammals, birds, humans) range from about 0.002 to 100. The maximum exposures span 12 orders of magnitude demonstrating the capacity to quickly screen and differentiate chemicals with high risk of exposures to ecological receptors. The simulations can be used to prioritize data needs and testing requirements to reduce unnecessary animal testing.

1.02.T-04 MLinvitroTox: A Machine Learning-Based Hazard-Driven Prioritization for Environmental High-Resolution Mass Spectrometry Analysis

***Katarzyna Arturi*[1]** *and Juliane Hollender[2], (1)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Dübendorf, Switzerland, (2)Environmental Chemistry, Environmental Chemistry, Eawag, Swiss Federal Institute of Aquatic Science and Technology, Dübendorf, Switzerland*

High-resolution mass spectrometry (HRMS) followed by nontarget screening (NTS) workflow for converting thousands of molecular "features" into quantified chemical structures is a cornerstone tool for comprehensive mapping of global pollution. However, since a complete elucidation of a large number of HRMS signals is not yet feasible, prioritization of the "relevant" signals is a crucial step. While the traditional HRMS prioritization approaches are often based on signals' abundance or frequency underlining environmental exposures, they lack toxicological relevance critical for risk assessment. In this work, we propose to replace the traditional prioritization during NTS-HRMS/MS with a hazard-driven prioritization based on the unknown features' potential toxicity, focusing the analysis on the signals with the highest potential to cause harm. For the prediction of features' hazards, a machine learning tool (MLinvitroTox) was developed as a collection of optimized supervised classification models trained to predict hundreds of molecular toxicity endpoints from the high-throughput invitroDB (Tox21 and ToxCast) from the USEPA. When deployed on environmental data, MLinvitroTox takes molecular fingerprints of unknown HRMS/MS features as input (obtained from MSMS spectra via SIRIUS's CSI:FingerID) and outputs their "toxicity fingerprints," binary strings of 0' s and 1' s indicating their toxic activity in single endpoints. The results have shown that MLinvitroTox performs well in modeling, under validation, and with environmental samples. With optimal settings (XGB modeling algorithm, CSI:FingerID fingerprint [used in SIRIUS], smote oversampling of the minority class, repeated_cv as resampling), average sensitivity values (toxicity discovery rates) were > 0.95 for a third (28 \%) of the molecular toxicity endpoints and the majority of the known mechanistic targets (70 \%). Deployment of MLinvitroTox on MassBank spectra (validation) and environmental samples (testing) showed that MLinvitroTox not only performed well in modeling, but also worked with pure spectra (sensitivity > 0.85) and real-life HRMS/MS raw data. MLinvitroTox can be tailored to various applications, e.g., support of effect-directed analysis of digitally frozen samples or an in situ hazard-driven prioritization for a rapid chemical risk assessment in an early warning system.

1.02.P Applications of Computational Toxicology in Environmental Risk Assessment

1.02.P-Mo004 Improving Environmental Risk Assessment with Data Literacy and the Bayesian Regression Toolbox

Raoul Wolf, *Norwegian Geotechnical Institute (NGI), Norway*

From a data analysis perspective, environmental risk assessments (ERAs) are highly dependent on their domain context and data availability. The collection of appropriate data for an ERA can be challenging, as a variety of experimental and synthetic data are available, often with varying degrees of reliability. Identification of appropriate data sources is important, especially because expert curation of reliable data can be time and resource consuming.
For high quality ERAs, the understanding of the collected data is therefore crucial, especially the data-generating processes. Other important considerations are variations between experiments, incomplete data sets, or measurement limits. The evaluation of this information is important for choosing an appropriate modelling strategy, and, in the case of a Bayesian data analysis, the construction of meaningful priors.
Bayesian regression models (BRMs) offer great flexibility to address these challenges and can quantify uncertainties. Outside the Gaussian default, more appropriate probability distributions are available for count, survival, or concentration data. Information such as weights (reliability scores), censoring (values below measurement limits), or truncation (known lower or upper limits of a response variable) can also be included. This ensures that the data can be used "as is," without subjective data manipulation. More complex variations are possible, for example by accounting for nonlinearity or by adding a hierarchical component ("random effects").
A good understanding of BRM results is necessary to evaluate the quality of the model, as well as to draw the right conclusions of the posterior model results for an ERA. This includes both the understanding, but also the visualization and communication of the results and their uncertainties.
The above points can be collectively described as data literacy. A stronger focus on this concept, together with BRMs, has the potential to greatly improve the quality of ERAs under regulatory frameworks, as well as improve a shared understanding of the involved stakeholders.

1.02.P-Mo005 A Bayesian Network Tool for Predicting Fish Acute Toxicity Based on Fish Embryo Toxicity Test Data: Optimizing Weights of Evidence

Jannicke Moe[1]*, Anders Madsen*[2]*, Thomas Braunbeck*[3]*, Kristin A Connors*[4]*, Michelle Rau Embry*[5]*, Kristin Schirmer*[6]*, Stefan Scholz*[7]*, Raoul Wolf*[8] *and Adam Lillicrap*[1]*, (1)Norwegian Institute for Water Research (NIVA), Norway, (2)Hugin Expert, Denmark, (3)University of Heidelberg, Germany, (4)Procter & Gamble, (5)HESI, (6)Environmental Toxicology, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Dübendorf, Switzerland, (7)Chemicals in the Environment Research Section, Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany, (8)Norwegian Geotechnical Institute (NGI), Norway*

Fish Embryo Toxicity (FET) testing has been proposed as an alternative to using juvenile or adult fish in acute toxicity testing, to reduce the number of live animals required for hazard assessments of chemicals. The European Chemicals Agency has recommended the development of a Weight-of-Evidence (WoE) approach for strengthening the evidence from FET testing. While WoE approaches in the past have been largely qualitative, we have developed a Bayesian network (BN) model for using FET data in a quantitative and probabilistic WoE approach. The purpose of this BN model is to predict fish acute toxicity of a given chemical from data on fish embryo toxicity in combination with other types of available information (lines of evidence): quantitative structure-activity relationships (QSARs), toxicity to other species (algae and daphnids), and fish gill cytotoxicity. The tool is publicly available through a web-based user interface at https://swift.hugin.com/models/FET, and demonstrations of this tool can be provided upon demand. In previous presentations from this project, we have explored different approaches for estimating the weights for each line of evidence, as well as approaches to evaluating the model performance.
This presentation will focus on more advanced methods for optimizing the weights for the lines of evidence: the use of machine learning algorithms (i.e., the Expectation Maximization algorithm for parameter estimation from data) for estimating conditional probability tables. We will address the general problem of estimating a high number of "probability parameters" (entries in the conditional probability tables) from a limited number of cases (toxicity values). While the purpose of this model is to predict acute fish toxicity from fish embryo toxicity, our solutions can be relevant more generally for evaluating animal alternatives in regulatory toxicity testing, or even more generally for other types of environmental assessments.

1.02.P-Mo006 Computational Tools for the Development and Application of QSARs for the Estimation of Multiple Endpoints

Nicola Chirico[1]*, Linda Bertato*[1]*, Marco Evangelista*[1] *and* ***Ester Papa***[2]*, (1)University of Insubria, Italy, (2)DiSTA, University of Insubria, Italy*

In this work we present several computational tools recently developed at the University of Insubria to model and estimate properties of interest for the risk assessment of chemicals on the basis of Quantitative Structure Activity Relationships (QSARs). The software, i.e., IVBP-Suite, QSAR-ME Profiler, and Chemo-MBuilder, can run on platforms supporting the Java™ runtime (e.g., Windows™, Mac OS™ and Linux).
IVBP-Suite is dedicated to the estimation of the *in vitro* intrinsic clearance of chemicals by running QSARs based on experimental data measured in human, rat, and mouse. These models were developed following reactivity pathways based on putative cytochrome P450 (CYP) mediated reactions. To automate the selection of the pertinent QSARs the Smart-Cyp Toxtree plugin is automatically run.
QSAR-ME Profiler applies models for the prediction of endpoints characterizing properties, activities and fate of organic chemicals such as, for example, acute toxicity in multiple organisms, bioconcentration and biomagnification in fish, biotrasformation (*in vivo* and *in vitro*), and a PBT profiler. QSAR-ME Profiler includes functionalities for the study of structural similarity among molecules used to develop the QSARs, or new molecules profiled by the user. The molecular structures of chemicals of interest can be depicted and compared with the automatically detected most similar chemicals. QSAR-ME Profiler

includes sets of QSARs developed using Multiple Linear Regression (MLR) or Linear Discriminant Analysis (LDA) and validated according to OECD guidelines. Both IVBP-Suite and QSAR-ME Profiler automatically run PaDEL-Descriptor software for the calculation of the molecular descriptors, if not provided by the user.
Finally, the Chemo-MBuilder software streamlines QSARs development including overfitting control in variable selection and the evaluation of coincidental relationships between the descriptors and the endpoint, with a focus on calculation speed performances. The three software programs are designed to be user-friendly following simple workflows. Batch results are provided as tables, and the analysis of predictions is supported by the graphical user interface. IVBP-Suite and QSAR-ME Profiler are aimed to streamline, organize, and simplify the application of batteries of QSARs, which is particularly useful for their regulatory application, and are freely available from the internet (http://dunant.dista.uninsubria.it/qsar/). Chemo-MBuilder is currently under development.

1.02.P-Mo007 A Benchmark Dataset for Machine Learning in Ecotoxicology
***Christoph Schuer**[1], Lilian Gasser[2], Fernando Perez-Cruz[2], Kristin Schirmer[1] and Marco Baity-Jesi[3], (1)Environmental Toxicology, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Dübendorf, Switzerland, (2)Swiss Data Science Center, Switzerland, (3)Siam, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Dübendorf, Switzerland*
The application of machine learning methods to ecotoxicology is still in its infancy. Model performance is highly dependent on the features and the quality of the data set on which model training and testing are performed. Comparing model performances across studies done on different data sets is practically impossible, since data sets are different in number/kind of species and chemicals. Data set curation requires biological expertise, which might pose a barrier of entry for machine learning experts without the necessary background. To remove this barrier and to attract researchers from outside our field to apply their expertise to ecotoxicological problems, we, a team of ecotoxicologists and machine learning experts, provide an expert-curated and well-characterized data set on acute mortality and related endpoints in the three taxonomic groups of fish, crustaceans, and algae. We describe the process of feature selection and data cleaning. Apart from the core data set of ecotoxicological effect data, we expanded the data set with supplemental species-specific and chemical information. Based on the assumption that closely related species will react to chemical exposure more similarly than unrelated species, we included a phylogenetic distance matrix. Where available, we included ecological and life-history data. Chemical information is supplemented by chemical properties as well as different molecular representations for modeling. We discuss potential pitfalls regarding train-test splitting of such a complex data set to avoid data leakage. We present insights and patterns that can be deduced from the raw data alone, such as species sensitivity distributions (SSD). Additionally, we propose concrete tasks to the community that should be answered based on the data set and could help answer pressing questions from our field. These include predictions across taxonomic groups and the identification of potential surrogate species.

1.02.P-Mo008 Challenges with QSAR Models for Chemical Risk Assessment —
Comparing Empirical Data with Predictions from Three QSAR Platforms Across Six Endpoints
***Patrik Svedberg**[1], Pedro A. Inostroza[2], Thomas Backhaus[3], Erik Kristiansson[4] and Mikael Gustavsson[3], (1)Department of Biological & Environmental Sciences, University of Gothenburg, Sweden, (2)Biological and Environmental Sciences, University of Gothenburg, Sweden, (3)University of Gothenburg, Sweden, (4)Chalmers University of Technology, Sweden*
The total number of chemicals on the world market continues to increase, and toxicity testing is struggling to keep up. An important element of chemical risk assessment and, by extension, chemical regulation, is trustworthy toxicity estimations of the chemicals in question. *In silico* tools, such as ecotoxicity quantitative structure-activity relationship (QSAR) models, are being used to fill data gaps when empirical data are missing, but to what extent can we trust these predictions? In this paper, three freely available ecotoxicity QSAR platforms (ECOSAR, Vega and the Toxicity Estimation Software Tool - T.E.S.T.) have been tested against empirical data from the United States Environmental Protection Agency (USEPA) ECOTOX database and the European Food Safety Authority (EFSA), to determine performance for six common endpoints: acute and chronic toxicity for algae, daphnia, and fish. The empirical databases have been filtered based on OECD guidelines and QSAR endpoints, and for every chemical with data for at least one endpoint present, QSAR predictions have been generated. Each platform contains multiple QSAR models, so different approaches to gather the predictions in a single value per platform, substance, and endpoint were implemented. A number of different scenarios, based on handling of endpoint filters, pKa considerations, logP ranges, and platform processing methods, were set up and systematically explored to identify confounding factors or other attributes that might impact prediction quality. Finally, predictions were compared to empirical data to estimate platform performance under different scenarios. Initial results indicate that predictions from all platforms correlate well with empirical data for acute daphnia and fish endpoints, but for fish and algae chronic endpoints, there are issues with applicability domain and/or performance for both ECOSAR and Vega. Given that the results hold, caution is advised when using chronic QSAR predictions in chemical risk assessment and regulation.

1.02.P-Mo009 Tiered Methods for Screening-Level Ecological Hazard and Risk Assessment: Case Study Application to Octamethylcyclotetrasiloxane, D4
*Jon A. Arnot[1], **Liisa Toose, M.Sc.**[1], Todd Gouin[2], Alessandro Sangion[1], James M Armitage[3] and Li Li[4], (1)Arnot Research and Consulting Inc. (ARC), Canada, (2)TG Environmental Research, United Kingdom, (3)AES Armitage Environmental Sciences, Inc, Canada, (4)School of Public Health, University of Nevada, Reno*
Thousands of chemicals are undergoing hazard, exposure, and risk assessment using hazard- and risk-based methods in various regulatory programs worldwide. Hazard-based approaches compare a chemical’s persistence (P), bioaccumulation (B), and toxicity (T) to multiple bright-line “pass/fail” categorization criteria. Risk-based approaches quantitatively compare measured or

predicted exposure estimates to a toxicological effect threshold such as an environmental (no) effect concentration ((NO)EC) or a chemical intake rate threshold (IRT). In the case of inadequate or missing monitoring data, exposure models can be used or integrated with available data to address data gaps and better characterize uncertainty in exposure estimation. They can also provide valuable guidance for chemical prioritization or, alternatively, de-prioritization of chemicals. In the present study, we show that the PROduction-To-EXposure High Throughput (PROTEX-HT) model, the Chemicals in Products - Comprehensive Anthropospheric Fate Estimation (CiP-CAFE) model, and the Risk Assessment IDentification And Ranking (RAIDAR) model can be used in a tiered approach with temporally and spatially relevant production/import volumes and applicable functional use category information to estimate hazard, exposure, and risk for chemicals. We apply the RAIDAR model parameterized as the European regional environment (RAIDAR-EU) to a cyclic volatile methyl siloxane (cVMS), octamethylcyclotetrasiloxane (D4) as a case study. Tiered methods for estimating releases to the environment progress from conservative assumptions to more realistic assumptions, i.e., using CiP-CAFE. The model predictions at each Tier are compared with monitoring data. Tiers 2 and 3 show similar results indicating that CiP-CAFE can be used to predict release of chemicals such as D4. Additionally, literature toxicological exposure and intake endpoints are used to estimate potential ecological risk for various aquatic and terrestrial organisms. Our work illustrates that by using temporally and spatially relevant production and import volumes and use information for D4 in Europe, fate and food web concentrations can be reliably predicted. The work highlights how PBT assessment and exposure and risk estimation can be used together for more comprehensive chemical assessments. Finally, this process can be used to focus research to fill relevant data gaps and reduce animal testing.

1.02.P-Mo010 Predictive QSAR Models to Estimate the Toxic Potential of Pesticide's Metabolites to Honeybees
*Purusottam Banjare[1], **Ester Papa**[2], Jagadish Singh[1] and Partha Pratim Roy[1], (1)Department of Pharmacy, Guru Ghasidas Vishwavidyalaya (A Central University), India, (2)DiSTA, University of Insubria, Italy*
The metabolism of pesticides leads to changes in their molecular structure which may be sometimes beneficial or give as result toxic metabolites that may affect nontarget organisms such as honeybees. The estimation of the toxicity of metabolites has not been explored extensively by scientists, while it is an important part in pesticides or drug development to identify the possible mechanism of metabolism and their toxic or adverse effects. Experimental toxicity assessment for a large number of metabolites is a costly measure in terms of time, money, and number of sacrificed animals. In this background experimental toxicity data (NOEL) measured in honeybees for 26 metabolites of pesticides have been collected from the OPP-Ecotox database and subjected to QSAR model development. The model development was done by using multiple linear regressions (MLR) and genetic algorithm (GA) for feature selection. The 2D theoretical molecular descriptors were calculated using the PaDEL descriptor software. Further, the leverage approach was used to assess the applicability domain (AD) of the models and to check the reliability of predictions. All the QSARs have rewardable performances valuated by internal (Q^2_{LOO} = 0.590 - 0.726, R^2_{adj}: 0.777 – 0.798) and external validation (Q^2F_n = 0.741 – 0.870, R^2M_{avg} = 0.560 – 0.758, CCC_{ext} = 0.840 – 0.896) which assured the validity and the generalizability of these models within their applicability domain. Hence the outcomes of this study will be helpful for researchers to predict and screen the toxicity of metabolites to honeybees in the initial stage of development of parent compounds. Furthermore, they can provide information useful for the design of alternatives to parent pesticides leading to toxic metabolites, or, more in general, to support the risk assessment of pesticides.

1.02.P-Mo011 Machine Learning for Toxicity Categorization from Molecular Descriptors: An Alternative to Conventional QSAR Models
***Antonia Praetorius**[1], Jake O'Brien[2], Malcolm Reid[3], Kevin Thomas[4] and Saer Samanipour[5], (1)University of Amsterdam, Institute for Biodiversity and Ecosystem Dynamics, Netherlands, (2)Queensland Alliance for Environmental Health Sciences (QAEHS), University of Queensland, Australia, (3)Norwegian Institute for Water Research (NIVA), Norway, (4)University of Queensland, Australia, (5)University of Amsterdam, Netherlands*
Hundreds of thousands of chemicals have been registered for production and use worldwide and a significant fraction of those will eventually make their way into the environment. However, for most of these chemicals, knowledge on environmental fate (persistence, mobility) and toxicity is largely missing, and filling those gaps with experimental data is practically unfeasible for such a large number of substances. Therefore, models to predict hazard indicators for chemical prioritization and risk assessment play an increasingly important role and the reliance on such models requires continuous reevaluation and improvement of existing approaches. Most existing modeling strategies are known as quantitative structure activity relationship (QSAR) models. These rely on building linear and/or nonlinear relationships between the structural descriptors of the chemicals and the modeled activity/property. However, these models are often built on very similar chemical classes (i.e., homogeneous training sets) and are limited in terms of the number of chemicals evaluated. As a consequence, many chemicals fall outside of the applicability domain of the QSAR models and the models are often used in extrapolation mode when used for prediction, which may result in large prediction errors.
Here we present an alternative strategy to QSAR models for chemical prioritization, on the example of acute aquatic toxicity as a predicted endpoint. We developed a machine learning-based direct classification strategy, where molecular descriptors are directly converted into toxicity categories, without a separate (and error-prone) prediction of the chemical activity (here: 96h lethal concentration, LC50). As a proof-of-concept our model was trained and tested with experimentally derived 96 h LC50 values for acute fish toxicity for 907 organic chemicals. The model was then applied to predict toxicity categories for 32 000 chemicals from the NORMAN Substance Database (Norman SusDat). Compared to a conventional QSAR model based on the same training and test set, our direct classification model showed a five-fold decrease in wrong categorization. Our model can be applied both to data-driven toxicity categories (e.g., derived via k-means clustering from a given dataset) or to fixed regulatory derived categories (e.g., from the Globally Harmonized System of Classification and Labelling of Chemicals [GHS]) and represents an important step toward a more data-driven environmental risk assessment.

1.02.P-Mo012 Addressing Uncertainty in Chemical Partitioning Properties and Prospects for Improvement

***Trevor N Brown, PhD**, Jon A. Arnot and Alessandro Sangion, Arnot Research and Consulting Inc. (ARC), Canada*

Physical-chemical properties are a fundamental aspect of environmental toxicology and chemistry, and chemical evaluations. These properties are key determinants of chemical fate in the environment, in organisms, and in experimental test systems. Properties such as water solubility (WS), vapor pressure (VP), octanol-water partition ratio (K_{OW}), octanol-air partition ratio (K_{OA}), and air-water partition ratio (K_{AW}) are among the most commonly required data for understanding chemical fate and distribution in natural and artificial systems, and for determining the potential for adverse effects to humans and the environment. Compared to the vast number of chemicals produced and used by society, relatively few have complete high quality measurements of these fundamental properties. For many chemicals (e.g., those with low VP, low WS) technical methods are not adequate to measure these properties. Given the critically important nature of these chemical properties and significant data gaps there is a need to develop and validate reliable methods for their prediction. Uncertainty and applicability domain (AD) are vital considerations when considering measured or predicted properties to inform decision making. Quantitative Structure Property Relationships (QSPRs) and other estimation methods have been developed and applied for decades. Poly-parameter Linear Free Energy Relationships (PPLFERs) are also established tools for predicting physical-chemical properties of chemicals. Poly-parameter Linear Free Energy Relationships combine system parameters, that describe the system properties, and solute descriptors, that depend on the chemical. Here we describe the development and validation of a new suite of predictive tools using the Iterative Fragment Selection (IFS) methods. The IFSQSARs provide explicit estimates of AD and uncertainty with predictions. We describe the general approach to developing and validating the IFSQSARs and compare their performance against other commonly used QSPRs (e.g., USEPA's EPI Suite, OPERA models) and against empirical data. To facilitate applications and comparisons of the new IFSQSARs they have been implemented in the freely available on-line Exposure And Safety Estimation (EAS-E) Suite platform (www.eas-e-suite.com). These QSPRs have been integrated into the EAS-E Suite platform, which allows for the prediction of K_{OW}, K_{OA}, K_{AW}, VP, and WS which can then be used to parameterize the various fate, toxicokinetic, bioaccumulation, exposure, and risk models in EAS-E Suite.

1.02.P-Mo013 iSafeRat® Platform: Development and Improvement of Mechanistic High Accuracy-QSAR Models to Predict Acute and Chronic Aquatic Toxicity

***Floriane Larras** and Paul Thomas, KREATiS, France*

Quantitative Structure Activity Relationship models are relevant alternative methods in response to the need to reduce testing on vertebrates, time to market, and cost compared to standard methods. The iSafeRat® platform, developed by the (eco)toxicologists and chemists of KREATiS, aims, among others, to provide reliable predictions of chemical acute and chronic toxicity to fish, daphnia, and algae, and also Activated Sludge Respiration Inhibition Test, considering their mechanism(s) of action (MechoA). So far, 30 High Accuracy-QSAR models have been created, mostly dedicated to acute toxicity predictions for multiple mechanisms of action and thus a wide variety of structural groups (e.g., MechoA 1.1, membrane destabilisers such as alkyls, alcohols, ketones; MechoA 2.1, enzymatic hydrolysis, e.g., esters, amides; MechoA 3.1, reactive substances, e.g., aldehydes, epoxides, etc.). However, the development of aquatic chronic toxicity QSAR models for these MechoA has also been a high priority. For example, chronic toxicity data can be already required by REACH for substances manufactured or imported in quantities of 100 tonnes or more per year and are often the subject of ECHA draft decisions. Thus, while recent updates to iSafeRat® accounted for the improvement of the applicability domain of existing models (e.g., including new chemical structures such as phosphates), emphasis have been placed on the development of new models for chronic toxicity. The development of such models is a challenging task as high-quality chronic toxicity data are scarce, especially for organisms like fish and also for particular chemical functions. But more than generating data, the development of chronic models also supported the mechanistic understanding of chemical toxicity to aquatic organisms. Indeed, the comparison of acute and chronic regressions for the same biological compartment and the same mechanism of action unraveled potential hints to further investigate. The poster will include details of the validity check for new iSafeRat® models.

1.02.P-Mo014 Development of an i*n silico* Structural Profiler Facilitating Mechanistically Grounded Classification of Aquatic Toxicants

***James Firman**[1], Franklin Bauer, PhD[2], Geoffrey Hodges[3], Bruno Campos[3], Jayne Roberts[3], Steve Gutsell[3], Paul Thomas[2], Mark A. Bonnell[4] and Mark Cronin[5], (1)School of Pharmacy and Biomolecular Sciences, Liverpool John Moores University, United Kingdom, (2)KREATiS, France, (3)Unilever - Safety and Environmental Assurance Centre (SEAC), United Kingdom, (4)Environment and Climate Change Canada, Canada, (5)Liverpool John Moores University, United Kingdom*

When considering environmental safety assessment of chemicals within regular industrial use, it is acknowledged that data gaps in many instances exist. The adoption of predictive (*in silico*) toxicological methodologies, spanning QSAR and structural rule-based systems, has been advanced as practical means by which this issue might be addressed. Amongst these techniques, the chemical classification and mode of action assignment schemes devised by Verhaar et al. (1992) and Russom et al. (1997) have achieved particular prominence. Despite their utility, such profilers are by now decades old: their coverage of chemical space and taxa is restricted, and the resolution offered in terms of mechanistic detail limited.

As such, we have sought development of an updated scheme–expanding the breadth both of chemical and taxonomical coverage relative to its forebears. Further advancement was offered in terms of characterisation of toxic mechanism–which took advantage of improved knowledge of molecular initiating events (MIE), and thus provided a link to the broader framework of adverse outcome pathways. The novel scheme was structured such that screened compounds were granted progressively finer grains of mechanistic classification, extending from highest tier (reactive domain: narcosis, nonspecific chemical reactivity, specific

biological interaction) through grouping (10 being present: e.g. mitochondrial disruption) and subgrouping (totalling 25: e.g., specific impairment of electron transport chain component) on to MIE (a sum of 60: e.g., inhibition of succinate dehydrogenase). Formal representation of MIE was achieved through derivation of structural alerts (183 in total) encoded as SMILES arbitrary target specification (SMARTS).
The implementation of this rule-set as a practical, freely accessible profiling tool was realised through construction of a workflow within KNIME analytical software, employing the SMARTS strings as its basis (accessible from www.doi.org/10.5281/zenodo.7100972). Screening of representative compound inventories revealed superior coverage relative to Verhaar and Russom schemes, as regards both quantity of substances classified and applicable phyla/species recognised. Integration with the existing KREATiS MechoA rule-set is further proposed as means through which present shortcomings may be efficiently addressed.

1.02.P-Mo015 Comparison of the Performance and Domains of *in silico* Schemes to Classify Environmental Chemicals

Mark Cronin[1]*, James Firman*[2]*, Franklin Bauer*[3]*, Geoffrey Hodges*[4]*, Bruno Campos*[4]*, Jayne Roberts*[4]*, Steve Gutsell*[4]*, Paul Thomas*[3] *and Mark A. Bonnell*[5]*, (1)Liverpool John Moores University, United Kingdom, (2)School of Pharmacy and Biomolecular Sciences, Liverpool John Moores University, United Kingdom, (3)KREATiS, France, (4)Unilever - Safety and Environmental Assurance Centre (SEAC), United Kingdom, (5)Environment and Climate Change Canada, Canada*

In silico classification schemes are commonly applied to assist in grouping of chemicals ahead of read-across and the application of quantitative structure-activity relationships (QSARs). Chemistry-based knowledge has been used in this way for over 30 years, since the publication of the Verhaar scheme. These tools, which can be considered to be *in silico* New Approach Methodologies (NAMs), assist greatly in data gap filling for regulatory and other purposes. This investigation compared the performance and potential applicability domains of four schemes, with particular reference to a new classification system. The schemes considered were those of Verhaar, Russom, MechoA (Bauer) and, most recently, Sapounidou. *In silico* implementations of each were assessed by screening a test inventory of approximately 5500 common pollutants. In terms of profiling, all schemes are based on (slightly) different approaches, with the Sapounidou scheme including information from putative molecular initiating events to facilitate classification. MechoA was found to assign the greatest proportion of compounds to particular mechanisms, although the Sapounidou scheme has more information on the specific and reactive mechanisms of action. An in-depth analysis of the Sapounidou profiler was performed, screening over 70 000 structures from distinct inventories representing REACH chemicals, pharmaceuticals, cosmetics ingredients, botanical natural products, and pesticides. Whilst coverage of some inventories was good, further information to classify pharmaceuticals is required. Other areas where the domains of all profilers could be improved is in strengthening the identification of narcotics, to enhance confidence in this classification (some schemes simply default to narcosis should no specific mechanism /mode be assigned).

1.02.P-Mo016 A Comprehensive Similarity Approach to Identify Potential SVHC Chemicals

Yordan Yordanov[1]*, Emiel Rorije*[2]*, Jordi Minnema*[1]*, Markus Viljanen*[1]*, Willie Peijnenburg*[3] *and Pim Wassenaar*[1]*, (1)National Institute for Public Health and the Environment (RIVM), Netherlands, (2)Centre for Safety of Products and Substances, Dutch National Institute for Public Health and the Environment (RIVM), Bilthoven, Netherlands, (3)Leiden University, Leiden, Netherlands*

An automated method for screening and prioritization of chemicals is essential to ensure that available evaluation capacity is invested in those substances that are of highest concern. To facilitate the identification of substances of potential concern, we recently developed a structural similarity model that evaluates the structural similarity of substances with unknown properties to known Substances of Very High Concern (SVHC) [Wassenaar et al. 2022; https://doi.org/10.1002/jcc.26859]. Substances that are structurally similar to known SVHCs are be selected for further evaluation, as a high resemblance in chemical structure could be an indication of comparable effects (“similar property principle”).
Although this method works great at identifying chemicals that exhibit small structural differences with known SVHCs, it does not address the toxicokinetics and mode of action (MoA) of the chemicals. Extension of the ZZS similarity tool with other points of chemical and biological similarity can increase the confidence in the similarity predictions.
In this study we will investigate the extension of the chemical ‘global’ similarity to site specific similarity (i.e., structural alerts) and ‘local’ similarity (i.e., the chemical composition in close proximity to the relevant structural alerts). In addition, we investigate the benefits of adding a model that predicts biological similarity in the form of a physicochemical profile and bioassay-based profile.
By including various similarity descriptors our extended methodology is likely to result in an increased predictive performance. This will specifically result in improved predictions for chemicals that were previously identified as false positives which have a high overall (‘global’) similarity but are, e.g., lacking the structural alert causing the SVHC concern. In addition, improvements will likely be observed for previously identified false negatives which have a slightly larger difference in their (global) structure but are expected to result in a similar level of toxicity. Consequently, these model improvements could enhance the identification of potential SVHC chemicals.
The poster we intend to present will focus on the above-mentioned improvements regarding chemical and biological similarity based on preliminary findings.

1.02.P-Mo017 Identification of Machine Learning Algorithms and Molecular Fingerprints for the Development of a Target-Specific Bioactivity Prediction Model Based on ToxCast Bioassay Data

Jaeseong Jeong*, Su-Yong Bea and Jinhee Choi, School of Environmental Engineering, University of Seoul, Seoul, Korea, Republic of (South)*

Machine and deep learning approaches have been increasingly used in toxicology. The ToxCast program uses high-throughput screening (HTS) to screen biological activity to determine the potential toxic effects of environmental chemicals. It covers nearly 10K chemicals using 1473 *in vitro* bioassays. In this study, we identified the best model for 737 ToxCast assays to develop an effective bioactivity prediction model based on the ToxCast data. For each assay dataset, 30 models were trained by combining six algorithms (gradient boosting tree, random forest, multilayered perceptron network, k-nearest neighborhood, logistic regression, and naïve Bayes) and five molecular fingerprint representations of the chemical structure (MACCS, Morgan, layered, RDKit, and pattern). The synthetic minority oversampling technique (SMOTE) was used to balance the data. Of the 737 best models for each assay, 35 models with acceptable performance were selected based on the F1 score and accuracy. Finally, the selected models were analyzed according to the number and type of training data, and the type of algorithm and molecular fingerprints used for learning. It is important to utilize and study existing HTS data because biological activity data enable toxicity evaluation based on the mechanism of toxicity.
We believe that our results can be used as a cornerstone for a wide range of *in silico* toxicity prediction studies.

1.02.P-Mo018 Deconvoluting Chemical Mixtures in Aquatic Environment by Integrative High-Throughput Screening, Nontarget Analysis, and Artificial Intelligence
*Fei Cheng[1], Beate Escher[2], Huizhen Li[1], Maria Koenig[2], **Yujun Tong**[1], Yuan Liu[1], Dali Wang[1], Jiehui Huang[1], Fan Wu[1], Peihong Xie[1], Zhiqiang Yu[3], Yuanyuan Pei[1], Bryan W. Brooks[1,4], Eddy Yongping Zeng[1] and Jing You[1], (1)Jinan University, China, (2)Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany, (3)Guangzhou Institute of Geochemistry, Chinese Academy of Sciences, Guangzhou, China, (4)Environmental Science, Baylor University*
Ecosystems are often exposed to complex mixtures of chemicals. Identifying causative toxicants is essential to risk assessments but there are many data gaps among chemical occurrence and biological effects. Based on a novel event-driven taxonomy (EDT) framework that clusters chemical stressors by bioactivity, an artificial intelligence-assisted integrated testing strategy (ITS) was constructed for assessing aquatic risk by integrating high-throughput screening cell bioassays and chemical predictions. This EDT-based ITS was then evaluated using complex sediment mixtures eliciting aryl hydrocarbon receptor activation and oxidative stress response. While mixture prediction using the target analysis that was oriented by expert knowledge explained less than 10% of observed sediment bioactivity, a big data-driven suspect analysis based on text-mining expanded the fraction explained to >80%. Additionally, deep learning models were developed to extract the fingerprints of bioactive suspect candidates and convert these fingerprints to high resolution mass spectrometry-recognizable fragment ions for nontarget analysis using GC-qToF-MS. Overall, we present a mixture deconvolution ITS based on a novel model of “bioactivity-fingerprint-toxicant” to connect the patchy datasets through artificial intelligence.

1.02.P-Mo019 *in-silico* Model-Based Exploration of the Importance of Gut Metabolism in Human Exposure and Toxicokinetic Modeling
***Shenghong Wang**[1], Zhizhen Zhang[1], Mingliang Fang[2], Dingsheng Li[1] and Li Li[1], (1)School of Public Health, University of Nevada, Reno, (2)Nanyang Technological University, NEWRI, Singapore*
Intestinal metabolic biotransformation or gut metabolism plays an important role in both the absorption and elimination of chemical contaminants: The preabsorptive intestinal and hepatic biotransformation, also known as the “first-pass effect,” reduces the absorption of ingested chemical contaminants into the systemic circulation, whereas postabsorptive hepatic and intestinal biotransformation reduces the human body burden of chemical contaminants by eliminating them from the systemic circulation. While *in silico* high-throughput physiologically based toxicokinetic (PBTK) models consider hepatic biotransformation, intestinal biotransformation, also known as gut metabolism, is often overlooked, and the relative importance of pre- and postabsorptive biotransformation is unclear. Experimental evidence has shown rapid intestinal biotransformation, e.g., with a half-life at a level of minutes for certain phthalate esters in metabolism by lipases. Neglecting intestinal biotransformation may result in a substantial overestimation of exposure to chemicals in high-throughput chemical screening. In this presentation, using an *in silico* PBTK model, we evaluate (i) the relative importance of pre- and postabsorptive biotransformation in controlling the presence of chemical contaminants in the human body, and (ii) important factors that govern such relative importance. Since *in vivo* biotransformation data are often inadequate for chemical contaminants, the model also includes an *in vitro* to *in vivo* extrapolation module to allow the use of *in vitro* data. The model shows that the relative importance of the rates of intestinal biotransformation and epithelium permeation greatly impacts intestinal absorption efficiency. In cases of phthalates where biotransformation occurs at a level of minutes, more than 60% of the ingested amount is biotransformed in the gastrointestinal tract before absorption. Overall, our work highlights the importance of intestinal biotransformation in human exposure and toxicokinetic modeling. This model also enables us to more accurately screen the absorption efficiency of chemicals through dietary and nondietary ingestion.

1.02.P-Mo020 Considerations for Applying the Parallel Artificial Membrane Permeability Assay (PAMPA) in the Screening of Gastrointestinal Absorption of Chemicals of Environmental or Occupational Concerns
***Shenghong Wang**, Zhizhen Zhang, Dingsheng Li and Li Li, School of Public Health, University of Nevada, Reno*
Chemicals present in the environmental and occupational settings can exert adverse health effects on humans after gastrointestinal absorption into the systemic circulation. Parallel Artificial Membrane Permeability Assay (PAMPA) has gained advocacy for its application to measure the effective permeability toward pharmaceuticals. However, since chemicals of environmental or occupational concerns differ from pharmaceuticals in hydrophobicity and volatility, a thorough, mechanistic understanding of chemical mass transfer in PAMPA is warranted if we seek to expand the applicability of PAMPA. Here, we introduce an *in-silico* mass balance model, which describes chemical mass transfer in PAMPA based on inputs of fundamental physicochemical properties, e.g., molecular weight, partition coefficient, and dissociation constant. The model’s performance is evaluated by an

agreement between predicted and measured permeabilities of 1383 chemicals, which indicates that 95% of the estimated permeabilities either fall in the same order of magnitude or are more conservative than the measurements. The model predicts an inverted U-shaped dependence of permeability on the octanol-water partition coefficient (log K_{OW} for neutral compounds and log D_{OW} for ionizable compounds), with the maximum permeability occurring in log K_{OW} or log D_{OW} ranging between 0 and 2. The model estimates a high membrane retention rate for hydrophobic chemicals, as well as the loss of volatilization to the headspace of the PAMPA apparatus for highly volatile chemicals. Notably, the measured permeabilities of hydrophobic chemicals are remarkably sensitive to specific experimental conditions, e.g., frequency of stirring, and incubation time, making measurements under different conditions less comparable. More importantly, for highly hydrophobic chemicals (log K_{OW} or log D_{OW} greater than 3.8), steady-state mass transfer, which is the fundamental assumption of PAMPA, can never be achieved. Therefore, the current design of PAMPA needs to be modified before its application to chemicals of environmental or occupational concerns. Our work provides an *in-silico* mechanistic approach in support of efficiently and defensibly predicting the permeability of chemicals and complements the current laboratory approach.

1.02.P-Mo021 Addressing Applicability Domain and Uncertainty in High-Throughput Toxicokinetic Data and Applications

Alessandro Sangion[1]*, James M Armitage*[2] *and Jon A. Arnot*[1,3]*, (1)Arnot Research and Consulting Inc. (ARC), Canada, (2)AES Armitage Environmental Sciences, Inc, Canada, (3)Department of Pharmacology and Toxicology, University of Toronto, Canada*

Quantitative knowledge of toxicokinetic (TK) processes is necessary to better understand relationships between external and internal exposures of chemicals. New Approach Methodologies (NAMs) such as *in vitro-in vivo* extrapolation (IVIVE) and high-throughput toxicokinetic (HTTK) modeling can be used to obtain TK data necessary for chemical priority setting, screening, and risk assessment. However, there is a need to systematically examine existing data and NAMs to foster confidence in their application for scientific evaluations and decision-making by establishing the applicability domains (AD) of existing HTTK models and databases. This case study determines the AD and assesses the uncertainty of current IVIVE and HTTK data and models to estimate administered equivalent doses (AEDs) from *in vitro* bioactivity test data.

Different *in silico* approaches are applied to calculate total elimination half-life (HL_T) and steady-state blood concentration (C_{SS}) to identify their AD, particularly relative to their required input parameters to better understand the chemical space that can be covered by current HTTK models. The comparison includes: i) Quantitative Structure Activity Relationship (QSAR) models to directly estimate HL_T and a composition model where tissue partitioning is a function of the composition of the tissue (i.e., storage lipid, membrane lipid, structural protein, serum albumin and water) to calculate volume of distribution (VD_{SS}), ii) a generic one-compartment physiologically based toxicokinetic (1Co-PBTK) model that can be parameterized to different mammals as implemented in the Exposure And Safety Estimation (EAS-E) Suite platform, and iii) the “3 Compartment steady state” model developed by the USEPA as implemented in the “httk” R package and accounting for metabolism on the basis of *in vitro* biotransformation data. The results of this work generally support the computational IVIVE and HTTK methods required to estimate AEDs. General guidance and recommendations are provided for applying HTTK methods for AED calculations and improving HTTK modelling and risk estimation.

1.02.P-Mo022 A Case Study on Skin Sensitization Assessment Using OECD QSAR Toolbox ***Heekyung Bae***[1]*, Hyejin Kim*[1]*, Yeonjung Jung Park*[1]*, Jinseon Son*[1]*, Kwangsik Park*[2]*, Sun-Young Park*[3]*, Ok-Nam Bae*[4]*, Sanghee Lee*[3] *and Hyeonsoo Park*[1]*, (1)TO21 Co., Ltd., Chemical Management Institute, Korea, Republic of (South), (2)College of Pharmacy, Dongduk Women's University, Seoul, Korea, Republic of (South), (3)National Institute of Environmental Research, Korea, Republic of (South), (4)Hanyang University, Ansan, Korea, Republic of (South)*

The QSAR toolbox is a software application intended for the use of governments, the chemical industry, and other stakeholders in filling gaps in (eco)toxicity data needed for assessing the hazards of chemicals. The QSAR toolbox incorporates information and tools from various sources into a logical workflow and identification of relevant structural characteristics and potential mechanism or mode of action of a target chemical. The OECD is continuously updating the toolbox so that it can be used for the evaluation of chemicals such as EU REACH, and updating to ver. 4.5 in September 2021, Automated Workflow to implement OECD GL 497 that can predict skin sensitization and confirm results for Skin Sensitization for Defined Approach (DASSAW) function has been added. OECD GL 497 is expected to be actively used to evaluate skin hypersensitivity of chemicals without conducting animal experiments because it can derive reasonable prediction results for skin hypersensitivity by combining the DASS function of the QSAR toolbox with the 2o3 method. Therefore, in this study, among substances classified as skin sensitization in the National Chemical Information System (NCIS) in Korea, substances for which *in vitro* test data exist (positive) were selected as positive substances, and among substances not classified as skin sensitizers, *in vitro* test data were selected. Existing (negative) substances were selected as negative substances and the skin hypersensitivity prediction results using the DASS function of QSAR toolbox were confirmed. Combining the skin hypersensitivity prediction result using the DASS function of the QSAR toolbox with the 2o3 method, the final conclusion for skin hypersensitivity classification was confirmed according to the scoring method per OECD GL 497. Through this, the usability of the evaluation results according to OECD GL 497 as registration data for chemicals such as EU REACH and K-REACH was confirmed.

1.02.P-Mo023 Behavioural Fingerprinting with Machine Learning to Characterise Micropollution in Wastewater Effluents

George Ruck[1]*, Alexandre Decamps*[2]*, Jean-Baptiste Aubin*[3]*, Jean-Luc Bertrand-Krajewski*[4]*, Maxime Dauphin*[2]*, Laura Garnero*[5]*, Kassandra Montalbano*[2]*, Hervé Quéau*[6]*, Didier Neuzeret*[2]*, Olivier Geffard Pr*[7] *and Arnaud Chaumot*[8]*, (1)UR RiverLy - Ecotox,*

National Research Institute for Agriculture, Food and Environment (INRAE), France, (2)ViewPoint, France, (3)INSA de Lyon, France, (4)INSA LYON, France, (5)UR RiverLy - ECOTOX, Laboratoire d'écotoxicologie INRAE, France, (6)INRAE, France, (7)UR RiverLy, Institut national de recherche pour l'agriculture, l'alimentation et l'environnement (INRAE), France, (8)INRAE (Institut National de la Recherche Agronomique), France
Advances in technology and chemical understanding are highlighting the abundance and the diversity of micropollutants present in wastewater effluents. Biosurveillance methods based on locomotion behaviour tracking, such as ToxMate monitoring, have proved effective in capturing surges of micropollution in wastewater effluents, alerting operators to periods of potentially detrimental discharge. Whilst on-line alerting to micropollution is an essential step, the question remains: What is the contamination nature at the origin of water quality degradation? We hypothesized that the diversity of species behaviour response when exposed to contaminants can help to discriminate between exposure to different types of contamination. The objective of this poster presentation is to show how time series modelling, coupled with machine learning, may be the key to better contaminant identification thanks to behaviour fingerprints determination.
ToxMate biosurveillance apparatus uses videotracking to generate positional data *(x,y)* at 10 frames per second for 16 organisms of three bio-model species of aquatic invertebrates: *Gammarus, Erpobdella,* and *Radix*. Statistical modelling of the resulting big-data time series allows the quantification of the studied biomarker: avoidance behaviour, which correlates in real time to sharp increases in micropollutant presence.

Time series data from ToxMate experiments, collected from laboratory exposure to more than 80 micropollutants, was studied using functional data analysis (FDA). Combining the signals in a multispecies behavioural tracking, multidimensional analysis (known as vector-valued FDA) was used to first model the data as instances of functional random variables using B-Spline approximations, and then use dimensional reduction techniques such as functional principal component analysis (FPCA) as well as ML algorithms such as K-Means clustering, K Nearest Neighbours, and Quadratic Discriminant Analysis classification methods to form groups of behavioural responses, defined as behavioural fingerprints. Our results show how FDA on time series data can be effectively used to cluster behavioural response patterns with machine learning methods.

This first effective identification of contaminant behavioural fingerprints paves the way for a future application of this methodology to operational wastewater monitoring seeking to facilitate timely dedicated treatment of effluents to reduce negative environmental impacts.

1.02.P-Mo024 Drainflow Prediction Based on Data-Driven Approach

***Qianwen He**[1], Sebastian Gebler[1], Sebastian Multsch[2] and Beate Erzgraeber[1], (1)BASF SE, Germany, (2)APD/EFM, BASF SE, Germany*
Prediction of drainflow is essential to capture the contaminants’ transport to surface water bodies. Drainflow prediction with physically based numerical models (e.g., MACRO) requires a large number of field-individual input parameters and extensive computation. However, the limitations can be overcome by using data-driven approaches with a low number of inputs and fast response time. This study explores machine learning as the alternative to the physically based MACRO model. More specifically, our study evaluates the prediction accuracy of daily drainflow under heterogeneous climate conditions in Germany. Therefore, a typical drained soil type in Germany was selected and parameterized. For this soil type and each of the 817 spatially overlapping meteorological stations, daily drainflow was simulated with the MACRO model. The simulations were then used to train the data-driven model built by the state-of-the-art machine learning approach, the XGBoost (extreme gradient tree boosting). Results show that the daily drainflow prediction is most sensitive to predictors as the current and past 30 days precipitation and temperature, as well as their past five-day cumulative values. Those predictors give an impulse to the model indicating the soil moisture and precipitation change before drainflow occurs. Further, the prediction accuracy is highly positively correlated with the drainflow frequency. When the number of drained days exceeds 200 per year, the accuracy of whether drained or not ranges from 60% to 80%. However, if drained days are less than 100 per year, the accuracy may decline to 30%, possibly due to the limitation of the regression models fitting within no flow conditions. Our study demonstrates the capability of the XGBoost to simulate the drainflow and points out the options of further training refinement. Considering the vast increase of meteorological data availability, such a data-driven approach illustrates its potential to facilitate large-scale application of physically based models.

1.03 Assessing Adverse Effects of Pollutants on Host-Associated and Free-Living Microbiomes using ′Omics

1.03.P-Th001 Structural Responses of Bacterial Communities from Water, Biofilm, and Sediments to Environmental Parameters with Particular Emphasis on Antibiotic Stress at River Basin Level

***Pedro A. Inostroza**[1], Gerdhard L. Jessen[2], Xiaowei Zhang[3], Werner Brack[4] and Thomas Backhaus[5], (1)Biological and Environmental Sciences, University of Gothenburg, Sweden, (2)Universidad Austral de Chile, Chile, (3)Nanjing University, China, (4)Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany, (5)University of Gothenburg, Sweden*
Microbial communities and especially bacterial communities are key players when it comes to biogeochemical processes sustaining ecosystems, but they are also responsible for degrading toxic chemicals and the development of resistance against antimicrobial drugs, which ultimately impacts human health. Bacterial responses to environmental conditions are diverse, ranging from diversity dissimilarities changes depending on their environmental compartment, type of environmental stress, and especially the type of pollution fingerprint they are exposed to. In the field of microbial ecotoxicology, there is not a standard approach when it comes to assessing the effect of trace organic chemicals derived from human activities, such as pesticides, pharmaceuticals, and personal care products, and industrial chemicals on bacterial communities; thus, the use of DNA- and RNA-

sequencing-based methods has the potential to shed light on determining alteration on biodiversity at the microbial level. In this study, environmental DNA (eDNA) was analysed from water, biofilm, and sediment samples collected in the River Aconcagua Basin (Central Chile) to evaluate: i) whether alpha- and beta-diversity changed depending on the type of land uses, ii) which environmental variables may better explain changes in community structure, and iii) to assess quantitatively and qualitatively at community level the consequences of antibiotic stress in a selected river basin characterised by intense agriculture, large mining, and the discharge of 10 wastewater treatment plants (WWTPs). Our results suggest no alpha-diversity differences between land uses for water and biofilms, while alpha-diversity was significantly lower in sediments from agriculture and nearby urban settlements. Samples from agriculture and nearby urban areas were similar in terms of their community differentiation, while reference areas were significantly different. This degree of differentiation was driven by the toxic stress caused by antibiotic mixtures, at least in two sites affected by nearby urban development and WWTP discharges. Finally, the potential ecological outcomes of these changes were assessed and significant changes in abundances of both sensitive species featuring relevant ecological functions and bacteria known for antibiotic resistance development were estimated in certain areas of the studied river basin.

1.03.P-Th002 Breast Milk Elemental Profile is Associated with Postnatal Maternal Factors

Joaquim Calvo-Lerma[1], Belén Callejón-Leblic[2], Dr. Cecilia Martínez-Costa[3], Tamara García-Barrera[2] and ***MCarmen Collado**[4]*, *(1)Institute of Agrochemistry and Food Technology-National Research Council (IATA-CSIC), Spain, (2)Research Center for Natural Resources, Health and the Environment (RENSMA). University of Huelva, Spain, (3)University of Valencia, Spain, (4)Food Biotechnology, Institute of Agrochemistry and Food Technology (IATA-CSIC), Spain*

Breast milk (BM) composition in macronutrients, microorganisms, immunoglobulins, or vitamins has been widely studied, but less attention has been paid to minerals, especially metals. Diet, but also other perinatal or maternal factors, could determine the composition in metals in BM, and also, the lactation time could have an impact on the elemental profile.

Breast milk samples were prospectively collected in a cohort of 99 mothers in follow-up in the MAMI project. The absolute quantification of BM elements was determined by inductively coupled plasma mass spectrometry (ICP-MS) at two lactation times. Breast milk microbial profiling by 16S rRNA amplicon gene sequencing in the Illumina platform was also obtained. Maternal-infant clinical records, perinatal factors including maternal BMI, mode of birth, and lactation stage (7-15 days and 1-2 months after birth), and maternal diet were considered.

Lactation time showed to determine the composition in metals: Cu, Zn, and Sb decreased with lactation time, while Pb increased significantly. In early samples, mothers who had vaginal delivery had significantly lower content of Al, while in the mature samples, the content of Cu and Zn were higher. In addition, mothers' consumption of animal protein and meat had higher Co and Cu in BM than those following a diet high in vegetable protein and fiber. Related to diet, we also found that the consumption of nuts and processed meat was positively correlated with As and Cd. Also, the metal composition was correlated with some bacterial genus in BM, including positive correlations between *Bifidobacterium* with Cu; *Enterobacteria* with As, Cd, and Sb; and negative correlations between *Lacticaseibacillus* and Fe and Cu. In contrast, the elemental composition in BM at the assessed lactation times was not related to any of the infant growth indicators.

It was concluded that diet can shape the composition in relevant metals for infant nutrition, including Co and Cu, while others such as Fe or Zn were not related to dietary patterns. Also, heavy metals such as As and Cd, which could have harmful effects, were related to some food groups. Other noncontrollable variables such as type of birth were also found to be a determinant of elemental composition, and in turn, the elemental composition was related to the BM microbiota. The findings of this preliminary study highlight the insights that assessing elemental composition of BM could provide to understand infant nutrition and growth.

1.03.T-01 Meta-Metabolomics to Uncover Short- vs Long-Term Response of Periphytic Microbiome to a Model Fungicide

Melissa Eon[1], Ilan Viemont-Lefeuvre[1], Arthur Medina[2], Chloe Bonnineau[3], Soizic Morin[1] and ***Nicolas Creusot**[1,4]*, *(1)INRAE BORDEAUX, France, (2)Gironde, National Research Institute for Agriculture, Food and Environment (INRAE), France, (3)UR RiverLy, INRAE Lyon, France, (4)Plateforme Bordeaux Metabolome, Villenave d'Ornon, France*

Agricultural activity leads to the release of thousands of compounds (e.g., fungicides) to aquatic ecosystems that might be harmful for exposed organisms such as periphytic microbial communities playing a key role in ecosystem functions. Although previous studies have shown adverse effect of fungicides on the structure and functions of periphytic biofilms, there is still a paucity of knowledge on short-term molecular/biochemical mechanisms involved in such long-term impairment on ecosystem function(s). This is strongly needed to support the discovery of ecosystem biomarkers. To tackle this challenge, untargeted meta-metabolomics is an approach of choice since it provides a comprehensive picture of the biochemical activity and the molecular phenotype of a community, as a result of interactions with the environment. In this context, the present study aims to highlight the link between short-term response at the molecular level (untargeted metabolomics) and long-term response at the physiological/function (photosynthesis, enzymatic activity) and structural (biomass, chlorophyll *a*) levels of periphytic biofilms to the model fungicides tebuconazole (TBZ) at environmental concentrations (5-100 µg/L). At the structural level, there was a clear increase in the amount of chlorophyll *a* at 100 µg/L of TBZ that could be associated to the potential replacement of the fungal community (impacted by the TBZ) by autotrophic organisms. At the physiological/functional level, no fluctuation of the photosynthetic yield was noted whereas some discrepancies were observed for the enzymatic activities. In particular, there was a marked difference in the β-glucosidase activity between the control and the exposed biofilms at six and 26 days. At the molecular level, faster changes of the metabolome were noted in the exposed biofilms since half of the metabolome of the exposed biofilm had changed at three days against five days in the control. Further enrichment analysis highlighted that the pathways modulated by the TBZ changed along the exposure suggesting a shift in the metabolism of the whole communities in accordance with the changes observed in the enzymatic activities. Altogether this study highlights that tebuconazole at environmental concentration can trigger fast change of the meta-metabolome (four hours exposure) that might led to mid-long-term change of the whole community metabolism as noted for the enzymatic activities, as well as structural changes (increasing abundance of autotrophs).

1.03.T-02 Effects of Erythromycin on Juvenile Rainbow Trout Gut Microbiome

Phillip Ankley[1], *Jonathan Karl Challis*[2], *Jenna Cantin*[1], *Emily Kennedy*[3], *Katherine Raes*[1], *Yuwei Xie*[1], *Markus Hecker*[1], *John Giesy*[4] *and Markus Brinkmann*[1], *(1)Toxicology Centre, University of Saskatchewan, Canada, (2)Lethbridge Research and Development Centre, Agriculture and Agri-Food Canada, Canada, (3)Toxicology, University of Saskatchewan, Canada, (4)University of Saskatchewan, Canada*

Erythromycin (ERY) is a commonly used antibiotic that can be found in wastewater effluent globally. Disruption of the fish gut microbiome is an emerging area of research in aquatic toxicology because of its importance for host health. The pseudo-persistence of ERY could have impacts on the fish gut microbiome and overall health of host fishes. The overall objectives of this experiment were to: 1) Understand uptake and depuration of ERY in rainbow trout, 2) profile juvenile rainbow trout gut microbiome response to ERY, and 3) assess plasma metabolome response of juvenile rainbow trout to exposure. Juvenile rainbow trout (90-day posthatch) were exposed via diet to three concentrations (0.1, 10, and 1000 µg/g) and one solvent control in six replicate tanks (five fish/tank). The exposure period lasted for seven days followed by a seven-day depuration period with mid-gut tissue, bile, and plasma being collected for downstream analysis using 16s rDNA metabarcoding, target analyte measurement, and target/nontarget analyte measurement, respectively. The microbial community was characterized by 16s rDNA metabarcoding, and target analytes included ERY and the metabolite N-demethyl erythromycin (DM-ERY). Analytes were screened in plasma using a full MS-ddMS2 Top 10 method with both positive and negative ionization. ERY-treated fish overall showed greater Choa1 diversity at 11 days but had lower evenness at four days when compared to control. Juvenile rainbow trout were dominated by phyla *Proteobacteria* followed by *Firmicutes*. There were indications of an increase in *Proteobacteria* in the 1000 µg/g treatment group even after 7-d recovery period (14-d). Using functional analysis, several pathways associated with ERY-treatment including Bifidobacterium shunt and heme b biosynthesis indicating reduction in fermentation ability and disruption in compound synthesis, respectively. Erythromycin was detected at the greatest concentration for four days compared to seven days for 1000 µg/g treatment group in bile but opposite in plasma. N-demethyl erythromycin was detected in plasma at greater concentrations than ERY but only detected in two bile samples. Erythromycin caused perturbation of juvenile rainbow trout microbiome that continued beyond exposure and was transformed quickly in juvenile fish, leading to elevated metabolite in plasma at seven days. Future steps include finalizing the profiling of the plasma metabolome of exposed fish to better understand implications to host fitness.

1.03.T-03 A Combination of ʹOmics Approaches to Evaluate the Effects of Metabolic Disorders of the Nonsteroidal Anti-Inflammatory Drug Diclofenac in *Mus musculus* Mice. Antagonism with Selenium

Gema Rodríguez Moro[1], *Marta Selma-Royo*[2], *Silvia Garrido-Dávila*[3], *MCarmen Collado*[4], *José Antonio Gómez-Morlote*[1], *Nieves Abril*[5] *and Tamara García-Barrera*[6], *(1)Universidad de Huelva, Spain, (2)Institute of Agrochemistry and Food Technology (IATA-CSIC), Spain, (3)Chemistry, Universidad de Huelva, Spain, (4)Food Biotechnology, Institute of Agrochemistry and Food Technology (IATA-CSIC), Spain, (5)University of Córdoba, Spain, (6)Research Center for Natural Resources, Health and the Environment (RENSMA), University of Huelva, Spain*

Biological systems are exposed to a complex environment in which contaminants can interact in a synergistic/antagonistic or agonistic fashion, and for this reason, the metabolism of toxic substances should not be considered in isolation. Due to the extensive use of diclofenac (DCF) as a nonsteroidal anti-inflammatory drug, its residues have been regularly detected in surface waters around the world, causing serious health problems. On the other hand, selenium (Se) is an essential trace element well known for its detoxification properties. In this work, we evaluated the metabolic disorders of DCF in gut content, testis and brain of *Mus musculus* mice and the role of Se supplementation. *Mus musculus* mice (30 animals) were distributed into three groups: Group A (Control), mice fed rodent diet; Group B (Control+Se), fed Se-supplemented diet (0.65 mg Se/kg of chow); Group C (DCF), 20 mg DCF/Kg of chow, Group D (DCF+Se), that combines Se-supplementation and DCF exposure. Gut, testis, and brain metabolome was analysed by gas chromatography-mass spectrometry (GC-MS) and ultra-high performance liquid chromatography coupled to quadrupole time of flight (UHPLC-QTOF). Subsequently, the data were processed by multivariate statistical analysis to identify the metabolites altered under DCF and Se exposure. Partial least squares-discriminant analysis showed significantly separated clusters among exposed groups versus control, so *Mus musculus* undergoes metabolic disorders promoted by DCF exposure. Moreover, the gut microbiota profile was determined by 16S rRNA gene sequencing following Illumina protocols and the microbially produced metabolites by untargeted metabolomics. These results confirm that exposure to DCF and supplementation with Se cause single and joint alterations in microbiota composition and in the gut, testicular, and brain metabolome. The most significantly altered metabolic pathways were glyceropospholipd metabolism in brain, biosynthesis of unsaturated fatty acids and glyoxylate and dicarboxylate metabolism in testis, and finally primary bile biosynthesis in gut content. Our results highlight the possibilities of the applied metabolomics approach as a key tool to elucidate the mechanism of toxicity of drugs and understand the metabolic response of free-living organisms to environmental issues.

1.03.T-04 A High-Throughput Approach to Explore the Transformation Potential of the Human Gut Microbiome for Xenobiotic Interaction and Internal Exposure

Laura-Fabienne Fröhlich[1], *Victor Castaneda-Monsalve*[2], *Qiuguo Fu*[1], *Bettina Seiwert*[3], *Thorsten Reemtsma*[4], *Nico Jehmlich*[2] *and Martin von Bergen[2], (1)Analytical Chemistry, Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany, (2)Molecular Systems Biology, Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany, (3)Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany, (4)Department of Analytical Chemistry, Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany*

The influence of the microbiome on human health is becoming increasingly evident. One area of concern is the transformation products (TPs) resulting from the microbial metabolization of xenobiotics in the anaerobic gastrointestinal tract. While the literature on transformation of environmental chemicals by the microbiome is growing, the effects on humans of xenobiotic-induced changes on the ecology of the microbiome and toxicity of xenobiotics altered by biotransformation on humans are still poorly understood.

In this study we explored the transformation potential of the SIHUMIx (Simplified Human Gut Microbiome x) in vitro model, which can be cultivated in bioreactors. This screening tested a larger number of pesticides, which included versatile structures to facilitate possible biotransformation. After incubation we (1) assessed changes in biotic and biotic spiked samples, (2) prioritized those with significant decrease, and (3) assessed the formation of TPs.
Our findings proved the applicability of the SIHUMIx in combination with nontargeted LC-MS in high-throughput screening for toxicant transformation in the microbiome for the first time. Subsequent experiments will test these findings in *in vivo* models (zebrafish, mice) and compare biotransformation of the human microbiome with previous findings on biotransformation in the environment. This is relevant for humans, but also for many other living organisms in the environment.

1.03.P Assessing Adverse Effects of Pollutants on Host-Associated and Free-Living Microbiomes using ′ Omics

1.03.P-Th003 Bioavailability of Flumequine and Diclofenac in a Mice Model Exposed to a “Chemical Cocktail.. Impact of Antibiotic-Induced Depletion of Gut Microbiota and Selenium Supplementation

*Noemí Aranda-Merino[1], Antonio Marín-Garrido[2], Maria Ramos-Payán[3], Nieves Abril[4], Miguel Ángel Bello-López[2] and **Rut Fernandez-Torres**[5], (1)Departamento de Química Analítica.Facultad de Química, Universidad de Sevilla, Spain, (2)Departamento de Química Analítica. Facultad de Química, Universidad de Sevilla, Spain, (3)Departamento de Quimica Analitica. Facultad de Química, Universidad de Sevilla, Spain, (4)University of Córdoba, Spain, (5)Quimica Analítica Facultad de Química, Universidad de Sevilla, Spain*

Ecosystems are exposed to a complex environment in which pollutants may interact through antagonistic or synergistic schemes, which highlights the need for global studies on the biological response of the living organisms that inhabit these ecosystems. Although there are studies on the effects of pollutants and their biological responses in living organisms, in most of them, only those produced by a substance or group belonging to a single chemical group are studied (e.g., metals, pesticides, or pharmaceuticals). Controlled exposure assays to chemical cocktails involving several families of potentially toxic chemicals can yield highly relevant information, despite their complexity in the interpretation of results, as biological systems will produce different responses due to the interaction between substances and the aforementioned synergistic or antagonistic effects.

In this project a controlled exposure experiment on mice (*Mus musculus*) to a “chemical cocktail” containing metals (As, Cd, Hg) and pharmaceuticals (diclofenac [DCF] and flumequine [FMQ]) have been realized and additionally the role of antibiotic depletion of gut microbiota and the presence of selenium as antagonist have been also evaluated.
Samples were extracted using a vortex assisted liquid-liquid extraction procedure and then measured using a chromatographic method by ultra-high performance liquid chromatograpy (UPLC) coupled to quadrupole time of flight mass spectrometry detection. Levels of FMQ and DCF as well for the 3-, 4-, and 5-hydroxy diclofenac metabolites were measured. Results on their bioavailability have been discussed according to exposure conditions of each test group. Additionally, a computational identification of 48 DCF and FMQ metabolites based on previously reported in literature was realized.
Selenium seemed to affect pharmaceutical absorption and DCF metabolism; however, FMQ seemed to be unaffected. Despite the presence of the metal in the cocktail, this did not seem to affect it significantly; significant differences in groups with microbiota depleted were obtained in the Se-supplemented diet group, as the depleted microbiota seemed to affect the levels of DCF considerably. The number of metabolites identified was lower when the animals were fed a metal-drug chemical cocktail.

1.03.P-Th004 Exploring the Effects of “Chemical Cocktails” into Brain and Testicular Metabolomes. Intertwined Mechanisms with Gut Microbiota and Selenium

***Cecilio Parra Martínez**[1], Marta Selma-Royo[2], MCarmen Collado[3], Nieves Abril[4] and Tamara García-Barrera[5], (1)University of Huelva, Spain, (2)Institute of Agrochemistry and Food Technology (IATA-CSIC), Spain, (3)Food Biotechnology, Institute of Agrochemistry and Food Technology (IATA-CSIC), Spain, (4)University of Córdoba, Spain, (5)Research Center for Natural Resources, Health and the Environment (RENSMA), University of Huelva, Spain*

Insights about the crosstalk between the gut microbiota and the brain through the gut-brain axis have been extensively reported as well as the potential impact of pollutants on that communication. Among pollutants, mercury (Hg) and arsenic (As) are well-known neurotoxicants, but selenium (Se) has been demonstrated to counteract this effect due to its antioxidant character and neuroprotective action. Thus, the biological effects of pollutants should not be explored in isolation and for this reason, we developed an experiment to evaluate the joint impact of a “chemical cocktail” (CC) of As, cadmium (Cd), Hg, and pharmacologically active compounds (PACs) on brain metabolism and the potential roles of Se-supplementation and gut

microbiota. Thus, 50 *Mus musculus* mice were divided in five groups: control group, CC, CC + Se, CC+microbiota depletion by antibiotics (ABX), and CC+ ABX + Se. Mice brain and testicular tissues were analysed by an analytical multiplatform based on gas chromatography-mass spectrometry (GC-MS) and ultra-high performance liquid chromatography coupled to quadrupole time of flight (UHPLC-QTOF). Bacterial composition was determined by 16S rDNA gene sequencing using Illumina apparatus. We observed an increased mortality in groups CC and ABX-CC with the worst outcome for the ABX-CC group, but the mortality ratio returned to normal values in groups CC-Se and ABX-CC-Se. Numerous metabolites were identified in the different groups, including organic acids, fatty acids, amino acids, and glycerophospholipids in brain, as well as glycerophospholipids and sphingolipids (testis). Selenium was not capable of modulating metabolic pathways in the ABX mice model after the CC exposure. However, in spite of the key impact of the CC into the gut microbiota composition, diversity, and richness, Se modulated the abundance of several metabolites in brain and testicular tissues impacting also gut microbiota. The number of altered brain and testicular metabolites by the exposure to xenobiotics decreases after Se supplementation and they were also affected by microbiota depletion by antibiotics. Moreover, the concentration of arsenic species, Hg, and PACs varied among the different groups demonstrating the impact of Se and microbiota as well as their interactions with the xenobiotics.
Our results suggest the presence of numerous intertwined mechanisms between gut microbiota, metabolites, Se, and xenobiotics that should be explored to delve into the impact of pollution real in living beings.

1.03.P-Th005 Impact of a Metal-Drug "Chemical Cocktail" on Mice Bile Acids Profile

*Antonio Marín-Garrido[1], Noemí Aranda-Merino[2], Nieves Abril[3], Miguel Ángel Bello-López[4], Maria Ramos-Payán[5] and **Rut Fernandez-Torres**[6], (1)Departamento de Química Analítica. Facultad de Química, Universidad de Sevilla, Spain, (2)Departamento de Química Analítica.Facultad de Química, Universidad de Sevilla, Spain, (3)University of Córdoba, Spain, (4)Universidad de Sevilla, Spain, (5)Departamento de Quimica Analitica. Facultad de Química, Universidad de Sevilla, Spain, (6)Quimica Analítica Facultad de Química, Universidad de Sevilla, Spain*

Bile acids (BAs) are endogenous steroids with a marked hepatotropic character that play important roles in the absorption and digestion of dietary fats and fat-soluble vitamins. They are also the main route of cholesterol breakdown. These endogenous metabolites are essential for monitoring general metabolism and clearly indicate alterations in metabolic pathways. Evident changes in the concentration of individual BAs and their metabolic profiles can usually be detected in response to any alteration in the organism and have therefore been considered important biochemical markers.

In this work, the main objective was to evaluate the alteration of bile acid profiles in an *in vivo* animal model (*Mus musculus*) after exposure to a "chemical cocktail" containing several environmental pollutants from different chemical groups (metals and drugs), to analyse the potential impact of their presence on the biological response of the living organisms under study. Additionally, the role of antibiotic depletion of gut microbiota and the presence of selenium as antagonist were also evaluated.

For this purpose, a controlled exposure experiment to a "chemical cocktail" containing metals (As, Cd, Hg) and drugs (diclofenac and flumequine) was carried out in mice to evaluate the effect on their bile acid profile. To this end, plasma and liver samples from exposed mice were extracted and the bile acids (cholic acid, taurocholic acid, glycolic acid, taurodeoxycholic acid, ursodeoxycholic acid, and deoxycholic acid) were analysed by liquid chromatography coupled to time-of-flight mass spectrometry detection.

The results showed significant differences in the concentration of bile acids measured in the livers of mice from the different groups. Taurocholic acid appears to be the compound with the greatest differences between the different groups analysed and therefore the compound most affected in the bile acid profile. On the other hand, the levels of deoxycholic acid, glycolic acid, and ursodeoxycholic acid decreased drastically in the exposed groups compared to the control groups.

1.03.P-Th006 The Influence of Florfenicol Coated Fish Feed on the Gene Expression of the Atlantic Salmon (*Salmo salar*) Gastrointestinal Tract and its Microbiome

***Daniela Maria Pampanin**[1], Giovanna Monticelli[1], Jason Tyler Magnuson[1], David Peggs[2], Joseph H Bisesi[3] and Daniel Schlenk[4], (1)University of Stavanger, Norway, (2)Skretting Aquaculture Innovation, Stavanger, Norway, (3)Environmental and Global Health, University of Florida, (4)Environmental Sciences, University of California, Riverside*

The use of antibiotics to treat fish diseases in aquaculture is still necessary, and dosages and treatment lengths greatly vary depending on local regulations. Although concerns about the impacts of antibiotics in aquatic organisms are reported worldwide, the potential adverse effects on commensal gut microbiota and fish health are still not fully understood. Herein, changes in the fish gastrointestinal tract (GIT) transcriptome and its microbiome due to treatment with florfenicol (FFC), a fluorinated synthetic analog of thiamphenicol and a broad-spectrum bacteriostatic antibiotic, were investigated.

Juvenile Atlantic salmon (*Salmo salar*) were treated with commercial feed coated with FFC (10, 20, and 30 mg/kg) for 18 days and afterwards were subjected to 15 days of recovery, to simulate real field scenarios. The GIT tissues were used for mRNA sequencing analysis (metatranscriptomics) to quantify gene expression in the host GIT and its microbiome. After FFC treatment, 1058 unique Enzymes Commission numbers (ECs) and 69 unique pathways were identified. No statistically significant differences were determined for ECs and pathways between treated and control groups. After recovery, 1201 unique ECs and 71 pathways were identified. A total of 9 ECs, involved in metabolic pathways and the biosynthesis of secondary metabolites, were statistically different when comparing treatment vs. control. A dose dependent effect was observed, as measured by an increased number of differentially expressed genes (DEGs) from the low to high dose of FFC.

With regard to transcriptomics responses in the fish intestine, the top predicted canonical pathways in common between treatments were categorized as DNA replication, cell death and survival, and apoptosis, indicating potential gut inflammation. Top predicted canonical pathways after the 30 mg/kg treatment included EIF2 signaling, protein ubiquitination, LXR/RXR activation, and FXR/RXR activation, indicating potential activation of xenobiotic metabolism. After recovery, top predicted canonical pathways in common between treatments were EIF2 signaling and mTOR signaling (which are both critical for cell growth and proliferation via lipid synthesis regulation), lysine degradation II and V (lysine is an essential amino acid strongly related to fish growth), and regulation of eIF4 and p70S6K signaling. The same dose dependent effect, observed in the microbiome, was confirmed in the fish GIT.

1.03.P-Th007 Antimicrobial Effects on the Gut Microbiome of a Leaf-Shredding Amphipod ***Alexander Feckler**[1], Mirco Bundschuh[2], Ondrej Adamovsky[3], Sven Katzenmeier[4], Hana Vespalcova[3] and Thorsten Stoeck[4], (1)Eußerthal Ecosystem Research Station, University of Koblenz-Landau, Germany, (2)iES Landau, University of Kaiserslautern-Landau (RPTU), Germany, (3)Recetox, RECETOX, Masaryk University, Czech Republic, (4)Ecology Group, Technical University Kaiserslautern, Germany*
Host-associated microbiomes support, for instance, nutrient uptake and their processing. Disturbances in such microbiomes can cause severe diseases in humans and mammals, whereas the consequences for the physiology of (aquatic) invertebrates are largely unknown. However, literature points to changes in invertebrates' gut microbiomes as a consequence of direct wastewater and antibiotic exposure, which are likely linked to physiological implications. At the same time, the impact of antimicrobials on the gut microbiome via the nutritional quality of their hosts' diet and dietary exposure to chemicals is mostly ignored. Here, we assessed the bacterial microbiome of a leaf-shredding amphipod (*Gammarus fossarum* Koch) via metabarcoding after exposure toward the antibiotic ciprofloxacin at 500 µg/L, the fungicide azoxystrobin at 15 µg/L, and their mixture through different pathways, that is water, food, and a combination of both (n = 10). We observed significant effects of ciprofloxacin, azoxystrobin, and the mixture of both on the bacterial composition in the gut microbiome ($p \leq 0.028$), while only for ciprofloxacin and the antimicrobials' mixture a pathway-dependency for the observed effects were detected ($p \leq 0.012$). In the latter case, the strongest effects were observed for the water exposure and the combination of both pathways. This suggests that the antibiotic was the driving force for the bacterial shifts caused by the antimicrobials' mixture. Various bacterial families were either severely suffering or benefitting from the antimicrobials' presence, while the identity of affected bacterial families was substance-specific. A benefit for bacteria in this environment points to a reduced pressure for competition, leading to a reproductive advantage. Given that knowledge on structural changes cannot directly be linked to physiological changes in the microbiomes' host, further analyses are currently ongoing. These analyses are intended to predict shifts in the bacterial metabolome and produce microbial community-wide metabolomic potential scores for a more mechanistic understanding of the physiological responses of antimicrobially exposed *G. fossarum* reported in earlier publications.

1.03.P-Th008 Consequences of the Fragrance Amyl Salicylate on the Mediterranean Mussel *Mytilus galloprovincialis* and on Host-Microbiota Interactions
***Ilaria Bernardini**[1], Jacopo Fabrello[2], Marco Vecchiato[3], Serena Ferraresso[1], Massimiliano Babbucci[1], Luca Peruzza[1], Giulia Dalla Rovere[1], Luciano Masiero[4], Maria Gabriella Marin[5], Luca Bargelloni[1], Andrea Gambaro[6], Tomaso Patarnello[1], Valerio Matozzo[5] and Massimo Milan[1], (1)University of Padua, Italy, (2)Biology, University of Padua, Italy, (3)National Research Council (CNR), Institute of Polar Science (ISP), Italy, (4)University of Padova, Italy, (5)Department of Biology, University of Padova, Italy, (6)Department of Environmental Sciences, Informatics, and Statistics, Ca' Foscari University of Venice, Italy*
Amyl salicylate (AS) is a fragrance that due to its massive use may be spread into the environment, threatening the ecosystems including wild and farmed organisms. In this regard, this substance was recently detected in water of the Venice Lagoon, becoming a hazard for animals, including mollusk bivalves such as the Mediterranean mussel (*Mytilus galloprovincialis*) that have an important economic and ecological role in this area. Despite high levels of AS occurring in water of the Lagoon of Venice, no studies investigated the possible consequences of AS exposures on species inhabiting this ecosystem to date. Thus, the present research used a multidisciplinary approach to investigate the potential effects of the amyl salicylate on Mediterranean mussels. Bioaccumulation capacity, cellular, biochemical, and molecular analyses (RNA-seq and microbiota characterization) were evaluated in mussels treated for seven and 14 days with low and high AS Venice Lagoon environmental concentrations (0.1 and 0.5 µg/L, respectively). The chemical study did not show a great bioaccumulation capability of AS, whilst the highest concentration of the tested compound led to the disruption of several key cellular and molecular processes after the long-lasting exposures. Among them, potential immunotoxicity and changes in transcriptional regulation of pathways involved in energy metabolism, stress response, apoptosis, and cell death regulations have been observed. In contrast, exposure to the low AS concentration demonstrated weak transcriptional changes and transient increased representation of opportunistic pathogens, such as the Arcobacter genus and *Vibrio aestuarianus* species. In conclusion, this research provides the first results of a pilot study on the effects of AS on one of the most widely farmed marine mollusk species in the Venice Lagoon and worldwide.

1.03.P-Th009 Impact of Contaminants of Emerging Concern on Groundwater Microbial Communities
***Nicola Montemurro**[1], Maria vila-Costa[2], Sandra Pérez[3], Antoni Ginebreda[2] and Anna Jurado[4], (1)Department of Environmental Chemistry, IDAEA-CSIC, Spain, (2)Environmental Chemistry, Spanish Research Council (CSIC), Institute of Environmental Assessment and Water Research (IDAEA), Spain, (3)Onhealth, IDAEA-CSIC, Spain, (4)IDAEA-CSIC, Spain*
Rapid urban growth and climate change are negatively impacting water resources. Additionally, water shortages are encouraging

research into potential alternative freshwater resources such as urban aquifers. As urban aquifers contain a wide range of pollutants such as pharmaceuticals (PhACs), the question is whether these urban groundwaters (UGWs) can be used as safe drinking water. Current knowledge about the microbial communities (MCs) that occur in UGWs is scarce. In addition, microbes can affect the normal attenuation processes of these contaminants or lead to opportunistic stress-resistant microbial strains. In this study, the MCs of the aquifer were analyzed to determine the microbial abundances and composition. The Barcelona city area was chosen as a pilot area due to the deterioration of the quality of the aquifers over the past years and the proven presence of numerous organic and inorganic contaminants. In this regard, river and several UGW samples were collected in March and October 2021 from the shallow aquifer of the Besòs Delta River, the main contamination source of which is a polluted river that receives discharges from wastewater treatment plants. For the analysis of PhACs, solid-phase extraction and high-pressure liquid chromatography coupled with high-resolution mass spectrometric methodology (HPLC-HRMS) were performed. A subset of samples was analyzed for the composition of the microbial communities using a 16S-amplicon sequencing approach. Preliminary results showed that approximately 40 PhACs such as anticonvulsants, antihypertensives, antibiotics, and antivirals were detected in river samples. Of these, about half were present in UGW samples. Furthermore, the sampling points located near the river compared with the farthest points showed the highest concentrations due to the majority of substances, suggesting a natural attenuation phenomenon of drugs susceptible to adsorption or redox processes. Relationships between the number and concentration of detected pollutants and microbial characteristics (diversity, abundances, and composition) were also investigated. Functionalities including key biogeochemical processes such as denitrification and ammonia oxidation within MCs were estimated by means of PICRUSt2 and compared to environmental parameters. This study provides insights into the impacts of organic contaminants on the structure and function of UGW MCs and the potential role of microorganisms modulating the fate of these pollutants.

1.03.P-Th010 Metabarcoding of Multiple Microbial and Metazoan Taxa in Grossly Contaminated Estuaries Reveals their Differential Sensitivity to Metal Toxicity

Abdullah Aleidan[1] *and Alastair Grant*[2]*, (1)School of Environmental Sciences, UEA, Norwich, Norfolk, United Kingdom, (2)School of Environmental Science, University of East Anglia, Norwich, United Kingdom*

Environmental monitoring in the marine environment has normally been carried out using morphological identification of macrofaunal or meiofaunal communities. These methods are time-consuming and require considerable taxonomic expertise. We have carried out DNA metabarcoding using multiple PCR primer pairs to quantify community composition of bacteria, archaea, metazoa, fungi, and diverse eukaryote microbes along a well-studied metal pollution gradient in Southwest England. The approach allows us to quantify essentially the whole range of organisms present, including neglected and poorly characterised taxa, and how this changes along a gradient from clean to severe contamination. Metal pollution has impacts on most taxonomic groups, but there are substantial differences in their sensitivity and the extent to which the influence of pollution is masked by the effects of other environmental variables.

1.03.P-Th011 Not Just Plastic: Understanding the Complex Micro-Environment of Wastewater Treatment Plant Microplastics and their Role in Shaping the Plastisphere

Olga Pantos Dr[1]*, Gavin Lear Prof*[2]*, Joanne Kingsbury Dr*[1]*, Louise Weaver Dr*[1]*, Dawn Smith Dr*[3]*, Hayden Masterton*[1]*, Sally Gaw Prof*[4] *and Jessica Wallbank*[2]*, (1)ESR, Christchurch, New Zealand, (2)University of Auckland, New Zealand, (3)Scion, New Zealand, (4)University of Canterbury*

Wastewater treatment plants (WWTPs) are a rich source of microbes, microplastics (MPs), and organic and inorganic chemicals. Plastics provide a physical surface for microbes to settle and benthic communities to develop. Chemicals are also a key component of the plastisphere, present in both the plastic substrate and associated with the biofilm. These include both the chemical additives inherent in the plastics, and extrinsic chemicals from other sources which in the WWTP environment include such things as pharmaceuticals, biocides, and industrial chemicals. Extrinsic chemicals can become associated with the plastisphere through adsorption to the plastics and the associated biofilms. Plastics' surface properties, polymer type, and associated chemicals may all influence plastisphere community composition and consequently the risk posed to the environment when discharged from the WWTP.

Of specific concern are the pathogenic or antibiotic-resistant bacteria (ARB) which have previously been identified within the plastisphere, where it is proposed that they use plastic as a raft for biofilm formation and survival. With large quantities of MPs exiting WWTPs through either liquid effluent or biosolids the identification and characterisation of these microbes is critical.

To date, no studies have characterised WWTP plastisphere communities in New Zealand. This study aims to determine the potential impacts plastics and associated chemicals have on the microbial communities present in the WWTP system, whether certain pathogenic species survive, and what effects these communities may also have on the plastics. Next-generation sequencing was applied to identify changes in microbial biofilm community compositions on five common plastics of either virgin or artificially UV-aged condition. Biofilm was sampled from linear low-density polyethylene (LLDPE), nylon-6, polyethylene terephthalate, polylactic acid, and oxo-LLDPE paddles and glass slides after two and six weeks, and six and 12 months of constant immersion in a WWTP oxidation pond. Trace elements in both the biofilm and plastics were analysed using inductively coupled plasma-mass spectrometry (ICP-MS). A more comprehensive understanding of the potential role of wastewater plastispheres, including survival and enrichment of pathogenic microbes or ARBs and the interactions with inorganic contaminants, will highlight the need for more control strategies to prevent the release of two important classes of contaminants, microbes and trace elements, into the environment in the future.

1.03.V Assessing Adverse Effects of Pollutants on Host-Associated and Free-Living Microbiomes using ′Omics

1.03.V-01 Insights into the Functional and Structural Alterations of a Simplified Human Intestinal Microbiota Model Caused by Pesticides Using Proteomics and Metabolomics

Victor Castaneda-Monsalve[1]*, Laura-Fabienne Fröhlich*[2]*, Qiuguo Fu*[2]*, Ulrike Rolle-Kampczyk*[1]*, Sven-Baastian Haange*[1]*, Martin von Bergen*[1] *and Nico Jehmlich*[1]*, (1)Molecular Systems Biology, Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany, (2)Analytical Chemistry, Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany*

The human gut microbiota is a complex ecosystem involved in key functions essential for the host. These include protection against pathogens, immune-system modulation, fermentation of nondigestible dietary fibers, and biotransformation of xenobiotics. The symbiotic intestinal microbial community is sensitive to external disturbances, caused by the interaction of the host with its environment, increasing the risk of dysbiosis and, thus, affecting the health of the host. Nevertheless, regardless of their known importance and potential ability to metabolize xenobiotics and their secondary products, microbiota models are not part of risk assessment assays, and information on the effects of environmental contaminants on the composition and function of the human intestinal microbiome is still sparse. In this study, we investigate the response of a simplified gut microbiota *in vitro* model exposed to 54 pesticides in environmentally relevant concentrations for 24 h. To examine the effect on the structure and function of the Simplified Human Intestinal Microbiota (SIHUMIx), the profiling of the taxonomic composition using metaproteomics, and the detection of short-chain fatty acids (SCFAs) through metabolomics was performed. Nineteen of 54 pesticides caused a reduction in at least one of the nine most common SCFAs detected. Ethoxyquin, flufenacet, fluoroxypyr, foramsulfuron, primicarb, prochloraz, and propamocarb significantly reduced the concentration of the main SCFAs: acetate, lactate, propionate, and butyrate. On the taxonomic level, out of the 54 pesticides, 20 produced a significant change in at least one of the SIHUMIx strains. While half of the positive hits caused a change in only one of the bacterial strains, the other half caused the simultaneous reduction of multiple gram-positive species such as *Clostridium ramosum, Bifidobacterium longum, Lactobacillus plantarum,* and *Clostridium butyricum.* This study presents a high-throughput *in vitro* approach, where multiple pesticides were screened in parallel against a stable microbiota model, and significant effects on the community's structural integrity and energy metabolism were observed. We anticipate our assay to be part of the efforts to achieve a better understanding of microbiota-xenobiotic interactions, leading to better decision-making regarding pesticide regulation in the interest of improving human health.

1.04 Daphnia - The Good, the Bad, and the New?

1.04.T-01 Can *Daphnia magna* be used as a Surrogate Species to Predict Environmental and Human Health Defects of Pollutants

Carlos Barata Dr[1] *and Hugo Moro*[2]*, (1)Environmental Chemistry, Spanish Research Council (CSIC), Institute of Environmental Assessment and Water Research (IDAEA), Spain, (2)IDAEA-CSIC, Spain*

The aquatic crustacean *Daphnia magna* is an established ecotoxicological and ecological model that is routinely used to assess the acute and chronic toxicity of new and existing chemical pollutants. Quite recently it was found that many molecular drug targets in humans were also present in the *D. magna* genome. Accordingly in USA *D. magna* has been proposed as a biomedical model. This is in line with the need to reduce animal experimentation and the increasing use of New Approach Methodologists and Adverse Outcome Pathways (AOPs) in both environmental and human risk assessment of chemical products. We present results obtained for the last 10 years by our team where we have successfully developed two *D. magna* toxicological models: the *D. magna* serotonergic neurological model sensitive to selective serotonin reuptake inhibitors (SSRIs) and the obesogenic-like model able to predict and assess the molecular mode of action and their adverse outcomes. As in humans selective serotonin reuptake inhibitors (SSRIs) increased brain serotonin levels in the *D. magna* brain and decreased the responses to stress. Obesogenic compounds enhanced the accumulation of storage lipids. Just recently we have been developing a *Daphnia* model for assessing pollutant effects on Developmental Origins of Neurobehavioral Deficits and Diseases (DONDaD) that has established a link between short-term exposure to environmental pollutants during specific developmental windows and different neurological disorders. A *D. magna* brooding female contains at least three types of developmental eggs: developing embryos in the brood pouch, and provisioned and unprovisioned eggs in the ovaries. This means that by exposing an adult female during a reproductive cycle that lasts 3-4 days at 20ºC, then transferring to clean medium and collecting the first three consecutive clutches, it would be possible to assess delayed pollution mediated effects in juvenile stages upon exposure to key developmental stages. We tested DONDaD using environmental low concentrations of two SSRIS (fluoxetine and sertraline) and the obesogenic pesticide tributyltin across different experiments. Behavioural effects measured in 3-4 day-old juveniles evidenced clear stage-specific different responses among exposed juveniles and developing stages. Ongoing studies of the transcriptomic and metabolomic pathways involved in the observed developmental stage specific effects will help to elucidate the molecular mechanisms.

1.04.T-02 *Daphnia* as Model System to Address Questions at the Interface of Evolutionary Ecotoxicology and Multiple-Stressor Research

Julie Verheyen[1]*, Vienna Delnat*[2]*, Ine Van Hileghem*[2] *and Robby Stoks*[2]*, (1)Biology, KU Leuven, Belgium, (2)KU Leuven, Belgium*

While the water flea *Daphnia* has been widely appreciated as an ideal model organism in evolutionary ecotoxicology, and increasingly in multiple-stressor research, we here show its high potential to also address outstanding questions at the interface of both fields. Despite the increasing interest in evolutionary ecotoxicology and in interactions between pollutants and natural stressors such as warming, little is known about the genotype-dependency of these interactions within a single population. As a result, we cannot evaluate the potential of stressor interactions to evolve in a single population. Moreover, we have limited abilities to predict the interaction type (additive, antagonistic, and synergistic) between pollutants and another stressor, as it is unknown whether this can be predicted based on the sensitivities to each stressor in isolation. Capitalizing on the presence of parthenogenetic reproduction, hence the possibility to work with clones, we here demonstrate how *Daphnia* can be an ideal model organism to address such evolutionary questions at the interface of global change biology and ecotoxicology. As an example study we focused on the interaction pattern between heat extremes and pesticide exposure. We studied genotype-dependent effects of sequential exposure to a heat spike and a pesticide (esfenvalerate) in a set of six clones from the same natural population of *D. magna*. A key finding was that these clones strongly differed in interaction type whereby we identified antagonistic, additive, and synergistic interactions for two life history traits (survival and time to maturation) for the same multiple-stressor combination. These genotype-dependent interaction patterns may fuel the evolution of stressor interaction patterns and also be the underlying reason for the observed inconsistencies among studies for the same multiple-stressor combination, which also challenges current ecological risk assessment for pollutants based on single genotypes. Furthermore, by using the tolerances of the six clones to the heat spike and to the pesticide, we could show that the interaction type between the heat spike and esfenvalerate could be predicted based on the tolerance to the pesticide. Specifically, more pesticide-tolerant genotypes showed a stronger synergism. This case study therefore illustrates the potential of *Daphnia* as a model to advance our insights in outstanding topics that integrate evolutionary ecotoxicology and multiple-stressor research.

1.04.T-03 Image-Based High-Content Screening of Mitochondrial Membrane Potential in *Daphnia magna*

***Cedric Abele**, Amira Perez, Paula Pierozan, Magnus Breitholtz and Oskar Karlsson, Environmental Science, Stockholm University, Sweden*

The high complexity of interactions between biota and anthropogenic chemicals requires methods that are able to rapidly provide information about sublethal effects and toxicological mechanisms. The aim of this study is to optimize a high-content imaging workflow using molecular staining to assess the (eco)toxicity of chemicals in the aquatic test organism *Daphnia magna.*

JC-1 is a lipophilic cation that can permeate both the cell and mitochondrial membrane. JC-1 forms red-orange light emitting J-aggregates when the mitochondrial membrane potential is high, and stays in its green-light emitting monomeric form when the membrane potential is low. The red-to-green signal ratio is therefore an indicator of exposure for chemicals interfering with the membrane potential of mitochondria. To establish suitable protocols for JC-1 whole animal staining in *D. magna* juveniles we used the model compound 2,4-dinitrophenol (2,4-DNP), which lowers the mitochondrial membrane potential by uncoupling the oxidative phosphorylation.

We first tested different concentrations of the JC-1 staining solution and time. In the next step, we exposed juveniles to a concentration series of 2,4-DNP. Five individuals were sampled at several time points within a period of 24 h and stained with JC-1. The red and green fluorescence intensity were measured in 384 - multiwell plates. Images were acquired in an automatic multipoint confocal fluorescence microscope. An additional aim of the study is to connect the image acquisition to an automated image analysis workflow, which enables quantification of the fluorescence intensities. Based on the intensities we want to determine concentration-response relationships and compare them to the *Daphnia* sp., acute Immobilisation Test OECD Test 202 for testing of chemicals.

The study revealed JC-1 J-aggregate formation in the cells of *D. magna*, indicating that the stain did distribute to mitochondria. The results also demonstrated a concentration-response relationship between the 2,4-DNP concentration and JC-1 signal. Importantly, we were able to see effects much earlier, both in time and concentration, compared to OECD Test 202.
In summary, we demonstrated that molecular staining of whole organisms and image-based high-content screening can provide valuable toxicological data in a higher throughput manner in *D. magna*. This approach can contribute to the understanding of a chemical's mode of action, which will improve the effect assessment of chemicals.

1.04.T-04 Insights into Microplastic Particles Distorting Chemical Communication

*Matthias Schott[1], **Magdalena M. Mair**[2] and Christian Laforsch[3], (1)Animal Ecology I, University of Bayreuth, Germany, (2)Statistical Ecotoxicology, University of Bayreuth, Germany, (3)University of Bayreuth, Animal Ecology I, Germany*

The abundance of micro- and nanoplastic (MNP) particles is reported in all parts of the earth, in all bodies of water, all soils, and in organisms. Several studies indicate effects of MNPs on organism and ecosystem level, but the modes of actions are not well understood. As most plastics are chemically inert, the particle effect itself is discussed not to be the sole reason for affecting organisms. One mechanism discussed frequently is the ability of microplastic particles to adsorb chemicals from the surrounding medium. In the present study, we looked at the capacity of MNPs to distort chemical communication (infodisruption) in *Daphnia magna* by removing some semiochemicals from the contaminated medium. If infochemicals are absorbed by the plastic particles and are thus removed from the system, a following subtle change in infochemical concentration will alter or distort the message. For example, changes in neurotransmitter levels will impact cognitive and perceptive capabilities, changes in the availability of pheromones and predator cues will change an individual's reproductive success and survival probability, and a small change in hormonal titres can result in an up- or downregulation of the biosynthesis of specific proteins.

We have tested in a series of experiments whether a conserved and widespread hormone (methyl farnesoate) attaches to various plastic particles. Methyl farnesoate is a hormone that induces the production of males when conditions in the environment become

unfavourable in *D. magna*. We then conducted bioassays with *D. magna* to test whether the reduction in hormone concentration due to adsorption to microplastic particles is large enough to impact the daphnids' development.
Our results provide insight into how infodisruption by MNPs can alter the life history of animals and severely impact ecosystems in the process.

1.04.T-05 Assessment of the Impact of Single and Mixtures Stressors on *Daphnia magna*: Using Enzyme Markers and Metabolomics as Endpoints of Physiology
Anna Michalaki[1], *Allan McGivern*[2], *Gernot Poschet*[3], *Michael Büttner*[3], *Rolf Altenburger*[4] *and Konstantinos Grintzalis*[2], *(1)School of Biotechnology, Dublin City University, Dublin, Ireland, (2)Dublin City University, Dublin, Ireland, (3)Heidelberg University, Centre for Organismal Studies (COS), Germany, (4)Department of Bioanalytical Ecotoxicology, Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany*
The continuous global increase in population and consumption of resources due to human activities has a significant impact on the environment. Therefore, assessment of environmental exposure to toxic chemicals as well as their impact on biological systems is of significant importance. Freshwater systems are currently under threat and monitored. However, current methods for pollution assessment can neither provide mechanistic insight nor predict adverse effects from complex pollution. Using daphniids as a bioindicator, we assessed the impact in acute exposures of eight individual chemicals and specifically two metals, four pharmaceuticals, a pesticide and a stimulant, and their composite mixture combining phenotypic, biochemical, and metabolic markers of physiology. Results from individual chemicals showed distinct biochemical responses for key enzyme activities such as phosphatases, lipase, peptidase, β-galactosidase, and glutathione-S-transferase. Following, a more realistic mixture scenario was assessed with the aforementioned enzyme markers, feeding rate, and a metabolomic analysis. A clear dose-dependent effect for the composite mixture was validated with enzyme markers of physiology, and the metabolomic analysis verified the effects observed, thus providing sensitive metrics in metabolite perturbations. Additionally, exposure to the composite mixture resulted in a "shut down" of feeding. Our study highlights that sensitive enzyme markers can be used in advance on the design of metabolic and holistic assays to guide the selection of chemicals and the trajectory of the study, while providing mechanistic insight. In the future this could prove to become a useful tool for understanding and predicting freshwater pollution.

1.04.P Daphnia — The Good, the Bad, and the New?

1.04.P-Mo025 Ecotoxicological Effects of Copper at Two Different Temperatures on — The Impacts of Climate Changes
Micael Mendes Neves[1], *Fernando J. M. Gonçalves*[2] *and **Ana Marta Goncalves***[3], *(1)University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Aveiro, Portugal, (2)University of Aveiro, Aveiro, Portugal, (3)University of Coimbra, MARE - Marine and Environmental Sciences Centre / Department of Biology and CESAM, University of Aveiro, Portugal*
In the last decades, climatic changes have been a great concern among the scientific and political communities. Nowadays, climatic changes effects have been reported associated to extreme climatic events like the rise in temperature, floods, and droughts with impacts on several activities (e.g., agriculture) and in the ecosystems. The exponential increase in world population and growth in food consumption are placing unprecedented demands on agriculture and natural resources. Hence, more research is needed, not only for a more diverse array of pesticides, but also for commercial formulations, applied in the field.

Copper belongs to the group of transitional essential metals, of vital importance for every organism at low concentrations, becoming toxic at high amounts, being considered the third most toxic metal after cadmium and mercury.

This work aimed to determine the impact of copper in a primary consumer (*Daphnia magna*) at two distinct temperatures (20ºC and 25ºC) and how temperature impacts those effects. Immobilization and reproduction bioassays following the guidelines for the testing of chemicals with some adaptations (reproduction) were performed. Our results show that an increase in metabolic rate induces early maturity with the 1st brood emerging at 6th day and the appearance of the 7th and 8th broods at 25ºC. Furthermore, with increased exposure treatment tested induce a desynchronization in the release of the broods with the highest concentration showing a statistically significant impact on the number of broods at the highest temperature. At 25ºC mortality rate was concentration dependent reaching 100% in the highest treatment. Two-way ANOVA and ANCOVA with the use of the Tukey test indicate statistically significant differences caused by the interaction of temperature and concentration and temperature ($P<0.05$) in most parameters analysed. This study highlights the importance of temperature on contamination scenarios and in the population of freshwater systems.

1.04.P-Mo026 Are Microplastics at Environmentally Relevant Concentration Toxic: Evidence from *Daphnia magna* under Global Warming
Chao Zhang, *Shandong University, Qingdao, China*
Currently, one prominent problem in ecotoxicological studies on microplastics is that most exposure concentrations are far greater than the actual concentrations of microplastics in the environment, and microplastics are sometimes considered not harmful at environmentally relevant concentrations. Yet, such studies were conducted under standard thermal conditions and thereby ignored the impacts of higher mean temperatures (MT), and especially daily temperature fluctuations (DTF) under global warming. On the other hand, we know next to nothing about how microplastics affect the adaptation of organisms to global warming. In this study, *Daphnia* magna was exposed to an environmentally relevant concentration of polystyrene microplastics (5 μg L^{-1}) under six thermal conditions (MT: 20 ℃, 24 ℃; DTF: 0 ℃, 5 ℃, 10 ℃) over two generations to investigate the interactive effects of

nanoplastics and global warming. Results showed that nanoplastics had no effects on *Daphnia* at standard thermal conditions (constant 20 °C). Yet, nanoplastics increased the fecundity, heat tolerance, amount of energy storage, net energy budget, and cytochrome P450 activity, and decreased the energy consumption when tested under an increased MT or DTF, indicating a hormesis effect by nanoplastics under global warming. Notably, the increased heat tolerance indicated nanoplastics could induce adaptation of *Daphnia* to warming, which was due to the reduced energy consumption and/or increased energy availability. Overall, the present study provided novel insights for the toxicity studies of nanoplastics and highlighted the importance of including DTF and thermal adaptation in the realistic ecological risk assessment of nanoplastics under global warming.

1.04.P-Mo027 Unexpected Interactive Effects of Nitrate and Heatwave Exposure on the Survival, Growth, and Reproduction of *Daphnia magna*
Sabiha Akter[1]*, Katharina Wilfert*[2]*, Jonas Schoelynck*[1] *and Gudrun De Boeck*[1]*, (1)Biology, ECOSPHERE, University of Antwerpen, Antwerpen, Belgium, (2)Biomedical Sciences, University of Antwerp, Belgium*
Due to eutrophication, freshwater ecosystems are increasingly exposed to anthropogenic stressors such as nitrate. Additionally, climate change causes more intensive and frequent heatwaves, which have a tremendous impact on all trophic levels of the ecosystem. Any change in the lower phytoplankton trophic level may also impact the higher trophic levels such as to the *Daphnia magna*. Individual effects of heatwaves, high nitrate concentrations, and changing food quality have been studied on *Daphnia magna*, but less is known about their intractive effects. In this study a 3x3x2 factorial design was used where 48-hour-old *D. magna* were exposed to combinations of ecologically relevant nitrate concentrations (0, 50, or 200 mg/L) and different heatwave scenarios (no, short, or long). They were either fed with a control diet or an experimental diet of microalgae that were exposed to the same conditions as the *Daphnia*. Throughout the 45-day-long experiment, the interactive effects of nitrate, temperature, and feed on mortality, maturation, number of offspring, and body size were evaluated. Although it was suspected that exposing *D. magna* to a long heatwave scenario in combination with a high nitrate concentration would result in an overall low performance, this was not the case. Results show that *Daphnia* cultured in the absence of nitrate had a longer maturation time, higher mortality, smaller body size, and a lower number of offspring, regardless of the temperature or the type of feed. The restricted continuous proliferation of microalgae at the nitrate-limited condition (0 mg/L) reduced the food availability causing this higher impact on *D. magna* life history traits. Heatwaves shortened the lifespan of the *Daphnia*. Daphnids cultured in high (200 mg/L) nitrate with control feed performed better than with experimental feed, which indicates that at the high nitrate condition, the experimental phytoplankton was either unable to meet the energy requirements or it introduced extra stress to the *Daphnia*. Interestingly, quantity and quality of the feed had a higher impact on daphnids than nitrate concentration or temperature. Nevertheless, nitrate and temperature cannot be dismissed as stressors for *D. magna* as they clearly impact the algae that *D. magna* feeds on.

1.04.P-Mo028 Resurrected *Daphnia* as Indicators of Microevolutionary Adaptive Mechanisms to Multiple Stressors
Florian Gigl[1]*, Sarah E Crawford*[2]*, Luisa Orsini*[3] *and Henner Hollert*[4]*, (1)Department Evolutionary Ecology and Environmental Toxicology, Goethe University Frankfurt, Frankfurt am Main, Germany, (2)Goethe University Frankfurt, Frankfurt am Main, Germany, (3)University of Birmingham, United Kingdom, (4)Evolutionary Ecology & Environmental Toxicology, Goethe University Frankfurt, Frankfurt am Main, Germany*
The resilience of an organism is characterized by good adaptation and the resulting robustness to constantly changing environmental conditions. Due to increasing anthropogenic influences such as intensification of agriculture, population growth, advancing global industrialization, and the climate change associated with it with increasing evidence, conditions in different ecosystems are changing rapidly, making quick and targeted adaptation difficult for many organisms. However, ecotoxicology is generally concerned with the acute and chronic effects of contaminants on aquatic organisms and the environment over a short period of time, which would not consider genetic adaptations in exposed populations. Thus, long-term studies are critical to understanding ecological and evolutionary processes in nature and in assessing how species respond to and persist during environmental change. The emerging field of the evolutionary toxicology examines effects of pollutants on organisms both at the organismic and the molecular level. When combined with resurrection ecology approaches, evolutionary toxicology provides a novel opportunity to examine evolutionary adaption at the genetic level to the deteriorating environment conditions over a long period of years to centuries without the traditional limitations of long-term or multigenerational studies. Resurrection ecology utilizes dormant eggs, for example, of the keystone species *Daphnia*, retrieved from dated lake sediment cores that are hatched from over years to centuries ago.

The aim of this research is to examine the effects of climate change and chemical exposure on the model keystone organism *Daphnia magna* using resurrection ecology approaches. The chemical test substance is the polycyclic aromatic hydrocarbon (PAH) phenanthrene. Phenanthrene is a common PAH, often found in the environment due to incomplete combustion of fossil fuels and offers key insights into historical exposures through chemical profiles archived in lake sediment profiles. Chronic (21-d reproduction test, OECD 211) and acute (Immobilisation test, OECD 202) effects on resurrected ancient and modern *D. magna* clones from four different lake phases of Ring Sø (Brædstrup, Denmark) will be investigated using standardized bioassays to assess apical endpoints. Furthermore, RNA sequencing, a high-throughput next generation sequencing method, will be used to analyse stress-related gene expression patterns, encoded within the RNA of *Daphnia*.

1.04.P-Mo029 Cadmium Chloride Toxicity across 20 *Daphnia magna* Clones
Marianne Barnard[1]*, Luisa Orsini*[2] *and John Colbourne Prof*[3]*, (1)School of Biosciences, University of Birmingham, United Kingdom, (2)University of Birmingham, United Kingdom, (3)Michabo Health Science Ltd, United Kingdom*
Daphnia magna is recommended by the OECD as a test species for acute ecotoxicity testing. Although EC50 responses to

toxicants can vary across different clonal lines, test guidelines do not specify a *D. magna* strain/genotype. We used *D. magna* lines resurrected from the sedimentary archive of a lake with documented changes in chemical pollution over time and exposed 20 of these lines to cadmium chloride. The observed EC50 varied significantly among lines up to two orders of magnitude. The genetic variation among clonal lines, as well as historical environmental stress, may contribute to significant variation in reported EC50 values for chemicals. This study shows that extrapolating EC50 levels from a single strain may lead to under- or overestimation of toxicity. It potentially points to the limited power of EC50 estimates for environmental risk assessment.

1.04.P-Mo030 Effect of Historic Pesticide Exposure Upon Response to DDT in *Daphnia*
Niamh Eastwood, *William A. Stubbings, Mohamed Abou-Elwafa Abdallah and Luisa Orsini, University of Birmingham, United Kingdom*
Daphnia are a keystone species in freshwater communities, and their response to environmental stress can be used to infer wider community response in small-scale laboratory settings. Changes in their reproduction and transcription are often used to understand the effect of environmental toxicants such as pesticides. The insecticide DDT was widely used until the second half of the 20th century when it was banned in many areas of the world, in part due to its nature as a persistent organic pollutant and its possible adverse effects on human health. However, it is still used today in parts of Africa and East Asia for effective control of disease-bearing insects.

In this study, we utilise *Daphnia* resurrected from a sedimentary archive with known historical presence of DDT to assess how historical exposure to chemical stress may affect naive and experienced Daphnia genotypes to DDT exposure. Using liquid chromatography-mass spectrometry (LC-MS), we measured DDT in the sediment of the lake from which the *Daphnia* originated.

We study fitness-linked life history traits and biomolecular responses of *Daphnia* to environmentally relevant concentrations of DDT, and identify evolutionary mechanisms underpinning response to recurrent and novel stress.

The potential impact of novel chemical stress on the keystone grazer *Daphnia* has important implications for aquatic food webs, given its central role in lentic freshwater environments worldwide.

1.04.P-Mo031 Chronic Exposure of *Daphnia magna* to Insecticides: Unconventional Effect on Reproduction and Sensitivity of Behaviour as Biomarker
Floriane Tisserand[1], *Christophe Reis*[2], *Federica Gilardi*[3], *Aurélien Thomas*[3] *and Nathalie Chèvre*[2], *(1)IDYST, Ecotoxicology, Faculty of Geoscience and Environment, University of Lausanne, Lausanne, Switzerland, (2)Faculty of Geoscience and Environment, University of Lausanne, Lausanne, Switzerland, (3)Unit of Toxicology, CURML, University of Lausanne, Switzerland*
Aquatic organisms are chronically exposed to a multitude of pollutants over several generations. Chronic exposures at low concentrations can induce physiological changes and thus have direct adverse effects on populations. Nowadays, classical endpoints measured during chronic exposure focus on reproductive endpoints. However, other parameters may be impacted by long-term exposure and could be interesting to study regarding the ecological relevance of the test results. The behaviour is one of those parameters. Indeed, change in the behaviour can affect the population survival. For example, the organisms may no more be able to escape predation or to feed. In my study, I aimed in highlighting the physiological changes in *Daphnia magna* (reproduction, mortality, and size) through a parental exposure of 21 days to concentrations of 0.1 to 300ng/L to the insecticide diazinon. I also evaluated the effect of the pollutant on the swimming behaviour of organisms. Indeed, diazinon, as an acetylcholinesterase inhibitor, is expected to affect the behaviour of the daphnids. The first results show a significant decrease of the cumulative reproduction over 21 days from the lowest concentration at 0.1ng/L with an increase of this phenomenon up to 33ng/L before decreasing to the normal level from 100 to 300ng/L. On the other hand, the size of the organisms after 21 days does not show any significant difference. The effects on swimming behaviour are currently being processed.

1.04.P-Mo032 Differential Susceptibility to Arsenic in Glutathione S-Transferase Omega 2 (GST-O2)-Targeted Freshwater Water Flea *Daphnia Magna* Mutants
Eunjin Byeon, Haksoo Jeong and ***Jae-Seong Lee****, Department of Biological Sciences, Sungkyunkwan University, Korea, Republic of (South)*
To examine the role of glutathione *S*-transferase omega class (*GST-O2*) genes in the biotransformation and detoxification in *Daphnia magna*, various responses such as *in vivo* endpoints, arsenic speciation, enzymatic activities, and gene expression pathways related to arsenic metabolism were investigated in wild-type (WT) and *GST-O2*–targeted mutant (MT) fleas produced by CRISPR/Cas9. Sensitivity to arsenic in MT fleas was higher than in WT fleas. Also, the reduction rate of arsenate (As^{V}) to arsenite (As^{III}) in the MT group was significantly lower and led to accumulation of higher arsenic concentrations, resulting in decreased protection against arsenic toxicity. Relative mRNA expression of other *GST* genes in the *GST-O2*–targeted MT group generally increased but the enzymatic activity of GST decreased compared with the WT group. Oxidative stress on arsenic exposure was more strongly induced in the MT group compared with the WT group, resulting in a decrease in the ability to defend against toxicity in *GST-O2*–targeted mutant *D. magna*. Our results suggest that *GST-O2* plays an important role in arsenic biotransformation and detoxification functions in *D. magna*.

1.04.P-Mo033 Toxicity of Atmospheric Particulate Matter from a Brazilian Industrial Area on *Daphnia magna*
María del Pilar Gonzalez Muñoz[1], *Andrea Cordero*[1], *David Salvatierra*[1], *Marisa Narciso Fernandes*[2], *Cristiano Araújo*[1] *and*

Camilo Seabra Pereira[3], (1)Institute of Marine Sciences of Andalusia (CSIC), Spain, (2)Univeridade Federal de Sao Carlos, Brazil, (3)Department of Marine Sciences, Federal University of São Paulo, São Paulo, Brazil
Mining, iron, and steel industries are a continuous source of air pollution due to the amount of atmospheric particulate matter (PM) they release. This PM is a complex mixture formed by metallic nanoparticles and metals, which can reach aquatic ecosystems and may have significant ecological consequences. The aim of this study is to evaluate the toxicity of the PM, collected in a Brazilian region (State of Espírito Santo, Southeast Brazil) influenced by the steel and iron mining industry, and to know the possible impact it may have on aquatic organisms. For this purpose, the crustacean *Daphnia magna* was exposed to different environmentally relevant concentrations (0.01, 0.1, 1, 5, 10 g/L). The endpoints studied were: avoidance throughout 24 h in a nonforced exposure system, reproduction (number of neonates per female after 21 days of exposure), acetylcholinesterase activity (AChE) after 48 h, and finally, feeding rates in a short-time exposure (48 h) and in a long-time exposure (21 day + 48 h). As results, there was a negative effect of this material on the organisms, with the exception of reproduction, which was increased as from 1 g/L and the first brood occurred earlier as from 5 g/L. The avoidance was concentration-dependent and represented 88% and 100% at the two highest concentrations. The AChE activity was significantly inhibited in 5 and 10 g/L. The postexposure feeding rates were lower in long-term exposure at the highest concentration. According to our results, the concentrations with statistically significant differences were 5 and 10 g/L. In addition, in order to explain this material's toxicity, a chemical analysis was performed to characterize the metals present in this compound, but no direct relationship was observed. This study highlights the need to understand the toxic effects generated by metal mixture present in MP coming from anthropogenic activities on aquatic organisms, to perform adequate safety regulations, because of their toxicity, persistence in the environment, and potential bioaccumulation in living organisms.

1.04.P-Mo034 Establishing the Effects of Aquatic Pharma-Pollution on Female *Daphnia magna* Strauss 1820 Biological Organization

***Stefania Scurtu**[1], Kristyna Mrstna[2], Thomas McCloughlin[2], Dylan O'Flynn[2], Linda Holland[2], Denise Harold[2], Blanaid White[2], Jenny Lawler[2], Anne Parle-McDermott[2] and Fiona Regan[3], (1)School of Chemical Sciences, Dublin City University, Dublin, Ireland, (2)Dublin City University, Dublin, Ireland, (3)Water Institute, Dublin City University, Dublin, Ireland*
Contaminants may cause adverse effects at all levels of biological organization, manifested from molecule to ecosystem levels. Illuminating the cause-and-effect linkage between stressors and responses across the levels of biological organisation affords advances in environmental risk assessment. We investigate the effect of emerging contaminants detected in surface waters on the aquatic ecosystem.

To improve our understanding of anthropogenic pharmaceutical pollution within aquatic environments, we investigated aquatic pharma-pollutants within the well-characterized *Daphnia magna* model. Bioaccumulation of contaminants within the tissues of adult female *Daphnia magna* Strauss 1820 acutely exposed to environmentally relevant venlafaxine concentrations as a single compound as well as a mixture containing 11 emerging contaminants categorised as Watchlist compounds by The Water Framework Directive (metformin, gemfibrozil, sulfamethoxazole, trimethoprim, venlafaxine, carbamazepine, diclofenac, erythromycin, clarithromycin, azithromycin, and gabapentin) were quantified using liquid chromatography-mass spectrometry (LC-MS) analysis. Initial monitoring results for Watchlist chemicals identified that venlafaxine is the most predominantly observed analyte in surface waters. Therefore, this analyte has been chosen in this study of biological effects.

The chronic effects of the pharmaceutical were then established by observing transgenerational effects on organism survival, reproduction, morphology, organ function, and epigenetic alterations. Preliminary results have shown the bioaccumulation of contaminants within *Daphnia Magna* Strauss 1820 tissues. Analysis of reproduction studies on individuals chronically exposed to environmentally relevant concentrations of venlafaxine shows a decrease in offspring numbers with an increase in heart rate. The study aims to further correlate transcriptomic alterations investigated by RNAseq analysis to population effects including body length and width of first-generation females (F0) and first filial (F1) individuals.

1.04.P-Mo035 Acute Toxicity, Oxidative Stress, and Apoptosis due to Short-Term Triclosan Exposure and the Multi- and Transgenerational Effects in the Freshwater Water Flea *Daphnia magna*

*Jin-Sol Lee[1], Yunmoon Oh[1], **Jae-Seong Lee**[2] and Hyung Sik Kim[1], (1)School of Pharmacy, Sungkyunkwan University, Korea, Republic of (South), (2)Department of Biological Sciences, Sungkyunkwan University, Korea, Republic of (South)*
In this study, the median lethal concentrations of triclosan (TCS) were determined as 184.689 and 349.511 μg/L in neonate and adult stages of the freshwater water flea *Daphnia magna*, respectively, based on the acute toxicity assessment. Furthermore, 50 and 100 μg/L TCS have induced oxidative stress and the changes of reactive oxygen species (ROS) content and antioxidant enzymatic activities in *D. magna* have been analyzed. However, several apoptosis-mediated proteins showed TCS-induced oxidative stress damage in response to 25 μg/L TCS, indicating that apoptotic proteins were the most sensitive mediators. Also, the multi- and transgenerational effects of TCS were evaluated in *D. magna* over three generations on various *in vivo* endpoints, DNA damage responses, and biochemical reactions. The transgenerational group exposed to TCS showed more negative impacts on antioxidant responses, DNA fragmentation status, and biological endpoints than the multigenerational exposure group, leading to decreased reproduction and higher ROS content. The transcriptional expression levels of glutathione *S*-transferase genes in the transgenerational exposure group were upregulated compared to those in the multigenerational group, but they were fully recovered in the F2 offspring group. Our findings provide an in-depth understanding of the adaptive effects of multigenerational TCS exposure groups.

1.04.P-Mo036 Toxicity and Phototoxicity of UV Filter and Microplastics Mixtures on *Daphnia magna*

***Haemi Kim**, Dokyung Kim and Youn-Joo An, Konkuk University, Korea, Republic of (South)*

In aquatic environment, microplastics can adsorb other pollutants. One of these pollutants is ultraviolet (UV) filters. Although some countries prohibited the use of UV filters, they are still contained in personal care products and commonly used. Therefore, this study aimed to evaluate the combined toxic and phototoxic effects of polystyrene (PS) microplastics and UV filter avobenzone on aquatic organism, *Daphnia magna*. In an acute toxicity test, *D. magna* were exposed to single and combined test solutions according to UV irradiation for 48 h. The test concentration of microplastic was 20 mg/L and avobenzone concentrations were 7.5 mg/L and 10 mg/L. To assess the phototoxicity, test solutions were UV irradiated for 6 h before *D. magna* was exposed. Significant immobilisation rates were observed in the single and combined groups, and the immobilisation rate increased in the UV irradiated groups. In the combined group, despite higher food uptake, they did not growth well. In addition, *D. magna* reserved more energy in the UV irradiated groups compared to the non-UV irradiated groups. Although *D. magna* obtains energy through food uptake, they reserve energy for survival rather than growth. The results of this study indicated that the combination of microplastics and ingredients of personal care products under UV irradiation can have adverse effects on the aquatic organism *D. magna*.

1.04.P-Mo037 Molecular Consequences of Traditional and Biodegradable Microplastic Exposure in a Keystone Freshwater Crustacean

*Clifton Lewis[1], Roberto Feuda[1], Iseult Lynch[2], Eamonn Mallon[1], Luisa Orsini[2], Hollie Marshall[1] and **Katie Reilly**[2], (1)University of Leicester, United Kingdom, (2)University of Birmingham, United Kingdom*

Daphnia are a well-established test organism for aquatic toxicants, and to date have been widely used to determine the environmental risks of chemicals and more recently nanomaterials and microplastics (MP). With the growing interest and concern about the potential impacts that MP can have on individuals and ecosystems, the environmental sampling and toxicity studies have increased in variety and complexity, covering a range of test organisms and MP combinations (i.e., polymers, morphologies, sizes, ages/weathering, or degradation stage, etc.). Studies exploring the toxicity effect of MP in *Daphnia* have expanded from high dose and short-term (acute) exposures into increasingly realistic exposures, over longer time frames with varying doses and environmental conditions. Through these increasingly realistic exposures, we can use *Daphnia* as a model to better understand how MP may be affecting the aquatic ecosystem, and to determine what are the driving factors of these toxicity responses.

Daphnia magna were used as a model and exposed to a panel of different microplastic fragments. Polymers included polyethylene, polystyrene, cellulose acetate, and polylactic acid to determine the effect of traditional polymers compared to newer biodegradable (under specific defined conditions) polymers. Fragments were created in the lab from spherical beads, before sequential sieving into the correct size fraction for exposures. Following this, the fragments were characterised to determine their distribution in the test medium and an initial dose response was quantified for each polymer, before a chronic exposure at the EC20 concentration from the acute studies was undertaken. During the chronic exposure, life history data were captured including total neonates, time to first brood, and total growth over time. Following this, *Daphnia* were frozen for RNA extraction, and samples were taken to determine the epigenetic changes in the *Daphnia* relative to the unexposed control group. This enabled molecular level toxicity analysis to establish if there were any sublethal changes in the daphnids gene expression as a response to the different polymer exposures. By exposing genetically identical *Daphnia magna* (Bham 2 clonal lines) we can quantify the response to traditional and biodegradable polymers, to determine if the presence of biodegradable polymers poses less of a threat in the environment compared to traditional polymers that have been the focus of most toxicity studies to date.

1.04.P-Mo038 Environmental Exposure Effects: Making a Predictive Model for Acute Toxicity to Nanomaterials due to Difference in the Environmental Conditions

***Katie Reilly**[1], Marta Swirog[2], Ewelina Wyrzykowska[3], Thomasz Puzyn[2], Thomas Exner[4] and Iseult Lynch[1], (1)University of Birmingham, United Kingdom, (2)QSAR Lab Ldt., Poland, (3)University of Gdansk, Poland, (4)Seven Past Nine*

The importance of the environmental parameters in toxicity testing of nanomaterials (NMs) is being increasingly recognised due to the reactive surface area and NMs' responsiveness to their surroundings, for example, the importance of the dissociation constant values, which relate to the surface charge of the NMs, and how they are influenced by the environmental conditions such as pH during NMs' exposures or environments, or how NMs interact with natural organic matter (NOM). In addition, NOM has been shown to bind to NMs and can act as a natural stabiliser, by binding to the surface of the particles and preventing agglomeration.

Daphnia magna have been widely used in aquatic toxicity testing of NMs to date, and a wealth of data on the impacts of exposure conditions and toxicants is currently available which can allow ranking of toxicant hazard. However, less considered to date is the impact of environmental parameters of the exposure, for example, the role of pH, specific salts such as sulfides, or the presence of NOM, we can make predictions about how NM toxicity may differ or evolve over different exposure periods. In this study, *Daphnia* were exposed to a panel of metal and metal oxide NMs under a range of different exposure conditions including pH, NOM content, and temperature to see how acute toxicity to *Daphnia* changes. These data then feed into a predictive quantitative structure-activity (QSAR) model to determine which parameters are the main drivers for toxicity.

In addition, this study is also used as a case study for how instance maps used to visualise the key steps in an experiment and especially those steps where a transformation of the NMs' physicochemical properties might occur such as upon dispersion, upon passage through daphnid guts, etc., whilst also linking together the different protocols and data capture templates. This can be used to highlight the role of the environmental parameters in these NM transformations and/or on organism health, and how the NMs or organisms influence or change the environmental conditions. Through this, we can ensure that the metadata needed to support the environmental variability and understanding within the predictive toxicity model is also captured, to develop this to its full potential.

1.04.P-Mo039 Investigating the Effect of Pesticides on *Daphnia* Clonal Populations using a Stochastic Model
***Gian Marco Palamara**[1], Nele Schuwirth[2], Stuart Dennis[1] and Peter Reichert[1], (1)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Dübendorf, Switzerland, (2)Systems Analysis and Modelling, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Dübendorf, Switzerland*
Daphnia is widely used in long-term population experiments to identify sublethal pesticide effects and assess chronic toxicity. However, population experiments are often laborious and subject to stochasticity (demographic, environmental, and genetic). Therefore, large variation among a limited number of replicates can lead to misleading results based on classical statistical analyses. Model-based analysis can support the interpretation of such experimental data to identify sublethal pesticide effects. The goal of such an analysis is to identify the most important processes that determine population dynamics and lead to stochasticity, and describe them in the model. The main challenge for this task is choosing an adequate level of model complexity. Models should be as simple as possible and as complex as necessary for an adequate description of the system.

In this study, we used a stochastic, age structured population model applied to data from long-term population experiments. Experiments consisted of three different clonal populations of *Daphnia galeata* in 1L aquaria with and without chronic pesticide treatments (Diazinon and Diuron) at sublethal concentrations. The clones were selected from three lakes in Europe, characterised by different levels of pollution. We tested different formulations of fertility and mortality and compared the inferred parameter estimates from the different treatments. We used a systematic model selection process based on a nested design of the model structure and Bayesian inference to identify mechanisms from population experiments.

Posterior analysis helped to choose an adequate model description for life-history characteristics under the specific experimental conditions: a zero-inflated negative binomial distribution for fertility and mortality without density dependence. For the Diazinon treatments, a comparison of the inferred posterior parameter distributions indicated the need for a mortality rate that increases with time, indicating cumulative chronic toxic effects of Diazinon for all the *Daphnia* populations. Furthermore, different *Daphnia* clones produced eggs in the different treatments, based on their previous adaptation to levels of toxicity. With this study, we demonstrate how we can use stochastic models to infer mechanisms from population data to help identify sublethal pesticide effects. The model-based analysis can also help to support the optimization of the experimental design of future studies.

1.04.P-Mo040 Automated Evaluation of *Daphnia* Neonate Number and Size in Ecotoxicological Assays
***Sizenando Nogueira Abreu**[1], Fatima Jesus[2], Joana Pereira[2], Amadeu M.V.M. Soares[3], Rui Martins[2] and Miguel Oliveira e Silva[4], (1)CESAM & Department of Biology, University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Aveiro, Portugal, (2)University of Aveiro, Aveiro, Portugal, (3)University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Aveiro, Portugal, (4)TekenBio, Portugal*
The evaluation of offspring number is often one of the most frequently evaluated endpoints in conventional long-term ecotoxicological tests (e.g., the *Daphnia magna* reproduction test, OECD test guideline 211, 2012). Neonate size is also a very important endpoint that has been additionally evaluated in a variety of studies such as in multigenerational toxicity tests. The evaluation of these endpoints is very demanding in time- and sampling efforts, and requires larger numbers of test organisms compared to conventional long-term ecotoxicological tests, adding extra effort counting the offspring and evaluating neonate size. An automated counting and neonate size estimation would be mostly useful in assessing very large numbers of offspring such as in the continuation of reproductive success over multiple generations.

This study aims first to evaluate an automated device to count and estimate neonates' size in reproduction tests using *Daphnia magna* as a model organism. Secondly, upon validation, the methodology was applied in a classical reproduction test (NaCl: 0.0 gL^{-1}, 1.0 gL^{-1}, 2.0 gL^{-1}, 4.0gL^{-1}), being brood neonate amount, and neonate size automatically evaluated. Manual and automated approaches have been compared.

Results indicate high correlation (r^2>0.9) comparing manual and automated counting and neonates' size estimation. Thus, the use of the automated approach indicates no deviation from the classical reproduction bioassay, but minimizing time and labor intensity.

Although being a highly useful tool in the conventional *Daphnia* reproduction test, the automated computer counting would be mostly useful in assessing the reproductive success over multiple generations, minimizing both costs and labor intensity, mostly when involving endless brood neonate counting and neonate size evaluation that have limited the use of multigenerational toxicity tests and thereby its incorporation as standard procedures.

1.04.P-Mo041 Exposure to Artificial Light at Night Adversely Affects Reproductive Output in *Daphnia magna*
*Diana Campos, Ana Luísa Machado, Amadeu M.V.M. Soares and **João L.T. Pestana**, University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Aveiro, Portugal*
Light pollution imposes novel challenges on species living in urban/suburban areas and has become an emergent issue of

environmental concern given the human health and detrimental ecological effects. Anthropogenic-induced changes to light conditions and artificial light at night (ALAN) can disrupt biological rhythms and alter biological fitness through inhibition or suppression of the hormone melatonin. This time-keeper hormone plays a pivotal role of relaying information about changes in day-length and modulates circadian behavioural responses and many physiological and reproductive processes. However, effects of light pollution and of ALAN are seldom studied in aquatic invertebrates.

Here we present preliminary data on the effects of ALAN based on a standard 21-d life table experiment with the cladoceran *Daphnia magna*, for which the circadian pattern of melatonin production is well known. Artificial light at night was simulated using white LEDs with a high content of blue light in the emission spectra and are being considered a more economical solution for urban lighting. Daphnid neonates (<12 h old) were used and in the ALAN treatments had daylight as in the control photoperiod (dark nights) but during the night period were exposed to low light intensity (1 and 10 lux) which is considered relevant for aquatic ecosystems under light pollution. These ALAN treatments were crossed with an exogenous melatonin treatment (1 µM) here used as a positive control (to counter the expected ALAN-induced reduction of internal melatonin concentrations) to further investigate the physiological role of melatonin and a mediator of light pollution effects in *Daphnia*.

Results show that exposure to ALAN adversely affected *D. magna* reproductive output with significant reductions in the number of broods, total number of offspring per female, and also the intrinsic rate of population increase (r) observed for organisms exposed to 10 lux during night periods. Significant effects of the interaction (ALAN x Melatonin) do suggest that melatonin can indeed be involved in the observed response to ALAN and call for research into its role in *D. magna* response to stress. Ongoing work is exploring effects of ALAN on other endpoints such as oxygen consumption and feeding rates to better understand how shifting light conditions can influence fitness and tolerance of *Daphnia* populations in urban aquatic ecosystems.

1.04.P-Mo042 Alterations of Swimming Behaviour of *Daphnia magna* upon Acute and Chronic Exposure as a Sensitive Endpoint

*Vanessa Saalmann[1,2], Kirsten Germing[1] and **Lena Kosak**[3], (1)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany, (2)University Düsseldorf, Düsseldorf, Germany, (3)Ecotoxicology, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany*

The crustacean *Daphnia magna* is a useful model organism widely used in ecotoxicological testing with a substantial amount of toxicological data available for this organism. *D. magna* has a strong phototactic behaviour characterised by swimming toward (positive phototaxis) or away (negative phototaxis) from light and is therefore highly suitable to study behavioural responses. *Daphnia* swimming is in general dependent on body size and can also be affected by factors such as light, water temperature, presence of food, and predators. Changes in the swimming behaviour of daphnids can be early indicators of stress and later on also for immobilization.

So far, according to the OECD Guidelines 202 and 211, immobility and reproduction are the main endpoints used for the determination of toxicity. Sublethal effects can be induced by chemicals at lower levels and may require more sensitive biomarkers. As a first step alterations of swimming behaviour, phototactic behaviour, and response to kairomones should be evaluated upon exposure to pharmaceuticals in environmentally relevant concentrations.

D. magna is exposed to a series of substances for 48 h and 21 d in order to evaluate the classical acute and chronic effects on immobilisation and reproduction, according to the OECD Guideline tests (202 and 211). Furthermore, the behavioural endpoints of *D. magna* will be investigated during acute and chronic exposure at different time points. In addition, in the reproduction tests with chronic exposure for 21 d beside the parental daphnia (F0 generation) also the juvenile daphnia (F1 generation) are investigated, to evaluate generational effects and differences in sensitivity.

The results of the different tests will be evaluated with respect to the sensitivity of the different endpoints and time points considered (classical ECx values vs. behaviour). In addition, the effects of each test substance will be compared with respect to the sensitivity of the different behavioural endpoints. The different behavioural endpoints will be evaluated according to their applicability, to use the behavioural endpoints as a more sensitive endpoint allowing a predictability of substance effects.

1.04.V Daphnia — The Good, the Bad, and the New?

1.04.V-01 Evaluation of Possible Vardio- and Neurotoxic Effects by Methyl, Ethyl, Butyl, or Propyl Parabens in *Daphnia magna*

*Kojo Eghan, Sangwoo Lee and **Woo Keun Kim**, Korea Institute of Toxicology (KIT), Korea, Republic of (South)*

Parabens have endocrine-disrupting effects, which means they can alter the hormonal control of energy metabolism, causing obesity and metabolic health problems, as well as cardiovascular and neurological problems. However, there is presently inadequate proof of parabens′ adverse health effects on aquatic species. Our goal is to evaluate if the four parabens (methyl, ethyl, butyl, and propyl parabens) have any adverse effects on *Daphnia magna′s* cardiovascular and neurological systems. Physiological tests (heart rates and thoracic limb activity) and gene transcription analyses were performed 48 h after acute exposure to *Daphnia magna* at various concentrations. The heart rates and thoracic limb activity of the exposed daphnids were inhibited in a time and dose-dependent manner. The butylparaben group had the highest heart rate inhibitions. Butylparaben once again demonstrated the strongest significant suppression of thoracic limb activity in the highest concentration group. Ethylparaben and propylparaben had no effect on gene transcription in the cardiomyopathy group. At least one gene in the GABAergic synapse and acetylcholine receptor groups was substantially affected by all parabens. The upheaval in *Daphnia magna's* heart rate and limb activity produced by the four examined parabens is extremely considerable, according to our findings. Unexpectedly, the cardiomyopathy group had fewer genes that were significantly impacted. Exposure to parabens does not appear to have had a significant impact on the nervous system. Nonetheless, with its high sensitivity to environmental changes *Daphnia magna* is a suitable species for evaluating cardiotoxicity and neurotoxicity of chemicals. More research is needed, and is now underway, to fully comprehend the complex mechanism by which the neurobehavioural system of *Daphnia magna* is impacted.

1.04.V-02 Transgenerational Response to Novel Chemicals in *Daphnia*: Implications for Remediating Chemical Mixtures
Muhammad Abdullahi, *School of Biosciences, University of Birmingham, United Kingdom*
Anthropogenic chemicals used in most production processes have not been comprehensively assessed for their risk and impact on humans and wildlife. Current toxicological approaches employ acute toxicity tests using unrealistic chemical concentrations that organisms rarely encounter in the environment to ascertain their safe use, ignoring the long-term pathological effect of exposure to environmentally relevant concentrations. Legacy and persistent chemicals are transported globally and usually end up in the environment as unintentional pollutants causing long-term adverse effects. They can cause the deterioration of ecosystem services whilst negatively impacting humans and wildlife. Yet the chronic impact of these chemicals is rarely assessed.

Here, we study the transgenerational impact of ecologically relevant concentrations of five chemical groups on the keystone species, *Daphnia magna*: the industrial chemical PFOS, the pharmaceuticals diclofenac and trimethoprim, the biocide atrazine, and the heavy metal arsenic. We exposed *Daphnia* genotypes resurrected from a lake with a known history of chemical pollution to these chemicals to understand how historical exposure to chemicals influences adaptive response to novel chemical stress. We measured within- and transgenerational plasticity on fitness traits after exposure of "experienced" and "naïve" genotypes. As the revived *Daphnia* originates from the same genetic pool sampled from different times in the past, we were able to quantify the long-term evolutionary impact of chemical pollution by studying genome-wide diversity and identifying functional pathways affected by historical chemical stress. Our results suggested that historical exposure to chemical stress reduced genome-wide diversity leading to lower cross-generational tolerance to novel chemical stress. Lower tolerance is underpinned by reduced gene diversity at detoxification, catabolism, and endocrine genes in experienced genotypes. We show that these genes sit within pathways that are conserved and potential chemical targets within humans and other species.

1.04.V-03 Transcriptional Responses of *Daphnia magna* to Sublethal Cu and Zn Exposures
Berkay Paylar[1], *Yared Hailaye Bezabhe*[2], *Jana Jass*[3] *and Per-Erik Olsson*[3], *(1)Varbergagatan 226, Sweden, (2)Orebro University, Örebro, Sweden, (3)School of Science and Technology, Orebro University, Örebro, Sweden*
Metal contamination in aquatic environments is a major concern due to their persistence and has received a great deal of attention in recent years. The waterflea *Daphnia magna* is an important model species for metal toxicity studies and water quality assessment. However, most of the research has focused on physiological endpoints such as mortality, growth, and reproduction in laboratory settings and neglected toxicogenomic responses. In this study, we analysed *D. magna* transcriptomics responses to Cu (120 µg/L) and Zn (300 µg/L) exposures in an environmental water obtained from a pristine lake with the adjust water hardness of 150 mg/L $CaCO_3$. Exposure levels for transcriptomic analysis were determined by calculating EC_5 values for each metal at the end of a 96-h exposure with varying metal concentrations. A total of 2688 and 3080 genes were found to be differentially expressed (DEG) between control and Cu and Zn, respectively. Of these, 1793 gene differentially expressed were common for both Cu and Zn, whereas there were 895 unique DEGs for Cu and 1287 DEGs unique for Zn. Gene ontology enrichment was carried out to identify molecular functions and biological processes affected by the metal exposures. Results revealed some of the well-known biomarkers as well as novel targets for metal toxicity screening at a genomic level. Overall, this work was carried out to gain insight into the copper and zinc regulated stress response mechanisms in *D. magna* at transcriptome level.

1.04.V-04 Computer Classification Methods for Gene Selection in *Daphnia magna* Toxicogenomics
Berkay Paylar[1], *Jana Jass*[2], *Per-Erik Olsson*[2] *and Martin Längkvist*[3], *(1)Varbergagatan 226, Sweden, (2)School of Science and Technology, Orebro University, Sweden, (3Center for Applied Autonomous Sensor Systems, Orebro University, Sweden*
Zinc is an essential element that influences many cellular functions. Depending on bioavailability, zinc can cause both deficiency and toxicity. Zinc bioavailability is influenced by water hardness; therefore, water quality analysis for health-risk assessment should consider both the zinc concentration and the water hardness. However, exposure media selection for traditional toxicology tests are set to defined hardness levels and do not represent the diverse water chemistry compositions observed in nature. Moreover, these tests commonly use whole organism endpoints such as survival and reproduction that require high numbers of test animals and are labour intensive. Gene expression stands out as a promising alternative that provides insight to molecular events that can be used for risk assessment. In this work, we applied machine learning techniques to classify the zinc concentrations and water hardness from *Daphnia magna* gene expression by using quantitative PCR. A method for gene ranking was explored using techniques from game theory, namely Shapley values. A 10-fold cross-validation was used to compare ranking algorithms. The best accuracy for hardness classification was achieved by using Quadratic Discriminant Analysis (QDA) with 0.88±0.10 followed by Random Forest (RF) with 0.86±0.12 accuracy. However, QDA resulted in a significantly lower accuracy for zinc and combination classification. Neural Network (NN) and RF were the best classifiers resulting in consistent and high accuracy for all classifications tested. The machine learning algorithm was able to predict sample source correctly up to 92% accuracy. The results show that standard machine learning classifiers are capable of classifying both zinc concentrations and

the water hardness simultaneously, and that Shapley values are a versatile and useful alternative for gene ranking, providing insight into the importance of individual genes.

1.05.P Epigenetic Changes Modulating the Response of Organisms to Environmental Challenges: From Phenotypic Effects to Microevolution Patterns

1.05.P-Th012 Incorporating Epigenetics in Adverse Outcome Pathways: The EPIBOOST Project

*Inês PE Macário[1], Alicia S Arroyo[2], Alejandro Rodríguez[2], **Joana Pereira**[3], Jana Asselman[4] and Laia Navarro-Martin[5], (1)Cesam, University of Aveiro, Aveiro, Portugal, (2)Spanish Research Council (CSIC), Institute of Environmental Assessment and Water Research (IDAEA), Spain, (3)University of Aveiro, Aveiro, Portugal, (4)Blue Growth Research Lab, Ghent University (UGent), Ghent, Belgium, (5)Department of Environmental Chemistry, Spanish Research Council (CSIC), Institute of Environmental Assessment and Water Research (IDAEA), Spain*

Lately, environmental studies started appraising several 'omics, e.g., epigenomics, as remarkable tools to improve Ecological Risk Assessment (ERA) frameworks. Besides the mechanistic enlightening of toxicity that these 'omics can provide in general, the discovery of molecular initiating events and molecular pathways for adverse outcome pathways (AOPs) is promoted. While epigenetic modifications are likely primary molecular initiating events as per their role in constraining gene expression, there are still important challenges to overcome in order to incorporate epigenomics into regulatory frameworks, especially because consistent links to effects at the level of the phenotype (and then to higher levels of biological organization for improved ecological relevance) are yet to be established, as well as are trends and parallels across species. This is the foundation of the EPIBOOST research, a project addressing environmental epigenetics concerning aquatic organisms and model pollutants. EPIBOOST will focus on AOPs initiated by DNA methylation in model freshwater and marine organisms (microalgae, microcrustaceans, and fish), exposed to three model chemicals representing persistent or emerging threats nowadays or in the near future (metals, antibiotics, and toxins). Briefly, samples will be screened for global methylation and analysed via whole-genome bisulfite sequencing. Gene expression will be assessed via targeted or untargeted approaches to understand whether gene expression correlates to the changes in the epigenome. Phenotypic effects ranging from the subcellular to the population level will be assessed in parallel concerning specific (e.g., photosynthetic efficiency, neurotoxicity) and more general (e.g., growth rates, behaviour) responses to stress. Such a comprehensive approach will allow a meaningful insight on the AOPs for the selected model contaminants in the aquatic compartment, and particularly support the validation of epigenetic modifications as robust molecular initiating events.

1.05.P-Th013 Time- and Dose-Dependent DNA Methylation Changes in Earthworms Exposed to Cadmium: Genome Wide and Gene-Specific Epigenetic Perspective

***Maja Srut**[1], Ovidiu Paun[2], Gerhard P Aigner[3], Verena Pittl[3], Birgit Fiechtner[3], Bernhard Egger[3] and Martina Höckner[3], (1)University of Innsbruck, Austria, (2)Department of Botany and Biodiversity Research, University of Vienna, Austria, (3)Institute of Zoology, University of Innsbruck, Austria*

The heavy metal cadmium (Cd) can cause DNA hypermethylation, which has already been demonstrated in many invertebrates, including earthworms. However, detailed characterisation of DNA methylation landscape upon Cd exposure, as well as mechanisms behind the DNA hypermethylation, are still largely unexplored. Therefore, in this study, we used the earthworm model *Lumbricus terrestris* to explore time- and dose-dependent effects of Cd on global, genome wide, and gene-specific DNA methylation and its underlying mechanisms. Earthworms were exposed to two Cd concentrations (10 and 25 mg/kg) for a period of 12 weeks and sampled at several time points (1, 2, 4, 12 weeks). Global cytosine hypermethylation was revealed using specific antibodies in dot blots, whereas bsRADseq was used to determine genome wide DNA methylation changes and pinpoint specific genomic regions mostly affected by Cd exposure. To study the underlying mechanisms, we determined the gene expression as well as the activity of DNA methylation and demethylation components like DNA methyltransferases (DNMT1 and 3), and ten-eleven translocation (TET) genes. However, neither gene expression nor DNMT and TET enzyme activity showed significant differences in the Cd exposure groups. More specifically, we focused on the gene body methylation (gbm) of metallothionein 2 (MT2), one of the most important Cd detoxification proteins. Using bisulfite conversion and sequencing we were able to detect some changes in MT2 gbm; however, these changes could not be correlated to MT2 gene expression. The results of this study demonstrate the importance of studying epigenetic marks and underlying mechanisms in organisms under pollution pressure and point to missing links, which need to be further explored.

1.05.P-Th014 Multigenerational DNA Methylation Patterns Following Copper Exposure in *Daphnia*: The Role of Exposure History

***Guilherme Jeremias**[1], Telma Veloso[2], Fernando J. M. Gonçalves[2], Filip Van Nieuwerburgh[3], Joana Pereira[2] and Jana Asselman[4], (1)Department of Biology and CESAM, University of Aveiro, Aveiro, Portugal, (2)University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Aveiro, Portugal, (3)Ghent University, Laboratory of Pharmaceutical Biotechnology, Belgium, (4)Blue Growth Research Lab, Ghent University (UGent), Ghent, Belgium*

Epigenetic mechanisms are moving to the forefront of environmental sciences because of their key role in shaping gene-environment interactions, phenotypic plasticity, and evolutionary responses. Specifically, environmentally induced DNA methylation changes are known to shape biological responses to chemical contamination, and the transgenerational inheritance of methylation marks across nonexposed generations has been confirmed in invertebrate and vertebrate species. Here, we focused on the freshwater invertebrate *Daphnia magna*, with the goal of further understanding the involvement of DNA methylation in their response and eventual adaptation to copper contamination. To do so, we specifically tested the hypothesis that different histories of exposure to Cu could determine different epigenetic signatures, which would be carried on into nonexposed generations. Accordingly, daphnids with different histories of past exposure to Cu were exposed to toxic levels of the metal for one generation (F0) and then monitored for three subsequent unexposed generations (F1, F2, and F3), with copper-induced DNA methylation changes, their potential transgenerational inheritance, and life-history traits being recorded. Overall, DNA methylation changes targeted important genes for counteracting the effects of metals and oxidative stress, including *dynein light chain*, *ribosomal kinase,* and *nuclear fragile X mental retardation-interacting protein*. Also, contrasting overall and gene-specific methylation responses were observed in organisms differing in their exposure history to Cu, with different transgenerational methylation responses being also identified among the two groups, without apparent life-history costs. Overall, results confirmed the capacity of Cu to promote DNA methylation transgenerational inheritance in a manner related explicitly to the history of exposure, thereby highlighting the potential for the development and incorporation of epigenetic biomarkers in risk assessment frameworks.

1.05.P-Th015 Transgenerational Transcriptional Responses in *Daphnia magna*: The Role of Copper Exposure History

Guilherme Jeremias[1], *Ana-Belen Muniz-Gonzalez*[2,3], *Jose-Luis Martinez-Guitarte*[2], *Fernando J. M. Gonçalves*[3], *Jana Asselman*[4] *and Joana Pereira*[3], *(1)Department of Biology and CESAM, University of Aveiro, Aveiro, Portugal, (2)National Distance Education University (UNED), Spain, (3)University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Aveiro, Portugal, (4)Blue Growth Research Lab, Ghent University (UGent), Ghent, Belgium*

Chemical exposures can extend their effects beyond "directly" exposed generations and influence the offspring response to future stressors. Thus, the establishment of transgenerational effects is a powerful phenomenon holding beyond exposure periods. Here, we assessed the transgenerational effects after Cu exposure in the invertebrate *D. magna* at the transcriptional level, while also evaluating the influence of acclimation history on such responses. To do so, daphnids with different histories of exposure, i.e., organisms acclimated in a Cu-enriched medium vs. blank ASTM for three generations, were exposed for one generation (F0) to an elevated concentration of the metal, and then the transcriptional response from F0 and F3 (F3 is the first truly unexposed generation) was inspected by real-time PCR employing an array with 41 genes (involved in detoxification and antioxidant response, DNA damage repair, circadian rhythm, and epigenetic regulation). Results showed that daphnids with different histories of exposure to Cu presented distinct transcriptional profiles at F0 and F3, with nonacclimated organisms showing higher modulation on gene expression. Despite the different exposure histories, histone modifier genes were always found to be transcriptionally altered in F0 and F3, suggesting the involvement of histone modifications in the response of *D. magna* to metal exposure. Besides, markedly distinct transgenerational transcriptional responses were found between the two groups of organisms, with nonacclimated daphnids showing a greater number of genes with modulated expression. Overall, results confirmed the influence of exposure history on transcriptional responses, and the ability of metals to determine transgenerational transcriptional responses across non-exposed generations.

1.05.P-Th016 Marine Pollutant Tributyltin Affects DNA Methylation and Fitness of Banded Murex (*Hexaplex trunculus*) Populations

Maja Srut[1], *Anita Erdelez*[2], *Iva Sabolić*[3], *Dorotea Grbin*[3], *Martina Furdek*[4], *Robert Bakarić*[3], *Melita Peharda*[2] *and Anamaria Štambuk*[3], *(1)University of Innsbruck, Austria, (2)Institute of Oceanography and Fisheries, Croatia, (3)Department of Biology, University of Zagreb, Croatia, (4)Division for Marine and Environmental Research, Ruder Boskovic Institute, Croatia*

Banded murex, *Hexaplex trunculus,* is a marine gastropod whose reproductive fitness can be severely affected by very low concentrations of antifouling compound trybutil-tin (TBT). Trybutil-tin has a strong xenoandrogen impact on snails, causing development of imposex (e.g., superimposition of male sexual characteristic in females), thereby affecting the fitness of entire populations. Trybutil-tin is also known as a DNA demethylating agent and an obesogenic factor. The aim of this study was to unravel the interactions between TBT bioaccumulation, phenotypic responses, and epigenetic and genetic endpoints in native populations of murex snail *H. trunculus*. Seven populations inhabiting environments along the pollution gradient were sampled in the coastal eastern Adriatic. Those included sites of intense marine traffic and boat maintenance activity, and sites with low anthropogenic impact. Populations inhabiting intermediately and highly polluted sites exhibited higher TBT burden, higher incidence of imposex, and higher wet mass of snails than populations on low polluted sites. Other morphometric traits and cellular biomarker responses did not show clear differentiation among populations in relation to the marine traffic/pollution intensity. Analysis of methylation sensitive amplification polymorphism (MSAP) revealed environmentally driven population differentiation and higher epigenetic than genetic within-population diversity. Moreover, decrease in genome-wide DNA methylation coincided with the imposex level as well as with the snail mass, suggesting epigenetic background of animal phenotypic response.

1.05.P-Th017 Genotoxicity and Epigenotoxicity of CMIT/MIT on *Daphnia magna*: Trans- and Multigenerational Effects

Jiwan Kim *and Jinhee Choi, School of Environmental Engineering, University of Seoul, Seoul, Korea, Republic of (South)*

CMIT/MIT (the mixture of 5-chloro-2-methyl-4-isothiazolin-3-one and 2-methyl-4-isothiazolin-3-one) is the biocide consistently detected in the aquatic environment due to its broad-spectrum usage in various industrial fields. The ecotoxicological information of CMIT/MIT is very limited to within-generational toxicity evaluation, though multigenerational exposure frequently occurred. Furthermore, despite a possible role of epigenetics on genotoxicity, their relationship is poorly known in the ecotoxicological context. For that reason, we investigated whether parental (PE) and multigenerational exposure (ME) of CMIT/MIT led trans- and/or multigenerational effects by measuring various phenotypic biomarkers over four consecutive generations. Genotoxicity and epigenotoxicity of CMIT/MIT in *Daphnia magna* were also examined using the Comet assay and global DNA methylation. Our results showed the deleterious effects of CMIT/MIT at various endpoints of *Daphnia*, which had experienced the different exposure histories. Parental effects in the PE scenario can be transgenerational or recovered after the termination of exposure.

More interestingly, the ME could result in acclimatory/defensive responses. It was also found that changes in DNA damage were closely associated with the altered reproduction of daphnid, but their possible relationship with global DNA methylation was not found. Overall, this study provides the ecotoxicological information of CMIT/MIT from multifaceted endpoints and aids in understanding of multigenerational phenomena under the CMIT/MIT exposure. It also emphasizes the consideration of exposure duration and multigenerational observation in the evaluation of ecotoxicity, in terms of risk management for widely used biocides, such as CMIT/MIT.

1.05.P-Th018 Investigation of Inter- and Intraspecific Sensitivity to CMIT/MIT in *Daphnia magna* and *pulex* Using Epigenetics and Proteomics Analysis

Jiwan Kim[1]*, Marie-Agnes Coutellec*[2] *and Jinhee Choi*[1]*, (1)School of Environmental Engineering, University of Seoul, Seoul, Korea, Republic of (South), (2)INRA, France*

The adaptive response of organisms to environmental change involves both genomic and epigenomic components. Adaptation, whether genetically or/and epigenetically derived, underpins the sensitivity and tolerance of exposed organisms. Therefore, adaptation needs to be considered in evaluating the adverse outcomes induced by toxicants. This study investigates variation in sensitivity and epigenetic responses to chemical exposure using the strains stemming from different *Daphnia* populations. To this end, we assessed the comparative toxicity of a mixture of 5-chloro-2-methyl-4-isothiazoline-3-one and 2-methyl-4-isothiazolin-3-one (CMIT/MIT), an isothiazolinone biocide used in various types of consumer products, by measuring mortality, reproduction, physiological traits, global DNA methylation, and proteomic expression. The results showed a more significant variation in sensitivity to CMIT/MIT between conspecific strains (*Daphnia pulex* Rennes [DPR] vs. *Daphnia pulex* Alsace [DPA]) than between congeneric species (*Daphnia magna* INERIS clone A [DMI] vs. *Daphnia pulex* Rennes [DPR]). Furthermore, under control conditions, DPR (the strain most sensitive to CMIT/MIT) had a larger body size, a higher heart rate, and a higher level of global DNA methylation than its counterpart (DPA). Interestingly, the trend of global DNA methylation level alteration differed between the two strains. We also observed the strain-specific patterns of CMIT/MIT-induced differential protein expression, suggesting the role of protein alteration and associated pathways in the observed difference in susceptibility to CMIT/MIT. Collectively, our results indicate that epigenetic changes can contribute to intraspecific variation, and this variation at multiple levels should be considered in the evaluation of the ecotoxicity of biocide chemicals.

1.05.P-Th019 Mechanisms of Nonlethal Heat Shock Induced Cross-Tolerance to Hydrogen Peroxide in Two Strains of Monogonont Rotifer *Brachionus plicatilis* Species Complex

Luana Granada[1,2]*, Inês Filipa Cigarro Morão*[1]*, Marco F.L. Lemos*[1]*, Peter Bossier*[2] *and* ***Sara Novais***[3]*, (1)Polytechnic of Leiria & MARE, Portugal, (2)Ghent University, Laboratory of Aquaculture & Artemia Reference Center, Belgium, (3)Instituto Politécnico de Leiria, Portugal*

Temperature is one of the main environmental factors influencing the presence and performance of organisms in aquatic ecosystems and affecting their survival and growth in aquaculture. Rotifer *Brachionus* sp. is a key species for aquaculture sustainability and, thus, the possibility to induce phenotypic traits that allow the organisms to cope with environmental stress poses a great advantage. It has been observed in several organisms, including in *Brachionus* sp., that short exposures to high temperatures lead to molecular changes (e.g., induction of heat-shock proteins, epigenetic modifications), resulting in induced thermotolerance. Therefore, this study aimed to evaluate the potential of nonlethal heat shock (NLHS) to also induce tolerance to other stressors, in two strains of rotifers belonging to the *Brachionus plicatilis* species complex. Exposure of organisms to 42°C for 30 min, followed by a recovery at 25°C for 8 h demonstrated to successfully increase tolerance to subsequent exposures to high salinity and hydrogen peroxide for one of the strains, and cadmium chloride for both strains. The mechanisms underlying the cross-tolerance effect to hydrogen peroxide after NLHS were further studied. Results showed an up-regulation of superoxide dismutase gene and higher levels of HSP70 in rotifers previously exposed to NLHS in the strain where cross-tolerance was successfully achieved. Moreover, epigenetic modifications were also observed. Genes encoding histone lysine methyltransferase (*KMT3E*), demethylase (*KDM1*), and acetyltransferase (*KAT6*) were significantly up-regulated, and the levels of histone H3 acetylation were also increased in heat shocked rotifers during the subsequent exposure to hydrogen peroxide. There was also the indication that heat shocked rotifers had higher histone H3 lysine methylation and acetylation levels, and lower levels of serine phosphorylation than control rotifers (without the NLHS) when exposed to hydrogen peroxide. However, levels of histone H3 acetylation decreased to control values before the end of the experiment (18 h exposure to H_2O_2), suggesting that the epigenetic effects observed may be transient and some more cycles of NLHS may be needed to promote a persistent effect. This study showed that the exposure to an environmental stressor (temperature) was able to induce changes in rotifer's epigenetic markers, resulting in positive phenotypic outcomes.

1.06.A Fish Model Species in Human and Environmental Toxicology

1.06.A.T-01 Molecular and Cellular Effects Underlying Insecticide-Induced Neurobehavioural Alterations in Zebrafish Larvae

Sarah Könemann[1]*, Melissa von Wyl*[1]*, Severin Ammann*[1]*, René Schönenberger*[2]*, Ksenia J Groh*[1] *and Colette Michèle vom Berg*[1]*, (1)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Dübendorf, Switzerland, (2)Environmental Toxicology, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Dübendorf, Switzerland*

Molecular targets of insecticides are similar in insects and vertebrates. Insecticides thus pose a risk of potential neurotoxicity to aquatic vertebrates, such as fish. Neurotoxic effects often manifest as an alteration in an organism's behaviour. Hence, behavioural endpoints are used to assess the neurotoxicity of chemicals. A frequently used method is the zebrafish light-dark transition (LDT) test, which measures the larvae's locomotion in response to light changes. Despite the popularity of the LDT, knowledge gaps exist regarding the underlying mechanisms that cause neurobehavioural effects. Therefore, this study aimed at investigating the links between insecticide-induced locomotor defects and (i) cellular changes in neuromuscular components (NMCs) and (ii) molecular changes such as mRNA expression of genes related to NMCs, as well as neurotransmitter concentrations. The locomotor behaviour of zebrafish larvae was measured after six-day exposure to two sublethal insecticide concentrations. Effects on NMCs were analyzed with fluorescence labelling and a birefringence approach. Exposure to the tested organophosphate (OP), carbamate (CBM), and neonicotinoid (NN) insecticides led to reduction in locomotion, while no effect was observed for the pyridine-derivatives. The other tested endpoints showed a different effect pattern for almost all insecticides. Among the NMCs, only the CBM methomyl and the NN imidacloprid affected motor axon growth. Furthermore, methomyl and the NN thiacloprid affected muscle integrity. The *ache* (acetylcholinesterase) gene was upregulated after exposure to most OPs and CBMs, while *smyd1b*, which plays a role in muscle development, was upregulated only after methomyl exposure. Metabolomics analyses showed that the acetylcholine concentration increased in fish exposed to methomyl, while glutamine and histidine concentrations were reduced in methomyl and thiacloprid-exposed fish, respectively. Kynurenine was increased after thiacloprid exposure, suggesting acute stress in these treatments. Our results demonstrate that locomotion is an integrative endpoint, caused by multiple underlying effects. By investigating these effects on various levels of biological organization, this study improves the mechanistic understanding of insecticide-induced neurobehavioural effects.

1.06.A.T-02 Identification of Effect-Biomarkers for Vascular Disruptors as an Endpoint to Predict Developmental Toxicity Using Zebrafish Embryos

Julia Nöth, *Paul Michaelis, Stefan Scholz and Wibke Busch, Chemicals in the Environment Research Section, Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany*

Inhibition of angiogenesis is an important mode of action for teratogenic effect of chemicals and drugs. Teratogenic drugs such as thalidomide but also environmental chemicals (herbicides, fungicides, and pesticides) have been shown to interfere with angiogenesis. Therefore, methods for the detection of angiogenesis inhibition by chemicals as an indicator of teratogenic effects form an important component for the integrated assessment of chemicals using alternative 3R-compliant approaches. The zebrafish embryo represents such an alternative model that offers the complexity of developmental differentiation of an entire organism while allowing for small-scale and high-throughput screening. Additionally, the transparency of its body allows for the application of imaging techniques as a screening method for chemical-induced morphological effects. Here we present a novel automated imaging-based method to detect angiogenesis inhibition. By subtracting video frames, we were able to identify the location and number of blood vessels according to moving blood cells. In order to identify a suitable model compound and exposure scenario for subsequent transcriptome analysis zebrafish embryos were exposed to various tyrosine kinase inhibitors (SU4312, SU5416, sorafenib, and PTK787). By video subtraction we confirmed that the compounds provoke concentration-dependent angiogenesis inhibition, with highest specificity for exposures starting at 24 h postfertilization. Based on the comparison of specificity and lethality, we selected SU4312 as a model compound, to perform concentration- and time-resolved microarrays. The final aim is to screen chemical induced vascular disruption by noninvasive, high-throughput video imaging and molecular biomarkers specific for anti-angiogenesis.

1.06.A.T-03 Zebrafish Early Life Stages in the Study of Metabolic Disruption: The Case of Paraoxonase 1

Rik van den Boom, *Lucia Vergauwen, Katyeny Manuela da Silva, Alexander Van Nuijs, Adrian Covaci and Dries Knapen, University of Antwerp, Belgium*

Endocrine disrupting chemicals (EDCs) have been investigated for their disruptive effects on steroid hormone pathways. Some EDCs such as bisphenol A (BPA) have also been shown to disrupt energy metabolism, which could result in adverse health effects. Currently, the underlying mechanisms are not fully understood and there is an urgent need for assays to characterize these metabolic disrupting compounds (MDCs). Two different assays were developed using different life stages of the zebrafish. In each assay, zebrafish were studied in different metabolic and toxicological scenarios to investigate the role of paraoxonase 1 (PON1), an antioxidant enzyme associated to metabolic disorders by genome-wide association studies, in metabolic disruption. In the first assay, 14-day-old larvae were used to study the effects of metabolic disruption on PON1. Metabolic disruption was induced by a five-day feeding regime with a custom Western diet and aquatic exposure to different doses (200 µg/L or 2000 µg/L) of a known MDC, BPA. The Western diet feeding regime resulted in a nonsignificant increase of weight, length, and oxidative stress. The addition of BPA exposure on top of the Western diet resulted in a significantly increased weight, length, and oxidative stress, indicating that the metabolic disrupting effects of BPA further exacerbated the metabolic changes induced by the diet. PON1 activities increased either in all Western diet groups, or in a combination of the Western diet and exposure to 2000 µg/L BPA in response to the diet- and dose-dependently increasing oxidative stress. In conclusion, this assay successfully studied metabolic disruption, and was able to identify that PON1 likely performed part of the antioxidant response to the increasing oxidative stress caused by metabolic disruption.

In zebrafish embryos, we investigated which effects indicative of metabolic disruption can already be measured at 120 h postfertilization (hpf). Until this age, zebrafish are considered a new approach methodology (NAM), an alternative to animal testing. Embryos were exposed from 2 to 120 hpf to different MDCs including BPA, peroxisome proliferator-activated receptor γ (PPARγ) agonist rosiglitazone and the PPARγ antagonist T0070907. Embryos showed dose-dependent increases in yolk size for all tested compounds. The embryonic assay can quickly identify MDCs using a NAM approach, whilst the larval assay allows for the study of MDCs in interaction with a dietary component.

1.06.A.T-04 A Battery of Behaviour-Based Assays in Larval Zebrafish to Elucidate Acute and Developmental Neurotoxicity Mechanisms

David Leuthold[1], *Nadia Katherine Herold*[2] *and Tamara Tal*[3], *(1)Chemicals in the Environment Research Section, Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany, (2)Bioanalytical Ecotoxicology, Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany, (3)Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany*

Approximately one in six children is diagnosed with a developmental disability including learning and intellectual disability. While causes are often elusive, chemical exposure during prenatal and early postnatal development can demonstrably interfere with neurodevelopment. However, due to extensive time, cost, and animal number requirements of developmental neurotoxicity (DNT) guideline studies in rats, the potential hazard of most chemicals remains unknown. To fill this gap, we devised a battery of 11 automated behaviour assays in larval zebrafish, a 3R-compliant model amenable to higher-throughput chemical screens. The battery captures various stereotypical visual and acoustic behaviours including habituation, a form of nonassociative learning. We hypothesized that behaviour-rich phenotyping of chemicals provides a comprehensive readout of potential adverse outcome pathways (AOPs) that dictate a broad range of events and interactions that orchestrate nervous system development and function. According to the AOP "Impairment of Learning and Memory," we focused on the NMDA receptor (NMDAR) as a target of chemical exposure. In an initial step, the DNT NAM was evaluated against seven drugs with distinct mechanisms including NMDA and GABA receptor (GABAR) antagonism. In line with effects reported in rats, exposure to the prototypical NMDAR antagonist MK-801 caused a deficit in habituation learning. Surprisingly, cluster analysis revealed high phenotypic similarity to the GABAR antagonist picotoxin, pointing to a potential second mechanism of MK-801, GABAR antagonism. The battery was further evaluated against a set of 10 USEPA ToxCast chemicals positive for *ex vivo* NMDAR antagonism. In addition to methadone, acute exposure to clorophene, a biocide and preservative in cosmetics, was confirmed to affect habituation learning *in vivo*. Defective habituation learning was also observed in a developmental exposure paradigm (0.25-4 d postfertilization), indicating clorophene-induced DNT. Strikingly, in addition to an NMDAR-mediated learning deficit, clorophene exposure caused "paradoxical excitation," a phenomenon linked to GABAR agonism. Pharmacological intervention using GABAR antagonist picrotoxin blocked clorophene-induced sedation, substantiating its gabaergic interaction. In summary, these nonexhaustive examples highlight the capacity of this behaviour-based NAM to illuminate AOPs, to reduce/replace existing *in vivo* approaches and to accelerate DNT research.

1.06.A.T-05 A New Test System for Assessing Toxicity of Chemicals with Low Water Solubility: Dechlorane Plus as a Case Study

Marion Sebire[1], *Sara Losada*[1], *Ellen Blaker*[1], *John Bignell*[1], *Matthew Green*[1], *Paula Milliken*[2], *Jon Barry*[1], *Elena Sostare*[3], *Rosemary Elizabeth Barnett*[3], *John Colbourne* [3], *Ralf Welber*[3], *Mark R. Viant*[3], *Lisa Annie Baumann*[4] *and Ioanna Katsiadaki* [1], *(1)Centre for Environment Fisheries and Aquaculture Sciences (Cefas), United Kingdom, (2)Ecotoxicology, Centre for Environment Fisheries and Aquaculture Science (Cefas), United Kingdom, (3)Michabo Health Science Ltd, United Kingdom, (4)University of Heidelberg, Germany*

Global regulatory authorities require chemical toxicity data from vertebrate test systems, including fish, to identify, mitigate, and manage any adverse environmental effects arising from their use. The current regulatory tests for environmental chemical hazard assessment are based on waterborne exposures. However, many potentially toxic chemicals are highly hydrophobic/lipophilic (water-octanol coefficient – Kow – >6) and present a practical challenge for conducting aquatic exposures (high volumes of solvents, welfare issues), especially at early life stages. To date only one regulatory test guideline, the fish bioaccumulation test (OECD TG305), offers a dietary chemical delivery option. Although TG305 does not aim to assess toxicity assessment, the existing guidance can be easily adapted to most aquatic tests, including for endocrine disrupting chemicals (EDCs).

We designed such a test system using Dechlorane Plus (DP), a very strongly hydrophobic (Log Kow>6), persistent and bioaccumulative chemical with poorly understood toxicity (at the time, DP was under pending decision to enter the POP list) and potential for endocrine disruption. In order to capture potential effects at early life stages, including embryos that do not feed, we started the dietary exposure of the parent generation, similarly to TG229/230 and follow-up with the Fish Embryo Toxicity Test (TG236). There were four treatment groups: Control (0 µg/g DP), Low (0.1 µg/g DP), Medium (1 µg/g DP), and High (10 µg/g DP). This bespoke test aimed to obtain a comprehensive toxicity assessment of DP over two generations of fish, building on the way resources for developing NAMs (new approach methodologies) by focusing on the zebrafish embryo responses with the aim of developing predictive markers of exposure/toxicity and ultimately, an adverse outcome pathway (AOP).

1.06.B Fish Model Species in Human and Environmental Toxicology

1.06.B.T-01 Ecosafety Evaluation of Biogenic Matrices for Agricultural Reuse Using Zebrafish Embryos

Silvia Giorgia Signorini[1], *Stefano Tagliabue*[2], *Roberta Pedrazzani*[3], *Michele Menghini*[3], *Luca Del Giacco*[2], *Alberto Diana*[2], *Alessandro Abbà*[3], *Marta Domini*[3], *Sara Castiglioni*[4], *Giorgio Bertanza*[3], *Andrea Binelli*[5] *and Camilla Della Torre*[5], *(1)Department of Biosciences, Università degli Studi di Milano, Italy, (2)Università degli Studi di Milano, Italy, (3)Università degli Studi di Brescia, Italy, (4)Environmental Health Sciences, Istituto di Ricerche Farmacologiche Mario Negri, Italy, (5)Dipartimento di Bioscienze, Università degli Studi di Milano, Italy*

The use of biogenic matrices as fertilizers and amendments is considered a good solution to improve soil properties and resilience. Nevertheless, there are growing concerns related to their potential hazard to ecosystems and human health, due to the potential presence of harmful organic pollutants, metals, and microbiological contaminants. For this reason, there is an urgent need to develop effect-based tools to guarantee their safe application into the environment. In this scenario, this project aimed to compare the ecotoxicity of four different types of biogenic matrices: manure (M1 and M2), compost (C), bovine manure digestate (D), and sewage sludge (S1–S2–S3), which all have fertilizing properties, using zebrafish (*Danio rerio*) embryos. To this aim, we assessed acute toxicity and sublethal effects as behavioural alterations, metabolic disruption, and neurotoxicity of elutriates (at dilutions: 1:100, 1:50, 1:25, and 1:10) as well as of the whole matrix (through contact assay, at a concentration of 1:300). All matrices, except for S2 and S3, displayed 100% of embryotoxicity at the dilution 1:10 at 120 hpf, whereas no relevant embryotoxicity was induced at 1:50 and 1:100 dilutions, except for S1 and D. Concerning metabolic endpoints, the Seahorse analysis showed that all the samples have boosted both basal oxygen consumption and maximal respiration in comparison to control embryos. Regarding behaviour, S2 displayed increased motility compared to the control at all the tested dilutions and S3 at the dilution of 1:100 and 1:50, while no significant differences were observed in the other matrices. Finally, acetylcholinesterase activity displayed no statistically significant variation regardless of the matrix or the dilution. In conclusion, our results highlighted that these biogenic matrices, at high concentrations, may affect biochemical and physiological functions of zebrafish embryos at a similar extent (S2 and S3 being the best substrates, while S1 and D the worst). In particular, they can alter swimming performance, metabolism, and embryo development. The integration of our data with results related to chemical characterization and other bioassays, still ongoing, will provide an overall and representative view of the real features of these matrices, which shall be carefully evaluated also in view of the land-application conditions.

1.06.B.T-02 Integrative Assessment of Ocean Pollution Impacts in Blue Sharks (*Prionace glauca*)
Sara Novais[1]*, Luís Alves*[2]*, Tiago Filipe da Silva Simoes*[2]*, Ariana Borges Moutinho*[2]*, Filipe R. Ceia*[3]*, Juan Munoz-Arnanz*[4]*, Begona Jimenez*[5]*, Luís J. Gómez*[6]*, Ana-Lourdes Oropesa*[6]*, Emma Sehlhoff*[7]*, Ken Kraaijeveld*[7]*, Dick Roelofs*[8] *and Marco F.L. Lemos*[2]*, (1)Instituto Politécnico de Leiria, Portugal, (2)Polytechnic of Leiria & MARE, Portugal, (3)MARE - Marine and Environmental Sciences Centre, University of Coimbra, Portugal, (4)Institute of Organic Chemistry - Spanish Research Council (IQOG-CSIC), Spain, (5)Institute of Organic Chemistry - Spanish National Research Council (IQOG-CSIC), Spain, (6)University of Extremadura, Spain, (7)Department of Bioinformatics, University of Applied Sciences Leiden, Leiden, Netherlands, (8)KeyGene, Netherlands*
Blue sharks (*Prionace glauca*) are one of the most widely distributed and caught shark species worldwide. Although an increasing number of studies have been tracking the concentrations of pollutants in the tissues of these sharks, much less is known about how they can affect organisms' health. Therefore, this study aimed to further understand how different types and levels of contamination can impact blue sharks' general fitness, with the ultimate goal of developing a good and reliable set of tools to assess sharks' health and biomonitor oceanic environments. For this goal, a total of 60 sharks were opportunistically captured as by-catch aboard a fishing vessel, and sampled for the analyses of contaminant levels (metals and Persistent Organic Pollutants [POPs]), stable isotopes (δ13C and δ15N), and biological responses in different tissues: 1) at molecular level – whole transcriptome sequencing analysis (RNAseq); 2) at cellular level – fatty acid (FA) profile and oxidative stress related biomarkers; 3) at tissue level – histopathological alterations. Results showed that sharks captured closer to the continental shore exhibited higher levels of contaminants in comparison to the ones captured in a more pelagic environment, being the accumulation mostly influenced by their geographical distribution, rather than sex, size, or trophic level of their prey. Transcriptomic data showed several differentially expressed genes in each of the four sampled tissues when comparing the individuals caught in the two geographical areas, and strong correlations with metals (e.g., fatty acid metabolism) and POPs (e.g., immunoglobulins). The liver FA profile revealed that female sharks seem to be the most affected group, presenting significantly lower levels of the main classes of FAs in individuals caught in the coastal area, explained by strong negative correlations with both metals and POPs. Similar zone-related differences were found in biomarker responses and strong positive correlations between, e.g., As, PCBs, and PBDEs, and DNA damage. Histopathological lesions were also observed in the sampled tissues, having overall higher severity levels with higher contaminant concentrations. These results show clear indications of higher stress, cellular damage, and tissue injuries in organisms with higher pollutant levels, highlighting the suitability of this species and these tools to monitor contamination and its effects in different areas of the Atlantic, under real exposure scenarios.

1.06.B.T-03 Probiotic Administration Counteracts Bisphenol A-Induced Toxicity at Brain-Gut-Microbiome Axis Level in *Danio rerio* Adults
Christian Giommi[1]*, Danilo Basili*[2]*, Sara Mangiaterra*[3]*, Giacomo Rossi*[3]*, Hamid R Habibi*[4]*, Francesca Maradonna*[2] *and Oliana Carnevali*[2]*, (1)Department of Life and Environmental Sciences (DiSVA), Polytechnic University of Marche (UNIVPM), Italy, (2)Università Politecnica delle Marche (UNIVPM), Italy, (3)Università Di Camerino, (4)Biological Sciences, University of Calgary, Canada*
Several studies demonstrated that Bisphenol A (BPA) possesses toxicity at brain and intestinal levels both in mammalian and teleost species. The pollutant induced toxicity at the intestinal level could cause damage at the central level or vice versa though the brain-gut-microbiome axis. Probiotics beneficial effects were observed in numerous vertebrate species and could represent a tool to decrease the BPA induced alterations. In this regard, SLAB51 is a probiotic formulation which ameliorated gastrointestinal pathologies and showed neuroprotective ability in diverse veterinary trials. The ability of SLAB51 to counteract BPA toxicity was here investigated on brain-gut-microbiome axis in zebrafish adults in a chronic (28 days) exposure to 10 µg/L BPA plus SLAB51 (10^9 CFU/g) (BPA+P); results were compared with those of an untreated control (C) and of those treated with BPA or SLAB51 (P) alone. At brain level, while females reported only an increase of microvessel alteration, males were more impacted by BPA toxicity since neuronal degeneration, microvessel alteration, and perivascular edema were present. The TUNEL assay indicates an increase of cell death in the brain in both male and female fish exposed to BPA associated with the upregulation of neurodegeneration markers such as TAU aggregates and glial fibrillary acidic protein (GFAP). In BPA+P treated fish, the same biomarkers presented levels similar to C ones, demonstrating the counteracting effects of probiotics on BPA toxicity. In the gut,

BPA induced a reduction of intestinal fold length and an increase of the lamina propria thickness similar in both the male and female gut, while a reduction of intestinal muscle thickness was only observed in female fish. At the transcript level, BPA reduced *litaf* in both sexes and *il-1β* and *il-10* only in females, suggesting the contaminant ability to impair the immune system. In BPA+P group no gut alterations were found. The gut microbiota analysis evidenced in BPA and BPA+P the presence of *Pseudomonadales*, which can use BPA as substrate for growing, while the *Cetobacterium,* a vitamin B12 producing bacteria, was detected in P and BPA+P exposed fish, this vitamin being useful for improving organism health status. These results show for the first time the ability of SLAB51 to counteract BPA toxicity in zebrafish gut and brain, suggesting the possible use of this formulation in the treatment of toxicity induced by a chronic exposure to environmental BPA levels and possibly other endocrine disruptors.

1.06.B.T-04 Widespread Psychoactive Pollutant Disrupts Fish Circadian Activity Rhythms ***Hung Tan***[1], *Jake Martin*[1,2], *Lesley A. Alton*[1], *John A. Lesku*[3,4] *and Bob B.M. Wong*[1], *(1)School of Biological Sciences, Monash University, Australia, (2)Wildlife, Fish and Environmental Studies, Swedish University of Agricultural Sciences (SLU), Sweden, (3)School of Agricultural, Biomedicine and Environment, La Trobe University, Australia, (4)Research Centre for Future Landscapes, La Trobe University, Australia*
Pharmaceutical pollution is an emerging driver of global change, with the capacity to alter key behavioural and physiological traits in exposed animals. Antidepressants are among the most commonly detected pharmaceuticals in the environment. Despite well-documented pharmacological effects of antidepressants on sleep in humans and other vertebrates, very little is known about their ecologically relevant impacts as pollutants on nontarget wildlife. Accordingly, we investigated the effects of acute three-day exposure of Eastern mosquitofish (*Gambusia holbrooki*) to current field-realistic levels (nominal concentrations: 30 ng/L and 300 ng/L) of the widespread psychoactive pollutant, fluoxetine, on circadian activity patterns and restfulness, as indicators of disruptions to sleep. Using automated tracking software, we tracked approximately 10 000 hours of behavioural video footage, quantifying the activity levels of 140 adult individuals across the full 72-h exposure period. Here, we show that exposure to fluoxetine disrupted diel activity patterns, which was driven by augmentation of daytime inactivity. Specifically, unexposed control fish were markedly diurnal, swimming farther during the day and exhibiting longer periods and more bouts of inactivity at night. However, in fluoxetine-exposed fish, this natural diel rhythm was eroded, with no differences in activity or restfulness observed between the day and night. As a misalignment in the circadian rhythm has been shown to adversely affect fecundity and lifespan in animals, our findings reveal a potentially serious threat to the survival and reproductive success of pollutant-exposed wildlife.

1.06.P-Th020 Elemental Concentrations in the Invasive Australian Redclaw Crayfish, *Cherax quadricarinatus*, Pose Human Health Risks in the Largest Floodplain System of South Africa
Johannes Hendrik Erasmus, *Wynand Malherbe, Nicholas J Smit and Victor Wepener, Water Research Group, Unit for Environmental Sciences and Management, North-West University, South Africa*
The Australian redclaw crayfish, *Cherax quadricarinatus*, has been introduced globally for aquaculture and aquarium trade purposes, and invasive wild populations have established in several African countries, including South Africa, Eswatini, Zambia, and Mozambique. Due to the growth in population numbers of these invasive crayfish, several low-income and rural communities are utilising them as an inexpensive, easily accessible protein source. Although this crayfish has been introduced on a global scale, limited research has been done on element accumulation in this species, and the risks that consumption may pose to humans. This study focused on elemental accumulation (As, Cd, Cr, Cu, Hg, Ni, Pb, Zn) in the redclaw crayfish from two rivers of the largest floodplain system of South Africa, the Phongolo River floodplain (PRF). The carcinogenic and noncarcinogenic human health risks associated with its consumption were calculated. The element accumulation order in the PRF was Zn > Cu > Pb > Cr > As > Ni > Hg > Cd, whilst the highest concentrations of As, Cd, Cr, Hg, and Pb were recorded in the Phongolo River. High concentrations of Cu, Ni, and Zn were associated with the Usuthu River tributary. Carcinogenic health risks were associated with consumption of the crayfish from all of the sites for As, Cr, and Ni, where 19, 10, and 6 out of 100 000 people could develop cancer from exposure to these elements, respectively. Concentrations of Pb also posed a level of concern for cancer risk at all of the sites. The Hazard Quotient of *C. quadricarinatus* collected in the Phongolo River were 1.7 for As and 2.2 for Hg indicating a high probability of adverse noncarcinogenic health risk. These results highlight that wild populations of invasive redclaw crayfish do not only pose a threat on aquatic ecosystems, but the consumption of these crayfish from the PRF could potentially also cause several carcinogenic and noncarcinogenic human health risks when consumed.

1.06.P-Th021 Lipidic Effects of Metals in Liver of Blue Shark (*Prionace glauca*) and Small-Spotted Catshark (*Scyliorhinus canicula*)
Tiago Filipe da Silva Simoes[1], *Ana Fernandes*[1], *Luís Alves*[1], *Marco F.L. Lemos*[1] *and Sara Novais*[2], *(1)Polytechnic of Leiria & MARE, Portugal, (2)Instituto Politécnico de Leiria, Portugal*
As apex predators, sharks play a key role regarding the health and balance of marine ecosystems. However, these are very susceptible species to increasing oceanic pollutants exposure and bioaccumulation during their long lifespans. The liver is one of the largest organs in these species, extremely important in biological processes such as detoxification or buoyancy. It is composed of several classes of lipids and, consequently, an enormous diversity of fatty acids that are important as energy resources, membrane constituents, or as metabolic and signalling mediators. There are several studies addressing lipids and fatty acids as promising indicators of environmental contaminants' effects in coastal or deep-sea organisms but these studies in sharks are still scarce. Since metals have been demonstrated to accumulate in muscle and liver tissues from several marine organisms, normally leading to lipid oxidation, the present work aimed at exploring how different metals accumulated in two shark species (*Prionace*

glauca and *Scyliorhinus canicula*) could be associated to changes in different classes of fatty acids (FA) in their livers. To this purpose, liver samples were collected from approximately 60 individuals from each species, and their FA profile and content analysed and correlated with the metal levels accumulated in their tissues, having also in consideration biotic and abiotic factors such as age, gender, and geographical distribution. Elements such as Al, AS, Fe, Hg, Se, and Zn were detected for both species and results indicated general higher accumulation levels in *P. glauca* comparatively to *S. canicula*. Liver FA profile was found to be different between species, but also within species, considering maturation stage and gender. The analysis suggests that *P. glauca* females are the ones most influenced by the pollutant levels, with several FA classes being strongly and negatively correlated with the majority of the metals detected. However, a set of FAs were found with the same trend for both genders of the species (-trans and n9 FAs). In *S. canicula*, the elements that most influenced the variability of responses in FA profile were Hg, Fe, and Zn, with trans-palmitoleic, eicosenoic, and DHA FAs presenting significant correlations with those metals. Similar studies are essential for a better understanding of the impacts that environmental factors can cause on the physiology of these organisms and to infer about the possible ecological consequences of such impacts.

1.06.P-Th043 Do Halogenated Environmental Toxins Cause Immunosuppression in Baltic Sea Salmon?
Dennis Lindqvist[1]*, Carolina Vogs*[2]*, Harri Alenius*[1]*, Sheung Wai Tang*[1] *and Emma Wincent*[1]*, (1)Institute of Environmental Medicine, Karolinska Institutet, Sweden, (2)Department of Biomedical Science and Veterinary Public Health, Swedish University of Agricultural Sciences (SLU), Sweden*
The Baltic Sea is one of the most contaminated seas in the world, heavily polluted with numerous organohalogen compounds, causing large body burdens in Baltic Sea wildlife, such as Baltic Sea salmon (*Salmo salar*). Using the zebrafish embryo model (ZFE), we set out to test the hypothesis that exposure to organohalogen mixtures may contribute to the adverse health status observed among the salmon population, through impaired immune system function.

We identified 41 organohalogens in serum of Baltic Sea salmon and based on their relative prevalence and prior knowledge regarding toxicity, nine of these were selected and evaluated for their ZFE toxicity, toxicokinetic parameters, transcriptional responses, and lastly impact on the development and function of neutrophils and macrophages upon chemical and inflammatory stress.

Several dose-dependent morphological effects were observed, including scoliosis, edemas, reduced growth, and abolished swimbladder inflation. While the individual components of the mixtures caused different effect-profiles, most morphological effects appeared in an additive manner when exposed as a mixture. By performing RNAseq based transcriptomic profiling, the main effects identified were altered metabolic function and a suppressed immune system. This was further supported by studying ZFE reporters with fluorescently labelled immune cells, indicating both a reduced number of mature immune cells, as well as reduced function upon inflammatory stress.
Although the results need to be confirmed using relevant fish species, our data strongly indicate potential risks for immunotoxicity in wildlife fish exposed to these compounds. Moreover, the large difference in toxicokinetic properties observed for the compounds tested here, resulting in distinct internal-dose profiles over time, highlights the necessity of proper determination of external and internal concentrations for accurate ranking of toxic potency.

1.06.P Fish Model Species in Human and Environmental Toxicology

1.06.P-Th023 Neurobehaviour Changes of Adult Zebrafish Under Exposure to Chemical Ingredients in Commercial Fragrant Products
Hanseul Lee[1] *and Kitae Kim*[2]*, (1)Seoul National University of Science and Technology, Nowon-gu, Seoul, Korea, Republic of (South), (2)Seoul National University of Science and Technology, Korea, Republic of (South)*
The growing number of chemicals in commercial products raises concerns about unintended or intended exposure, negatively impacting human health and the environment. Through Association Rule Mining analysis, a total of 212 substances on the basis of the top 10% occurrence among 100 fragrance products, citronellol, geraniol, and their mixture were selected as the most suspicious substances in fragrance products. To investigate their potential in neurotoxicity we exposed 50-fold diluted no-effect concentrations (i.e., citronellol 0.2 µg/mL, geraniol 0.4 µg/mL, and a mixture of both substances) obtained from 96-h acute embryonic toxicity testing to zebrafish adults for 14 days. The photomotor response test (PMR), novel tank test (NTT), and T-maze test were conducted to measure neurobehavioural changes. In the NTT, exposure to citronellol and geraniol exerted a tendency to decrease in time and distance in the top area. Also, significant changes were observed in the PMR test, indicating that photomotor response was suppressed. In the T-maze test, there was no significant difference in the movement distance of the left and right zones in the exposed group, suggesting that memory ability was damaged. Neurotransmitter analysis indicated that the level of 5-hydroxyindoleacetic acid (5-HIAA) associated with depression was significantly decreased in the citronellol group and mixture group compared to the control. Also, a significant decrease in acetylcholine (ACh), which plays an important role in cognitive functions, was observed in the mixture group. In summary, our study shows that long-term exposure to low concentration of citronellol and geraniol, major ingredients of commercial fragrance products, had the potential for neurotoxicity in zebrafish, suggesting a cautionary use of fragrant chemicals.

1.06.P-Th025 Utilizing a Population-Genetic Framework to Test for Gene-Environment Interactions Between Zebrafish Behaviour and Chemical Exposure
Lisa Truong[1]*, Preethi Thunga*[2]*, Yvonne Rericha*[1]*, Jane La La Du*[1]*,* ***Michael T Simonich***[1]*, David Reif*[2] *and Robyn Leigh Tanguay*[1]*,*

(1)Oregon State University, (2)North Carolina State University
Individuals within genetically diverse populations display broad susceptibility differences upon chemical exposures. Understanding the role of gene-environment interactions (GxE) in differential susceptibility to an expanding exposome is key to protecting public health. However, a chemical's potential to elicit GxE is often not considered during risk assessment. Previously, we have leveraged high-throughput zebrafish (*Danio rerio*) morphology screening data to reveal patterns of potential GxE effects. Here, using a population genetics framework, we apportioned variation in larval behaviour and gene expression in three different PFHxA environments via mixed-effect modeling to assess significance of GxE term. We estimated the intraclass correlation (ICC) between full siblings from different families using one-way random-effects model. We found a significant GxE effect upon PFHxA exposure in larval behaviour, and the ICC of behavioural responses in the PFHxA exposed population at the lower concentration was 43.7%, whilst that of the control population was 14.6%. Considering global gene expression data, a total of 3746 genes showed statistically significant GxE. By showing evidence that heritable genetics are directly affecting gene expression and behavioural susceptibility of individuals to PFHxA exposure, we demonstrate how standing genetic variation in a heterogeneous population such as ours can be leveraged to test for potential GxE.

1.06.P-Th027 Novel Insight into the Mode of Action of Metabolic Endocrine Disruptors (MDCs) in the Developing Intestine Through the Use of a Transgenic tg(cyp3a65:GFP) Zebrafish Model

Chedi Erradhouani[1], *Benjamin Piccini*[2], *Frédéric Sohm*[3], *Nathalie Hinfray*[4], *Edith Chadili*[4], *Patrick Balaguer*[5], *Selim Ait-Aissa*[1], *Xavier Coumoul*[6] *and Francois Brion*[2], *(1)INERIS, France, (2)Ineris, Unité d'Ecotoxicologie des substances et des milieux, France, (3)INRA, France, (4)Ineris, Ecotoxicology of Substances and Environments, France, (5)INSERM, France, (6)Université Paris Cité, France*

Metabolic endocrine disruptors (MDCs) have the ability to promote metabolic changes which could ultimately result in obesity, diabetes, and/or nonalcoholic fatty liver disease in humans. Significant advances have been made on the modes of action by which MDCs disrupt metabolic pathways but there are still needs to further study their modes of action on less investigated molecular and cellular pathways and develop relevant mechanism-based models. In this study, we developed and characterized a transgenic zebrafish (zf) model *tg(cyp3a65:GFP)* expressing Green Fluorescent Protein (GFP) under the control of the promoter of cyp3a65, ortholog of human cyp3a, which play a critical role in xenobiotic but also cholesterol metabolism. *In vivo* imaging and immunohistochemistry showed an early constitutive GFP expression during embryonic development starting at 72 h postfertilization (hpf) in enterocytes of the anterior part of the intestine. Mono-exposure of embryos from 72 to 120 hpf to zfPXR and zfAhR ligands (clotrimazole and TCDD, respectively) induced GFP after 24 h and 48 h of exposure, showing that these two transcriptional factors play a role in the regulation of cyp3a65. Further investigations showed that zfPXR and zfAhR act cooperatively to induce cyp3a65 expression as coexposure experiments resulted in a higher induction as compared to single exposure experiment to zfPXR or zfAhR ligands. Furthermore, we showed that CH223191, an AhR antagonist, promoted the expression of *cyp3a65* but also the effect of clotrimazole on the *tg(cyp3a65:GFP)* model since both the basal and the clotrimazole-induced cyp3a65 expression were higher when the AhR signaling pathway was blocked by CH223191.

Overall, we successfully developed a stable transgenic model allowing study of the the expression of a key target gene in the developing intestine of zf. We showed that the zfPXR and zfAhR are critical in the regulation of the cyp3a65 gene and that these two signalling pathways interact in an ambivalent manner. While there is still a need to pursue this research to enhance our knowledge on the mechanism regulating *cyp3a65* in intestine, the *tg(cyp3a65:GFP)* zebrafish embryo represents a promising model to develop a mechanism-based bioassay to screen the activity of chemicals (which is currently under progress). The causal links between *cyp3a65* disruption and potential metabolic adverse effect(s) also represent a challenge for efficient use in a hazard assessment perspective.

1.06.P-Th028 Evaluation of Developmental Toxicity, Immunotoxicity, and Endocrine Disruption Caused by Exposure to Triazines, Triazoles, and Short-Chain Per- and Polyfluoroalkyl Substances

Maxim Carlier[1], *Peter Cenijn*[2], *Majorie van Duursen*[3], *Wilbert Bitter*[4] *and Timo Hamers*[3], *(1)Vrije University Amsterdam, Netherlands, (2)VU Amsterdam, A-LIFE-Environment & Health, Amsterdam, Netherlands, (3)Amsterdam Institute for Life and Environment (A-LIFE), Section Environment & Health, Vrije University Amsterdam, Netherlands, (4)Molecular Microbiology, Vrije University Amsterdam, Netherlands*

Because persistent and mobile (PM) substances have a high probability to end up in drinking water, information on their hazards is crucial to keep drinking water safe for consumption. Many triazoles, triazines, and short-chain PFAS are persistent and mobile due to their specific molecular structures. Within the EU-H2020 project ZeroPM, in vitro toxicity profiles were determined for 16 triazoles, nine triazines, and 11 short-chain PFAS with respect to developmental toxicity, immunotoxicity, and endocrine disruption. Developmental toxicity was assessed in zebrafish embryos using a standardized scoring system. This general morphology score indicates a delay in embryonic development. The embryos were also scored for teratogenicity based on several tail and head malformations and edema. The No Observed Adverse Effect Concentration (NOAEC) of the developmental toxicity tests were tested in two immunotoxicity assays with zebrafish embryos. In the first test, the embryos were infected by yolk sac injection with fluorescently labeled *Mycobacterium marinum* and subsequently exposed to the chemicals of interest. At 96 hpf the fluorescence was measured as a proxy for bacterial load. The second immunotoxicity assay measured the migration of neutrophils and macrophages. Transgenic zebrafish with fluorescent neutrophils or macrophages were exposed to the chemicals of interest and their tailfin was amputated at 72 hpf. The number of macrophages and neutrophils at the site of amputation were counted after three hours. A lower number of phagocytes indicates that exposure to the chemical interferes with their migration. As tests for endocrine disruption, agonism, and antagonism toward the estrogen receptor (ER), an ogen receptor (AR) and thyroid hormone receptor (TR) were assessed using reporter gene cell lines. Exposure to nine triazoles showed an antagonistic response toward the AR, with IC50s between 4.2 and 56 µM. Additionally, two triazines showed antagonism toward the AR with IC50s near 100 µM. Seven of the chemicals that antagonized the AR also showed an antagonistic response in the ER, while two others showed an agonistic response in the ER. Result from the *in vitro* toxicity profiling will be calculated into external benchmark concentrations, using QIVIVE models developed by ZeroPM partner Fraunhofer-ITEM. Comparison of these external benchmark concentrations to exposure estimates for PM substances modeled by ZeroPM partner TG Environment, will ultimately result in a risk prioritization tool for PM substances.

1.06.P-Th029 *In vitro* and *in vivo* Experiments to Evaluate the Endocrine Disrupting Toxicity of DEHTP in Relation to the HPG and GH/IGFs Axis

Kijeong Yun[1]*, Inhye Lee*[2] *and Kyunghee Ji*[1]*, (1)Yongin University, Korea, Republic of (South), (2)Occupational and Environmental Health, Yongin University, Korea, Republic of (South)*

Bis(2-ethylhexyl) phthalate (DEHP) is widely known to cause reproductive toxicity and endocrine disruption in animals and humans. In response to the restriction of DEHP, di-2-ethylhexyl terephthalate (DEHTP) has often been used as an alternative. In the present study, adult zebrafish pairs were exposed to various concentrations of DEHTP for 21 d, and the effects on reproduction, sex hormones, and transcription of the genes belonging to the hypothalamic-pituitary-gonad (HPG) axis were investigated. Using the H295R cell line, the potential endocrine disrupting effects of DEHTP were also assessed. The effects on development, growth hormones, and changes in expression of the genes related to growth hormone/insulin-like growth factors (GH/IGFs) axis were investigated after exposure to DEHTP in zebrafish embryos for 96 h. Egg production was significantly decreased at ≥30 µg/L DEHTP, and plasma concentrations of testosterone (T) were significantly increased in female fish. In male fish, however, significant decreases of T were observed along with significant increase of E2 and up-regulation of *vitellogenin* transcript. This observation was consistent with increased E2 and enhanced expression of CYP19 mRNA of H295R cells. Body length and growth hormone levels were significantly reduced when zebrafish embryo were exposed to ≥30 µg/L DEHTP, and transcription of genes related to GH/IGFs axis was significantly downregulated. Our observations showed that exposure to low level DEHTP could affect the feedback circuit of HPG axis and GH/IGFs and impair the reproduction as well as development.

1.06.P-Th030 Screening for the Potential Disruption of the Thyroid or Estrogen-Receptor Signaling Pathway using the Zebrafish Embryo

Andrea Weiner[1]*,* ***Christoph Rummel***[1]*, Oihane Jaka*[1]*, Maria José Mazón*[1]*, Jorge Hurtado de Mendoza*[2] *and Arantza Muriana*[3]*, (1)BBD BioPhenix S.L. - Biobide, Spain, (2)GRIlab, Spain, (3)R&D Department, BBD BioPhenix S.L. - Biobide, Spain*

The plethora of chemical substances and their mixtures pose an increasing risk to human and environmental health. A special cause of concern are endocrine-disrupting chemicals (EDCs) that interfere with an organism's normal functioning of the endocrine system. The main sources of EDCs in surface waters are industrial and municipal effluents that are discharged to the aquatic environment. Of particular interest are estrogenic EDCs (EEDCs) or substances that alter the thyroid signalling pathway due to their deleterious effects on the organism's metabolism, development, and reproduction. There is evidence for the multiple cross-talk between the hypothalamus-pituitary-thyroid (HPT) and hypothalamus-pituitary-gonadal (HPG) axis; however, adequate, cost-effective, and efficient tools are required to screen chemicals and their mixtures as EDCs.

Here, we present a parallel assessment of model substances to identify their potential to disrupt the thyroid- and/or estrogen-receptor signaling pathways by the use of the zebrafish model as a proof of concept. By the use of the transgenic fish lines tg(tg:mCherry) and the tg(cyp19a1b:GFP), zebrafish embryos were exposed to a set of known EDCs to assess the fluorescence levels of the thyroid gland and cerebral structures. By measurements of the reporters that are modulated by the promoter activity of the thyroglobulin or respective cyp19a1b brain aromatase, the enzyme which is responsible for the synthesis of estrogens from androgens, the tested compounds were classified. To identify potential downstream effects of the impaired endocrine system, a new liquid chromatography coupled to tandem mass spectrometry (HPLC/MS-MS) method was developed to quantify the thyroid hormone (TH) levels of T4, T3, 3,5-T2, and 3,3'-T2 in whole-embryo homogenates. Additionally, gene expression analyses for the thyroid- and estrogen-signalling pathway were performed using RT-qPCR applying known markers to assess the transcription levels of thyroid (*tsh*β, *tpo,* and/or *tg*) and estrogenicity-relevant (*vtg*, *esr1*, and/or *esr2a*) genes.

This content screening method improves the screening of chemicals for their endocrine disruption potential and to further characterize their Mode of Action (MoA). The joint assessment of the HPT- and HPG-axis helps to better understand the potential interference of chemicals in this crosstalk and advances the assessment of potential adverse outcomes.

1.06.P-Th031 Transcriptomic Profiling of Clobetasol Propionate Induced Immunosuppression During a TLR-7-Dependent Immune Challenge in Zebrafish Embryos

Benedikt Luckner[1,2]*, Fabian Essfeld*[3]*, Steve Uwa Ayobahan* [3]*, Elke Eilebrecht*[1] *and Sebastian Eilebrecht*[1]*, (1)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany, (2)Eco'n'OMICS, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany, (3)Fraunhofer Attract Eco'n'OMICs, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany*

These days, our environment inevitably has to face increasing pollution with chemicals, their active ingredients, and metabolites. To assess their potential hazard toward nontarget organisms and the ecosystem, the approval of new chemicals is subject to strict regulations and intensive testing. However, currently comprised endpoints do not comprehensively allow the identification and differentiation of modes of action and lack the ability to assess effects on certain biological key mechanisms. For instance, the modulation of the immune system is still neglected, although its adverse impact at the scale of individuals, populations, and whole ecosystems is well confirmed. Reasonably, the complexity of the immune system and the lack of representative biomarkers hinder the development of reliable immunotoxic screening methods. To fill this gap, 'omics techniques represent promising tools, permitting a broad-viewed response analysis at the global level of gene expression from a single sample. With transcriptomic and proteomic analysis of chemically immunosuppressed and immune-challenged zebrafish embryos, our study aims to identify ecotoxicogenomic fingerprints and biomarkers for immune-related modes of action to promote the development of said screening methods. To trigger the desired effects, two pharmaceutical agents, clobetasol propionate (immunosuppressor) and imiquimod (immunostimulator), were used. Implementing imiquimod, an anti-tumoural agent with the potential to undesirably cause psoriasis, this study also aims to provide an alternative system for immunotoxic screening methods, increasing the predictability of immune-related side effects of new pharmaceutical agents in humans, beside its application in the ecotoxicological assessment. So far, pretests with clobetasol propionate have been completed, revealing 250 nM as an appropriate concentration to trigger an immunosuppression in a sublethal manner. Respective experiments for imiquimod are ongoing. With these determinations set, transcriptomic and proteomic profiles of immunosuppressed and subsequently immune-challenged zebrafish embryos will be assessed based on RNA sequencing and LCMS/MS data. Identified differentially expressed genes may serve as suitable biomarkers for an immunotoxicity assessment, while their anticipated implementation to current guidelines in the future will represent an important step toward a more comprehensive environmental hazard assessment.

1.06.P-Th032 Evaluation of the Toxicity of Guanitoxin-Producing Cyanobacteria on *Danio rerio* Hepatocytes Culture (ZF-L)

Larissa Souza Passos[1]*, Fernanda Rios Jacinavicius*[2]*, Vanessa Geraldes*[3]*, Paloma Nathane Nunes Freitas*[3]*, Gabriela Helena Silva*[4]*, Diego Stefani Teodoro Martinez*[4] *and Ernani Pinto*[3]*, (1)University of São Paulo (USP), Brazil, (2)Faculdade de Ciências Farmacêuticas, USP, Brazil, (3)Centro de Energia Nuclear na Agricultura, USP, Brazil, (4)Centro Nacional de Pesquisa em Energia e Materiais, CNPEM, Brazil*

Human actions are increasingly degrading aquatic ecosystems. These alterations can modify the composition of the primary producers, promoting the excessive proliferation of microorganisms, including cyanobacteria. Cyanobacteria can produce secondary metabolites, such as guanitoxin, the only naturally occurring anticholinesterase organophosphate, with a potential effect similar to synthetic insecticides. This study, therefore, investigated the acute toxicity of guanitoxin-producing cyanobacteria *Sphaerospermopsis torques-reginae* (ITEP-024 strain) extracts in hepatocytes of *Danio rerio* (ZF-L cell line). Different concentrations (0, 1, 4, 8, 16, 31.25, 62.5, 125, 250, 500 mg/L) of the ITEP-024 aqueous and methanolic extracts were tested in *D. rerio* for 24 h. We evaluated the viability of zebrafish hepatocytes by the Alamar Blue assay (cytotoxicity indicator). The secondary metabolites produced by the ITEP-024 strain were analyzed by LC-MS/MS. The results showed an interaction between the aqueous extract containing guanitoxin and ZF-L cells, showing an influence on cell viability and being an indicator of cytotoxic effects. The assay proved to be a powerful tool for detecting the impact of cyanobacterial cells on the cell population. The values referring to cell viability showed that the concentration of 500 mg/L presented five times fewer intact cells than the negative control after a 24-h exposure. The $EC(I)50_{24h}$ was 100.2 mg/L. Analysis of LC-MS/MS indicated the guanitoxin presence in the aqueous extract of the ITEP-024 biomass. In conclusion, aqueous extracts of *S. torques-reginae* showed damage in the cell viability of zebrafish hepatocytes. ZF-L cell line toxicity represents the first report on the toxicity of a guanitoxin-producing strain in cellular assays with *D. rerio*. The study contributes new information to the scientific literature on the toxicity of a guanitoxin-producing strain in zebrafish hepatocytes, which has shown promise as a biomarker in ecosystems impacted with *S. torques-reginae*. We showed evidence that guanitoxin monitoring is urgently needed and can be part of the government's public health policy. The toxicity responses alert the biological risk to aquatic fauna of an ecosystem contaminated.

1.06.P-Th033 Are Early Life Stages of Fish Affected by Paroxetine? A Case Study with *Danio rerio*

Carla Ferreira Melo[1]*, Cátia Venâncio*[2]*, Peter Kille*[3] *and* ***Miguel Oliveira***[1]*, (1)University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Aveiro, Portugal, (2)University of Coimbra, Portugal, (3)Cardiff University, United Kingdom*

Paroxetine (PAR) is a selective serotonin re-uptake inhibitor (SSRI) antidepressant that has been increasingly detected in surface waters worldwide raising concern toward potential detrimental effects on nontarget organisms. Therefore, there is the need to understand the potential effects of PAR on fish to increase the knowledge regarding potential environmental impacts. Thus, the present study aimed to assess the short-term effects of PAR (commercial and active ingredient formulation) to early life stages of zebrafish (*Danio rerio*) focusing on lethality, developmental abnormalities, and locomotor behaviour. Organisms were exposed up to 144 h to a concentration range of PAR (40 µg/L to 13500 µg/L) and lethality, morphological abnormalities, as well as swimming activity were assessed. Paroxetine commercial formulation (PAR-c) proved to be more toxic than PAR active ingredient formulation (PAR-a) and the juvenile stage displayed higher sensitivity. Paroxetine induced morphological abnormalities (scoliosis) in a dose-dependent manner, but only from 96 h postfertilization onward, suggesting that PAR toxicity may be related to fully development of the biotransformation system. Moreover, PAR-c exposure (40 µg/L and 400 µg/L) significantly decreased fish swimming activity in both dark and light periods and demonstrated ability to interfere with fish stress response induced by sudden light transitions (dark/light and light/dark). A 21-day period depuration revealed inability to allow full recovery of PAR acute exposed fish. Data highlight the need for more studies regarding effects of PAR to fish.

1.06.P-Th034 The Zebrafish Embryo – An Alternative to Mammalian Teratogenicity Tests in Assessing Effects of Pharmaceuticals?

Katharina Brotzmann *and Thomas Braunbeck, University of Heidelberg, Germany*

Therapeutic drugs represent one of the greatest benefits, but also challenges, to modern society. Via improper disposal, industrial waste, and wastewater treatment plants, pharmaceuticals are increasingly released into natural ecosystems, potentially expressing effects in nontarget organisms. To protect the environment and the health of humans, hazard and risk assessments of these chemicals became mandatory in the registration process and ecotoxicological studies. However, the rapid increase of toxicity tests, which were mostly performed in mammalian model organisms, led to ethical concern in the scientific community and the public. Thus, there is a need for the development and implementation of alternative methods for toxicity and ecotoxicity testing.

In accordance with this, zebrafish (*Danio rerio*) embryos were investigated for the potential to identify mammalian neuro- and liver toxicity induced by the antiepileptic drug valproic acid and up to 14 analogues. For the identification of neurotoxic potencies, substances were tested with the Fish Embryo Acute Toxicity (FET) test; a subsequent comparison of selected FET endpoints to *in vivo* mouse data expressing exencephaly resulted in a good correlation between zebrafish embryos and mice.

For liver toxicity, histological evaluations revealed drug-induced liver alterations. Additional comparisons of the deduced hepatotoxic potency to the molecular structure of each compound led to a structure-activity relationship, which had, so far, only been documented in yeast cells, mosquito larvae, *Xenopus* embryos, mice, rats, and human HepG2 cells. Drug induced accumulation of lipid droplets as a marker of steatosis, however, could not be documented for valproic acid or any analogue, although toxicokinetic analysis revealed an accumulation of the parent compounds in zebrafish embryos.

In summary, although steatosis as an endpoint in liver toxicity could not been seen with the selected substances, a good correlation between zebrafish and mammals could be observed for valproic acid induced neurotoxic effects and the structure-activity relationships based on hepatotoxic potencies. Considering the variety of therapeutic drugs, zebrafish embryos present a versatile tool in the evaluation of toxic and teratogenic potencies of pharmaceuticals in vertebrates.

1.06.P-Th035 Effects of Amitriptyline and Metabolite Nortriptyline on Eye Development in *Danio rerio*

Marwin Jafari[1]*, Jason Tyler Magnuson*[2]*, Katharina Brotzmann*[3]*, Sebastian Eilebrecht*[4] *and Daniela Maria Pampanin*[2]*, (1)Department of Chemistry, Bioscience and Environmental Engineering, Universitetet i Stavanger, Stavanger, Norway, (2)University of Stavanger, Norway, (3)University of Heidelberg, Germany, (4)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany*

Marine ecosystems are exposed to a multitude of different active pharmaceutical ingredients (APIs), of which the nontarget effects on marine biota are not fully understood. The antidepressant amitriptyline has been shown to have the potential to bioaccumulate and to cause long lasting behavioural effects in zebrafish (*Danio rerio*). To better understand the source of these behavioural changes, our study aimed to investigate the effects of amitriptyline, as well as its metabolite nortriptyline, on the eye development of zebrafish larvae. To test the hypothesis that adverse development of the eyes is the source of behavioural changes, a series of endpoints were investigated. Sublethal concentrations of amitriptyline (300, 3.00, and 0.30 µg/L) as well as nortriptyline (300, 3.00 and 0.30 and 0.03 µg/L) were tested and compared against a negative control of culture water, a solvent control of 0.01% DMSO, and a positive control of 3.5 µM phenanthrene. Endpoints include the morphology of the eye at 72 h and 96 h postfertilization (hpf), as well as histology of the eye after 96 hpf. Additionally, expression of genes associated with eye and neuronal development (e.g., *EGR1*, *ptgdsb*, *cryba1a*) will be assessed after 24, 48, 72, and 96 hpf to better understand how these substances may affect early development of embryos and larvae. Preliminary results show a decrease of eye diameter of 1.2% and 0.72% after 72-h treatment with 300 µg/L amitriptyline and nortriptyline, respectively, which was not found to be statistically significant, and a decrease of 4.6% after exposure to phenanthrene, which was statistically significant ($\alpha = 0.05$). At 96 hpf, a significant decrease in eye diameter was measured again when comparing larvae exposed to phenanthrene to those exposed to DMSO (3.1%), but not for groups exposed to nortriptyline or amitriptyline. The fraction of coagulated eggs ranged from 0% to 10%, with no correlation between lethality and concentration, which confirmed that the exposure scenario was within the sublethal range. Although the tested APIs did not show a statistically significant effect on the eye diameter in zebrafish larvae, histology and gene expression analyses will be carried out as those are known to be highly sensitive endpoints compared to physiology.

1.06.P-Th036 Does Light Pollution Affect Zebrafish Embryos Response to Antineoplastic Drugs?

Maria S. Costa[1]*, Carla Quintaneiro*[1]*, Amadeu M.V.M. Soares*[2]*, João L.T. Pestana*[2] *and* ***Marta S. Monteiro***[3]*, (1)Biology, University of Aveiro, Aveiro, Portugal, (2)University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Aveiro, Portugal, (3)CESAM & Biology Department, University of Aveiro, Aveiro, Portugal*

As most of the world's population lives in urban areas, urban aquatic ecosystems are currently subjected to multiple stressors such as light and chemical pollution. Studies dealing with artificial changes in lighting conditions have shown that artificial light at night (ALAN) disrupts biological rhythms and also reduces biological fitness through changes in melatonin levels.

In addition to light pollution, urban aquatic ecosystems are subjected to emissions from hospitals, communities, and industry, increasing concentrations of human pharmaceuticals. As the incidence of cancer increases worldwide, the number of antineoplastic drugs prescribed has also increased exponentially. The immunosuppressant mycophenolic acid (MPA) is one of the most widely used cytostatic drugs due to its successful use in the prevention of rejection of transplanted organs, autoimmune diseases treatment, and angiogenesis inhibition. This drug is considered a priority cytostatic due to its high-volume use, resistance to wastewater treatments, and presence in surface waters (up to 600 ng/L).

Given the ubiquity and co-occurrence of light pollution and antineoplastic drugs, it is critical to evaluate their combined impacts on urban aquatic ecosystems. The mechanistic relationships that determine how changes in lighting conditions affect early life stages of fish and their resistance to antineoplastic agents are currently not understood.

Given the central role played by melatonin, this limitation needs to be addressed. In addition to regulating circadian rhythms, melatonin also regulates antioxidant activity, immune and metabolic and behavioural processes. In this context, this work aims to understand how the exposure to ALAN and the expected change in melatonin levels modulate mycophenolic acid toxicity in zebrafish (*Danio rerio*) embryos. A combination of ecotoxicological approaches were performed with zebrafish embryos, where both ALAN (from light emitting diodes), exogenous melatonin (to counter the expected ALAN-induced reduction of internal melatonin), and sublethal concentrations of mycophenolic acid were manipulated. The parameters analyzed include fish embryo development, heart rate, behaviour, oxidative stress biomarkers, and melatonin levels. The results obtained will allow to what degree ALAN affects zebrafish embryos to be assessed, if exogenous melatonin counteracts ALAN-induced effects, and how ALAN mediates the response of fish to mycophenolic acid exposure.

1.06.P-Th037 Impairment of Sensory Organ Development in Petroleum-Exposed Zebrafish Embryos — Response of the Visual System

Bianca Dechent[1], *Lisa Annie Baumann*[2], *Lisa Gölz*[3], *Constanze Heinzen*[4], *Jakob Pfefferle*[1], *Virginie Lecaudey*[4], *Frederic Strobl*[5], *Henner Hollert*[1] *and Sarah Johann*[6], *(1)Evolutionary Ecology & Environmental Toxicology, Goethe University Frankfurt, Frankfurt am Main, Germany, (2)Environment and Health, VU University, Amsterdam, Netherlands, (3)University of Heidelberg, Germany, (4)Department Developmental Biology of Vertebrates, Goethe University Frankfurt, Frankfurt am Main, Germany, (5)Goethe University Frankfurt, Frankfurt am Main, Germany, (6)Department Evolutionary Ecology & Environmental Toxicology, Goethe University Frankfurt, Frankfurt am Main, Germany*

Crude oil not only serves as an energy source but also forms the foundation for commonly used products such as polymers, chemicals, and pharmaceuticals. Since the demand for these products is rising steadily, also oil exploration and transportation is predicted to increase over the upcoming decades. Consequently, the risk emerging from oil releases to the environment permanently exists. Substances released to the water phase partition rapidly; thus the immediate application of appropriate measures after an oil spill is of high relevance. One of the most abundantly applied methods is the use of chemical dispersants, which are known to increase acute toxicity on exposed aquatic species. Besides the well-examined effects of oil on the cardiovascular system of various fish species, recent studies with zebrafish also found evidence for potential neurotoxicity and, in particular, oculotoxicity. Within this work we address the impact of crude oil and associated dispersants on the visual system in zebrafish and aim to understand underlying mechanisms leading to the observed eye impairment. Zebrafish embryos were exposed to sublethal effect concentrations (EC_{10}) of (I) crude oil, (II) dispersed crude oil, and (III) dispersant for up to 120 h postfertilization (hpf). The eyes of exposed zebrafish larvae were examined for structural and functional impairment. The structural analysis was performed using immunohistology of red-green double-cones in cryosections of larval retina. These photoreceptor cells are known to occur most abundantly in the zebrafish retina and facilitate the evaluation of the thickness of the outer and inner segment. Additionally, immunostaining of the less frequently occurring UV-cone provides information about the composition of the retina. For the investigation of the functionality, we used a transgenic zebrafish line that expresses fluorescent lw2-opsin, which is responsible for longwave red-light detection and expected to occur in high numbers in the zebrafish retina. Opsins form a group of proteins facilitating the phototransduction. To further investigate the impact on the developing sensory system, a set of behavioural endpoints was analyzed in 24, 72, 96, and 120 hpf embryos (spontaneous tail coiling, touch-evoked response, light/dark transition test). Results of the structural and functional analysis will support the further characterization of toxicity pathways of crude oil fractions at environmentally relevant concentrations.

1.06.P-Th038 Impairment of Sensory Organ Development in Petroleum-Exposed Zebrafish Embryos – Response of the Lateral Line System

Alischa Helena Becker[1], *Lisa Annie Baumann*[2], *Bianca Dechent*[1], *Lisa Gölz*[3], *Constanze Heinzen*[4], *Virginie Lecaudey*[4], *Jakob Pfefferle*[1], *Frederic Strobl*[5], *Henner Hollert*[1] *and Sarah Johann*[6], *(1)Evolutionary Ecology & Environmental Toxicology, Goethe University Frankfurt, Frankfurt am Main, Germany, (2)Vrije University Amsterdam, Netherlands, (3)University of Heidelberg, Germany, (4)Department Developmental Biology of Vertebrates, Goethe University Frankfurt, Frankfurt am Main, Germany, (5)Goethe University Frankfurt, Frankfurt am Main, Germany, (6)Department Evolutionary Ecology & Environmental Toxicology, Goethe University Frankfurt, Frankfurt am Main, Germany*

Although we are at a turning point in the transformation of the global energy sector, we continue to observe an increasing demand for crude oil in modern society. Hence, through steadily increasing oil production, consumption, transportation, and rapidly moving exploration, huge and small diffuse oil spills still pose a severe risk to the aquatic environment. Representative for the pelagic community, fish early life stages exposed to crude oils, e.g., during spawning season, were found to be highly sensitive. Recent studies provide evidence that in addition to well-known cardiotoxic effects, neurotoxicity also plays a role. In this respect, impairment of development and functionality of the visual system has been shown. Besides eye development, other sensory organs may be affected by oil exposure. In this context, the aim of the present study was to investigate whether water-accommodated fractions (WAF) of native and chemically dispersed crude oil impact the development of the lateral line system (LLS) of fish. This distant-touch sensory system is involved in a multitude of behavioural traits and consequently crucial for survival. We expected a sensitive response to WAF exposure due to the direct contact of LLS hair cells with the surrounding medium. A set of morphological and behavioural endpoints was examined in the transgenic zebrafish line *cldnb:lyn-eGFP*. Expression of a membrane-localized GFP under control of the claudinb promotor visualizes the lateral line primordium and neuromast cells, facilitating tracing of *in vivo* LLS development. Shortly after fertilization, zebrafish embryos were exposed to different WAFs at sublethal effect concentrations that do not induce visible morphological malformations (EC_{10}). Using confocal laser scanning microscopy, LLS assessment in developing embryos (48 hpf-72 hpf) was conducted by analyzing the number of neuromasts along one side of the embryo's trunk. Potential impairment of neuromast structure was quantitatively investigated by DAPI (nuclei)/DASPEI (hair cells) staining. As an endpoint of developmental neurotoxicity spontaneous tail coiling in 24 hpf zebrafish embryos was investigated. First results indicated a delay in neuromast development, a significantly reduced number of neuromasts, and a significantly reduced spontaneous tail coiling in oil-exposed embryos. Overall, the present results will contribute to a deeper understanding of neurotoxic mode of actions of petroleum exposure.

1.06.P-Th039 Automated Counting, Measuring, and Screening of Zebrafish Embryos
Ines Domingues[1], Bruna Veira[2], Fatima Jesus[1], Amadeu M.V.M. Soares[3], Mário Pereira[4], Rui Martins[1], Miguel Oliveira e Silva[5] and ***Sizenando Nogueira Abreu****[6], (1)University of Aveiro, Aveiro, Portugal, (2)Department of Biology, CESAM, Campus Universitário de Santiago, Portugal, (3)University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Aveiro, Portugal, (4)Department of Biology, University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Aveiro, Portugal, (5)TekenBio, Portugal, (6)CESAM & Department of Biology, University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Aveiro, Portugal*
Zebrafish Embryo Toxicity (ZET) model is increasingly recognised as a highly valuable toxicity testing platform. The ZET assay focuses on the early stages of embryo development and is considered a more humane model compared to adult zebrafish testing. However, these studies often imply the counting and screening of several hundreds of eggs, which is a time-consuming procedure highly subjected to human error. D-Counter (TekenBio) is equipment for automated detection of small organisms (such as daphnids) avoiding laborious manual work, such as counting of organisms. Recently, it has been also tested and validated for counting zebrafish eggs/embryos, a model widely used in ecotoxicology and health sciences. In this work D-Counter was used to study the fecundity of zebrafish couples kept in the University of Aveiro facilities in what concerns number of eggs per batch, viability, and egg size (diameter). Thus, D-Counter was used for i) counting and measuring 2.5 h postfertilization eggs of each batch, and ii) counting discriminately the number of coagulated, nonviable (unfertilized or with abnormal development) and viable eggs in each batch. These parameters were also determined manually using a stereomicroscope and compared to the automated measurements to assess the equipment's accuracy. Results indicate a very good correlation between the equipment and the manual measurements (r^2>0.98). These data will be used to study the correlation between the number of eggs in the batch, embryo size, and embryo viability.

1.06.P-Th040 Answering Environmental Toxicology Questions Through LC-TIMS-HRMS Based Toxicometabolomics of Zebrafish Exposed to Xenobiotics – Lipid Metabolism Under the Spotlight
Dimitrios E. Damalas*[1], Eleni Panagopoulou[1], Adamantia Agalou[2], Dimitris Beis[2] and Nikolaos Thomaidis[1], (1)National and Kapodistrian University of Athens, Greece, (2)Biomedical Research Foundation Academy of Athens, Greece*
Given the large number of xenobiotics, there is an important gap in the literature concerning their adverse effects on aquatic organisms. The impact of xenobiotics in the aquatic ecosystem is evaluated in more depth when the whole metabolome (xenobiotics, their biotransformation products, and endogenous metabolites/lipids) of aquatic organisms is studied. However, there is a clear need in the literature for further information on biochemical perturbations underlying the mode of action of xenobiotics.

Through toxicometabolomics, a broad range of toxic responses can be captured in an untargeted way. Therefore, toxicometabolomic studies involving zebrafish larvae (ZLF) have become increasingly popular for linking apical endpoints to biochemical perturbations (as part of adverse outcome pathways [AOPs] determination). Lipids are important for many biological functions of a living organism such as energy storage and cell signalling and growth, among others, while they constitute the building blocks of membranes. A number of environmental contaminants have been reported to interact with lipid metabolic pathways and can lead to oxidative stress and lipid peroxidation.

Here, we highlight a liquid chromatography-trapped ion mobiliy-high resolution mass spectrometry (LC-TIMS-HRMS)-based untargeted toxicometabolomics workflow that i) measures the full complement of detectable endogenous chemicals in tissue samples from ZFE exposure experiments, ii) points out the altered metabolites/lipids, and iii) provides annotations of high confidence. Exposure of ZFL to triclosan (TCS) is used as an example.
Even though the exposure concentration used in the toxicokinetic experiment did not induce any observable effects, significant changes in the lipidome level were reported. Most of the detected lipids were up-regulated while LPC and PC were the lipid classes with the highest signal increase in TCS exposed samples. An overtime increase of the detected lipids was observed, demonstrating lipid accumulation as a toxicity effect of TCS. These observations can be linked with inhibition of beta-oxidation, peroxisomal stress, and hepatic lipotoxicity. Overall, the considerable breadth and depth of detectable lipids are encouraging for using ZFL and untargeted MS-based lipidomics to probe a variety of responses to environmental exposures as well as for evaluating impacts from individual high priority chemicals. Moreover, the developed toxicometabolomics workflow captures a broad range of toxic responses in an untargeted fashion that would meet the needs of modern environmental toxicology.

1.06.P-Th041 Use of Zebrafish Embryotoxicity and Reprotoxicity Tests to Asesss Environmental Chemicals Effect on Reproduction and Development
Andrea Weiner[1], Mari Paz Gallego[1], Itziar Irrijalba[1], Christoph Rummel[1], Celia Quevedo[1] and ***Arantza Muriana****[2], (1)BBD*

BioPhenix S.L. - Biobide, Spain, (2)R&D Department, BBD BioPhenix S.L. - Biobide, Spain
The ICH S5 (R3) guideline on reproductive toxicology that applies to all pharmaceuticals for which reproductive and/or developmental toxicity studies are appropriate proposes the use of alternative assays as part of an integrated testing strategy to minimize the use of animals. The guide provides a list that contains 29 Reference chemicals that have been shown to induce specific malformation or embryo-fetal lethality plus three Negative Chemicals that can be used to support the sensitivity of an alternative assay.

Our research focused on the predictivity of the zebrafish developmental and reproductive toxicity assays. Zebrafish is a highly popular model in environmental toxicology and provides an ethically acceptable small-scale analysis system with the complexity of a complete organism. This model enables continuous developmental monitoring as well as simple adult testing and has been widely used for the generation of relevant answers on mammalian developmental and reproductive risk assessment and hazard. Our goal is to further validate this model for its use by testing the compounds indicated in the ICH S5 guideline and complementing them with other endpoints. To determine the teratogenic risk of these chemicals, the presence of morphological alterations in zebrafish embryos is analyzed at two different stages and the teratogenic indexes (TI) are established as the ratio between LC50/EC50 for each stage. As this assay is performed in externally fertilized embryos, embryotoxicity is directly analyzed, but reprotoxicity could be studied further evaluating the effect of some of the listed compounds in adult zebrafish males by the *in vivo* sperm quality assessment. In this assay, the development and maturation of gametes is evaluated by assessing the sperm quality (progressive motility, curvilinear velocity, and linearity) by CASA analysis and even expression of specific marker genes (ziwi, sycp3l, and shippo1) by qPCR.

This assay complements the developmental toxicity with the effect on the male reproductive system, having a more accurate evaluation of embryotoxicity and reprotoxicity in the same model, helping to increase the accuracy and sensitivity of the teratogenicity assay by more than 80% and 88%, respectively, compared to mammals; therefore, this is a well-integrated strategy to minimize the use of mammals to predict developmental and reproductive toxicity effects, both in the zebrafish model.

1.06.P-Th042 Offshore Renewable Energy: Toxicity of Metallic Elements Released in the Marine Environment by Anticorrosive Protections in Medaka (*Oryzias melastigma*)
***Mélanie Blanc-Legendre**[1], Christelle Caplat[2], Georges Safi[3] and Xavier Cousin[4], (1)France Energies Marines, Plouzané, France, (2)Sorbonne University, Biologie des Organismes et Ecosystèmes Aquatiques (BOREA) Université de Caen Normandie UNICAEN, France, (3)France Energies Marines ITE-EMR, Plouzané, France, (4)MARBEC, Univ. Montpellier, CNRS, Ifremer, IRD, INRAE, Palavas-les-flots, France*
Cathodic protections such as galvanic anodes (GACPs) are used to prevent corrosion of metallic materials that are immersed in seawater. The exponential development of offshore windmill parks raised questions regarding toxicity of GACP-released metallic elements toward marine organisms. In this study, we exposed medaka (*Oryzias melastigma*) as a model species to (i) the cocktail of elements released from a functioning aluminum-based galvanic anode, or (ii) a solution of aluminum chloride used as a reference. Fish were exposed during their entire life cycle (fertilization up to three month adults). Seven dilutions were prepared to cover a wide range of concentrations. To evaluate toxicity, the following endpoints were monitored: survival, growth, and reproductive output. In addition, several behavioural endpoints were evaluated to assess potential negative effects on exploratory abilities, learning (associative and memory), spontaneous activity, and anxiety. Toxicity key values such as LC50, EC50, No Observed Effect Concentration (NOEC), and Lowest Observed Effect Concentration (LOEC) were calculated for chemical risk evaluation.

Monitoring of elements released by the galvanic anode revealed that fish were exposed to aluminum total concentrations ranging from ~2000 $\mu g\ L^{-1}$ down to ~70 $\mu g\ L^{-1}$. Preliminary results show no acute toxicity (survival, teratogenicity, locomotion) at concentrations $\leq$ 2000 µg/L of total aluminum on early-life stages of medaka (up to 12 d postfertilization). Long-term exposures are still ongoing and the data (available in the beginning of 2023) will be used to refine the chemical risk analysis for aluminum and to define it for GACPs. Overall, the results of this study will serve as a basis to give recommendations to the different stakeholders on the safe use of cathodic protections in future projects related in particular to the development of offshore renewable energy.

1.06.P-Th044 Barrier Function of the Marine Medaka (*Oryzias melastigma*) Chorion
***Jakob Pfefferle**[1], Frederic Strobl[2], Xavier Cousin[3], Henner Hollert[1] and Sarah Johann[4], (1)Evolutionary Ecology & Environmental Toxicology, Goethe University Frankfurt, Frankfurt am Main, Germany, (2)Goethe University Frankfurt, Frankfurt am Main, Germany, (3)MARBEC, Univ. Montpellier, CNRS, Ifremer, IRD, INRAE, Palavas-les-flots, France, (4)Department Evolutionary Ecology & Environmental Toxicology, Goethe University Frankfurt, Frankfurt am Main, Germany*
The marine medaka, *Oryzias melastigma*, has been identified as a promising model species for marine ecotoxicology and shares many advantages for early life stage testing with the well-established freshwater model species zebrafish (*Danio rerio*). Therefore, the standardized Fish Embryo Acute Toxicity (FET) test has been successfully adapted to *O. melastigma* within previous work. To allow a comparison to other model species, different species-specific aspects such as development, metabolism, and sensitivity have to be considered. In this context, the present study focused on the chorion barrier function. The protective role of the chorion as a physical barrier has already been identified as an important factor for the uptake of chemicals and thus the resulting toxicity. As the chorion of medaka is about 10x thicker compared to zebrafish, this might be an indication for an increased barrier function resulting in deviating uptake kinetics. In a first experiment the influence of solvents (DMSO) on

the chorion permeability and thus, the compound uptake, was investigated in *O. melastigma* and *D. rerio* using fluorescent dyes. Our results confirmed previous findings that solvents increase the chemical uptake and supported the hypothesis that the medaka chorion provides a stronger barrier compared to zebrafish. Furthermore, structural properties of the chorion were analyzed using scanning and transmission electron microscopy (SEM, TEM) with particular interest on the property of the pore canals and the overall chorion surface conditions after the commonly applied removal of villi as a pretreatment step within FET. In this context, also the molecular weight as a relevant criterion for chorion passage was evaluated. To identify the molecular weight threshold for the transport of compounds through the pore canals, medaka embryos were exposed to solutions of polyethylene glycols (PEG) with different molecular weights. Solutions were prepared in hyperosmotic concentrations, which caused an immediate loss of fluid and shrinkage of the chorion. Eggs exposed to PEG solution containing glycols < 6000 kDa were able to regain the original shape and equilibrium by uptake of surrounding solution. Hence, the higher molecular weight PEG solutions were most likely not able to pass the chorion. Additionally, an enzymatic dechorionation procedure was optimized to further investigate the role of the chorion and to extend the potential for early life stage testing with the marine medaka.

1.06.P-Th045 Element Accumulation in the Evil-Eye Blaasop, *Amblyrhynchotes honckenii* (Bloch), and its Parasitic Isopod, *Cinusa tetrodontis* Schjödte et Meinert, 1884, in South Africa

Linda Van Der Spuy[1], *Johannes Hendrik Erasmus*[2], *Milen Nachev*[3], *Bjoern Schaeffner*[1], *Bernd Sures*[3], *Victor Wepener*[2] *and Nico Smit*[4], *(1)North-West University, South Africa, (2)Water Research Group, Unit for Environmental Sciences and Management, North-West University, South Africa, (3)Aquatic Ecology, University of Duisburg-Essen, Germany, (4)Biological Sciences, North-West University, South Africa*

Marine Protected Areas (MPAs) conserve fish species and promote the conservation of marine life; however, almost nothing is known regarding potential impacts on conserving marine fish parasites. Despite their importance as key components in ecosystems, marine parasites remain severely understudied. Yet, these organisms can successfully be used as bioindicators to determine the success of conservation interventions, as well as the extent of chemical pollution within specific marine ecoregions. A relatively novel field within ecotoxicology is environmental parasitology, a field that deals with the interaction between parasites, their hosts, and environmental pollution. Recognizing the need for a more interdisciplinary research approach, this study combines parasitology with ecotoxicology to determine the potential of the parasitic isopod, *Cinusa terodontis* Schjodte et Meinert, 1884, of the Evil-eye pufferfish, *Ablyrhynchotes honckenii* (Bloch), as a bioindicator for element accumulation both inside and outside MPAs. The concentrations of Al, As, Cd, Cr, Cu, Mn, Hg, Ni, Pb, Se, and Zn were determined in muscle and liver tissues of both infected and uninfected fish, as well as parasites from Witsand, in close proximity to an MPA, and Mossel Bay, outside an MPA, on the South African temperate coast. Concentrations of Cu, Mn, Ni, Pb, and Zn in *C. tetrodontis* differed significantly between the two sites, where Mossel Bay (outside an MPA) had higher concentrations of Ni, Pb, and Zn. Interestingly, Hg concentrations were higher in samples from Witsand compared to Mossel Bay, with the exception of uninfected liver tissues. The parasitic isopod, *C. tetrodontis*, accumulated significantly higher concentrations of Al, As, Cu, Ni, Pb, Se, and Zn compared to its fish host. In general, infected fish had lower concentrations compared to uninfected fish. Only Cd levels in liver tissues of uninfected fish in Mossel Bay were significantly lower than the levels in infected fish. This study highlights the importance of utilizing this interdisciplinary approach, and the benefits of utilizing parasitic bioindicator species in the management of MPAs and future conservation strategies.

1.06.P-Th046 Hepatic Morphological Acute Damages of Neotropical Fish Exposed to Low Concentrations of Fire Suppression Agents (FSA)

Kainã Rocha Cabrera Fagundes[1], *Felipe Santana*[2], *Maysa Carvalho .*[1], *Denis Abessa*[3] *and Renata Mari*[1], *(1)UNESP- Campus do Litoral Paulista, Brazil, (2)Biological and Environmental Sciences, UNESP- Campus do Litoral Paulista, Brazil, (3)São Paulo State University (UNESP), Brazil*

Fire Suppression Agents (FSA) are used worldwide in firefighting in general. They form a foam covering, thus providing a physical impediment of oxygen and isolating the flammable surface from contact with fire. They also act by cooling the surface of the material, such as the flame retardants. In 2015, fuel tanks of the Petrochemical Terminal of the Santos Harbor caught fire and thousands of FSAs were used and reached the Santos estuary. Therefore, this study aimed to evaluate the histopathological effects of different FSAs in hepatic tissue of neotropical fish. For this purpose, three brands of FSAs were tested: Ageo (A), Cold Fire (C), and F500 Fire (F). The *Poecilia reticulata* (guppy, animal model) were acclimatized and maintained at 25ºC±2 ºC, under constant aeration with photoperiod of 12h:12h light:dark and salinity of 14. They were fed daily *ad libitum* with Alcon Basic®. Twelve specimens were used for different brands and concentrations. The groups were: control (CTL), concentrations 0.1% (I), 0.001% (II), and 0.00001% (III) in duplicate in 5 L aquariums for each treatment for 96 h. Then, the animals were euthanized, the livers were collected, and they were submitted for the histological routine; 5 µm cuts were stained with hematoxylin-eosin (HE) and Masson′s Trichrome (MT). The concentration I was lethal in all treatments, making the analysis unfeasible. Survival occurred at concentrations II and III only for Ageo, and for Cold Fire and F500 Fire at the lowest concentration (III). The CTL group livers showed normal parenchymal morphology. In the treatment with Ageo, the livers showed hypertrophy of blood vessels and venous congestion, in addition to sparse vacuolation of hepatocytes. At the lowest concentration, both the Cold Fire and F500 Fire brands showed hemorrhage and a few lymphocytes were found associated with the hemorrhage centers and the vessel branches in the parenchyma. In addition there was necrosis associated with blood vessels. The predominance of vacuolated cells throughout the hepatic parenchyma, filled with mainly water, indicated acute edema caused by the chemical lesions by the FSAs, resulting in necrosis. We concluded that all FSAs used in the test led to acute morphological responses in all concentrations, without any inflammatory response. The lethality was at morphological level with any possibility of biochemical, immune, and physiological responses, as already described in previous studies by the other authors.

1.06.V Fish Model Species in Human and Environmental Toxicology

1.06.V-01 Neurotoxic Effects by Bifenthrin Exposure in Zebrafish

***Sangwoo Lee**, Kojo Eghan and Woo Keun Kim, Korea Institute of Toxicology (KIT), Korea, Republic of (South)*

Bifenthrin, a pyrethroid insecticide, is used to treat various crops. Bifenthrin consequently has the potential to disrupt both terrestrial and aquatic populations since its effects are propagated across invertebrate life stages and generations, trophic levels in aquatic food webs, and ecological barriers to riparian food webs. In spite of this, studies of bifenthrin in aquatic organisms are lacking.

Wildtype (WT) and transgenic (TG) [*Tg(elavl3:EGFP)* and *Tg(mbp:mGFP)*] zebrafish were exposed to 0, 0.1, 1, 11.1, 33.3, 100, and 300 µg/L for 120 hpf. Phenotypic assessments including hatching rates, survival, normal development, tail coiling and touch evoked responses, body length, and weights were undertaken from 24 hpf. Furthermore, at 120 hpf brightfield images were taken for the WT zebrafish, and fluorescence imaging was done for the TG lines. Genes related to autism and developmental neurotoxicity were also screened. Zebrafish at 120 hpf was also monitored to track its locomotor activity.

After 72 hpf, the 100 µg/L and 300 µg/L exposure group started showing signs of abnormal development, and this was evident in their body lengths, too. Moving duration, distance moved, body contact, and proximity were all significantly affected by bifenthrin exposure. Also, three genes related to autism were significantly affected; nine genes screened for developmental neurotoxicity were all significantly affected. Neurogenesis and myelination processes were disrupted as seen through fluorescence imaging with the TG lines. Both phenotypically and genotypically, zebrafish systems are significantly distressed by bifenthrin.

From the results obtained so far**,** zebrafish establishes itself as an excellent alternative model for neurotoxicity testing, hereafter, bifenthrin's neurotoxicity on zebrafish is found.

1.06.V-02 Development of a Toxicity Fingerprinting System to Identify Developmental and Acute Neurotoxicants in Larval Zebrafish

***Nadia Katherine Herold**[1], David Leuthold[2] and Tamara Tal[3], (1)Bioanalytical Ecotoxicology, Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany, (2)Chemicals in the Environment Research Section, Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany, (3)Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany*

Exposure to an increasing number of environmental chemicals has been associated with acute neurotoxicity (ANT) or developmental neurotoxicity (DNT) in humans. The majority of chemicals in commerce have not been evaluated for ANT/DNT because of a lack of next-generation toxicity tests. We developed an 11-endpoint behavioural battery to assess ANT/ DNT in larval zebrafish. This new approach method (NAM) contains endpoints for the light-dark transition test, acoustic and visual startle responses, habituation learning and potentiation, and memory retention. This work describes the ongoing development of a toxicity fingerprinting system that can be used to identify potential underlying mechanisms by which exposure to environmental chemicals causes ANT/DNT. To build acute neurotoxicity fingerprints, 5-d postfertilization (dpf) zebrafish were exposed to compounds (0.8 µM–120 µM) that target neurodevelopmental receptors including the GABA-B (CGP13501), NO-cGMP (ODQ), and NMDA (MK-801) receptors for 60 min before behaviour was assessed. Acute behavioural fingerprints for the toxicologically relevant receptors PPARa (GW7647) and PPARγ (T0070907) were generated. Compounds previously described to be nontoxic to the developing nervous system in human *in vitro* assays were also assessed (fluconazole, sodium benzoate, sodium saccharine hydrate) and all fingerprints were generated relative to the vehicle control (0.4% DMSO). In line with human *in vitro* DNT data, acute exposure to fluconazole, sodium benzoate, or sodium saccharine hydrate did not alter swimming behaviour. These compounds were classified as negative control chemicals for the zebrafish ANT assay. Exposure to the remaining chemicals produced a wide array of toxicity fingerprints comprised of chemicals that caused decrements in habituation learning (MK-801) or changes in the visual (GW7647, CGP13501, T0070907, ODQ) and/or acoustic startle (GW7647, CP-673451, ODQ, CGP13501, T0070907) response, with varying directionality. Future work will expand the acute fingerprinting system to cover additional neurodevelopmental and toxicological pathways. In summary, this work deployed a novel zebrafish NAM to generate acute toxicity fingerprints. In the future, the same strategy will be applied to generate DNT fingerprints. Ultimately, the ANT/DNT fingerprinting system will be deployed to identify potential mechanisms by which environmental chemicals cause neurotoxicity outcomes using a 3R compliant, alternative test system.

1.07.P Freshwater and Marine Harmful Algal Blooms (HABs): The Detection, Fate, Effects, Monitoring, and Management of Blooms

1.07.P-Th047 Raman Spectroscopy and Structural Analysis of Cyanobacteria and Harmful Algal Blooms

***Christoph Wetzel** and Bernhard Roth, Leibniz University Hannover, Hannover Centre for Optical Technologies, Germany*

Cyanobacteria, also known as blue-green algae, represent the majority of harmful algal blooms which can appear in marine or fresh water. The presence of such algal blooms is a problem for bathing lakes as well as drinking water or food production in general. The reason for this is that the cyanobacteria are capable of producing cyanotoxins which can be harmful and potentially even lethal to humans, animals, and aquatic life. In principle, by simple visual inspection of the bloom, it cannot be determined whether an algal bloom is harmful to the environment or not. Currently, to assess the type and toxicity level of algal blooms laboratory-based analytics are used which is time consuming and also cost intensive. Thus, fast and ideally real-time as well as reliable and highly sensitive concepts for the analysis of algal bloom in aqueous environment are required.

Generally, Raman spectroscopy, also known as fingerprint spectroscopy, is capable of analysing the structure of algae and bacteria noninvasively, label-free, and without physical contact. The technique delivers molecular information of the content of biological samples and, therefore, enables a fast differentiation and determination of algal or bacterial cells.

In this work, we present a concept based on Raman spectroscopy and imaging to study, analyse, and quantify harmful or toxic cyanobacteria or algae from liquid samples. To demonstrate the capability of our approach, we investigate different species of cyanobacteria and show that on the basis of the acquired Raman spectra, a detection of harmful algae and cyanobacteria is possible. Raman measurements are performed in the visible wavelength range using an in-house measurement setup. To obtain structural information from the inside of the cells, the cells need to be bleached prior to the analysis and processing of the Raman spectra.

Consequently, processed Raman spectra, recorded from such samples, deliver information about the structural components and also about the cell composition.

We will present the experimental Raman setup developed for the studies and show our latest results on the reliable assessment of harmful cyanobacteria and algae. Also, we discuss next steps to automated real-time measurements and monitoring.

1.07.P-Th048 Monitoring Cyanobacteria Levels in Recreational Waters: Success with STEM in a Community Sailing Program
Dana Norton[1]*, Gary C du Moulin*[2]*, Leonardo Parodi Ambrose*[3]*, Connor Quigley*[1]*, Anna Lena Leutiger*[1]*, Charles Zechel*[1] *and Yakira M Becker*[4]*, (1)Community Boating Inc., Boston, (2)Quality Systems and Compliance Strategies, (3)Boston University, (4)Northeastern University* Harmful algal blooms (HABs) are becoming more common in urban waterways due to human influences. Harmful algal blooms are elevated levels of algae and bacteria in an aquatic environment and can negatively affect local ecosystems and human health. Cyanobacteria is photosynthetic bacteria that releases toxins called cyanotoxins that are harmful to human health and a common species for HABs in the lower basin of the Charles River in Boston, MA, USA. Community Boating (CBI) offers direct access to the Charles River for thousands of people, increasing potential for exposure to cyanobacteria HABs. This research aims to track development and dynamics of cyanobacteria population within CBIs operational area, assist government agencies in tracking trends due to climate change and current land use practices, and assess waterbody/human health vulnerability. A graduate toxicology student and a professional microbiologist oversaw junior sailors to teach scientific methodologies including sample collection and microscopic analysis for this project. Samples were collected in two locations: Longfellow Bridge area (depth ~33 feet), where most sailing activities occur, and the Mooring field (depth ~6 feet), where watercraft are launched. Each site was sampled with a 3-meter-long plankton net pull with a 50-µm mesh net and a 3-meter-deep integrated tube sample.

Approximately 200 samples were collected at consistent times each day by boat. Samples were processed using fluorometry and microscopy to determine cyanobacteria density and speciation. Surface water temperature, air temperature, GPS coordinates, and time were recorded for each sample. Phycocyanin, which represents the presence of cyanobacteria, was found to be between 25 mg/L and 100 mg/L at the Longfellow Bridge and 50 mg/L to 100 mg/L at the Mooring field. There were no HABs reported during the time of testing. This study happened in severe drought conditions; therefore runoff and combined sewer overflows (CSOs) had little or no impact in contributing pollutants. The lack of CSOs during this summer's investigations provided insights into the natural presence of cyanobacteria without the complicating component of excess pollution. Cyanobacteria bioconcentration in the Charles peaks in July as a potential result of longer daylight hours and increase in nutrients. This study provides valuable input into further investigations that can provide guidance to stewards of the river environment as well as enhance the safety of river recreation.

1.07.P-Th049 Development of a *Microcystis aeruginosa* Culture Method to Produce Sufficient Amounts of Microcystin to Conduct Multispecies Acute and Chronic Toxicity Tests
James M. Lazorchak[1]*, Susanna DeCelles*[2]*, Alex Kascak*[2]*, Sarah Goodrich*[3]*, Toby Sanan*[4]*, Jingrang Lu*[4] *and Ian Struewing*[4]*,*
(1)Office of Research and Develoment, US Environmental Protection Agency, (2)Pegasus co US EPA Cincinnati, (3)Pegasus c/o US EPA ORD Cincinnati, (4)US Environmental Protection Agency
There is a lack of information to estimate safe exposure levels of toxins produced by cyanobacteria to freshwater aquatic life. The uncertainty in concentrations and purity of standards for cyanotoxins and their costs present a challenge for conducting acute and chronic toxicity tests. To address this, different approaches to culture cyanobacteria for toxicity assessments were compared. Microcystin-producing *Microcystis aeruginosa* (with *mcy* genes confirmed by qPCR and RT-qPCR) was used in these cultures. Toxins were collected by removing cells from culture media by centrifugation and then lysing the cells by freeze thawing them three times. Initial culture efforts using 2-L to 80-L cultures grown for similar periods (~150 days) in BG11 media resulted in a range of cell densities ($3.7\text{-}4.4 \times 10^6$ cells/mL) and consequently a range in total microcystin concentrations (37-73 µg/L) of the lysates. Another method using a different culture volume (eight flasks of different ages combined into 21 L), similar age of culture (~150 days), and a cell density of 1.7×10^6 cells/mL, resulted in a microcystin concentration of 885 µg/L. This culture volume was repeated and resulted in a cell density of 1.4×10^6 cells/mL and a microcystin lysate concentration of 426 µg/L. Due

to the apparent variability in toxin yields, an approach was taken to grow *M. aeruginosa* cultures specifically up to a stationary phase in 250-mL and 1-L flasks. However, final toxin concentrations from the cell lysates were too low to be suitable for adequate aquatic toxicity testing, with microcystin concentrations of only ca. 25 µg/L. A final method developed using an aerated culture under nutrient replete conditions with lower temperature and illumination in two carboys containing 14 L culture media in each, resulted in a 28-day cell density of 9.5 x10^6 cells/mL and a concentrated lysate microcystin concentration of 9400 µg/L. This culture method was repeated two additional times and resulted in cell densities of 2.6 x 10^7 cells/mL (28 days) and 2.5 x 10^7 cells/mL and 2.3 x 10^7 cells/mL (21 days). Large batch culture acute toxicity tests resulted in LC50s of 528 µg/L for *Ceriodaphnia dubia*, 892.6 µg/L for *Daphnia magna*, and 892.6 µg/L for *Neocloeon triangulifer*. For chronic tests, IC25s for the small batch cultures for total microcystins for *C. dubia*, *Pimphales promelas*, *Hyalella azteca*, and *N. triangulifer* were 8.9, 74.0, 408.9, and 10.1 µg/L, respectively. Additional results will be presented.

1.07.P-Th050 Effects of Binary Mixtures of Cyanotoxins and Xenobiotics on the Growth Rate of the Freshwater Algae *Chlorella vulgaris*

*Carlos Pinheiro[1], Joana Azevedo[2], Alexandre Campos[2], Vitor Vasconcelos[2] and **Susana Loureiro**[1], (1)CESAM & Department of Biology, University of Aveiro, Aveiro, Portugal, (2)University of Porto, Interdisciplinary Centre of Marine and Environmental Research (CIIMAR), Portugal*

Aquatic organisms are constantly exposed to several natural and anthropogenic contaminants such as cyanotoxins, metals, and pesticides in eutrophic brackish and freshwaters mainly due to toxic cyanobacterial blooms and human activities. However, the environmental risk of their combinations with the aquatic environment is still unknown. The present study aimed to investigate the growth response of *Chlorella vulgaris* exposed for seven days to four single-chemical compounds (microcystin-LR, cylindrospermopsin, terbuthylazine, and cadmium) and five binary mixtures. In the single-chemical exposures, terbuthylazine was the most toxic to *C. vulgaris*, followed by cadmium, cylindrospermopsin, and microcystin-LR, which was the least toxic. The MIXTOX tool was used to compare the obtained data from the laboratory experiments with the predicted data generated by the conceptual model for independent action based on individual toxicities. Deviations for synergistic/antagonistic interactions, dose ratio, and dose level dependency were also tested for the best data fit. Several response patterns were obtained in the mixture exposures depending on the mixture. Antagonism was the prevailing interaction between the chemical compounds in a 4-d exposure period, while dose level dependency was the only deviation obtained in a 7-d exposure period. In the case of dose level dependency, synergism at low doses of each chemical compound was observed in three of the five tested binary mixtures. This synergistic effect represents a significant risk for aquatic organisms simultaneously exposed to cyanotoxins and anthropogenic contaminants in the environment.

1.07.P-Th051 Nutrient Limitations and Differential Gene Expression of *Prymnesium parvum* Throughout Growth Curve

***Shisbeth Danyra Tabora Sarmiento**[1], Reynaldo Patino[2] and Gregory Mayer[1], (1)Environmental Toxicology, Texas Tech University, (2)Biological Sciences and Natural Resources Management, US Geological Survey*

Anthropogenic activities are known to imbalance the nutrient cycle in environmental systems. *Prymnesium parvum* is an algal species known to produce harmful algal blooms that are responsible for numerous fish kill events worldwide. Some studies have advanced our knowledge of *P. parvum* toxin production; however, the genetic underpinnings of toxin production still need clarification. This study aims to provide a detailed transcriptomic analysis of *P. parvum* throughout its growth phase during natural conditions and during pesticide exposures to determine if pesticides can alleviate stress-related responses, as suggested by prior studies. The hypotheses for this study are (1) expression of genes required for *Prymnesin* synthesis will increase throughout *P. parvum* growth phase as toxicity increases, (2) decreased nitrogen and/or phosphorus increases *P. parvum* toxicity, and (3) glyphosate (and its metabolite AMPA) help compensate for nitrogen and phosphorus depletion. For this investigation, *Prymnesium parvum* cultures were maintained in a modified UTEX artificial seawater medium [ASM]. RNA was extracted from three replicates at three different growth phases, analysed for integrity, and sequenced. Nutrient levels were recorded throughout the growth phase, and separate cultures maintaining a constant balance were used for further analysis. To determine toxicity of the *P. parvum* culture, *Daphnia pulex* were exposed to *P. parvum* at concentrations typically found during toxic blooms. Modified UTEX ASM was spiked with environmentally relevant concentrations of glyphosate and AMPA, and RNA extractions and toxicity tests were followed as previously described. Results of toxicity tests from *Daphnia pulex* exposed to *P. parvum* showed increased toxicity throughout the growth curve, with average mortalities of 75% (early exponential), 95% (late exponential), and 100% (late stationary). Preliminary results of RNA sequencing showed differences in gene expression across the growth curve. This research will advance our knowledge of *P. parvum* toxicity mechanisms, thus improving detection and management strategies to reduce toxic bloom frequency and intensity.

1.07.P-Th052 Widely Used Herbicide Promotes Toxigenic Cyanobacterial Growth and Decreases the Reproductive Output of its Parasitic Fungi

***Erika Berenice Martinez Ruiz**[1], Ramsy Agha[2], Stephanie Spahr[3] and Justyna Wolinska[2], (1)5, Leibniz Institute of Freshwater Ecology and Inland Fisheries (IGB), Berlin, Germany, (2)Leibniz Institute of Freshwater Ecology and Inland Fisheries (IGB), Berlin, Germany, (3)Ecohydrology and Biogeochemistry, Leibniz Institute of Freshwater Ecology and Inland Fisheries (IGB), Berlin, Germany*

Metolachlor (MET) is a widely used herbicide. It negatively affects phytoplanktonic nontarget organisms, such as cyanobacteria, by inhibiting their growth and photosynthetic activity.

Chytrids are zoosporic fungi ubiquitous in aquatic environments that parasitize cyanobacteria and consequently keep their growth in check. To date, little is known about the effect of pollutants on chytrids infections and, consequently, about the ecological processes associated to these parasite interactions. Traditionally, ecotoxicological tests have focused on the single-species level. However, it is pivotal to understand how pollutants affect ecological interactions between species, like host-parasite interactions. Therefore, we tested the effect of environmentally relevant concentrations of MET on the interaction between the toxigenic cyanobacterium *Planktothrix agardhii* and its chytrid parasite *Rhizophydium megarrhizum*.

Cyanobacteria growth was higher in the uninfected treatment at 10 $\mu g\ L^{-1}$ and 100 $\mu g\ L^{-1}$ MET than in the control. Thus, MET might promote cyanobacterial bloom formation. Prevalence and intensity of infection were not affected by MET exposure, suggesting chytrids could control cyanobacterial growth promoted by pollutants. However, after 7 d of exposure to the highest MET concentrations, chytrid sporangia were smaller, which may imply a negative effect on the chytrid at longer exposure times. This study shed light on how widely used anthropogenic pollutants could favour cyanobacterial bloom formation. Moreover, it suggests that parasitic chytrid infections might help to control cyanobacterial growth even in polluted environments.

1.07.P-Th053 Response of a Coastal Amphipod to Single and Binary Exposures of a Toxic Seaweed and a Dinoflagellate
Tiago Filipe da Silva Simoes[1]*, Ariana Borges Moutinho*[1]*, Hugo R. Monteiro*[2]*, Helena David*[3]*, Ana Amorim*[3]*, Sara Novais*[4] *and Marco F.L. Lemos*[1]*, (1)Polytechnic of Leiria & MARE, Portugal, (2)University of the Azores, Biotechnology Centre of Azores (CBA), (3)MARE – Marine and Environmental Sciences Centre / ARNET – Aquatic Research Network, University of Lisbon, Portugal, (4)Instituto Politécnico de Leiria, Portugal*
Global environmental changes have been associated with the proliferation of potentially harmful algae species (HABs) in coastal ecosystems, which may release high concentrations of toxic compounds, which can be harmful to inhabiting biota and present ecological consequences to the aquatic ecosystem. *Asparagopsis armata* is a bloom-forming red seaweed that produces an array of organohalogens, with considerable toxic potential to other aquatic organisms. *Ostreopsis* cf. *siamensis* is a potentially harmful dinoflagellate for which very little is known about its toxins and toxicity. This study aimed to evaluate the ecotoxicological influence of these two distinct benthic species in the representative invertebrate of coastal environments, *Echinogammarus marinus*. To this end, the amphipod juveniles were exposed to a gradient of macroalgae exudate dilutions (0 to 16%) and live microalgae densities (0 to 14,566 $cells.mL^{-1}$) to evaluate survival after acute exposure (48 h). LC50 values were estimated at 5.84% exudate and 452 microalgae $cells.mL^{-1}$, respectively. Then *E. marinus* juveniles were exposed to sublethal (LC10) concentrations of the stressors, isolated, and mixed, using a simple experimental design. After exposure (48 h), organisms were left to recover during 24 h in a clean medium and were transferred to a medium with *Fucus* sp. Seaweed exudate (food stimulus), and their motility was tracked during 30 s. Motility in amphipods was more affected by *O.* cf. *siamensis* LC10 than the equitoxic concentration of the exudate from *A. armata*, with an average total distance of about 3.6 times less than the exudate, and 6.8 times less comparatively with control treatment. Exploration rates and frozen events (alive but immobilized) followed the same trend. Combining equitoxic levels of stressors in the same exposure resulted in the same motility effects as those observed for the isolated exudate. Moreover, combining *O.* cf. *siamensis* LC20 and *A. armata* LC10 resulted in increased motility, almost reaching the observed in the control treatment. Overall, the present work came to demonstrate that both algae species are toxic to other organisms, but also suggests that, depending on their densities in the environment, *A. armata* and *O.* cf. *siamensis* may neutralize each others′ toxic effects in the environment.

1.07.P-Th054 Toxicity of *Ostreopsis* cf. *siamensis* and *Prorocentrum lima*: Effects in the Coastal Amphipod *Echinogammarus marinus*
Ariana Borges Moutinho[1]*, Hugo R. Monteiro*[2]*, Jadilson M. Damasceno*[1]*, Helena David*[3]*, Ana Amorim*[3]*, Sara Novais*[4]*, Marco F.L. Lemos*[1] *and* ***Tiago Filipe da Silva Simoes***[1]*, (1)Polytechnic of Leiria & MARE, Portugal, (2)University of the Azores, Biotechnology Centre of Azores (CBA), (3)MARE – Marine and Environmental Sciences Centre / ARNET – Aquatic Research Network, University of Lisbon, Portugal, (4)Instituto Politécnico de Leiria, Portugal*
Benthic harmful algal blooms (BHABs) have been associated with negative impacts in coastal waters, primarily through the production of toxins that affect marine communities and the trophic web. The benthic dinoflagellates *Ostreopsis* cf. *siamensis* and *Prorocentrum lima*, which occur in temperate marine waters and may give rise to BHABs, have been studied in recent years. However, gaps persist regarding the underlying mechanisms of BHAB toxicity on many invertebrates of estuaries and marine coastal areas. This work aims to evaluate the lethal and sublethal effects of the harmful dinoflagellates *O.* cf. *siamensis* and *P. lima* on juveniles of the amphipod *Echinogammarus marinus,* and infer about possible pathways of toxicity in this macroinvertebrate. Juveniles were exposed during 48 h to a range of microalgal densities, and acute toxicity thresholds were estimated for survival and immobilization. The ability of recovery from sublethal exposures was assessed after a 24-h period in a clean medium, and endpoints of motility were measured (average speed and total distance). Mechanisms of toxicity were analysed with biochemical biomarkers of neurotransmission (AChE), detoxification response (GST), oxidative damage (LPO), and energy metabolism (ETS and LDH/IDH). A decrease in survival of *E. marinus* juveniles occurred with increasing microalgal densities, comparing with the controls (0 cells/mL). Effects were more pronounced with *O.* cf. *siamensis* for both 24 h and 48 h (LC50 = 6520 and 2143 cells/mL, respectively) than with *P. lima*, for which LC50 values were estimated to be > 241 800 cells/mL. After 24 h, juveniles exposed to *O.* cf. *siamensis* were less responsive to stimulus than those in contact with *P. lima* (EC50 = 1844 vs. > 241 800 cells/mL). This trend continued after 48 h (EC50 = 664 vs. 111 851 cells/mL). After exposure at sublethal dinoflagellate densities, juveniles did not fully recover their motility: the average speed registered was significantly lower than in control treatments. These observations suggest a more prolonged toxic effect. In view of these results, and based on preliminary analyses, changes at the biochemical level may occur, particularly in the energy metabolic pathway and in mechanisms of the cholinergic

system. Overall, this work puts in evidence the noxious effects of harmful microalgae species on the gammarid here tested, which may translate into potential consequences for the coastal trophic web dynamics.

1.07.P-Th055 Adaptation Responses of the Cyanobacteria *Halomicronema metazoicum* to Consequences of Climate Change Scenarios
Silvia Simonetti[1], *Patrizia Romano*[1], *Maria Cristina Gambi*[2], *Valerio Zupo*[3] *and Ilaria Corsi, PhD*[1], *(1)University of Siena, Italy, (2)National Institute of Oceanography and Applied Geophysics, Trieste, Italy, (3)Stazione Zoologica Anton Dohrn (SZN), Italy*
Marine communities are nowadays exposed to multiple stressors and to rapid changes in their natural environment. Altogether, such stressors could impact single taxa up to populations with consequences on biodiversity and ecosystem functions. Ocean acidification (OA) is considered one of the major threats of climate changes and may have awful consequences on marine life. The rise in carbon dioxide ocean absorption alters the seawater chemistry leading to surface pH fall and influencing the chemistry of toxic compounds with consequences that have been overlooked. Despite the seriousness of such changes certain species have been found to be able to deal with and tolerate naturally acidified conditions in their natural habitats. Understanding the mechanisms at the base of this resistance could provide useful insight on how marine organisms will respond to multiple stressors in a climate changing scenario. Recent studies have underlined the implication of ATP-binding cassette (ABC) transporters in acid stress response of some Cyanobacteria strains. Here we investigated the potential involvement of ABC in the resistance to low seawater pH (range 7.7-6.5) in the marine cyanobacterium *Halomicronema metazoicum* collected from a natural acidified marine area (Ischia Island, Italy). *Halomicronema* mattes have been exposed to low-pH conditions simulating OA scenarios (7.7, 7.2, 6.5) for 30 days and the expression of ABC-like gene *slr2019* at two time points (7 d and 30 d) have been assessed. All mattes were alive after 7 d and 30 d of exposure and an upregulation of *slr2019* gene has been found at pH 7.7 after 7 d while no gene modulation has been observed at lower pHs (7.2 and 6.5). An hormesis response to decreasing pH values could be hypothesized, being characterized by a rise at lower doses and a decrease with increasing low pH conditions. Such a trend suggests the involvement of ABC response to slightly low pH conditions but possibly being ineffective at lower pHs. Preliminary results show that *H. metazoicum* is able to tolerate low-pH environments and the potential involvement of ABC proteins in acid stress resistance. More research investigating cellular and molecular mechanisms behind adaptive responses to OA could help to predict the consequences of future predicted changes on marine communities and the response of natural population to multiple stressors scenarios.

1.07.P-Th056 Control of Harmful Algae by Infochemicals Derived from *Daphnia* According to Water Temperature and *Daphnia* Species
Gwiwoong Nam, *Gersan An and Jinho Jung, Korea University, Korea, Republic of (South)*
Harmful algal blooms (cyanobacterial blooms) have been increased due to eutrophication and global warming. Cyanobacteria can negatively affect the environment by releasing toxins such as microcystins causing serious toxic problems. As primary feeders of cyanobacteria, *Daphnia* can control cyanobacteria by direct control such as feeding and indirect control such as release of infochemicals. In this study, we focused on the *Daphnia*-derived infochemical and investigated the control of cyanobacteria using *Daphnia*-derived infochemical. Using infochemicals from *Daphnia magna* (international standard species) and *Daphnia galeata* (domestic species), experiments were performed on *Microcystis aeruginosa* (1.00×10^6 cell mL^{-1}). Colony formation, growth rate, reactive oxidative stress (ROS), extracellular, and intracellular microcystin-LR of *Microcystis aeruginosa* were observed over 15 days of exposure. *Microcystis aeruginosa* control effects were confirmed in both species, but *Daphnia galeata* infochemical showed better control ability than *Daphnia magna* infochemical despite its small body volume.

1.07.P-Th057 Graphene-Mediated Removal of Cyanotoxins for Water Security
Jesse L. Roberts, *Sarah Grace Zetterholm, Chris S. Griggs and Angela Evans, Environmental Laboratory, US Army Engineer Research and Development Center (ERDC)*
Cyanobacterial toxins such as microcystin-LR (MC-LR), anatoxin-a (ATA), and saxitoxin (STX) represent a global environmental threat to ecosystems and drinking water supplies. Here we show the direct use of graphene as a rational interface for removal of MC-LR via interactions with the aromatic ring of the ADDA chain of the MC-LR toxin and the sp-2 carbon network of graphene. Mesoporosity of graphene is ideal for larger molecules and provided significant enhancements to both adsorption capacities and kinetics when benchmarked against microporous granular activated carbon (GAC) for the adsorption of all three cyanotoxins (MC-LR, ATA, and STX). Graphene showed superior adsorption capacity of 75.4 mg/g experimental, and 131 mg/g extrapolated for removal of MC-LR compared to 0.982 mg/g experimental and 0.973 mg/g extrapolated for GAC. Sorption kinetic studies showed graphene adsorbs 99% of MC-LR (1.6 mg/L) with pseudo-second-order kinetics in 30 min, compared to zero removal observed for GAC at 24 h at the same mass and concentration. Although noncovalent interactions typically rely on computational methods for mechanistic insight, nuclear magnetic resonance (NMR) titration was used to probe primary interactions between graphene and MC-LR adduct. With increasing graphene, the aromatic 7.2 ppm adduct peak broadened while aliphatic peaks remained sharp indicating interactions between the aromatic ring on MC-LR and graphene sp2 orbitals are a dominant interaction. With rapid kinetics and adsorption capacities two to three orders of magnitude higher than GAC, it is anticipated that graphene will offer a novel molecular approach for removal of toxins and emerging contaminants with aromatic systems.

1.08 Long-Term and Multigenerational Impacts from Early-Life Exposure to Contaminants

1.08.T-01 Metabolic and Developmental Alterations in Fish Exposed to Waterborne Environmental Contaminants
Hamid R. Habibi, *Department of Biological Sciences, University of Calgary, Calgary, Alberta, Canada*
Studies in our group and investigators demonstrated the presence of many environmental contaminants in the water samples collected from three rivers in Southern Alberta, Canada. We detected synthetic estrogens, industrial chemicals, and pharmaceuticals close to the municipal area and natural hormones, pesticides, and herbicides in the agricultural areas. Significant increases in the female-to-male ratio and developmental abnormalities were observed in fish populations, linked to contaminants with hormone-like activity. To investigate the mechanisms underlying the adverse impacts of contaminants, we performed controlled laboratory experiments in which fish were exposed to environmentally relevant concentrations of some chemicals detected in the water, individually and in a simple mixture. We provided evidence that the adverse effects of contaminants are synergistic rather than additive when present in a mixture. Our results also provide evidence that exposure to environmental contaminants adversely affects the hormones of the brain–pituitary–gonadal axis, as well as inducing changes in lipid, amino acid, energy, carbohydrate, nucleotide, and cofactor/vitamin metabolism in the brain, liver, and testis of fish. The use of the microarray approach demonstrated significant changes in several canonical pathways, including cell cycle and proliferation, inflammatory, innate immune response, stress response, and drug metabolism. We observed developmental abnormalities following exposure to Bisphenol-A (BPA), phthalates, sulfolane, and zearalenone. Exposure to BPA during the embryonic stage at a critical period was found to disrupt brain development leading to hyperactivity at a later stage. On a positive note, we observed a potential beneficial action of probiotics against adverse actions of contaminants and the transgenerational effects of BPA. Elucidating the mechanisms and determining the source of contaminants can help with better screening, remediation, and implementation of best practices to reduce exposure to contaminated food and water.

1.08.T-02 Early Life Exposure to Endocrine Disruptors: Key Learnings from Metabolome Mapping of Rat Models
***Sara Evangelista**[1], Walter Lichtensteiger[2], Margret Schlumpf[2], Jesus Tresguerres[3], Beatriz Linillos Pradillo[3], Marja Lamoree[1] and Pim Leonards[4], (1)A-Life, Vrije University Amsterdam, Netherlands, (2)GREEN Tox, Switzerland, (3)Departments of Physiology and of Biochemistry and Molecular Biology, Universidad Complutense, Spain, (4)Vrije University Amsterdam, Netherlands*
Exposure to endocrine-disrupting chemicals (EDCs) in humans during pregnancy and early stages of life can impair normal brain development and reproductive function patterns, leading to severe pathologies later in life. Environmental studies have investigated bisphenol (BPA mostly) and phthalate developmental neurotoxicity. However, many EDCs such as pyrethroids, per- and polyfluoroalkyl substances (PFAS), organophosphate flame retardants, and plasticizers are hardly related to neurodevelopmental diseases, and new knowledge has to be gained. Metabolomics has shown to be a powerful tool in environmental toxicology in recent years: the key function of steroid and thyroid hormones, neurotransmitters, and lipids for brain development, homeostasis, and metabolism makes all of them potential candidates in the discovery of sensitive biomarkers for neuroendocrine toxicity in animals and humans. We, therefore, applied targeted and untargeted metabolomics to map the metabolic pathways mostly influenced by the exposure to six EDCs, namely bisphenol F (BPF), permethrin (PMT), butyl benzyl phthalate (BBzP), triphenyl phosphate (TPHP), perfluorooctane sulfonic acid (PFOS), and 1,2-cyclohexane dicarboxylic acid diisononyl ester (DINCH) in rats during pregnancy and lactation. Hormone levels measurements are pivotal for *in vivo* mechanistic evaluation of EDCs' mode of action (MoA) and risk assessment. This study is specifically designed to detect and extend all the possible metabolic endpoints relevant for assessing neuro-endocrine toxicity EDCs mediated at the early stages of life.

1.08.T-03 Poly- and Perfluorinated Chemicals Alter Development and the Lipidome of Fathead Minnow Embryos
***Nancy D. Denslow**[1], Kevin J Kroll[1], Anna Marqueño[2] and John A Bowden[1], (1)University of Florida, (2)Environmental Chemistry Dept., IDAEA-CSIC, Spain*
Per- and polyfluoroalkyl substances (PFAS) have been released into the environment through a multitude of industrial and consumer-based products. Per- and polyfluoroalkyl substances have become an important emerging concern worldwide, as these substances are found in biota, water, and sediments and constitute potential hazards to environmental and human health. They are known endocrine disruptors, causing infertility and hormone disruption in addition to immunotoxicity, hepatotoxicity, and cancer, but their modes of action are still not well-delineated. While it is generally thought that PFAS act through activation of the peroxisome proliferator-activated receptor (PPARα), the concentrations required for transactivation are higher (100 µM) than levels normally found in blood. It is possible that alternative biochemical mechanisms are involved at concentrations that appear in the environment. To begin to understand the toxicity mechanisms *in vivo*, early life stage fish exposures (0, 0.5, 5, 50 µg/L) were undertaken using dechorionated fathead minnow embryo. Exposures were conducted for 6 days (10 d postfertilization). Per- and polyfluoroalkyl substances altered proper heart development, heartbeat, and lipid profiles, suggesting activation of several different types of pathways in addition to PPARs. In RNAseq experiments with adults, the main pathways targeted included lipid related pathways, hormone biosynthesis, glucose metabolism, and respiratory chain, among others. These studies point to a main effect of PFAS on the less studied but fundamental biochemical pathways, including mitochondrial function, respiration, and metabolism. Per- and polyfluoroalkyl substances are persistent environmental hazards and how they perturb the endocrine system of aquatic organisms is an area of urgent research.

1.08.T-04 Transgenerational Effects of Ancestral Arsenic Exposure on Cognitive Performance and Dopamine Signaling Pathway in the Brain of Zebrafish
***Som Niyogi**, Mahesh Rachamalla and Arash Salahinejad, University of Saskatchewan, Canada*
Arsenic is a priority environmental pollutant because of its toxicity to human and nonhuman species including fish. It is known to

cause neurotoxicity primarily by inducing oxidative stress and neural dysfunctions, and chronic exposure to arsenic has been suggested to impair various behavioural functions including cognition. The present study was designed to investigate the transgenerational effects of ancestral arsenic (As) exposure on the cognitive performance of zebrafish (*Danio rerio*). Adult zebrafish (6 months old; F_0 generation) were exposed to four different concentrations of dietary arsenic (0 [control], 30, 60, and 100 As µg/g dry weight; as arsenite) for 60 d. The cognitive behaviour of fish was then examined using a latent learning paradigm in a complex maze, which showed a dose-dependent adverse effect of As on cognitive performance. The As-induced cognitive impairment was associated with increased As accumulation, dopamine level, and oxidative stress in the brain relative to that in the control. Moreover, marked alterations of several genes involved in the signalling of dopamine, which regulates important fish behaviours including learning, memory, and reward-motivated behaviours, were also observed in the brain of As-exposed fish. Following behavioural assessments, As-exposed females from each treatment were mated with control males, and vice versa, to produce F_1 generations of fish that were maternally (ME) and paternally (PE) exposed to As, respectively. Subsequently, adult males and females from each F_1 generation ME and PE treatment groups were bred again to produce F_2 generations of the respective ancestral As treatment groups. Both F_1 and F_2 generations were raised to adulthood (6 months) in clean water and diet before assessing their cognitive performance as described above. A strong cognitive effect was observed in both F_1 and F_2 generations from the maternal lineage of ancestral As exposure, even at the low dose (30 µg/g). In contrast, in the F_1 and F_2 generations from the paternal lineage of ancestral As exposure, the cognitive impairment was recorded only at the highest dose group (100 µg/g). Increased oxidative stress and dopaminergic dysregulation were also observed in the brain of F_1 and F_2 generations of fish irrespective of the maternal or paternal lineage of ancestral As exposure. Our study indicates that ancestral As exposure causes transgenerational neurobehavioural effects in zebrafish, likely via epigenetic alterations.

1.08.T-05 Effects of Environmentally Relevant Mixture Concentrations of Estetrol/Drospirenone in Zebrafish: A Multigenerational Study
Sebastien Baekelandt[1]*, Nathalie Leroux*[2]*, Jean-Baptiste Robert*[2]*, Antoine Bouchat*[2]*, Céline Gerard*[3]*, Céline Delierneux*[3]*, Valérie Cornet*[2] *and Patrick Kestemont*[2]*, (1)URBE, University of Namur, Belgium, (2)University of Namur, Belgium, (3)Estetra SRL, Liège, Belgium*
Natural and synthetic steroid hormones are widely found in aquatic ecosystems and have the potential for unintended consequences in the environment due to their ability to disrupt the normal endocrine function of wildlife. Notably, the synthetic estrogen ethinylestradiol (EE2), widely used in combined oral contraceptives, has been shown to be more potent than natural estrogens to aquatic organisms.

The natural estrogen estetrol (E4) was recently approved for use in a new combined oral contraceptive with the progestin drospirenone (DRSP). The aim of this study was to characterize and compare the endocrine disrupting potential of mixtures of E4/DRSP and EE2/DRSP to zebrafish, over multiple generations.

The Medaka Extended One Generation Reproduction Test (OECD Test Guideline No. 240) was adapted to zebrafish (*Danio rerio*). Fish were exposed over three generations (F0, F1, and F2) to different environmentally relevant mixtures of E4/DRSP or EE2/DRSP. Selected mixture concentrations represented increasing multiples (~1, 3, 10, and 30x) of the predicted environmental concentration of each substance.

EE2/DRSP mixtures: In the F0 generation, fecundity was significantly reduced in fish exposed to 3.2/32 ng/L (*i.e.*~ 10x environmental concentration). In the F1 generation, at concentrations as low as 1/10 ng/L (*i.e.*~ 3x environmental concentration), a significant change in gonadal development and a decrease in fecundity was observed. Vitellogenin synthesis was also significantly increased, and fish growth significantly decreased, at 3.2/32 ng/L (i.e., ~ 10x environmental concentration).

E4/DRSP mixtures: Only the highest tested mixture concentration (, ~30x predicted environmental concentration) resulted in effects on the F1 generation. Effects included an increase in the proportion of males. No impact on fecundity, growth, or vitellogenin synthesis was observed.

While a chronic exposure to environmentally relevant concentrations of EE2/DRSP severely impacted zebrafish population dynamics including an impairment of fecundity and gonadal development, relatively limited effects of E4/DRSP were observed in the zebrafish multigenerational exposure, with no impact on fecundity, growth, or vitellogenin synthesis. In conclusion, the data show that the combination E4/DRSP has a potentially more favorable toxicity profile to fish compared to EE2/DRSP and suggest that E4/DRSP may represent a more ecofriendly combined oral contraceptive.

1.08.P Long-Term and Multigenerational Impacts from Early-Life Exposure to Contaminants

1.08.P-Th058 Multigenerational Effects of the Novel Brominated Flame Retardant, 1,2,5,6-Tetrabromocyclooctane (TBCO), on Japanese medaka (*Oryzias latipes*)
Chloe Devoy[1]*, Yamin Raza*[1]*, Paul Jones*[2]*, Jon Doering*[3] *and Steve Wiseman*[1]*, (1)University of Lethbridge, Canada, (2)University of Saskatchewan, Canada, (3)Louisiana State University*
The novel brominated flame retardant (BFR), 1,2,5,6-tetrabromocyclooctane (TBCO), is a replacement option for major use BFRs that are being phased out of usage due to concerns about toxicity. Little is currently known about the toxic effects of TBCO; however, waterborne exposure has been demonstrated to induce toxicity in early life stage zebrafish (*Danio rerio*) and

dietary exposure has been demonstrated to impair reproduction in Japanese Medaka (*Oryzias latipes*). Maternal transfer is a mechanism by which developing offspring can be exposed to toxicants. Objectives of this research were to investigate effects of maternally deposited TBCO on development and reproductive success in three generations of Japanese medaka (F_1, F_2, F_3). Sexually mature fish (F_0 generation) were fed either a control diet or a low (40.6 µg/g) or high (1034.4 µg/g) diet containing TBCO for 21 d and three generations of embryos were reared to determine reproductive performance. Once the F_1, F_2, and F_3 generations reached sexual maturity, reproductive performance was assessed by use of a 21-d short term reproduction assay where fecundity and fertility were measured daily. Additionally, embryotoxicity was assessed during the final week of each reproduction assay. Molecular mechanism(s) of effect were investigated by use of enzyme-linked immunoassay (ELISA) and Quantitative Real-Time PCR. Concentrations of TBCO in eggs (F_1 generation) from fish given the low and high diets were 711.3 and 2535.5 ng/g wet weight, respectively, confirming maternal transfer of TBCO. Embryotoxicity was evident in the F_1 generation, but not the F_2 or F_3 generation. Cumulative fecundity of the F_1 generation in the low and high treatment were reduced by 33.9% and 33.3%, respectively, compared to the control. In the F_2 generation, cumulative fecundity of the low treatment returned to the level of the controls, but the high treatment was decreased by 29.8%. There was no decrease in cumulative fecundity in the F_3 generation compared to controls. This research ultimately provides insight into the long-term effects of TBCO as its usage is poised to increase. Maternally deposited TBCO causes embryotoxicity, and also causes multigenerational, but not transgenerational, decreases in fecundity of female Japanese medaka. Interestingly, recovery of fecundity was concentration dependent. Mechanistically, decreased fecundity was unlikely to have been caused by developmental reprogramming of steroidogenesis.

1.08.P-Th059 The Effects of UV-P on the Model Fish Species, Zebrafish (*Danio rerio*) Following Early Life Stage Exposure
Yamin Raza[1], *Emily Mertens*[1], *Zhe Lu*[2] *and Steve Wiseman*[1], *(1)University of Lethbridge, Canada, (2)University of Québec À Rimouski, Canada*
Benzotriazole ultraviolet stabilizers (BUVSs) are a class of chemicals that provide protection from UV-A and UV-B light, specifically at 280-400 nm. These anthropogenic compounds are added to a variety of products including building materials, waxes, personal care products, and paints to prevent UV degradation, cracking, and yellowing as a result of sun exposure. Despite the fact that BUVSs have a widespread occurrence in the aquatic environment, little is known regarding their effects on aquatic organisms. In fish, studies have reported that the BUVS, 2-(2H-benzotriazol-2-yl)-4-methylphenol (UV-P), is an anti-androgen and an agonist of the aryl hydrocarbon receptor (AHR). The overarching objective of this research was to characterize the effects of UV-P exposure on the reproductive success of adult zebrafish following early life stage (ELS) exposure and assess any molecular mechanism(s) of effect(s). To conduct this, zebrafish embryos were exposed, by use of microinjection, to UV-P at 0 (DMSO control), 0.04, and 0.4 mg/g–egg. Approximately 24 embryos were reared until complete yolk sac absorption, where embryotoxicity was assessed daily, where mortality and malformations, including spinal curvature, yolk sac edema, and pericardial edema were recorded. Heart rate was measured at 48 h postfertilization. To assess effects of ELS exposure on reproductive performance, the remaining injected embryos were reared until sexual maturity. At sexual maturity, fish underwent a 21-d reproduction assay, where fecundity and fertility were assessed daily. Upon termination of the reproduction assay, fish were euthanized, and gonads, liver, pituitary gland, and blood were collected for analysis of molecular and biochemical endpoints. There were no significant effects of UV-P on mortality, heart rate, hatching rate, or developmental malformations. Early life-stage exposure to UV-P did not have a significant effect on fecundity, relative to the control. However, there was a significant effect on fertilization success. Fertility was decreased by 10.0% in the 0.04 mg/g dose and by 21.1% in the 0.4 mg/g dose, relative to control. Results of this study provide novel insight on the effects of UV-P on early life stage development of fishes, how early life stage exposure can affect reproductive success at adult stages. This study will aid in providing an assessment of the risks associated with BUVSs to fish species.

1.08.P-Th060 Zygotic Exposure to Venlafaxine Leads to Long-Term and Multigenerational Impacts in Zebrafish
William A Thompson[1] *and* ***Mathilakath Vijayan***[2], *(1)Biological Sciences, University of Calgary, Canada, (2)University of Calgary, Canada*
Venlafaxine, a selective serotonin and norepinephrine reuptake inhibitor, is currently detected in surface waters receiving municipal wastewater effluent at concentrations in the parts per billion range. We have carried out several investigations to understand the impact of this antidepressant on developmental programming using zebrafish as a model. Our results revealed that zygotic exposure to venlafaxine impacts brain serotonin content, affecting neurogenesis in specific brain regions, including the hypothalamus. This also corresponded with altered behaviour, which we were able to rescue with exogenous serotonin treatment. As the hypothalamus is a key integrator of endocrine function, we focussed our studies on the impact of venlafaxine on the growth and stress axes in zebrafish. Zygotic exposure to venlafaxine reduced the specific growth rate in juveniles and compromised the stressor-induced cortisol response in adults. Sexually dimorphic responses were observed as adults in response to early-life exposure to venlafaxine, including diminished cortisol stress response and aerobic scope in females. We also observed multigenerational effects on neurogenesis and behaviour, as well as cortisol stress performance, in response to zygotic exposure to venlafaxine in zebrafish. Taken together, our results reveal that early-life exposure to venlafaxine affects neurodevelopment and disrupts the developmental programming of the endocrine axes in zebrafish. Although studies investigating the impact of environmentally relevant levels of antidepressants are sparse, our results reveal that venlafaxine deposition in the embryo either through maternal transfer or from environmental exposure may lead to long-lasting and multigenerational impacts in fish. While the mechanism remains to be elucidated, we hypothesize that these effects may be in part associated with the disruptions in the early development of the monoaminergic systems.

1.08.P-Th061 Dietary Exposure to the Flame Retardant, BDE-99, Induces Multigenerational Behavioural Alterations in Atlantic Killifish

Nicole Alexandra McNabb[1], *Bryan Clark*[2], *Tara Burke*[2], *Saro Jayaraman*[2], *Lesley Mills*[2], *Diane Nacci*[2] *and Andrew Whitehead*[1], *(1)Department of Environmental Toxicology, University of California, Davis, (2)Atlantic Coastal Environmental Sciences Division, US Environmental Protection Agency*

To truly evaluate the long-term impacts of exposure to environmental pollution, it is critical to assess multigenerational effects. Polybrominated diphenyl ether (PBDE) flame retardants are highly persistent and ubiquitous in the environment, yet little is known about their potential for multigenerational toxicity. Direct exposure to one of the two most dominant PBDE congeners, BDE-99, has been linked to various adverse impacts on development, neurobehaviour, and reproduction, but studies focusing on multigenerational effects are lacking. To address this, we tested whether exposure to BDE-99 has negative effects that propagate across generations using Atlantic killifish (*Fundulus heteroclitus*) as a vertebrate model system. Adult wild-caught killifish were fed control or contaminated diet for 64 d during breeding season with two concentrations of BDE-99, 37.5 and 150 ng/g fish wet weight/day. The exposed (F0) fish were spawned to produce the F1 generation, which was raised under uncontaminated conditions and subsequently spawned to produce the F2 generation. No significant differences in fecundity, fertilization rate, developmental morphology, hatch success, or larval survival were observed between treatments in any generation. To evaluate neurological impairment in the F1 and F2 generations, larval locomotor activity was tracked in response to alternating light and dark conditions. Parentally exposed F1 fish from some of the BDE-99 lineages expressed significant hypoactivity during the light phases, while results suggest that that behaviour is not altered in F2 larvae. At juvenile stages, novel tank diving tests were conducted to assess anxiety-like behaviour in the F1 and F2 generations. Results indicate an anxiolytic effect (greater percentage of time in the top zone of the tank) in the F1 fish parentally exposed to BDE-99; however, this behavioural effect was not propagated to the F2 generation. Archived juvenile brain tissues are being analyzed for genome-wide gene expression changes to infer potential mechanisms associated with observed behavioural phenotypes in the parentally exposed generation and generate hypotheses about other multigenerational neurotoxic effects of BDE-99.

1.08.P-Th062 Persistent Effects of Early Life Exposure of Zebrafish to Water from the Richelieu River (QC, Canada)

Hugo Marchand[1], *Benjamin Barst*[2], *Emily Boulanger*[3], *Nathalie Vachon*[4], *Magali Houde*[5], *Ke Xu*[1], *Saji George*[1] *and Jessica Head*[3], *(1)McGill University, Canada, (2)University of Alaska Fairbanks, (3)Faculty of Agricultural and Environmental Sciences, McGill University, Canada, (4)Ministère de l'Environnement, de la Lutte contre les changements climatiques, de la Faune et des Parcs du Québec, Canada, (5)Environment and Climate Change Canada, Canada*

Fish worldwide spawn in waters that are contaminated with complex mixtures of environmental chemicals. This may have important consequences on offspring, particularly if exposure occurs at a sensitive early life stage (ELS). Here we evaluated how ELS exposure to pesticide-contaminated river water affected the biology of a model organism, the zebrafish, as larvae and adults. Water samples were collected from an agricultural river (Richelieu River, QC, Canada) during the spawning season of listed fish in June 2019. Two surface water samples were collected at Chambly and Saint-Ours following heavy rain events when pesticide concentrations were the highest. Targeted pesticide analysis indicated that the Saint-Ours sampling site, located downstream of tributaries fed by agricultural drainage, had higher pesticide concentrations than the Chambly site. Zebrafish embryos (three replicates of 100 embryos each) were exposed to river water (Chambly or Saint-Ours) or laboratory water (control group) until 120 h postfertilization. Thereafter, zebrafish were raised to maturity in clean water. We found that exposure to river water delayed zebrafish hatching compared to controls but had no effect on larval survival or deformities. In adults that were exposed as embryos, the number of eggs produced was not different between the treatment groups. However, fertilization success for the fish exposed to river water collected at Chambly and Saint-Ours was lower than the control group (65, 72, and 81%, respectively). Overall, effects were more pronounced in the fish exposed to water from the more contaminated downstream site. These results increase our knowledge on the potential long-term effects of realistic mixtures of environmental contaminant exposure on ELS fish.

1.08.P-Th063 Embryo-Larval Toxicity and Molecular Toxicity Pathways of Maternally Transferred Hexabromocyclododecane (HBCD) in Fathead Minnows (*Pimephales promelas*)

Susari Malala Irugal Bandaralage[1], *Juan Ignacio Bertucci*[2], *Bradley Park*[3], *Alper James Alcaraz*[4], *Derek Green*[1], *Anita Masse*[1], *Jessica Ewald*[5], *Jianguo Xia*[5], *Doug Crump*[6], *Nil Basu*[5], *Natacha S Hogan*[4] *and* ***Markus Hecker***[4], *(1)University of Saskatchewan, Canada, (2)Contaminación Marina, Centro Oceanográfico de Vigo - IEO- CSIC, Spain, (3)University of Manitoba, Canada, (4)Toxicology Centre, University of Saskatchewan, Canada, (5)McGill University, Canada, (6)Ecotoxicology and Wildlife Health Division, Environment and Climate Change Canada, National Wildlife Research Centre, Ottawa, Canada*

Hexabromocyclododecane (HBCD) is a brominated flame retardant that presents a threat to aquatic organisms as it can be maternally transferred and has been reported to hinder development and survival in early-life stage (ELS) fish. However, little is currently known about the molecular mechanisms that drive the toxicity of HBCD. This study examined the apical and molecular response patterns following exposure to maternally transferred HBCD in fathead minnow (*Pimephales promelas*) larvae at seven (whole transcriptome) and 14 (apical and physiological) days postfertilization (dpf). Transcriptomics analysis revealed dysregulation of pathways involved in membrane integrity (inhibition of calcium channel) and metabolic processes (downregulation of amino acid, glucose, and lipid biosynthesis), while the larvae reared for 14 d exhibited a significant decrease in survival in the highest (100 mg/kg) treatment condition. These results indicate that maternal transfer of HBCD is of concern in fish and exposed progeny may lead to the inhibition of membrane transport and disruption in metabolic processes, collectively resulting in energy depletion and subsequent mortality. Most importantly, what can be inferred from the current study is that

HBCD can be maternally transferred to embryos, where it elicits a potentially different mechanism of toxicity than previously suggested by waterborne studies.

1.08.P-Th064 Transcriptomic Profile in Zebrafish (*Danio rerio*) Embryos Exposed to Environmental Concentrations of Glyphosate

Luis Terrazas Salgado[1]*, Raul Llera-Herrera*[2]*, Miguel Betancourt-Lozano*[3]*, Isabel Alvarado-Cruz*[4] *and Alejandra Garcia-Gasca*[4]*, (1)Ecotoxicology, Centro de Investigacion en Alimentacion y Desarrollo, A.C., Mexico, (2)National Autonomous University of Mexico, Mexico, (3)University of Arizona Cancer Center, (4)Center for Research in Food and Development, Mexico*

Glyphosate [N-(phosphonomethyl)glycine] is one of the most popular herbicides worldwide. The use of herbicides containing glyphosate as an active ingredient has intensified to combat herbicide-resistant weed species. Currently, glyphosate is present in 750 commercial herbicide products designed for intensive crop production, market gardening, and gardens in general. From the time that glyphosate was introduced into the market in 1970 until 2014, it has been estimated that 8.563 million kg of glyphosate has been produced worldwide. Globally, the use of glyphosate is increasing, and its residues have been found in drinking water and food products. The herbicidal mode of action of glyphosate results from the inhibition of a key enzyme (5-enolpyruvylshikimate-3-phosphate synthase) of the shikimic acid metabolic pathway that is involved in the synthesis of aromatic amino acids. This pathway is not present in mammals. However, aside from the toxicity attributed to some components of commercial glyphosate formulations, the controversy surrounding glyphosate toxicity remains unresolved, especially at environmentally realistic levels of exposure. Glyphosate residues have been identified in bodies of water adjacent to sites in which glyphosate herbicides have been applied. In natural aquatic environments, glyphosate concentrations have been found to range from 0.04 mg/L to 700 mg/L in different sites worldwide. Environmental standards in the United States limit the glyphosate concentration in water to 700 mg/L while the European Union has a more restrictive environmental standard of 28 mg/L. Therefore, the aim of this study was to evaluate the effects of glyphosate at environmental concentrations in zebrafish (*Danio rerio*) embryos. Embryos were exposed to 0, 1, 100, and 1000 µg/L glyphosate for 96 h, and mortality, heart rate, and hatching rate were evaluated. After the experiment, RNA was extracted from the embryos for transcriptional analysis. No mortality was recorded, and exposure to 100 µg/L and 1000 µg/L of glyphosate resulted in lower heart rates at 48 h. In addition, RNA-seq analysis revealed that glyphosate exposure induced subtle changes in gene transcription profiles. We found 30 differentially expressed genes; however, the highest glyphosate concentration (1000 µg/L) induced the greatest number of differentially expressed genes involved in oocyte maturation, metabolic processes, histone deacetylation, and nervous system development.

1.08.P-Th065 Effect of Mifepristone on the Development of African Clawed Frog (*Xenopus laevis*)

Michal Pech[1]*, Christoph Steinbach*[2]*, Martin Kocour*[2]*, Ilona Prokopová*[2]*, Marie Šandová*[2]*, Adam Bořík*[2] *and Hana Kocour Kroupová*[2]*, (1)Laboratory of Aquatic Toxicology and Ichtyopathology, University of South Bohemia in České Budějovice, Czech Republic, (2)University of South Bohemia in Ceske Budejovice, Faculty of Fisheries and Protection of Waters, Czech Republic*

The aquatic environment is constantly polluted with substances that can affect the endocrine system of aquatic organisms. These compounds, known as endocrine disruptors (EDs), display diverse types of hormonal activities, including antiprogestogenic activity. However, there is limited knowledge about the effect of substances with antiprogestogenic activity. Therefore, the objective of the present study was to assess the effects of compounds with antiprogestogenic activity on the development of amphibians. Mifepristone, a synthetic steroid hormone commonly used in human medicine as an abortifacient, was chosen as a model compound with antiprogestogenic activity. African clawed frog (*Xenopus laevis)* tadpoles were exposed to mifepristone at three concentration levels (2, 22, and 215 $ng \cdot L^{-1}$). Moreover, a control group with DMSO (0.001 %) was included. The experiment started when tadpoles reached stage 47-48, according to Nieuwkoop and Faber (NF), and continued until stage NF 66 when metamorphosis was complete. Exposure to mifepristone did not affect the developmental rate, weight, length, and sex ratio of tadpoles. Mortality was within an acceptable range of 1–5% throughout the test, with no differences among the groups. Histopathological examination of the gonads and thyroid gland did not reveal any significant changes. Therefore, we can conclude that mifepristone did not have a negative effect on the development of the African clawed frog. However, in the highest tested concentration of mifepristone (215 $ng \cdot L^{-1}$), gene expression analysis revealed up-regulation of mRNA expression of nuclear progesterone receptor (*npr*), membrane progesterone receptor (*mpr*), and luteinising hormone (*lh*) in the brain-pituitary complex of exposed frogs at stage NF 66. Higher mRNA expression of *npr* was also found in frogs exposed to 22 $ng \cdot L^{-1}$ mifepristone compared to the solvent control. These findings confirmed the antiprogestogenic activity of mifepristone in frogs because up-regulation of progesterone receptors occurs if progesterone availability in the body is reduced. This effect may have negative consequences for reproduction later in life.

1.08.P-Th066 Transgenerational Adaptation to Ocean Acidification Determines the Susceptibility of Filter-Feeding Zooplankton to Nanosized Plastic

Min-Sub Kim, Young Hwan Lee and ***Jae-Seong Lee****, Department of Biological Sciences, Sungkyunkwan University, Korea, Republic of (South)*

The adaptability of marine organisms to the impending challenges presented by ocean acidification (OA) is essential for their survival, and the mechanisms underlying OA adaptation have been reported in several marine organisms. In the natural environment, however, marine organisms are often exposed to a combination of environmental stressors, but the interactions between different adaptive responses have yet to be elucidated. Here, we investigated the susceptibility of filter-feeding rotifers to short-term (ST) and long-term (LT) (≥180 generations) high CO_2 conditions coupled with nanoplastic (NPs) exposure (ST+ and LT+), and tested how their susceptibility to NPs can be affected by parental exposure to high CO_2. The adaptive capacity of rotifers to elevated CO_2 caused differences in the ingestion and accumulation of NPs, resulting in a significantly different mode of action on *in vivo* endpoints between the ST+ and LT+ groups. Moreover, rotifers exhibited unique transcriptomic profiles in the ST+ and LT+ groups, although they possess less genetic diversity. In the ST+ group, NPs induced apoptosis via an oxidative stress-induced lysosomal dysfunction pathway, whereas in the LT+ group, mTOR signaling pathways and calcium homeostasis conferred high adaptability to co-exposure of OA and NPs. Furthermore, the micro-RNA-mediated epigenetic regulation was strongly correlated with the varied adaptive responses between the ST+ and LT+ groups, revealing novel regulatory targets and pathways depending on their capacity to OA adaptation. Our results, therefore, indicate that history of exposure to increased CO_2 levels is an important factor that determines the susceptibility of rotifers to NPs.

1.09.A Micro (Nano)Plastics: Occurrence, Fate, Uptake, and Mechanistic Approaches to Understand Their Risk for the Environment and Human Health

1.09.A.T-01 Eco-Corona Formation on Plastics: Impacts of Polymer Chemistry, Dissolved Organic Matter Composition, and Photochemical Weathering
Roman Schefer[1]*, Antonius Armanious*[2]*, Michael Sander*[3] *and Denise M. Mitrano*[1]*, (1)Environmental Systems Science, ETH Zürich, Zürich, Switzerland, (2)Department of Health Science and Technology, ETH Zürich, Zürich, Switzerland, (3)Department of Environmental Systems Science, ETH Zürich, Switzerland*
Understanding of plastic particle fate in freshwater environments is still limited and experiments elucidating underlying factors remain scarce. Plastic particle chemistry, size, shape, density, as well as the freshwater composition all influence its fate. Aging of plastics, either by photochemical weathering or by adsorption of dissolved organic matter (DOM), which leads to formation of an eco-corona, further alters the physicochemical properties of plastics. However, the impact(s) of photochemical weathering on the physicochemical properties of plastic, and how this impacts subsequent adsorption of DOM and eco-corona formation, is often neglected. Here we conducted systematic studies on adsorption of a selection of ubiquitous DOM (Suwannee River Humic Acid, Suwannee River Fulvic Acid, and Suwannee River Natural Organic Matter) to a set of the most environmentally prevalent polymer types (polyethylene, polypropylene, polyethylene terephthalate, and polystyrene) in their pristine and photochemically weathered forms. Both pristine and photochemically weathered polymer films were characterized by water contact angle measurements (changes in polarity and charge), Fourier transform infrared spectroscopy (chemical changes), and atomic force microscopy (changes in physical surface roughness). Photochemical weathering induced decreases in polymer film thicknesses and water contact angles, and increases in surface roughness and carbonyl index. Using Quartz Crystal Microbalance with Dissipation (QCM-D) allowed for determination of adsorption and desorption of DOM to and from the polymer surface. We spun coated polymers onto the QCM-D sensor surface and exposed them to solutions of DOM in synthetic freshwater to monitor DOM adsorption over time. As a result of the physicochemical changes, photochemically weathered polymers displayed a decreased DOM adsorption rate and final mass in synthetic freshwater and suggests higher adsorbed masses on apolar versus polar surfaces. This information will help to understand the rate and extent of eco-corona formation for DOM on different pristine and photochemically weathered plastics. Ultimately, this will allow us to produce more realistically aged materials to be used in further experiments on fate of plastic particles.

1.09.A.T-02 Influence of Microplastics Composition and Algae Aggregates on Particle Settling Rates in Freshwater
Francesco Parrella[1]*, Stefano Brizzolara*[1]*, Markus Holzner*[2] *and Denise M Mitrano*[3]*, (1)ETH Zürich, Zürich, Switzerland, (2)Swiss Federal Research Institute WSL, Switzerland, (3)Environmental Systems Science, ETH Zürich, Zürich, Switzerland*
To date, many studies have focused on the detection of microplastics (MPs) in natural waters, but only a few have been conducted to systematically understand the processes which drive MPs fate and distribution in freshwater ecosystems. This includes heteroaggregation with natural particles and small biota, and how these interactions affect transport in freshwater (e.g., settling dynamics). Freshwater snow (FWS), a mixture of algae and natural particles, is responsible for most of the flux of organic matter from the water surface to the sediments and can potentially act as a vector for MPs through the water column. Here, we systematically analyzed the settling rates of a variety of MPs in a plexiglass column, illuminated by a laser, and tracked with a stereoscopic camera system. Image sequences were acquired and analyzed with a tracing software to determine settling rates of particles in three test variants: 1) MPs of various size, density, and morphology; 2) FWS alone; and 3) MPs-FWS heteroaggregates. For each experimental set, our system allowed for the tracking of thousands of particles, which ensured statistical convergence of the results. Freshwater snow was created by mixing three strains of freshwater algae on a roller table over time. Our goal was to assess if the settling rates changed when MPs and FWS were aggregated together compared to their settling dynamics individually. For those MPs whose density is higher than water (PET, PLA), unsurprisingly, the settling rate increased with increasing particle size, but MPs fibers had a significantly slower settling velocity than the larger sizes of fragments. In all test variants, heteroaggregates settled faster than the individual MPs and significantly faster than the FWS alone, except for the case of MPs fibers. Conversely, those MPs whose density was lower than water (PP, PS) did not influence the settling rate of FWS no matter the MPs size. Collectively, we provide further insights on the settling rates of MPs and on a new experimental setup able to track thousands of particles per experimental run, as well as an indication as to how the presence of MPs can impact biogeochemical cycles through altering FWS settling. When MPs are incorporated into FWS, this faster settling rate will impact the flux of carbon, nitrogen, and phosphorus contained in FWS to the sediment, potentially having implications on productivity throughout the water column.

1.09.A.T-03 HDPE and PET Microplastics as Vectors of Microbial Pathogens
Alberto Katsumiti[1]*, Vanesa Benito*[2]*, Itziar Polanco*[2]*, Francesco Barbero*[3]*, Ibai Nafarrate*[2]*, Ainhoa Bilbao*[2]*, Isabel Rodríguez-Llopis*[2]*, Dmitri Ciornii*[4]*, Ivana Fenoglio*[3]*, Korinna Altmann*[5] *and Felipe Goñi de Cerio*[2]*, (1)Biotechnology, GAIKER Technology*

Centre, Zamudio, Spain, (2)Biotechnology, GAIKER Technology Centre, Basque Research and Technology Alliance (BRTA), Zamudio, Spain, (3)Department of Chemistry, University of Turin, Turin, Italy, (4)Bundesanstalt für Materialforschung und – prüfung (BAM), Germany, (5)Federal Institute for Materials Research and Testing (BAM), Berlin, Germany
High density polyethylene (HDPE) and polyethylene terephthalate (PET) are two of the most widely used thermoplastic polymers in food packaging in Europe. In the last years, several studies have reported the presence of HDPE and PET microplastics (MPs) in a large variety of food products and beverages raising concerns about the health effects of HDPE and PET MPs after ingestion. In addition to that, recent studies have indicated that HDPE and PET MPs may serve as substrate for the growth of microbial pathogens. *Vibrio parahemolyticus* (V) is a common foodborne pathogen commonly found in seafood. Consumption of seafood contaminated with *V. parahaemolyticus* is associated with acute gastroenteritis and serious septicemia. In the present study, we evaluated the potential toxicity of 5 µm HDPE (D50, commercially available) and 130 µm PET (D50, top-down cryomilled by centrifugal mill) MPs with and without *V. parahaemolyticus* biofilm (HDPE, PET, HDPE+V, and PET+V) to the human gastrointestinal (GI) system. Differentiated Caco-2 cells were exposed to different concentrations (1 to 100 µg/mL) of HDPE, PET, HDPE+V, and PET+V and effects on the GI barrier integrity (TEER, LY), cell viability (Alamar blue), and inflammatory responses (IL-6 and IL-8) were monitored from 1 h to 24 h of exposure. Scanning electron microscopy (SEM) and confocal laser scanning microscopy (CLSM) were used to analyse *V. parahaemolyticus* colonisation on MPs. Scanning electron microscopy and CLSM analysis showed that *V. parahaemolyticus* formed a dense biofilm on MPs surface after 3 days of incubation. Results from the *in vitro* experiments indicated that despite not affecting Caco-2 cells viability at all tested concentrations, HDPE, PET, HDPE+V, and PET+V affected GI barrier integrity and induced inflammatory responses at high doses. Exposure for up to 24 h to HDPE and PET decreased GI barrier integrity, but higher effects were found in exposure to HDPE+V and PET+V. Similarly, HDPE and PET induced IL-6 and IL-8 secretion, but inflammation was higher in cells treated with HDPE+V and PET+V treatments. Results indicated that HDPE and PET MPs may act as vectors of *V. parahaemolyticus* and induce important cellular responses, triggering a cascade of events that can culminate in severe cell and tissue damage.

1.09.A.T-04 Nylon 6,6 Microplastic Fibers Inhibit Differentiation of Human and Murine Airway Epithelium via Homeobox a5 Signalling
Shan Shan Song[1], Fransien van Dijk[1], Gail van Eck[1], Qiong Liang Liu[2], Marina de Jager[3], Sophie Bos, Chen Xi Li[2], Tobias Stoeger[2], Markus Rehberg[2], David Kutschke[2], Xin Hui Wu[1], Ingeborg Kooter[5], Devin Boom[5], Matthew Cole[6], Diana Spierings[1], Rene Wardenaar[1], Martijn Nawijn[1], Anna Salvati[1], Reinoud Gosens[1] and ***Barbro Melgert****[7], (1)University of Groningen, Netherlands, (2)Helmholtz Center Munich, Germany, (3)M.h.De.Jager@Rug.Nl, (4)Netherlands Organisation for Applied Scientific Research (TNO), Netherlands, (5)Plymouth Marine Laboratory, United Kingdom, (6)Molecular Pharmacology, University of Groningen, Netherlands, (7)*
Microplastics are a pressing global concern and are present in both indoor and outdoor air. Synthetic textiles shed fibers that accumulate indoors and this results in continuous exposure when indoors. Inhalation of high levels of microplastic fibers has been associated with interstitial and bronchial inflammation in nylon flock workers. However, exact health effects of microplastic fibers on the lungs are unknown.
Our aim was to assess the effects of nylon 6,6 (nylon) and polyethylene terephthalate (polyester) textile microplastic fibers on lung epithelial growth and differentiation.
We used alveolar and airway-type organoids derived from primary lung epithelial progenitor cells, isolated both from murine and human lung tissue, and incubated these with either nylon or polyester fibers or nylon leachate. In addition, mice received one dose of nylon fibers or nylon leachate intratracheally and 7 d later organoid-forming capacity of isolated epithelial cells was investigated.
We observed that in particular nylon microfibers inhibited developing airway organoids and not established ones, but nylon did not inhibit alveolar organoid formation. This effect was mediated by components leaching from nylon. Epithelial cells isolated from mice exposed to 75k or 150k nylon fibers or nylon leachate also formed fewer airway organoids, suggesting long-lasting effects of nylon components on epithelial cells. RNA sequencing analysis showed that the most prominently upregulated genes after exposure to nylon fibers included Homeobox a5 (*Hoxa5)*. Inhibition of *Hoxa5* protein during exposure to nylon restored both human and murine airway organoid formation, confirming an essential role of *Hoxa5* in the effects of nylon.
Our results show that components leaching from nylon 6,6 may especially harm developing airways and/or airways undergoing repair. This suggests that airborne nylon may be most harmful to young children with developing airways and/or to people undergoing high levels of epithelial repair. These could be people with a chronic lung disease or even healthy individuals suffering from a seasonal respiratory virus infection. We therefore strongly encourage to look in more detail at both hazard of and exposure to microplastic fibers.

1.09.P-Mo043 EnviroPlaNet Project: A Systematic Monitoring of Atmospheric Deposition of Microplastics in Spain
Carlos Edo*[1], Francisca Fernandez-Pinas[2], Francisco Leganes[2], May Gómez[3], Ico Martínez[3], Cintia Hernández-Sánchez[4], Javier González-Sálamo[4], Javier Hernández-Borges[4], Joaquín López-Castellanos[5], Javier Bayo[5], Cristina Romera-Castillo[6], David Elustondo[7], Rocío Alonso[8], Héctor García-Gómez[8], Rosario González-Cascón[9], Virtudes Martinez-Hernandez[10], Junkal Landaburu-Aguirre[10], Monica Incera[11], Jesús Gago[11], Beatriz Noya[12], Ricardo Beiras[12], Soledad Muniategui-Lorenzo[13], Roberto Rosal[14] and Miguel González-Pleiter[2], (1)Universidad de Alcalá, Alcalá de Henares (Madrid), Spain, (2)Biology, University of Madrid (UAM), Spain, (3)Marine Ecophysiology Group (EOMAR), Universidad de Las Palmas de Gran Canaria, Las Palmas de Gran Canaria, Spain, (4)Universidad de La Laguna, San Cristobal de La Laguna, Spain, (5)Universidad Politécnica de Cartagena, Cartagena, Spain, (6)Instituto de Ciencias del Mar-CSIC, Spain, (7)Universidad de Navarra, Pamplona, Spain, (8)Ecotoxicology of Air Pollution, CIEMAT, Spain, (9)Spanish National Institute for Agricultural and Food Research and*

Technology (INIA-CSIC), Madrid, Spain, (10)IMDEA Water Institute, Spain, (11)Instituto Español de Oceanografía, Spain, (12)University of Vigo, Spain, (13)Universidade da Coruña, Spain, (14)Chemical Engineering, University of Alcala, Spain
Plastic pollution is a global concern. The world's production continues to increase yearly, reaching more than 367 million tons in 2020. Part of these plastics reach the ecosystems as microplastics (MPs). From all the environmental compartments, the presence of MPs in the atmosphere has been poorly studied. The objective of this work was the systematic monitoring of the deposition of MPs in areas of Spain with different characteristics (population, economic activities, and climate) using a common method for sampling, quantification, and identification during the four seasons of a one-year sampling campaign with the purpose of clarifying the role of the atmosphere in the fate and dispersion of MPs.

The collection of airborne MPs was performed using a set of passive collection made of steel and glass specifically designed to help QC/QA during handling and monitoring stages. The results showed that fibres were the dominant shape followed by fragments, filaments, microspheres, and films. Their sizes ranged from 14 µm to 4725 µm. The spectroscopic analyses performed using micro-FTIR (Fourier transform infrared) revealed that near 50% of microparticles potentially identified as MPs were plastic polymers while the rest were identified as cellulose (38%) and a 12% of microparticles lacking enough evidence for unambiguous identification. A total of nine different polymers were determined. The majority of fibres were identified as polyester (PES) while the fragments were PES, polyurethane (PUR), and polymethyl methacrylate (PMMA). Filaments and microspheres were dominated by polyethylene terephthalate (PET), while all films were polyethylene (PE). The atmospheric deposition of MPs ranged from 0 to 98.4 MPs m^{-2} day^{-1} with an average 27 MPs m^{-2} day^{-1}. Statistical analysis showed a positive correlation between the population of the study area and the average atmospheric MP deposition ($R^2 = 0.87$). These results suggest a key role of the urban areas as sources of atmospheric MPs. Regarding environmental factors, a negative correlation was found between the average wind speed and the average atmospheric MP deposition ($R^2 = -0.91$), suggesting that winds could clean the atmosphere from MPs. This is the first study of atmospheric deposition of MPs performed over a one-year period with four samples taken, one per season and covering all the Spanish peninsular territory and the Canary Islands.

1.09.P-Mo044 Characterizing Human Exposure to Microplastics During Pregnancy ***Charles Rolsky**[1], Whitney Cowell[2], Michelle L. Berger[1], Greg Drozd[3], Eleanor Medley[4], Kurunthachalam Kannan[2], Varun Kelkar[5] and Leonardo Trasande[2], (1)Shaw Institute, Blue Hill, Maine, (2)Department of Pediatrics, New York University, (3)Department of Chemistry, Colby College, Waterville, (4)Department of Population Health, New York University, (5)Plastic Oceans International, Malibu, California*Plastic production has been increasing, on a global scale, since the 1950s. This has led to an upsurge in pollution from larger plastics, termed 'macroplastics' (>5 mm), as well as micro- (1 µm–5 mm) and nanoplastics (<1 µm). As more plastic is produced, utilized, and discarded, more opportunities are created for plastics, particularly nano- and microplastics (NMPs), to reach human populations. Ambient air, honey, table salt, bottled water, and more have been identified as direct exposure sources to humans. A variety of threats have been associated with NMPs exposure that include both physical and chemical toxicity. Once theorized, research has now demonstrated NMP contamination of human tissues and organs, including lung, placenta, liver, and more recently, breast milk. The effects of this contamination remain to be thoroughly understood, but regardless, more research is needed to document this exposure, especially as it relates to at-risk individuals, such as infants. Three small studies have aimed to shed light on the presence of NMPs in human placentas. This organ is unique as it is accessible from healthy adults and provides insight into the health of the mother and infant alike. As delivery rooms utilize copious amounts of plastic items, detecting any source of plastic contamination becomes paramount. Thus, we aim to study suspected human exposure to NMPs during pregnancy by quantifying and characterizing NMPs extracted from 300 placental samples collected during the first 14 months of the study, specifically targeting the chorion side, which we hypothesize could contain NMP contamination. This sample size is 17 times more than any previous placenta research project so will more broadly represent contamination in the population. Our study integrates sociodemographic, behavioural, lifestyle, and dietary health assessments to link potential exposure to higher rates of plastic-wrapped or processed food consumption, for example. Two novel methods of contamination controls will be implemented to reduce and/or document sources of plastic contamination from the delivery room or within the laboratory conducting the extraction. One employs the creation of a contaminant database of all medical plastics involved in birth and placenta removal. The other involves an innovative housing for extracted samples to reduce opportunity for airborne contamination, a suspected reason why some studies reporting NMP counts may be inflated.

1.09.P-Mo076 Visualization of Labelled Nanoplastics in Algae and Copepods, Using Stimulated Emission Depletion (STED)-Microscopy and Fluorescence Lifetime Imaging (FLIM)
***Marie Roos Sioen**[1], Maaike Vercauteren, PhD[2], Ronny Blust[3], Colin Janssen[4], Jana Asselman[5] and Raewyn M. Town[3], (1)Laboratory of Environmental Toxicology and Aquatic Ecology - GhEnToxLab, Ghent University (UGent), Ghent, Belgium, (2)GhEnToxLab, Ghent University (UGent), Ghent, Belgium, (3)ECOSPHERE, University of Antwerpen, Antwerpen, Belgium, (4)Laboratory for Environmental Toxicology (GhEnToxLab), Ghent University (UGent), Ghent, Belgium, (5)Blue Growth Research Lab, Ghent University (UGent), Ghent, Belgium*
The possible impact of nanoplastics (NPs, dimensions <1 µm) differs from microplastics (MPs), which are usually limited to the digestive organs of the affected organisms. Studies show that the rate of transport over cellular barriers increases as the plastic particle size decreases, and also the transportation process (through endocytosis or through paracellular routes) depends on the particle size.

The aim of this project was to develop a method to label and visualise nanoplastics in their interaction with marine primary producers and consumers. This entails both the possible adsorption and absorption, to study uptake mechanisms, retention rates, and possible accumulation.

The method development consists of different parts. First, the label-technique was optimised, using absorptive swelling as described by Karakolis et al. (2019), with the commercial dye 'IDye' (ex. 669 nm, em. 550 nm). This dye has shown extreme stability for fluorescence imaging purposes and is compatible with STED (Stimulated Emission Depletion) microscopy. Next, the suitability of this labelling technique for plastic-toxicity testing was checked. The acute toxicity of the dye toward algae and copepods was tested using OECD protocols. A dose-response curve was built around the assumed exposure concentration (1.4×10^{-8} mg mL^{-1}), and showed that the EC50 (0.0277 mg mL^{-1}), and the EC10 (0.00836 mg mL^{-1}) for marine algae are located far above this. Furthermore, to account for false positives and negatives in image analysis, the leaching of the dye from the particles, and the longevity of the fluorescence of the particles, is analysed as a function of time. The effects of the labelling on the plastic particle characteristics were compared to the nonlabelled plastics, using FTIR, Single Particle Tracking (SPT), and a Tecan plate reader.

This study focused on nanoparticles smaller than 200 nm, the size range at which different particles can no longer be distinguished due to the resolution limit of optical microscopes. To enable the visualisation of these particles, we worked with the super-resolution STED microscope. We were able to acquire significant increases in resolution. To visualise the labelled nanoplastics in interaction with the autofluorescent, phytoplankton species, we used FLIM (Fluorescence Lifetime Imaging Microscopy). This technique allowed us to differentiate between phytoplankton species and plastics due to differences in the exponential decay rate of the photon emission.

1.09.B Micro (Nano)Plastics: Occurrence, Fate, Uptake, and Mechanistic Approaches to Understand Their Risk for the Environment and Human Health

1.09.B.T-01 The Biofilm Attached onto Microplastics is a Critical Factor Modulating Their Role as Vectors for Co-Occurring Pollutants

Irene Verdu Fillola[1]*, Georgiana Amariei*[2]*, Cristina Rueda-Varela*[1]*, Miguel González-Pleiter*[1]*, Francisco Leganes*[1]*, Roberto Rosal*[2] *and Francisca Fernandez-Pinas*[1]*, (1)Biology, University of Madrid (UAM), Spain, (2)Chemical Engineering, University of Alcala, Spain*

Microplastics (MPs) have increasingly raised concerns about their environmental impact in recent years. There is evidence that plastic particles are present in every ecosystem on earth, where they could negatively impact the biota. In addition, MPs have been suggested to act as vectors of pollutants by sorbing and desorbing contaminants from their surrounding environment. Ingesting contaminated MPs might impair key organisms in the food chain. Microorganisms may also colonize MPs, forming biofilms that may affect the sorption and desorption of pollutants from MPs due to their ability to metabolize chemicals or form a possible sorptive phase. A wide range of MPs, pollutants, and microorganisms can be found in wastewater treatment plants, suggesting that they can represent an important source of entry of polluted/biofouled MPs into the environment.

In this study, we explore the role of polyethylene MPs as vectors for triclosan (TCS) and how the biofouling of these MPs by biofilms growing onto them, the so-called plastisphere, affects this vector effect. Waters from influent and effluent from a wastewater treatment plant (WWTP), and an *Escherichia coli* culture were used to promote biofouling. We also evaluated the biological impact of biofouled and nonbiofouled MPs as vectors of TCS on the filter feeder *Daphnia magna*. The sorption and desorption of TCS were assessed using MPs biofouled for four weeks and then put in contact with TCS for four hours. Biotic experiments were also conducted to test *D. magna* survival in chronic exposure (21 d) to 0-400 mg MPs/L. At the highest concentrations tested, nonbiofouled MPs were toxic, but in all cases the toxicity of MPs was higher when biofouled in wastewater effluent. Regardless of the source of biofouling, both biofouled and nonbiofouled MPs exposed to TCS were capable of sorbing and releasing it, turning more toxic to *D. magna* than those not exposed to TCS. Triclosan-loaded MPs were also more toxic to *D. magna* when allowed to be colonized in wastewater effluent. The results indicated that MPs can transfer pollutants to the biota, causing toxic effects. Several factors could modulate this toxicity, including the nutritional status and the microbial community growing in the biofilm. In addition, it was observed that the exposure to TCS modified the composition of the colonizing community, selecting taxa with TCS-resistant and degrading abilities.

1.09.B.T-02 Screening and Prioritization of Nano- and Microplastic Particle Toxicity Studies for Evaluating Human Health Risks – Development and Application of a Toxicity Study Assessment Tool

Todd Gouin[1]*, Robert Ellis-Hutchings*[2]*, Leah Thornton Hampton*[3]*, Christine L. Lemieux*[4] *and Stephanie Wright*[5]*, (1)TG Environmental Research, United Kingdom, (2)Dow Chemical Company, Midland, Michigan, (3)Southern California Coastal Water Research Project (SCCWRP), (4)Health Canada, Canada, (5)King's College London, United Kingdom*

Concern regarding the human health implications that exposure to nano- and microplastic particles (NMPs) potentially represents is increasing. While there have been several years of research reporting on the ecotoxicological effects of NMPs, human health toxicology studies have only recently emerged. The available human health hazard data are thus limited, with potential concern regarding the relevance and reliability for understanding the potential human health implications. In this study we develop and apply a NMP toxicity screening assessment tool (NMP-TSAT) for evaluating human health effects studies against a suite of quality assurance and quality control (QA/QC) criteria for both *in vivo* and *in vitro* studies. A total of 74 studies representing either inhalation or oral exposure pathways were identified and evaluated. Assessment categories include particle characterization, experimental design, and applicability for risk assessment, with critical and noncritical criteria organized to allow screening and prioritization. It is observed that the majority of studies evaluated using the NMP-TSAT have been performed on monodisperse particles, predominantly spheres (≈60%), consisting of polystyrene (≈46%). The majority of studies have tested particles <5 µm, with a minimal particle size of 10 nm and a maximum particle size of about 200 µm. The total assessment score (TAS) possible for in vivo studies is 52, whereas for in vitro studies it is 46, which is based on receiving a maximum score of 2 against 26 and 23 criteria, respectively. The evaluated TAS ranged from between 12 and 44 and 16–34, for *in vivo* and *in vitro* studies, respectively. Several key observations for strengthening future effects studies are identified, based on the results observed from the evaluation exercise, which includes a need for the generation and access to standard reference materials representative of human exposure to NMPs for use in toxicity test systems and/or the improved characterization and verification of test particle characteristics, and the adoption of study design guidance, such as recommended by OECD, when conducting either in vivo inhalation or oral ingestion toxicity tests.

1.09.B.T-03 Risk Assessment of Microplastics in Soil Ecosystems Using Quality Criteria Screening and Data Alignment Methods

Paula E. Redondo[1]*, Andreu Rico*[2] *and Albert A. Koelmans*[3]*, (1)Fundación IMDEA Agua, Alcala de Henares, Spain, (2)IMDEA Water Institute, Spain, (3)Wageningen University & Research, Netherlands*

The occurrence and impacts of microplastics (MPs) on freshwater and marine ecosystems have widely been investigated over the past decade. However, less attention has been given to terrestrial ecosystems, even though they constitute major MP sinks due to the continuous use of plastic during common agricultural practices, such as mulching and greenhouse films, or sewage sludge application. The aim of this study was to characterize the risks of MPs in soil ecosystems, considering strict quality criteria and data alignment methods. For this purpose, we conducted a literature search to compile studies reporting measured environmental concentrations (MECs) of MPs in soil ecosystems, as well as toxicity data for terrestrial species exposed to MPs under controlled laboratory tests. The quality of exposure and effect data was screened after adapting QA/QC tools to soil data. Then, exposure and effect data were aligned to the standard MP size range (1 µm to 5000 µm), and effect data were rescaled to account for the polydispersity of environmental MPs and the bioaccessible MP fraction. Two species sensitivity distributions (SSDs) were constructed, one for volume and one for area as ecologically relevant dose metrics (ERMs), which trigger the effect mechanisms of food dilution and translocation, respectively. Using both SSDs, we calculated the Hazardous Concentrations for 5% of the species (HC5, with 95% confidence interval) for volume and area as ERMs, and we compared them with the mean, minimum, and maximum MECs of MPs reported for soils with different land uses. The HC5 and 95% confidence limits obtained for volume and area as ERMs were 2.3×10^7 (8.9×10^5 – 2.4×10^9) and 6.2×10^8 (3.8×10^7 – 3.5×10^{10}) particles/kg of soil (dry weight), respectively. The most sensitive species in both SSDs was the earthworm *Aporrectodea rosea*. When plotting the MECs together with the HC5 and the confidence limits for volume and area, we observe that 10 and 22% of the mean and maximum MECs exceed the HC5 value obtained for volume, while no MECs exceed the HC5 value obtained for area. Our results indicate that soil invertebrates might be at risk at 10-22% of the locations, globally. The MECs exceeding the HC5 value for volume include agricultural soils with various potential MP sources, but also forests and coastal soils. Based on the outcomes of this work, we conclude that soil ecosystems seem to be at higher risk due to the presence of MPs compared to surface waters and freshwater sediments.

1.09.B.T-04 Short- and Long-Term Toxicity of Polyhydroxybutyrate Nanoparticles to the Freshwater Cnidarian *Hydra viridissima*

Ana Rita Santos[1]*, Cátia Venâncio*[2]*, Mónica Almeida*[3]*, Isabel Lopes*[3] *and* ***Miguel Oliveira***[3]*, (1)Department of Biology, University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Portugal, (2)University of Coimbra, Portugal, (3)University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Aveiro, Portugal*

The booming of manufacturing affordable plastic goods since the 1950s gave rise to an era of disposable items, powered by consumerism and convenience, which resulted in one of the greatest environmental concerns of our times. The improper use and disposal of petroleum-based plastics resulted in its accumulation in the environment with increasing reports of biological effects to biota. This motivated research on development of more sustainable alternatives, such as bio-based biodegradable polymers.

Recently, due to its biodegradability and physicochemical properties, polyhydroxybutyrate (PHB) has received growing interest. These innovative materials possess more attractive properties than conventional alternatives. Although PHB is currently available commercially, little is known about its environmental impact and effects on freshwater organisms.

In this context, this study aimed to fill the existing knowledge gap about the ecotoxiticy of nanosized PHB plastic particles (PHB-NPLs) (~200 nm) focusing on lethality, morphological changes, and feeding behaviour of the freshwater cnidarian *Hydra viridissima*, a promising model species for aquatic toxicology studies owing to the wide array of endpoints easily measurable and reported sensitivity.

1.09.P-Mo045 Multigenerational Effects of Microplastics to Springtail

Jin Il Kwak*, Lia Kim and Youn-Joo An, Konkuk University, Korea, Republic of (South)*

Environmental persistence of microplastics is ubiquitous and problematic. Despite that research on soil ecotoxicity of microplastics has been increased, the relationship between microplastics exposure to soil environment and springtail health has been insufficiently investigated. The purpose of the present study was the assessment of multigenerational effects of microplastics to springtail. The natural soil was amended with 16 µm of HDPE microplastics and *Folsomia candida* was exposed to the contaminated soil by following OECD test guidelines No. 232. Through exposure to F2 generation, mortality, reproduction, and growth, damages in digestive system were examined. It was observed that HDPE exposure mainly caused decrease of survival and reproduction rate and inhibitions in microvilli and mitochondrial membrane in the intestinal tissues into continuous exposure group. These results indicated that soil collembola health can be affected by microplastics pollution.

1.09.P-Mo046 Artificial Plastic Aging as a Framework for Microplastics Ecotoxicity Evaluation
Marcus Lukas[1], *Maria Kittner*[2], *Tanja Kremer*[1], *Rebecca Kochmann*[1], *Lisa Isernhinke*[1], *Korinna Altmann*[2] *and Ulrike Braun*[1], *(1)German Environment Agency (UBA), Dessau-Rosslau, Germany, (2)Federal Institute for Materials Research and Testing (BAM), Berlin, Germany*
Microplastics are widely distributed in aquatic and terrestrial environments, but up to now less is known on ecotoxicological impacts under realistic conditions. Research so far has focused mainly on the impacts on organisms by virgin plastic fragments or beats. However, plastics found in the environment are mainly a mixture of different polymers and additives and are degraded during aging processes, particularly. Although especially oxidized degradation products might escape from plastic materials during aging, there is a lack of information on potentially adverse effects on aquatic biota. The latter is of particular interest as oxidized chemicals might become more water soluble due to higher polarity and are therefore more bioavailable.

The present study focused on plastic leachates of polystyrene (PS) and polylactic acid (PLA), which were derived from alternating stress by hydrolysis and UV radiation. Test specimens of PS, PLA, or PLA/PS layers (each 50%) were alternately maintained in water at 45 °C for five days and UV radiated at 45 °C for two days, for a total of eight weeks. Ecotoxicological effects of potentially generated degradation products of plastics in the storage water (natural spring water) were detected by algae growth inhibition tests with *Desmodesmus subspicatus*.
Results clearly indicate inhibitory effects on algae growth by contaminants in the storage water of stressed plastics with increasing growth inhibition of proceeding hydrolysis and UV stress times. Here, different polymers cause variable responses of algae growth. First analyses indicate dissolved monomers and the degradation products of polymers as possible driver of detected ecotoxicological effects, since detected microplastic particles do not seem to harm algae. The existing data highlight the relevance of plastic aging as a framework for microplastic ecotoxicity evaluation and allow a proof of concept.

1.09.P-Mo054 Leveraging Physiology and Behaviour to Better Understand Exposure, Uptake, and Elimination of Micro- and Nanoplastics (MNP) in Pelagic and Benthic Species within the Context of Quantitative Risk Assessment
Benjamin Patrick de Jourdan[1], *Danielle A. Philibert*[1], *Davide Asnicar*[1] *and Craig Warren Davis*[2], *(1)Huntsman Marine Science Centre, Canada, (2)Toxicology & Environmental Science, ExxonMobil Biomedical Sciences, Inc.*
Significant ecotoxicological data have been developed for micro- and nanoplastics (MNPs). However, several challenges to interpreting these data within the context of ecological risk assessment (ERA) remain. One such challenge is the selection of species for use in derivation of ecological protection criteria (EPC). Previous studies have proposed EPC values; however significant variability in species sensitivity across the range of MNPs exists, resulting in significant uncertainty in the application of derived EPCs as well as in identifying gaps in species sensitivity distributions (SSDs).

The objective of this work is to systematically compile and evaluate physiology and behavioural data for freshwater and marine species for use in ecotoxicological study design, identification of sentinel species for ecosystem health and quality monitoring, and ERA. Data are compiled from existing databases (e.g., Traitbank, Biological Traits Information Catalogue (BIOTIC), World Register of Marine Species (WoRMS), COPEPEDIA/COPEPOD, FishBase, and FishTraits). Life-history traits are used to describe habitat and motility. A trophic coding system is used to categorize species based on feeding mode and ecosystem functional roles. A trophic guild is then assigned based on species food source and feeding mode. Particular attention is directed toward benthic invertebrates given the likely deposition of MNPs in sediments and the relative paucity of benthic ecotoxicity studies. Using existing systems, benthic invertebrates are coded according to food source, diet, food type/size, and feeding mode. Existing MNP studies (biomonitoring and ecotoxicity) will be reviewed to identify trends in studied trophic guilds and compare them with trophic guild classifications likely to be most relevant for MNP exposure.

A biologically relevant framework is proposed against which the relevance of existing (and developing) MNP test materials and future studies can be evaluated. This can provide a systematic basis for the inclusion or exclusion of species or materials for the purpose of ERA in various environmental compartments. Data can also be integrated into risk assessment frameworks, providing guidance on species selection for ecotoxicity studies. Finally, species which have desirable traits for biomonitoring may also be identified based on their biological and physiological traits as well as abundance, distribution, and where possible the availability of established ecotoxicity testing methods.

1.09.P Micro (Nano)Plastics: Occurrence, Fate, Uptake, and Mechanistic Approaches to Understand Their Risk for the Environment and Human Health
1.09.P-Mo047 Soil Ecological Risk Assessment of Microplastics Based on Species Sensitivity Distributions
Dokyung Kim, *Haemi Kim and Youn-Joo An, Konkuk University, Korea, Republic of (South)*
Microplastics threaten the soil ecosystem causing adverse effects on organisms such as mortality, growth inhibition, and physiological factors, etc. This study aimed to conduct soil ecological risk assessment for microplastics based on the probabilistic approach. Based on data from previous studies, the species sensitivity distributions (SSDs) and environmental exposure distributions (EEDs) were estimated. In SSDs, hazardous concentration for 5th percentile of species (HC_5) and HC_{50} in soil

ecosystem was derived as 88.181 and 2656.527 mg/kg soil, respectively. In EEDs, a 95th percentile upper concentration of microplastics in agricultural land was estimated as 667.752 mg/kg soil. As a result of comparison of EEDs and SSDs, the overlap of them has been identified. These results suggest that microplastics threaten the soil ecosystem; accordingly, the establishment of a countermeasure for protecting the soil ecosystem from microplastic pollution is needed. This study can provide the basic information for the establishment of a soil management strategy for microplastic pollution.

1.09.P-Mo048 Physiologically Based Kinetic (PBK) Modelling for Human Exposure to Micro- and Nanoplastics
Jiaqi Wang, MSc[1]*, Damian Roelofsen*[2] *and Ad M. J. Ragas*[2]*, (1)Radboud University, Netherlands, (2)Radboud University Nijmegen, Netherlands*
Micro- and nanoplastics (MNPs, plastic particles <5 mm) are increasingly found in our environment and our food. Humans can be exposed to MNPs via several routes including inhalation, food consumption, and dermal contact, potentially imposing adverse effects on human health. Physiologically based kinetic (PBK) models estimate internal concentrations over time in human organs based on absorption, distribution, metabolism, and elimination (ADME) processes. PBK models have become essential tools since they allow a mechanistic framework to understand the internalisation of MNPs. However, PBK models for human exposure to MNPs are lacking. Typically, relevant processes and empirical data (*in vitro* and *in vivo*) are required to parameterise PBK models. Therefore, the aim of the present study is to summarise (the existing data on) ADME processes and discuss possibilities to develop PBK models for MNPs.
An extensive literature search was conducted on ADME information on PBK modelling for MNPs. A total of three relevant modelling articles on MNPs were found. Multiple relevant reviews and experimental articles regarding MNPs were also included. Absorption from the gastrointestinal tract (GIT) is most likely to occur via transcytosis in M-cells. Translocation in GIT depends on particle size, while the scientific consensus on cut-off values appears to be lacking. Particles above 1 μm in the lung are likely to be retained by the mucus layer and enter the GIT via mucociliary clearance. Microplastics smaller than 1 μm can be translocated into the systemic circulation or lymphatic system. Currently, modelling absorption via GIT and lung as first-order kinetics seems most appropriate. Empirically derived tissue-to-blood distribution coefficients can describe the distribution of MNPs between tissue and blood. The reticuloendothelial system plays a major role in the uptake of MNPs and translocation into the lymphatic system. Elimination of MNPs is regarded as negligible. It is worthwhile to develop experimental assays to determine MNPs concentrations in human blood and tissues. Since PBK modelling heavily relies on empirical data, generating consistent datasets (absorption, distribution and validation for the same size range) helps develop and validate PBK models for MNPs.

1.09.P-Mo049 Shape Plays an Important Role in the Ecotoxicity and Environmental Aging of Microplastics
Gabriela Kalcikova*, Ula Rozman, Barbara Klun and Aleksandra Kuljanin, Faculty of Chemistry and Chemical Technology, University of Ljubljana, Slovenia*
Microplastics represent a very heterogeneous group of pollutants, distinguished not only by their variable sizes and materials, but also by their shapes. Recently, researchers revealed that shape plays an important role in the ingestion of microplastics by animals, but how their shape affects other processes is unknown. In this context, the aim of this study was to investigate the interactions with aquatic macrophytes, adhesiveness, and environmental aging of polyethylene microplastics of the same size but different shapes, namely fragments, spheres, and films.
The investigated microplastics were of similar size (about 100 μm), and none of them had any effect on the growth rate of the aquatic macrophyte *Lemna minor* and on the chlorophyll *a* content. On the other hand, the fragments significantly reduced the length of the roots. Comparing the bioadhesion of fragments, spheres, and films, it was found that significantly less spheres adhered to the plant biomass (0.28 ± 0.11, 0.02 ± 0.02, and 0.15 ± 0.06 microplastics/mg, respectively). The lowest amount of biofilm was developed on films, while the analysis of chlorophyll *a* content within biofilm showed that there were significantly more phototrophic microorganisms within the biofilm developed on fragments than on spheres and films. Our results shed light on the importance of the shape of microplastics for their interaction with the surrounding environment; spherical microplastics showed the greatest difference in the tested parameters compared to fragments and films. They also do not represent environmentally relevant microplastics, which is why the use of spherical microplastics in environmental microplastic research should be reconsidered.

1.09.P-Mo050 Investigating the Influence of Microplastic Morphology and Surface Characteristics on Nitrogen Transformation in Floating Treatment Wetlands
Meredith Keleigh Sutton[1]*, Daniel Miller*[2]*, Tiffany Messer*[3] *and Shannon Bartelt-Hunt*[1]*, (1)Civil and Environmental Engineering, University of Nebraska - Lincoln, (2)US Department of Agriculture, (3)University of Kentucky*
Floating treatment wetlands are used for nitrogen removal in urban and agricultural runoff, sources which also contain high concentrations of microplastics. In wastewater treatment plants, the addition of microplastics has been found to influence the microbial communities performing similar nitrogen transformation and removal processes, raising concerns over the influence of microplastic pollution on the microbial communities in floating treatment wetlands.
To assess the impact of microplastics on nitrogen transformation, microplastics were incorporated into microcosms with root samples collected from mature floating treatment wetland mats. Nitrification microcosms were evaluated in aerobic conditions over 6 h and denitrification microcosms were flushed with nitrogen gas to promote anoxic conditions and monitored over 48 h in order to calculate potential nitrification and denitrification rates. Experiments investigating the impact of polyethylene and polystyrene microplastics at 30 μm and 200 μm size ranges showed a decrease in the rate of denitrification at the larger size range for both polymer types and an increase in the rate of denitrification for polystyrene at 30 μm. For the nitrification experiments,

polyethylene at 30 µm showed a decrease in the potential nitrification rate. While these trends show microplastics can influence nitrogen transformation in wetland systems, the mechanisms influencing these observed changes in microbial activity have yet to be defined. Further, these experiments were conducted using unweathered microbeads which are not representative of environmental microplastic samples.

To work toward more environmentally relevant samples, microplastics were created using milling techniques followed by UV weathering. After each milling and weathering step, microplastics were evaluated to assess size ranges, surface charge, and surface roughness. The study of microplastic surface characteristics, in addition to chemical properties, may elucidate the interactions between microplastics and microorganisms. This work will provide a better understanding of the impact of morphology and surface characteristics in addition to particle size gradients on changes in nitrogen transformation rates in wetlands as well as begin to explore some of the primary mechanisms by which microplastics are influencing wetland microbial communities.

1.09.P-Mo051 Fate of Microplastic Particles in Stream Mesocosms
Tobias Schmitt[1]*, Brendan Mckie*[2] *and Mirco Bundschuh*[1]*, (1)iES Landau, Institute for Environmental Sciences, University of Kaiserslautern-Landau (RPTU), Germany, (2)Swedish University of Agricultural Sciences (SLU), Sweden*
The amount of plastic litter in aquatic environments is increasing worldwide. Plastic residues enter the hydrological cycle in a wide range of sizes and break down gradually to tiny particles (<5 mm) called microplastic (MP). A distinction is made between primary MP (pMP), which are intentional produced for industrial applications and personal care products, and secondary MP (sMP). Secondary MP are breakdown products of larger meso- (5 –25 mm) and macro- (<25 mm) plastics. Most sources of MP pollution are land based, with car tire debris and artificial turfs being a major factor. These particles find their way into the aquatic ecosystem either during surface run-off events or via wastewater treatment plants. As a result, streams and rivers receive significant amounts of plastic debris. There is, however, still a major lack of knowledge about MP's fate and especially its retention by aquatic plants in freshwater systems. Therefore, the impact of macrophytes on the fate of MP particles was investigated using 12 artificial streams at the Eußerthal Ecosystem Research Station (EERES, Eußerthal, Germany) comprising 3.5 m long stream channels, fed by stream water from a nearby stream. Polystyrene (PS) and polyvinyl terephthalate (PET), two of the most common MPs, were chosen as model sMPs. We used three vegetation densities (0%, 25%, 100%) of the macrophyte *Elodea nuttallii*. We hypothesized that the retention of MPs is positively correlated with *Elodea* density. Analyses to (i) evaluate the longitudinal transport of MP within streams by means of water and sediment samples, and (ii) assess the retention of MP by macrophyte patches of different densities are currently ongoing. With this study we aim to get an insight on how two of the most commonly found sMP are transported within slow flowing streams and to what extent these particles are retained by the macrophyte *Elodea nuttallii, s*ince the retention of particles can also create a potential risk for organisms inhabiting these vegetated zones.

1.09.P-Mo052 Modelling Environmental Microplastic Fate and Exposure
Yvette Agnes Maria Mellink[1]*, Merel Kooi*[1]*, Joris T.K. Quik*[2] *and Albert A. Koelmans*[1]*, (1)Wageningen University & Research, Netherlands, (2)National Institute for Public Health and the Environment (RIVM), Netherlands*
Exposure assessment is the basis of risk assessment for microplastic particles (MP). Since small microplastic and nanoplastic particles are almost impossible to detect, and their concentrations can only be estimated by interpolating in time and space, retrospective risk assessments must rely on modelling. This requires a holistic modelling approach, linking sources, transport, fate, and exposure of MP. In this research, we will develop and validate a range of microplastic transport and fate models, encompassing different spatial and temporal scales. The first step will be to develop a harmonized microplastic emission model, followed by the development of a 'unit world' multimedia model. Microplastic fluxes generated by this multimedia model will serve as input for a detailed spatiotemporal river transport model. While previous models were usually parameterized to simulate only the behaviour of monodisperse spherical microplastic particles, we will apply new approaches using probability density functions (PDFs). Using these PDFs we will be able to capture the full multidimensionality and diversity of environmentally relevant MPs as they exist in nature. Modelled MP-PDFs can then be tuned to threshold effect concentrations to characterize ecological risks in environmental systems. The toolset presented enables us to prospectively assess risks for decades to come.

1.09.P-Mo053 Quantifying Environmental Emission and Risk of Microplastics in a Semi-Enclosed bay: A Tokyo Bay Case Study
Wataru Naito[1]*, Masashi Gamo*[2]*, Yuriko Ishikawa*[2]*, Yuichi Iwasaki*[2]*, Hideo Kajihara*[2]*, Bin-Le Lin*[2]*, Hiroyuki Mano*[2]*, Isamu Ogura*[2]*, Kyoko Ono*[3]*, Naohide Shinohara*[2]*, Kiyotaka Tsunemi*[2]*, Kouji Ueda*[2] *and Mianqiang Xue*[2]*, (1)RISE Research Institute of Sweden, Sweden, (2)National Institute of Advanced Industrial Science and Technology (AIST), Japan, (3)Research Institute of Science for Safety and Sustainability (RISS), National Institute of Advanced Industrial Science and Technology (AIST), Japan*
In recent years, there has been growing concern about the impact of microplastics (hereafter MPs) on marine ecosystems, and political and social concerns have increased both domestically and internationally. The number of MP related studies in the marine environment is increasing every year, including monitoring in the environment, environmental behaviour, development of analytical methods, and ecological effects. However, there are few studies on quantitative assessment of MPs that contribute to develop realistic strategies for risk-based management for MPs. In this study, we reviewed domestic and international literature related to environmental risk assessment of MPs and quantify MP emission and environmental risk in the Tokyo Bay. A literature review was conducted to identify the latest trends in research related to the environmental emission estimation of MPs and the actual situation of MP concentration in Japan. To conduct a trial environmental risk assessment for Tokyo Bay, MP emission into

Tokyo Bay was calculated for MP contained in products, synthetic fibers derived from laundry, and tire wear particles. As one attempt to estimate a threshold concentration for the use in risk characterizations, we devised an estimation method for SSD using a hierarchical Bayesian model, which can quantitatively take into account the characteristics of MPs and attempted to estimate the hazardous concentration (HC5). In this talk, as a case study of Tokyo Bay, the results of environmental emission estimates of the selected sources and model analyses, as well as the risk estimates based on monitoring data of MPs, will be presented.

1.09.P-Mo055 Comparison of Species Sensitivity Distribution Methods for Risk Assessment of Microplastics
Sara J. Hutton, *Kenia Whitehead, Janet Anderson and Philip E Goodrum, GSI Environmental, Inc.*
Most papers published on ecological risks of microplastics (MP) are based on laboratory studies with limited exposure profiles or field studies that focus on the occurrence of MPs in aquatic organisms. However, the current scientific literature and knowledge regarding MP toxicity is sparse and often challenging to interpret. Examples of challenges with MP studies include incomplete/inconclusive reporting on microplastic characterization, and uncertainty in dose ranges (e.g., particle counts) due to particle aggregation. Given the limited number of high-quality studies that can be used in risk assessment, most efforts to quantify MP risk have lumped MPs into a single class rather than differentiating them based on a specific property (e.g., particle shape, polymer type). While this approach may currently be the most feasible, it may also be too simplistic and potentially under protective. In the past decade, there has been an increase in research and regulatory activity directed at supporting MP risk assessments. In 2016 the State of California, USA passed legislation requiring a comprehensive literature review to determine if a risk assessment could be conducted for human health (via drinking water) and aquatic organisms. California concluded that while there were insufficient data to conduct a formal risk assessment for human health, sufficient data were available to generate species sensitivity distributions (SSDs) based on no observed effect concentrations (NOECs) or lowest observed effect concentrations (LOECs). The SSDs were used to define four threshold levels; however, given the small sample sizes and well documented limitations associated with NOECs/LOECs, the confidence intervals calculated for each threshold almost entirely overlap. An alternative approach, first developed by USEPA's Office of Pesticide Programs to support ecological risk assessments of pesticides, and subsequently applied to site assessments of legacy contaminants, utilizes the full dose-response curve (DRC) rather than selected points of departure. The DRC method produces a composite DRC and confidence interval that reflects the range of different shapes of DRCs. Here we compare the threshold values for MPs when SSDs are constructed using the NOEC/LOEC approach and when the same study data are integrated using the DRC approach. We discuss the advantages and limitations of the approaches and demonstrate the implications of grouping MPs into subclasses based on common properties.

1.09.P-Mo056 Bioenergetic Status of Human Intestinal Caco-2 Cells After Exposure to Simulated Environmental Nanoplastic
Miao Peng[1], *Maaike Vercauteren*[2], *Charlotte Grootaert*[3], *Ana I Catarino*[4], *Gert Everaert*[5], *Andreja Rajkovic*[3], *Colin Janssen*[6] *and Jana Asselman*[7], *(1)Department of Animal Sciences and Aquatic Ecology, Ghent University (UGent), Ghent, Belgium, (2)GhEnToxLab, Ghent University (UGent), Ghent, Belgium, (3)Ghent University (UGent), Ghent, Belgium, (4)Flanders Marine Institute (VLIZ), Oostende, Belgium, (5)Ocean & Human health, Flanders Marine Institute (VLIZ), Oostende, Belgium, (6)Laboratory for Environmental Toxicology (GhEnToxLab), Ghent University (UGent), Ghent, Belgium, (7)Blue Growth Research Lab, Ghent University (UGent), Ghent, Belgium*
The ubiquitous human exposure to nanoplastic (NP) in our daily life increasingly raises concerns regarding our health. Currently, it is difficult to evaluate effects of NP in real-life exposure as substantial studies exposed human cells to pure nanopolymer particles with rather high concentrations, which cannot represent complicated NP samples suffering weathering in our living environment. In this study, the bioenergetic effects of four simulated environmental NP samples on human intestinal Caco-2 cells were investigated. To this aim, big micro-PET (polyethylene terephthalate) particles were mechanically milled into a lower size range sample (M-PET) with multiple shapes. Then the M-PET particles and a polystyrene (PS) mixture (100 nm and 700 nm, mixed) were irradiated by ultraviolet (UV) light for 1273 h, corresponding to 15 months of central European solar irradiance exposure. After weathering procedures, both virgin and UV-weathered M-PET samples were filtered by 0.8-µm filter to obtain nano-PET particles with size less than 800 nm. Subsequently, Caco-2 cells were exposed to nano-PET and nano-PS samples with and without UV weathering at realistic exposure levels (10^1-10^6 particles/mL) for 48 h. The mitochondrial respiration and glycolytic parameters of exposed cells were measured by Seahorse XF96 Analyzer. Based on these results, the harmful impacts of nano-PET on cellular bioenergy were stronger than those of nano-PS. Basal respiration, spare respiratory capacity, proton leak, and basal glycolysis were stimulated by stress from exposure to both virgin and UV-weathered nano-PET samples. Comparing virgin and UV-weathered nano-PET, the negative effects on mitochondrial respiration were alleviated while anaerobic glycolysis was enhanced for UV-weathered PET. Similarly, mitochondrial functions were more sensitive to virgin nano-PS while basal glycolysis was more vulnerable to UV-weathered PS sample. This research is the first to study bioenergetic responses of simulated environment NP samples on human health. It highlights that effects between virgin and weathered NP are different at a bioenergetic level, which has important implications for the risk assessment of NP on human health.

1.09.P-Mo057 Macroplastics to Microplastics: The Production of Microplastic Particles from Large Debris in Freshwater Systems
Austin D. Gray, Tyler Allen, Madison Ruschaupt, Alex Rosser, Clara Betts, Allison Montgomery, Rutha Patel, Mikail Bonham and ***Kathleen Mayer***, *Department of Biological Sciences, Virginia Tech*
Plastic pollution poses one of the greatest environmental challenges to date, mainly due to the microplastics produced. Microplastics can be produced from macroplastics in aquatic systems due to mechanical abrasion or weathering, UV degradation or photolysis, chemical degradation, and hydrolysis. As a result, it is extremely challenging to predict or model the abundance of

microplastic particles entering the environment. A common misconception of plastic debris is that it takes hundreds to thousands of years to degrade or mineralize. This underestimates the fragmentation that can occur along this period, contributing to varying rates of microplastics being produced over much shorter time scales. Previous work has identified that within a salt-marsh habitat, macroplastics can start producing microplastics in as little as eight weeks, with biofilm development occurring around week 4. In our assessment, we buried macroplastics (n = 5/polymer type) that represent common polymers found in the environment (polyethylene, polystyrene, polypropylene, polyethylene terephthalate, and polyvinyl chloride) and natural cellulose debris (n = 3/polymer type) in stream sediments from urban and forested areas to track the rate of fragmentation and biofilm development over the course of a year. To date, we have found through mRaman analysis that macroplastics from four of the five polymers started producing microplastics in as little as two weeks, faster than that observed in salt marshes in coastal systems and culturable bacterial communities in the same period, indicative of biofilm development. With a large emphasis on microplastic research focused on marine systems, it is important to note that ~80% of plastic debris comes from inland waters (streams, lakes, and rivers). With the fragmentation rate of microplastics being faster in these systems, it warrants more attention to the implications of microplastic pollution in freshwater habitats and what bacteria are preferentially selecting these polymers as a substrate.

1.09.P-Mo058 Mapping and Quantifying the Various Sources of Microplastic Pollution in the Elbe River Basin
Yichen Sun[1]*, Ad M. J. Ragas*[2] *and Jikke van Wijnen*[3]*, (1)Environment Science, Radboud University Nijmegen, Netherlands, (2)Radboud University Nijmegen, Netherlands, (3)Open University, Netherlands*
Microplastics (MPs) are found in many different environments. The aim of the present study was to quantify and map sources of MPs pollution in the Elbe River basin, which is the fourth largest river basin in Central and Western Europe. We identified the most relevant sources of MPs, including tyre wear, synthetic textile fibres, paint chips and plastic beads from cosmetics. The mapping was based on location-specific proxies, e.g., the per capita MP emissions from different sources combined with the population density of a given agglomeration. Methods were developed to include factors affecting the MP release process to produce more realistic estimates. For example, fabric type and washing temperature are both influencing the amount of microfibres released, and the amount of tyre wear particles released varies considerably from one vehicle to another when driving on different types of roads. The results of this study will be used as input for modelling the fate of MPs in the Elbe River basin. For this, we will use the "Exposure to Pharmaceuticals in the Environment" model (ePiE) which originally was developed for calculating concentrations of active pharmaceutical ingredients (APIs) in surface waters. The model will be adapted to simulate the advective transport and degradation of MPs in rivers to provide a more comprehensive understanding of the sources, fluxes, accumulation areas, and fate of the MPs in rivers.

1.09.P-Mo059 Wear and Tear of Synthetic COVID-19 Face Masks in an Artificial Wave Mesocosm System
Ulrike Scholz*, Fabian König, Daniela Pflanz and Stefan Meinecke, IV 2.5, German Environment Agency (UBA), Dessau-Rosslau, Germany*
The coronavirus pandemic prompted the extensive use of disposable face masks made of plastic polymers, and their use in public areas was mandatory in many countries. Unfortunately, their widespread use also led to their introduction into the environment through inappropriate disposal, i.e., littering or unintended loss. Being durable, they can remain in the environment for decades.

Though plastic pollution is one of the most pressing environmental issues of our time, little is known about degradation processes under natural conditions and the coronavirus pandemic has added a new item of concern. Mechanical abrasion plays an underestimated role in the formation of secondary microplastics of all plastic polymers and in this context, the degradation process of three different mask types (KN95, FFP2, and surgical face masks) was investigated in the semiterrestrial zone of the artificial wave mesocosm system at the German Environment Agency´s field station, where seminatural conditions can be simulated on a larger than laboratory scale.
For each face mask type, 3x5 masks were exposed to a stone-gravel-shore in two wave mesocosms and one unmoved body of water as control, for approximately 200 days. Loss of mass, but also changes in surface structure of the three different mask types, were monitored.

Loss of mass varied between the different masks with approximately 10%‒15% for the KN95 masks, 4%‒4.5% for the surgical face masks, and 4%‒6% for the FFP2 masks; thus not all masks display the same durability. All masks displayed clear signs of wear and tear, but especially the FFP2 and KN95 masks showed distinct signs of peeling. When the surface of the masks was viewed under a microscope and white light interferometer, fibers appeared fairly durable with only slight defibration or fraying of the outer melt-blown, nonwoven fabric layer, that was primarily exposed to the gravel shore.

1.09.P-Mo060 Integrated Toxicological Analyses of Marine Micro- and Nanoplastic Particles Using *in vivo* and *in vitro* Bioassays
Clara Alejandra Alejandra Kempkens Palacios[1,2]*, Muhammad Arslan Kamal Hashmi*[1]*, Andi Alijagic*[3]*, Anna Kärrman*[1]*, Anna Maria Rotander*[1]*, Nikolai Scherbak*[4]*, Maria Larsson*[4]*, Magnus Engwall*[1] *and Steffen H. Keiter*[1]*, (1)Orebro University, MTM Research Centre, Sweden, (2)Aquatic Ecotoxicology, Goethe University Frankfurt, Frankfurt am Main, Germany, (3)Orebro University, Örebro, Sweden, (4)School of Science and Technology, Orebro University, Örebro, Sweden*
Microplastics are detected at the base of the food chain, posing a potential threat to marine ecosystems but also raising concerns about potential impacts on humans due to adsorbed chemicals and additives exhibiting toxicity. Target-, suspect, and nontarget screening are used to identify the chemical composition of microplastics. However, due to the vast number of microplastics-

related toxicants and the cocktail effect caused by the mixture of chemicals, chemical analyses are insufficient for hazard assessment. Effect-Directed-Analysis (EDA) represents an integrative assessment of toxic fractions or chemicals, that combines biotesting, fractionation procedures, and chemical analysis methods. Effect-Directed-Analysis provides an accurate characterisation of the toxicity of bioactive chemicals using *in vivo* and *in vitro* bioassays.

This study is associated with the European research project "Response: Towards a Risk-Based Assessment of Microplastic Pollution in Marine Ecosystems" with the objective to develop a monitoring approach for marine plastic pollution. In this context, the present study aims to identify molecular and cellular toxicological effects in different *in vitro* and *in vivo* models after exposure to marine and beach plastic samples. For this purpose, the samples were cleaned and extracted, the polymers were chemically characterised, and their extracts were analysed by different types of bioassays. For the detection of endocrine disruption responses in nuclear hormone receptors we used estrogenic (ER), androgenic (AR), pregnane X (PXR), and thyroid (TR) CALUX® bioassays. For the detection of aryl hydrocarbon receptor-mediated activity and detection of genotoxicity, the DR CALUX® and P53 CALUX® bioassays were used, respectively. Ongoing fractionation is performed on extracts that caused mechanism-specific activity in the selected bioassays. Chemical analyses on the bioassay active fractions are used for the identification of toxic compounds. In addition, for the most toxic fractions, we intended to apply high-content screening by Cell Painting assay and different *in vivo* tests including developmental, behavioural, and gene expression analyses using zebrafish embryos (*Danio rerio*).

This study demonstrates the importance of an integrated study design composed of chemical identification of various organic compounds and different *in vitro* to *in vivo* bioassays and Cell Painting, to investigate the toxic effects of micro- and nanoplastics at different trophic levels.

1.09.P-Mo061 Polymer-Specific Biofouling Determines the Vertical Movement of Plastics in Freshwater
Maaike Vercauteren[1,2]*, Silke Lambert*[3]*, Esther Hoogerwerf*[3]*, Colin Janssen*[4,5] *and Jana Asselman*[3]*, (1)GhEnToxLab, Ghent University (UGent), Ghent, Belgium, (2)Blue Growth Research Lab, Ghent University (UGent), Ghent, Belgium, (3)Blue Growth Research Lab, Ghent University (UGent), Ghent, Belgium, (4)Laboratory for Environmental Toxicology (GhEnToxLab), Ghent University (UGent), Ghent, Belgium, (5)GhEnToxLab, University of Ghent, Belgium*
To improve successful plastic remediation and removal attempts, there is an urgent need to better understand the vertical transport of plastic particles and all factors that affect this transport, particularly in freshwater environments. The density of the particles will determine if a plastic particle stays afloat, sinks, or shows oscillating behaviour. The growth of biological entities (referred to as biofilm formation or biofouling) on the plastic particles can affect the total density of these particles and thus influence the sinking behaviour of plastics. As most research has focused on the marine environment, the effect of biofouling on the sinking behaviour in freshwater is still mainly unknown. The current research studied biofilm formation over time and in function of the polymer type to gain insight into the polymer-specific fate and transport of plastic debris in the freshwater environment. First, a mesocosm experiment simulating a freshwater environment was set up to study the difference in biofilm growth on plastic plates of different polymer types. Second, the biofilm growth on various plastic particles was studied for 62 days (nine weeks) with intermittent sampling. Based on these experiments, the effect of biofouling on the settling onset time and sinking velocity was modelled for various sizes and types of plastic particles. It was indeed proven that biofouling is a polymer-specific process whereby biofilms on polyethylene terephthalate (PET) and polystyrene (PS) showed exponential growth over time. Results of the polymer-specific modelling of the settling onset time indicated that the settling onset time is dependent on both the size and the density of the polymer particle. Smaller particles need less time to start settling compared to larger particles. Moreover, denser polymer types tend to start settling sooner compared to less dense polymer types. For sinking polymer types, the growth of a biofilm is believed to affect the terminal sinking velocity of a particle. The sinking velocity of PET does not seem to change a lot over time and experiences little to no effect of biofilm growth, in contrast to the biofilm formation on PS particles that does seem to have a bigger effect on the sinking velocity. The results of this study help to better understand the vertical transport of plastic particles and assess their fate in freshwater ecosystems.

1.09.P-Mo062 Microplastics on Beaches Along the Coast of Valencia (East of Spain)
Vasiliki Soursou[1]*, Julian Campo*[2] *and Yolanda Pico*[1]*, (1)Centro de Investigaciones sobre Desertificación, Universidad de Valencia, Moncada, Spain, (2)CIDE (CSIC UV GV), Spain*
The contamination of the marine environment by plastics is considered a serious public health issue worldwide and has attracted the interest of the scientific community during the last decade. Plastic fragments with size between 1 μm and 5 mm are known as microplastics (MPs) and their occurrence in environmental samples is widely studied. There are two categories of MPs according to their production, namely the primary MPs that are used in cosmetic products, detergents, etc., and the secondary MPs that are a result of the environmental degradation of bigger plastics. The Mediterranean Sea has become one of the most plastic polluted seas. The presence of MPs in sand samples from seven different beaches of the Valencian community in Spain was studied. The beaches were chosen for their touristic and economic importance. Two different sampling campaigns took place, the first during winter (February 2022) and the second during summer (July 2022) to compare the results and understand the influence of the high touristic activity that usually begins in May. The extraction of MPs from the sand was performed by density separation (floatation) to eliminate heavier (inorganic) particles from lighter (organic) particles. After filtration, the polymer type, color, size, and number of MPs found was performed by stereomicroscopy and micro-Fourier transform infrared (μ-FTIR) microscopy. The contamination of the sand samples by MPs was evident during both winter and summer season but the presence of MPs in the samples from the July campaign was significantly higher because of the increase of anthropogenic activity in the coastal areas due

to the heat. Textile and nylon fibers were the most abundant type of MP with swimming equipment and fishing net being their most probable sources.

1.09.P-Mo063 Biofragmentation of Microplastic in the Process of Digestion by the Snail *Lissachatina fulica* (Bowdich)
***Tae-Yang Lee**, Sang A Kim, Jin Il Kwak and Youn-Joo An, Konkuk University, Korea, Republic of (South)*
Microplastics can be fragmented through various factors in the environment. This study explored microplastic biofragmentation coming out in the digestive tracts of the African giant snail and whether mechanical fragmentation was by the radula. After ingesting polyethylene microplastics, the feces of snails were sampled and watched for identifying biofragmentation. Additionally, the radulas were observed to identify that the biofragmentation of microplastics was not caused by mechanical fragmentation. The surface of microplastics and radula were observed using field-emission scanning electron microscopy (FE-SEM). In addition, energy dispersive X-ray (EDX) point analysis checked the signal of the fragmented particles on the microplastic surface. As a result, the EDX signal of the fragmented particles from egested microplastics changed, indicating that oxidation of microplastics occurred. However, the fragmented particles were not located on the radula, so mechanical fragmentation was not presented. Our findings identified that organisms living in the soil play an important role in the fate of microplastics in the soil.

1.09.P-Mo064 Time-Course Accumulation in Target Tissues and Depuration Dynamics of Polystyrene Microplastics in Mussels and Polychaetes
***Nagore Blasco**[1], Mikel Ibeas[1], Mariana Calmao[1], Julene Aramendia[1], Kepa Castro[1], Urtzi Izagirre[2], Manuel Soto[3] and Nerea García-Velasco[1], (1)University of Basque Country (UPV/EHU), Spain, (2)UNIV BASQUE COUNTRY, Spain, (3)Plentzia Marine Station, University of the Basque Country (UPV/EHU), Spain*
Microplastics (MPs) occupy the same size fraction as sediment particles and some planktonic organisms, presenting a potential bioavailability to a broad scope of biota. They appear on surface waters but are also accumulated in sediments affecting benthic species. Microplastics can be eliminated through feces or accumulated in tissues leading to trophic transfer along the food chains reaching humans through consumption. The time established by FAO for mussel depuration for human consumption may not be effective for the elimination of MPs. The aim was (1) to decipher uptake, accumulation, and localisation of PS MPs in target tissues of *Mytilus galloprovinciallis* and *Hediste diversicolor* exposed to various concentrations (103 and 105 MP/mL, LC and HC) of MPs along a time course (1 h, 4h, 24 h, and 72 h); and (2) to study the depuration dynamics (24 h, 48 h, and 7 d) in mussels exposed for 24 h to MPs (104 MP/mL) of different size (0.25 µm, 1 µm, and10 µm). Mussels from Plentzia (2021) and polychaetes from Galicia (2020) were exposed to MPs, digested to quantify MPs incorporated, and processed for microscopical analysis. Microplastics were found in both species, mainly after exposure to HC. A decreasing trend with time regarding MPs number in mussels was observed, being the opposite for polychaetes and sediments. In mussels, particles were found in the stomach, digestive diverticula, ducts (lumen, epithelium) and gills (only in HC), showing a nongradual decrease over time. The stomach was the unique digestive structure that accumulated MPs after 72 h of exposure to both doses. After depuration, MPs were quantified at all timepoints for sizes of 1 µm and 10 µm, but not for 0.25 µm. Significantly higher quantities of 10 µm MPs than 1 µm MPs were quantified throughout depuration. A significant decrease was observed after 7 d depuration in mussels exposed to 10 µm. Microplastics were found in stomach, intestine, secondary ducts (lumen, epithelium), and gills of mussels exposed to both MPs. A trend to decrease MP number with depuration time in the digestive tract of mussels was recorded for 1 µm and 10 µm, although were still present at longer depuration times (7 d), which exceed the depuration time stipulated for molluscan consumption. Results enabled us to understand the distribution of MPs in tissues of marine species and the depuration dynamics in mussels (helpful for the establishment of depuration protocols for human consumption).

1.09.P-Mo065 Determination of Microplastics in Soil and Water from a Managed Aquifer Recharge System with Secondary Wastewater Treatment Plant Receiving Waters
***Albert Contreras Llin**[1], Lurdes Martínez-Landa[2], Cristina Valhondo[3], Jesus Carrera[4] and Silvia Diaz-Cruz[5], (1)Agencia Estatal Consejo Superior de Investigaciones Científicas, Spain, (2)Tecnical University of Catalonia UPC, Spain, (3)University of Montpellier- CNRS, France, (4)Spanish Research Council (CSIC), Institute for Environmental Assessment and Water Research (IDAEA), Spain, (5)IDAEA-CSIC, Spain*
Plastic materials are extremely versatile due to their low density, low thermal and electric conductivity, and corrosion resistance, allowing them to serve as a water and oxygen barrier. Their low price also contributes to their easy and widespread manufacture, where they are used in a wide range of applications from food packaging to medical and technological applications. Environmental conditions such as solar radiation, abrasion, and diverse interactions with organisms, among many others, cause plastic to degrade and fragment into smaller particles commonly known as microplastics (MPs). Microplastics might accumulate in the natural environment, considering the low degradability of most plastics; thus their analysis and determination are of utmost importance. Wastewater treatment plants (WWTPs) have been identified as one of the highest sources of plastic release into the environment.

In the present work, a simple analytical method for the simultaneous determination of MPs, including polyethylene (PE), polypropylene (PP), polystyrene (PS), polyvinylchloride (PVC), and polyethylene terephthalate (PET), in water and soil samples from a pilot managed aquifer recharge (MAR) system receiving water from a WWTP (Palamós, Spain), has been optimised and validated. Retention and removal of MPs will be assessed in different reactive barriers installed in the system, and the presence of MPs along the course of the WWTP will also be addressed. The method is based on a density separation of the MPs using a salt-saturated floatability solution, followed by an oxidative treatment using hydrogen peroxide and Fenton's reagent, for water and

soil samples, respectively, to eliminate the organic matter present in the samples. After the oxidation, the solution is allowed to settle, before collecting the supernatant, which is filtered through a 1 x 1 cm^2 silicon filter. Once particles are retained onto the filter, it is analysed by FTIR imaging, using a Nicolet™ iN™ 10 MX infrared imaging microscope.
The method allowed MP's correct characterisation, and thus was applied to evaluate the removal and retention efficiency of the WWTP as well as the reactive barriers installed. On both, notorious removal of bigger MPs is achieved but still, certain inefficiency on smaller MP's retention was observed, which might lead to the further spread of plastic debris into the aquatic environment. Best options will be proposed, with the aim of further diminishing plastic release into the environment.

1.09.P-Mo066 Impacts of Polyethylene Terephthalate in Manila Clam *Venerupis philippinarum*: Filtration Rate and the Body Accumulation

Yooeun Chae[1], *Jin-Soo Choi*[2], *Yunwi Heo*[2], *Hyeonji Nam*[2] *and June-Woo Park*[2,3], *(1)Ecological Risk Assessment Center, Korea Institute of Toxicology (KIT), Korea, Republic of (South), (2)Environmental Exposure & Toxicology Research Center, Korea Institute of Toxicology (KIT), Korea, Republic of (South), (3)Human and Environmental Toxicology Program, Korea University of Science and Technology (UST), Korea, Republic of (South)*

Plastic pollution in the marine environment is ubiquitous and is an emerging problem nowadays. These plastic wastes, especially microplastics (MPs) with very small sizes, can enter the marine environment and sink to the bottom of the sea. The accumulation of MPs in the benthic environment can cause various adverse effects in benthos like crabs, clams, and many invertebrates. In this study, we tried to determine the toxicity and implication of polyethylene terephthalate (PET) MPs on the benthic organism, *Venerupis philippinarum*, and determined the body accumulation of MPs. *V. philippinarum* was exposed to PET MPs with various sizes and shape (diameter <20 µm, Fragment S; diameter 45 µm–75 µm, Fragment M; diameter >150 um, Fragment L; length 200 µm–400 µm, Fiber S; length > 3 mm, Fiber L) in the range of 0.0005 mg/L to 100 mg/L for 96 h. To determine the impact of PET MPs on the filtration ability of clams, their filtration rates were measured at 0.5 h, 1 h, 2 h, and 4 h after exposure. Additionally, the MP accumulation in the body was observed under microscope. As a result, the filtration rates of clams exposed to every PET MP significantly decreased compared to control organisms and we could determine the accumulation of MPs in the body of clams, especially in the digestive gland. This study can suggest the possibilities of the accumulation of MPs in the marine organisms that live in the benthic environment and used as food resources and also the probabilities of the self-purification disorders in the marine ecosystem.

1.09.P-Mo067 Combining a Novel Radiolabelling Approach and a Traditional Radiometric Technique to Characterise the Biokinetics of Ultralow Levels of Nanoplastics in Mussels

Marion Sebire Dr.[1], *Maya Al-Sid-Cheikh*[2], *Terry Davis*[1] *and Franck Dal-Molin*[1], *(1)Centre for Environment Fisheries and Aquaculture Sciences (Cefas), United Kingdom, (2)Department of Chemistry, University of Surrey, United Kingdom*

Up until recently, only a few studies have addressed the effects of nanoplastics (NPs) on marine biota, mainly owing to the analytical challenges associated with the tracking of ultrafine particles in organisms. This highlighted a need for developing an innovative approach that could help better understand the associated biokinetic mechanisms and their role as vector of transport for other hazardous substances of concern.
In this study, a novel radiolabelling technique was applied to produce two different sizes of NPs (^{14}C-polystyrene; 20 nm and 250 nm in diameter). Mussels (*Mytilus* spp.) were exposed to a known concentration (<1 µg/L) of ^{14}C-NPs for up to 48 h, following by a 14-d depuration period. Bioaccumulation was verified by autoradiography and the levels of ^{14}C (i.e., NPs) in water and mussel samples were quantified by liquid scintillation counting (LSC). A validated oxidative method was used to prepare mussel samples prior to LSC.

The observations and results obtained from these exposure experimentations and analysis will be discussed in this presentation.

1.09.P-Mo068 Ingestion of SMPs (Small Microplastics < 100 µm) and TWPs (Tire Wear Particles) in King Prawns *Procambarus clarkii* from Highway Stormwater Runoff

Beatrice Rosso[1], *Silvia Spinello*[2], *Elena Gregoris*[3], *Carlo Barbante*[3], *Andrea Gambaro*[1] *and Fabiana Corami*[3], *(1)Department of Environmental Sciences, Informatics, and Statistics, Ca' Foscari University of Venice, Italy, (2)Ca' Foscari University of Venice, Italy, (3)National Research Council (CNR), Institute of Polar Science (ISP), Italy*

Plastic pollution from highway stormwater runoff is a direct pathway for conveying plastic and microplastics (MPs) from land-based sources to the aquatic and terrestrial environment. Vehicular traffic mainly (road dust) and atmospheric aerosol are relevant sources of MPs in stormwater runoff. Tire wear particles are the primary source of MPs in road and urban dust. Stormwater runoff, generated by rainfall events, can carry pollutants and MPs in freshwater bodies; they can be dispersed or released, posing a threat to a wide range of freshwater, terrestrial, and marine organisms. Organisms at the bottom of the trophic web (e.g., invertebrates) can ingest particles according to the dimension of their mouthparts, including small microplastics (MPs <100 µm; SMPs) and TWPs. Once in the trophic web, SMPs and TWPs may be bioaccumulated or biomagnified, reaching the top of the food web, even human beings. Due to the benthic lifestyle and diverse feeding strategies, crustaceans have been widely used as bioindicators of environmental quality regarding different pollutants. However, only a few studies specifically examine the presence of SMPs and TWPs in these natural populations, and assessing their baseline levels is still lacking for these species worldwide. There are currently no standardized methods and harmonized techniques for their collection, pretreatments, contamination procedures, and analysis in the biota compartment. Among the widespread invertebrates, king prawns (*Procambarus clarkii*) is a species of cambarid crayfish native to freshwater bodies of Mexico and the United States; it is often an invasive pest introduced in other continents, including Europe. Hence, this research aims to quantify and simultaneously identify

SMPs and TWPs ingested by organisms of *Procambarus clarkii* collected in the highway stormwater runoff near Venice, Italy. For each pool, gastrointestinal apparatus, muscle tissues, and the head were dissected and pseudodigested, avoiding denaturation/degradation of these contaminants. The quantification and chemical identification of SMPs and TWPs were performed through a cross-validation technique via Micro-FTIR and Pyr-GC/MS. Different polymer typologies were associated with highway tire degradation (e.g., rubbers, nylon). Pyr-GC/MS confirmed the presence of TWPs using specific markers. A potential translocation among the organism's organs was investigated by comparing the abundance of SMPs and TWPs in the different dissected parts.

1.09.P-Mo069 Bioaccumulation of Plastic Additives and Organic Pollutants in Zebrafish Through Microplastics

Arianna Bautista[1], *Alicia Herrera*[2], *Ico Martínez*[2], *Alessandro Auterio*[2], *Alberto Navarro*[2], *Marta Llorca*[1], *May Gomez*[2] *and Marinella Farre*[1], *(1)IDAEA-CSIC, Spain, (2)ULPGC, Spain*

Plastic pollution is an emerging threat with serious consequences for animal health and the environment. Among them, microplastics (MPLs) with a size below 5 mm are the ones that could cause harmful effects to biota since they can be ingested by a wide variety of species. The risks associated with these small fragments come from the material itself and the chemical contaminants that are absorbed into it from the surrounding water. To assess bioaccumulation in tissues, a feeding study of four treatments was conducted with zebrafish for 60 d. Exposure experiments were carried out through the diet (10% of total) and two more experiments, one using clean pellets from a factory and a blank control experiment without MPLs in the fish diet. The analysis of chemical pollutants was by liquid chromatography coupled to high-resolution mass spectrometry (LC- HRMS).

Our results verify the bioaccumulation of chemical pollutants in zebrafish tissues, also over the time. In addition, in some cases, pollutants have more tendency to adsorb to microplastics instead of being desorbed. The family of plasticizers show most of the compounds in level 2 of identification, while plastic synthesizers were quantified as the highest concentration in zebrafish tissues, followed by plasticizers.

Our main findings support the hypothesis that, in this real scenario, plastic additives and chemical pollutants adsorbed on environmental microplastics (EMPLs) bioaccumulate in the fish tissues due to long-term ingestion of MPLs.

1.09.P-Mo070 Small Microplastics (<100 µm) and Nanoplastics in the Venice Lagoon

Fabiana Corami[1,2], *Beatrice Rosso*[1,3], *Giulia Zaia*[2], *Anna Mercedi*[4], *Lucio Litti*[4], *Moreno Meneghetti*[4], *Giulia Vitale*[3,5], *Carlo Barbante*[1,2] *and Andrea Gambaro*[1,3], *(1)National Research Council (CNR), Institute of Polar Science (ISP), Italy, (2)Department of Environmental Sciences, Informatics, and Statistics, Department of Environmental Sciences, Informatics, and Statistics, Ca' Foscari University, Venice, Italy, (3)Department of Environmental Sciences, Informatics, and Statistics, Ca' Foscari University of Venice, Italy, (4)Department of Chemical Sciences, Nanostructures & Optics Laboratory, Department of Chemical Sciences, University of Padova, Padua, Italy, (5)Department of Environmental Sciences, Informatics and Statistics, Ca' Foscari University of Venice, Italy*

Concerning its ubiquity, plastic is considered the most impactful pollutant, which can be hazardous and toxic in relation to the presence of plastic additives (i.e., plasticizers, antioxidant and antistatic agents, lubricants, pigments, dyes, etc.). Plastic objects in the environment can fragment into different shapes, forming macro-, meso-, and microplastics. When forming plastic objects, plastic additives can be mixed with polymers or added later. Hence, plastic additives can be exposed or leach from fragments when breaking; fragment size is important because the smaller the particles, the easier they can be ingested by biota and enter the food web. Compared to large microplastics (≫100 µm, MPs), MPs <100 µm (SMPs) were slightly researched in the environment, as much as nanoplastics in the environment were less explored.

In two sites in the North basin of the Venice Lagoon, Sant'Erasmo and Palude Maggiore, two sampling campaigns were carried out in fall through winter 2019 and summer 2020, before and after the pandemic. Seawater samples were investigated for SMPs and other microlitter components, i.e., plastic additives, plasticizers, and natural and nonplastic synthetic fibers. After oleoextraction and purification, at least three aliquots of seawater samples were filtered on ANODISC filters according to a pretreatment procedure previously developed. The filters were analyzed via Micro-FTIR, where identification and quantification via microscopic counting were performed simultaneously.

Since Micro-FTIR is a nondestructive technique and its imaging LOD is 5 µm, the very same filter was then analyzed via Micro Raman to investigate the presence of plastics particles <5 µm and nanoplastics.

1.09.P-Mo071 Small Microplastics (<100 µm), and other Microlitter Components in the Channels of the Historical Center of Venice: Rio Marin as a Case Study.

Fabiana Corami[1,2], *Beatrice Rosso*[1,3], *Giulia Vitale*[3,4], *Elena Gregoris*[1,2], *Carlo Barbante*[1,2] *and Andrea Gambaro*[1,3], *(1)National Research Council (CNR), Institute of Polar Science (ISP), Italy, (2)Department of Environmental Sciences, Informatics, and Statistics, Department of Environmental Sciences, Informatics, and Statistics, Ca' Foscari University, Venice, Italy, (3)Department of Environmental Sciences, Informatics, and Statistics, Ca' Foscari University of Venice, Italy, (4)Department of Environmental Sciences, Informatics and Statistics, Ca' Foscari University of Venice, Italy*

Microplastic contamination has been an emerging issue in the last decade, although plastic contamination has been known since the 1970s and the term microplastics was coined in 2004.

Much data were produced to assess the distribution of microplastics in different environmental matrices; however, comparing results from different studies is still challenging due to the lack of standardized methods for sample pretreatment and analysis. Several studies employed microscopic methods, which do not allow the identification of polymers, while in other studies, after the microscopic counting, only a subset of particles was analysed via Fourier transform infrared (FTIR). Large microplastics (≫100 µm, MPs) were widely studied, while small microplastics (<100 µm, SMPs) were overlooked, especially in seawater, due to the employment of manta trawls (mesh size 330 µm or 100 µm). Small microplastics (SMPs) can be ingested by invertebrates at the bottom of the food web and enter it with potential bioaccumulation and biomagnification, posing a threat to human beings, as well. Besides, plastic objects have plastic additives, plasticizers, pigments, dyes, etc., which can be added together with the polymer when forming the plastic objects, or being different layers of the objects. Different particle shapes can originate from the fragmentation of plastic objects, which can be dispersed in the environment.
Plastic additives may exert toxic effects on biota once ingested as much as MPs, especially SMPs, may give rise to pseudosatiety phenomena, accumulating in the digestive tract or transferring to other vital organs, also giving rise to inflammatory processes.

In this study, seawater and sediment samples collected from a channel in the historical center of Venice were investigated for the occurrence of SMPs and other microlitter components. This channel, Rio Marin, begins in the Grand Canal, eventually joining the San Giacomo dell'Orio Canal, which also flows into the Grand Canal. Small microplastics and other microlitter components were extracted simultaneously, as much as they were simultaneously identified and quantified via microscopic counting. Samples were assessed using a previously developed pretreatment method and analyzed via Micro-FTIR.

1.09.P-Mo072 Quantification and Characterization of Microplastics and Additives in Soft Tissues of Farmed *Mytilus galloprovincialis* by Micro-FTIR

***Ilaria Savino*[1]*, Beatrice Rosso[2], Claudia Campanale[1], Giuseppe Corriero[3], Vito Felice Uricchio[1] and Fabiana Corami[4], (1)Italian National Research Council - Water Research Institute (CNR-IRSA), Italy, (2)Department of Environmental Sciences, Informatics, and Statistics, Ca' Foscari University of Venice, Italy, (3)Department of Biology, University of Bari, Italy, (4)National Research Council (CNR), Institute of Polar Science (ISP), Italy*

The documented presence of microplastics in edible marine organisms threatens human health through their consumption. In particular, bivalve mollusks are of great concern due to their known ability to filter large volumes of water, including pollutants such as microplastics. Nevertheless, farmed mollusks are still not widely studied, despite farming practices involving the use of synthetic nets, floats, and ropes, which could become a constant source of microplastics for organisms and the environment. This study assesses, for the first time, the presence of small microplastics (<100 µm), additives, and other components, in samples of *Mytilus galloprovincialis* collected from a mussel farm located in the Mar Piccolo of Taranto (southern Italy). The particles were investigated by differentiating in the gastrointestinal tract the gills, and the mantle to understand thoroughly where microplastics are absorbed and accumulated. The pretreatment method is based on pseudo-digestion at temperatures <40°C, without strong acids or oxidants that can degrade or denature polymers and may underestimate the effective abundance of particles. Polymer identification is important to predict microplastic behaviour in the environment and to evaluate specific analytical strategies. Therefore, a sample purification procedure allowed the simultaneous extraction of all particles and their subsequent chemical characterization by micro-Fourier transform infrared spectroscopy (micro-FTIR) with high yield. Large amounts of synthetic polymers, such as polypropylene, polystyrene, polyamide, and polyethylene, were found by analysing all soft tissues. The predominant polymer was polypropylene, whose source could be linked to the materials used during mussel farming. The acquisitions by micro-FTIR have detected the presence of additives specific to some polymers, such as nylon and bioplastics, but also ultraviolet stabilisers, plasticisers, and dispersant agents in paints for boats, representing an additional threat to the organisms. The particles detected in the mussels suggest a potential pathway for human exposure and highlight the need for continuous monitoring to perform a quantitative risk assessment and to take management measures.

1.09.P-Mo073 Microplastics Contamination of Mussels and Water from the Port of Sines, Portugal

***Carla Ofélia Silva*[1]*, João Pequeno[2], Susana Celestino[3], Cristina Espírito Santo[3], Teresa Silva[3], André Costa[3], Marta Mamede[3], David Jacinto[3], Teresa Cruz[3,4], João J. Castro[3,4] and Paula Sobral[2], (1)FCT-NOVA, Caparica, Setúbal, Portugal, (2)MARE - Marine and Environmental Sciences Centre | ARNET - Aquatic Research Network Associate Laboratory, NOVA School of Science and Technology, University of Lisbon, Portugal, (3)MARE - Marine and Environmental Sciences Centre | ARNET - Aquatic Research Network Associate Laboratory, Universidade de Évora, Portugal, (4)Departamento de Biologia, Escola de Ciências e Tecnologia, Universidade de Évora, Évora, Portugal*

Seaports are particularly susceptible to microplastic (MP) pollution through a series of human activities occurring in these areas. Thus, monitoring the biological communities and surface waters is important to assess the impacts of MP pollution. We aim to quantify on a seasonal basis the extent of MP pollution in the Port of Sines, an open deep-water seaport which is located on the southwest coast of continental Portugal and is the main port in the Iberian-Atlantic coast. With relevant national and international importance due to its strategic location and natural characteristics, it offers unique facilities to receive any type of vessel, which makes this port a potential source or sink of contaminants, including MP. Adjacent to this port, there are moderate to very exposed marine areas with regional and national importance for fisheries, tourism, and conservation. The present study reports the quantity, shape, colour, and polymer type of MP in whole soft tissues of mussels (*Mytilus* spp.) and seawater samples, both collected in May 2022. Here, a baseline evaluation of MP concentration at the seawater surface and column was conducted in triplicate with a manta and bongo net (150 µm mesh), respectively, for horizontal and vertical tows, in a total of six sampling sites outside and inside the port. Mussels and water were collected in the same sampling sites, stored in cooling boxes, transported to the laboratory, and kept at -20 ºC and 4 ºC with 70% ethanol, respectively, until further processing. Caution was taken regarding contamination by airborne fibres. Samples were digested with 10% hydrogen peroxide and filtered through a 0.10 µm nylon membrane. Microparticles were classified according to their type into two categories: fibres and fragments. Preliminary results show that all the mussels analysed (n = 60) presented microparticles. Of 311 microparticles observed, 71% were fibres and 29% were fragments. Both categories showed variations in length, size, and colour. Chemical analysis by Fourier transfrom infrared (FTIR) spectroscopy is in progress. This work will contribute to baseline data regarding microplastic pollution and accumulation in biota, for the Port of Sines and adjacent coastal areas. This will provide a solid background for future research to assess effects of MP in the marine environment and their potential hazards, helping policymakers to make knowledgeable decisions about plastic litter management.

1.09.P-Mo075 Ecotoxicological Assessment of Campania Rivers: A Focus on Microplastic Impact

***Sara Accardo**, University Parthenope*

Microplastics (MPs) in freshwater environments have been recognized as one of the important sources of plastic contamination in marine ecosystems.

Sediment is commonly thought of as the "final settling tank" for MPs. However, their impact on the ecosystem and potential ecotoxicological effects are still unclear.

This study presents the first investigation on the abundance and distribution of MPs contamination in freshwater streams in Campania, Italy.

Sediments were collected from different sampling points along the rivers to understand how the microplastic abundance varies along the river flow. Samples were analyzed for MPs content and each MP was visually identified, counted, photographed, and categorised according to size, colour, and morphology. Microplastics were characterised using Fourier transform infrared (FTIR) spectroscopy and Raman.

Moreover, the ecotoxicological status of these rivers were also assessed by performing a battery of ecotoxicological tests with organisms belonging to different trophic levels (bacteria, algae, and crustacean). All results were integrated to obtain a Toxicity Battery Index (TBI). The safety threshold of MPs for protecting the freshwater organism was also determined and used to assess the potential ecological risk posed by MP in the riverine ecosystem of Campania.

In addiction we aimed at expanding the knowledge on sublethal effects caused by exposure to sediments containing MPs. Accordingly, chronic effects on *Daphnia magna* were assessed.
Microplastics were identified at all sites in the range of 0.5–3 particles/g. Fibres were the dominant MP types by fragments and sphere. Black particles were the most common ones followed by transparent and coloured MPs. Based on the attenuated total reflectance (ATR)-FTIR analysis, polyethylene, polyethylene terephthalate, polystyrene, and polypropylene were the main plastic polymers. The test battery integrated index did not allow highlighting significant differences among the sites and showed a general slight ecotoxicological risk.
All data suggested that in the Campania rivers, the ecological risk posed by MPs on aquatic organisms was not negligible. These results represent a preliminary assessment of the MPs' impact on rivers and more detailed studies are needed, especially to expand the set of exposure and toxicity data used in the probabilistic risk assessment.

1.09.P-Mo077 Development of an Analytical Method for the Detection of Nanoplastics in Biological Samples: The Case of the Chironomid *Diamesa tonsa*

***Andrea Masseroni**[1], Gabriella Schirinzi[2], Jessica Ponti[3], Andrea Valsesia[3], Sara Villa[4] and Valeria Lencioni[5], (1)Department of Earth and Environmental Sciences, University of Milano-Bicocca, Italy, (2)European Commission, Ispra, Italy, (3)European Commission Joint Research Centre (JRC), Ispra, Italy, (4)Dept Earth and Environmental Sciences, University of Milano-Bicocca, Italy, (5)MUSE-Museo delle Scienze Trento, Italy*

In recent years, the scientific interest in nanoplastics (NPs) has increased because their unique properties make them potentially hazardous for organisms. However, limited data on NPs exposure are available due to the lack of reliable methods for their detection in complex matrices. In this perspective, a promising approach to overcome some of the analytical limitations of NPs detection is the use of bioindicators.
Diamesa tonsa is a chironomid (Diptera: Chironomidae) with larvae stages living in cold freshwaters, mainly in streams fed by snow and ice. Nanoplastic contamination has been recently demonstrated in surface snow at high altitude in the Alps. The present study aims to investigate the role of *D. tonsa* as a sentinel of NPs pollution. For this purpose, we tested on *D. tonsa* larvae the efficiency of a recently proposed method for the characterization of NPs in biological samples.
D. tonsa larvae were sampled in a glacier-fed stream of the Adamello-Brenta National Park (Trento, Italy). To validate the extraction and purification process, samples were spiked with palladium-doped polystyrene nanoplastics (Pd-PS-NPs) and then processed. The protocol involves enzymatic digestion, microfiltrations, centrifugations, and a microspotting on functionalized surfaces followed by Raman analyses. To obtain recovery rates, Pd concentrations were assessed in all extraction steps by inductively coupled plasma-mass spectrometry (ICP-MS) analyses.
Preliminary results showed a recovery of 40% in the final samples as measured by ICP-MS analysis. Scanning electron microscopy (SEM), transmission electron microscopy (TEM), and Raman evidenced that the enzymatic approach did not cause

alterations in Pd-PS-NPs. They also confirmed the effective presence of Pd-PS-NPs in the final samples allowing a semiquantitative characterisation.
The method enables the detection and semiquantitative analysis of NPs in a complex matrix; the evaluation of the presence of environmental NPs in *D. tonsa* is under study. These preliminary findings are essential to develop analytical techniques and approaches for the detection of NPs in the environment, to gain key data for NPs environmental risk assessment.

1.09.P-Mo078 Microcosm Study of the Effects of Polyester Microfibers on Indigenous Marine Amphipod (*Cyphocaris challengeri*) in the Strait of Georgia

*Oladimeji Ayo Iwalaye[1], **Kevin Landrini**[2] and Maria T. Maldonado[3], (1)University of British Columbia, Canada, (2)Ocean Wise Conservation Association, Canada, (3)Earth, Ocean and Atmospheric Sciences, University of British Columbia, Canada*

Microplastics remain contaminants of great concern because of their abundance, ubiquitous in all habitats of the world and threats posed to organisms inhabiting these habitats. While polyester (PET) microfiber is the most abundant microfiber found in Indigenous marine zooplankton, little is known about its effect on marine amphipods. We investigated the effects of PET microfiber on the survival, microfiber ingestion and retention, predation, and fecal pellets (FP) of marine amphipod (*Cyphocaris challengeri*) at different concentrations (0, 10, 100, 1000, 10 000, and 50 000 Mf/ L) and exposure times (24 h, 48 h, and 72 h) using microcosm experiments. Our study demonstrated that microfiber concentration had a greater influence on parameters investigated than exposure time. The exposure of *C. challengeri* to PET microfiber did not affect their survival. However, it significantly affected their feeding with a reduction in predation rate as microfiber concentration increased. This would make *C. challengeri* transfer less energy to their predators in the Strait of Georgia (SoG). The average number of ingested microfiber and ingestion rate increased significantly with microfiber concentrations. Nonetheless, microfiber retained was extremely low (0.037 ± 0.06 per ind^{-1} h^{-1}) implying that most *C. challengeri* evacuated ingested microfiber within 48 h postexposure. Also, encapsulation of PET microfiber in FP significantly increased their sinking velocity and density, and this will practically promote the downward transport of carbon in the SoG. Hence, there is an urgent need for a drastic reduction of the release of fibers from laundry and the design of equipment that will efficiently trap fibers and other microplastics types from laundry effluents in the wastewater treatment plants before their release into the environment.

1.09.P-Mo079 Exploring Changes in the Metabolome of Freshwater Benthic Invertebrates Exposed to Polyethylene Microplastics: A Two-Generational Investigation

***Hsuan-Cheng Lu**[1], Anu Kumar[2], Shima Ziajahromi[1], Steven Melvin[1], Peta Neale[1] and Frederic Leusch[1], (1)Griffith University, Australian Rivers Institute, School of Environment and Science, Australia, (2)Land and Water, Commonwealth Scientific and Industrial Research Organisation (CSIRO), Australia*

Constructed wetlands are primarily built to reduce pollutant loads in treated wastewater or stormwater before they are released into rivers and streams. However, they can also become sinks for retained pollutants that accumulate over time. A recent study found the average abundance of microplastics in the sediment of constructed wetlands in Australia was 1050 particles/kg dry sediment, which is higher than 80% of reported freshwater sediment samples globally. In addition, polyethylene fragments were the dominant microplastics identified. Consequently, it is important to understand the potential effects of microplastics on wetland benthic organisms. We therefore investigated the effects of irregular shaped polyethylene microplastics (1 μm –45 μm) in sediment on a common freshwater benthic invertebrate, *Chironomus tepperi*, at four environmentally relevant concentrations (125, 250, 500, and 1000 microplastics/kg sediment) over two generations. In the parental generation, significant reductions were observed for survival and emergence at both 500 and 1000 microplastics/kg compared to the control group, whereas growth (body length and body mass) was only affected at the highest exposure concentration. Conversely, no significant differences were observed for growth, survival, or emergence between treatments for the subsequent generation. To further understand the effects associated with sublethal exposure to microplastics, the metabolite profiles of *C. tepperi* larvae were also investigated. A dose-dependent decrease in several amino acids was observed in parental generation, which likely reflects a physical disruption of food/nutrient acquisition, or potentially an impact on energy generation. These results demonstrate the application of integrated apical and metabolomics approaches to provide useful information about the potential organismal and physiological effects of polyethylene microplastics on a benthic invertebrate under environmentally relevant concentrations.

1.09.P-Mo080 Interaction of Marine Algae and Nanoplastics: Impact on Growth and Extracellular Polymeric Substances (EPS) Production

***Marie Roos Sioen**[1], Maaike Vercauteren[2], Ronny Blust[3], Raewyn M. Town[3], Colin Janssen[4] and Jana Asselman[5], (1)Laboratory of Environmental Toxicology and Aquatic Ecology - GhEnToxLab, Ghent University (UGent), Ghent, Belgium, (2)GhEnToxLab, Ghent University (UGent), Ghent, Belgium, (3)ECOSPHERE, University of Antwerpen, Antwerpen, Belgium, (4)Laboratory for Environmental Toxicology (GhEnToxLab), Ghent University (UGent), Ghent, Belgium, (5)Blue Growth Research Lab, Ghent University (UGent), Ghent, Belgium*

Plastic pollution is one of today's most visible environmental problems, and its many aspects have been widely discussed in the media. However, the impact of plastics on aquatic and terrestrial ecosystems, as well as on human health, still remain largely unclear. Especially regarding nanoplastics (NPs, dimensions <1 μm), a knowledge gap exists. Nevertheless, it is assumed that the exposure route, extent and rate of biouptake and bioaccumulation, and the nature of adverse effects will differ from those of microplastics, due to the reactivity features of nanoscale entities and the fact that they are small enough to cross biological barriers.

The aim of the study was to look at the impact of nanoplastics on the growth cycle of marine phytoplankton species, and the effect on the production of extracellular polymeric substances (EPS) of the phytoplankton. Extracellular polymeric substances were analyzed as a proxy for aggregate formation as their sticky properties can induce heteroaggregation, and it is a known stress-response.

The algae species used for the experiment was *Rhodomonas salina,* a relevant algal species for the North Sea food web. The assumed realistic concentrations of nanoplastics are derived from microplastic concentration data in the North Sea and the conversion factor of 10^{14} as proposed by Besseling et al., 2019. This factor is based on mass conservation principles, for the fragmentation of spherical particles with a size of >0.1 mm–5 mm into 100 nm particles. The nanoplastics used are fragmented aged polyethylene terephthalate (PET, d = 0.68 µm, D_{90} =1.0 µm) and fragmented polypropylene (PP, d = 1.7 µm, D_{90} =2.9 µm), produced by the Joint Research Centre (JRC) of the European Commission in Milano.

We observed a significantly lower total cell yield at the end of the experiment after exposure to both aged PET and PP. For PP, the total cell yield decreased with increasing NP concentration. For PET, the total cell yield increased with increasing NP concentration, but was always lower than the cell yield of the control group. Also, an increase in EPS production is observed. This research gives valuable insights on the increased EPS production and possible aggregate formation after exposure to NPs. This can both affect the density and thus the location of the algae in the water column, as the availability of the algae to primary consumers, as their size increases. It also affects the stability, and thus the fate and transport of the nanoplastics in the water column.

1.09.P-Mo081 Influence of Particle Size on the Trophic Transfer and Uptake of Eu-Ps by the Terrestrial Snail: *Cantareus Aspersus*

Maria Kazour[1]*, Laura Zantis*[1]*, Rebecca Agati*[1]*, Willie Peijnenburg*[2]*, Thijs Bosker*[3] *and Martina G. Vijver*[3]*, (1)Leiden University, Institute of Environmental Sciences, Netherlands, (2)National Institute for Public Health and the Environment (RIVM), Netherlands, (3)Leiden University, Leiden, Netherlands*

There is a significant concern about the potential toxicity of nano- and microplastics (NMPs) in plants and organisms. Due to their small size, these NMPs might end up in organs and tissues and transfer throughout food chains. Moreover, there is a lack of knowledge on the fate of these NMPs on soil biota. To understand the influence of particle size on the trophic transfer of NMPs in a specific food chain, their uptake in plants (*Lactuca sativa*) and their transfer to garden snails (*Cantareus aspersus*) are investigated. Two particle sizes were tested: 100 nm and 300 nm of Europium doped polystyrene (Eu-PS). Plants were hydroponically grown in three different concentrations (low, medium, high: 15 µg/L, 150 µg/L, and 1500 µg/L, respectively) of Eu-PS spiked Hoagland solution for 21 d. Shoots were subsequently fed to garden snails (*Cantareus aspersus*) for 21 d. At the end of the experiment levels of Eu-PS were determined using inductively coupled plasma-mass spectrometry (ICP-MS) for the Hoagland solution, lettuce (shoots and roots), and of the snails' organs (soft tissue, digestive gland, and kidney). No leaching from the Eu-PS particles was detected in this study. Europium was detected in the roots of the plants in all exposure concentrations, and for both sizes, whereas for the shoots, Eu was detected only in the medium and high concentrations. The Eu-PS of both sizes was not detected in the digestive glands or in the different dissected organs of the snails. However, Eu was detected in the feces of those exposed to lettuce shoots of medium and high Eu-PS concentrations. These results indicate that snails did not accumulate Eu-PS in the organs and that NMPs pass through their system and end up in their excrement. This study shows, for the first time, the uptake and transfer of NMPs of 100 nm and 300 nm in the plants. In addition, our results show the transfer of the NMPs into the food chain with no observed accumulation in the snails. This developed approach can be used to assess the trophic transfer in various food webs leading to a better understanding of the fate of NMPs in the environment.

1.09.P-Mo082 Bad Romance — The Relationship Between Microplastic and Filter Feeders

Eden Harel[1]*, Noa Shenkar*[1] *and Ines Zucker*[2]*, (1)School of Zoology, George S. Wise Faculty of Life Sciences, Tel Aviv University, Israel, (2)Porter School of the Environment and Earth Sciences, Raymond and Beverly Sackler Faculty of Exact Sciences, Tel Aviv University, Israel*

Plastic pollution is a growing threat to marine organisms and ecosystems. Once the plastic litter reaches the ocean it is prone to degradation due to forces such as UV, water turbulence, heat, and biological activity. This increases the particle's surface roughness and porosity which causes the decrease in particle size to microsized particles (MP). As the size of the particles decreases the range of organisms able to ingest the particles increases. Micoplastics are often transported from the water column to marine food webs by filter-feeder organisms which play an important role in benthic-pelagic coupling. The ingested MPs may accumulate in the gut or may pass through the digestive system where they are subject to different pH fluctuations and to various digestive enzymes, ultimately excreted within the organism's feces. Feces sink down the water column transporting carbon to deeper waters, therefore acting as a vector of MP through marine zones. Ascidians (Chordata, Ascidiacea) are efficient filter feeders, able to remove minute particulate matter from the water column. Therefore, they present fundamental opportunities for understanding the interaction of plastic debris with marine organisms. Here, we use engineered MP particles of high environmental relevancy to examine the consequences of transit through an organism's digestive system. We examined the changes of the particle's surface area, size, morphology, and surface functionality. Particles were fed and later extracted from the feces of two solitary ascidian species: *Styela plicata* and *Polycarpa mytiligera*. Additionally, we measure the effect of the MP on gametes quality, fertilization, and early development of the ascidian *Hermania momus*. Our preliminary results reveal that the extracted MP (following digestion by ascidians) had a rough surface area coated by organic matter. This change in surface area and functionality may later influence the MP availability to other organisms. Currently, we examine how ascidians clear MP sized between 60 µm and 0.45 µm from the water column. Moreover, we expose gametes to MP treatments examining the fertilization success. Reproduction by spawning and external fertilization is very common among invertebrates; in the open water gametes are vulnerable to MP and other pollutants. Overall, as MPs transfer through marine food webs across marine ecosystems, it is essential to promote the understanding of the consequences of biological digestion.

1.09.P-Mo083 Development of Novel Molecular Indicators of Emerging Contaminants in Aquatic Environments
Enya Cody[1,2]*, Andrew Reynolds*[3]*, Gordon Chambers*[4]*, Orla Howe*[5] *and Michelle Giltrap*[2]*, (1)School of Food Science and Environmental Health, Radiation and Environmental Science Centre, FOCAS Research Institute, Technological University Dublin, Ireland, (2)School of Food Science and Environmental Health, Technological University Dublin, Ireland, (3)Radiation and Environmental Science Centre, FOCAS Research Institute, Technological University Dublin, Ireland, (4)School of Physics, Technological University Dublin, School of Physics, Clinical & Optometric Science, Ireland, (5)School of Biological and Health Sciences, Technological University Dublin, Ireland*
Projections estimate that 445.25 million tonnes of plastic will be produced in 2025 and will continue to increase by 30% in 2050. It has been predicted that 79% of plastic produced up to 2015 is residing in landfills and the environment, where it is degrading to micro/nanoparticles and having a negative effect on aquatic species. Bioplastics have been developed as a biodegradable alternative to traditional plastics, but little is known about their effect on aquatic species. Polylactic acid (PLA), a popular biopolymer, has been reported to induce behavioural and biochemical changes in *Danio rerio*, increase reactive oxygen and nitric oxide species in *Physalaemus cuvieri* tadpoles, and cause reduced survival in *Daphnia magna*. Although PLA has a similar/higher sorption capacity to conventional microplastics (MP), little is known about the toxicological mixture effects of bio-MPs and environmental contaminants.
This study aims to investigate the toxicity of PLA, while using nanopolystyrene (NP) as a control particle for the exposures. Mixture effects with emerging contaminants of concern are also investigated to determine if biopolymers exacerbate the toxicity of known pollutants of interest. Three freshwater fish cell lines will be used in this study: PLHC-1, topminnow liver (*Poeciliopsis lucida);* RTG-2, rainbow trout gonad (*Oncorhynchus mykiss*); and ZF4, zebrafish embryo (*Danio rerio*). Cytotoxicity and genotoxicity effects, as well as genomics, are used to evaluate the biological effects at a cellular level. In addition, whole organism comparison studies of the effects of NP on zebrafish embryos will be compared to the ZF4 embryo cell line to evaluate the effects on lower levels of organisation when low levels of mortality in zebrafish embryos were seen after 96 h exposure. These comparisons should provide distinct results of the potential for chronic toxicity effects on aquatic species that are currently unseen in standard acute exposure findings.

1.09.P-Mo084 Sublethal Effects on Behaviour and Feeding of Bioplastic Microparticles in *Daphnia magna*
Katerina Savva[1]*, Marta Llorca*[2]*, Marinella Farre*[2] *and Carlos Barata*[3]*, (1)Institute for Environmental Diagnosis and Water Studies (IDAEA-CSIC), Spain, (2)IDAEA-CSIC, Spain, (3)Environmental Chemistry, Spanish Research Council (CSIC), Institute of Environmental Assessment and Water Research (IDAEA), Spain*
Plastic pollution is nowadays an increasing concern environmental problem. In the past few years, in retail stores new bioplastics have been taking over, to offer a greener solution. These bioplastics are attained by renewable feedstock, such as polylactic acid (PLA) and polyhydroxybutyrate (PHB). As their demand is increasing, there is a need to investigate their environmental fingerprint, whilst studies have shown that the toxicity of their plastic additives may be higher than in fossil plastics. This study focused on the toxic effects to aquatic indicator organisms (*Daphnia magna)* of different single use items made of biomaterials PLA and PHB, and a highly used fossil material polyethylene (HDPE), in addition with their analytical standards. Assays were performed both with microparticles (MPs) of each material and their leachates. *D magna* juveniles were exposed for 24 h to different concentrations of MPLs and their leachates and effects on feeding and behaviour measured. Results showed a similar toxicity of PLA and PHB microplastic particles with an EC50 on feeding inhibition of 0.15 g/L. Behavioural defects of 0.15 g/L of bioplastics on baseline locomotion activity, visual motor responses (VMR), maximal response (MAX) to light, and nonassociative attenuation to repetitive light stimuli evidenced similar toxic effects of single-use consumer products made of PHB and PLA biopolymers. Plastic leachates obtained in methanol were about five times less toxic than particles. Particles and leachates of HDPE items and standards were less toxic than those of bioplastics. Overall, our results indicate that bioplastics and their leachates are more toxic than those of HDPE.

1.09.P-Mo085 Ecotoxic Effect of Biodegradable Plastic Bags Leachates on Marine Organisms

Sara Accardo[1] *and* ***Simona Schiavo***[2]*, (1)University Parthenope, (2)ENEA, Portici, Italy*
Plastic pollution is one of the greatest emerging threats to the environment in our time. Plastic can enter marine habitats on different pathways, e.g., as lost material from the fishing and shipping industry as well as migrated from land-based trash.

The combination of biotic and abiotic degradation leads to alternation and fragmentation of plastic and often to the formation of micro- (MP) and nanoplastics (NP).

The threat large and small plastic particles pose to marine life gained more and more attention during recent years and thus the usage of so-called bio- and biodegradable plastic has gained more attention. Bioplastics are promoted as an alternative to conventional petroleum-based nonbiodegradable plastics

However, whether biodegradable plastics are successfully tackling the problem is questionable as laboratory and field studies showed contrasting outcomes. Today, it remains unclear whether biodegradable formulations are advantageous to reduce plastic impact compared to conventional polymers. Plastics contain a complex mixture of known and unknown chemicals, some of which can be toxic. Bioplastics and plant-based materials are marketed as sustainable alternatives to conventional plastics. However, little is known with regard to the chemicals they contain and the safety of these compounds.

In this view the aim of this work is to evaluate the potential ecotoxicity of different types of plastic bag leachates in seawater. Conventional (polyethylene) and compostable bags (Mater-Bi) were cut and placed in artificial sea water for a period of three months. Periodically ecotoxicity tests upon different organisms (*Dunaliella tertiolecta*, *Vibrio fischeri,* and *Paracentrotus lividus*) were carried out. Results showed that *D. tertiolecta* was significantly affected by both kinds of plastic bags already after the first week of leaching to a slightly greater extent with regard to compostable bags. In the case of *P. lividus* the effect became evident starting from the 8th week for the conventional plastic bags and the last week of exposure for conventional ones. Instead, all the leachates exerted a hormetic effect upon the bacteria *V. fischeri*.

1.09.P-Mo086 Role of Container Materials on Polycyclic Aromatic Compound (PAC) Concentrations in Aqueous Phase: Implication for Aquatic Ecotoxicity Determination

Imane Aabbar, *Interdisciplinary Laboratory of Continental Environments, France*

In historically contaminated sites such as coking plants, other families of organic pollutants than the 16 regulated polycyclic aromatic hydrocarbon (PAHs) can occur. Polar polycyclic aromatic compounds (PACs) are present in the initial pollution and can be generated over time. Their aqueous solubilities are greater than those of the PAHs, and may induce the contamination of groundwater resources. It is important to evaluate the potential risk associated with the occurrence of PACs in bodies of waters.

A classical approach is to run a standard aquatic bioassay using model organisms, as rotifer (*Brachionus*calyciflorus) (ISO 20666, 2009) and algae (*Pseudokirchneriella subcapitata*)(ISO 8692, 2012) to evaluate the associated ecotoxicity.

The aim of this study is to determine the fate of PACs during standard *in vivo* aquatic ecotoxicity testing. Indeed, rotifers and algae tests are usually performed in polystyrene (PS) 24-well–96-well microplates, respectively, and little is known about the PAC sorption capacity to PS under test conditions. However, this information is crucial to determine the actual PAC concentrations to which organisms are exposed.

Tests were performed on a coking plant soil leachate stored in PS and glass bottles. Conditions were determined based on the bioassay conditions, i.e., 48 h at 25°C in darkness for rotifers and 72 h at 22°C under light for algae. Leachates were collected every 24 h for PS containers and until the end for glass bottles.

Results showed that the container material has a strong impact on the measured PAC concentrations in solution, especially for PAHs. A strong decrease in PAH concentrations was observed in PS containers under both test conditions and the effect was most apparent for high molecular weight compounds, most likely due to sorption phenomena. This decrease was absent with glass containers. Also, a reduction in low molecular weight compound concentrations was noticed with both materials in algae test conditions that may result from PAH photodegradation

Consequently, PAH concentrations to which organisms are exposed during ecotoxicity tests are expected to be much lower than expected based on PAH levels in fresh leachate.

These results pointed out the need to circumvent this experimental bias in order to calculate reliable ecotoxicity parameters. This could be done through an adjustment of protocol to the physicochemical properties and reactivity of studied molecules, or a calculation of theorical concentrations based on kinetic parameters of the process involved.

1.09.P-Mo087 Impacts of Polyethylene Terephthalate Microfiber and Microfragment on ROS Generation and Enzyme Activity in Manila Clam *Venerupis philippinarum*

Hyeonji Nam[1], *Yooeun Chae*[2], *Jin-Soo Choi*[1], *Yunwi Heo*[1] *and June-Woo Park*[1,3], *(1)Environmental Exposure & Toxicology Research Center, Korea Institute of Toxicology (KIT), Korea, Republic of (South), (2)Ecological Risk Assessment Center, Korea Institute of Toxicology (KIT), Korea, Republic of (South), (3)Human and Environmental Toxicology Program, Korea University of Science and Technology (UST), Korea, Republic of (South)*

The increasing global contamination of microplastics (MPs) in the marine environment is a significant concern to the environment and public health. The small size of microplastics implies that MPs are readily ingested by marine organisms and cause problems in marine ecosystems. The objective of this work is to identify the biological toxic effects of polyethylene terephthalates (PETs) MPs depending on their shape and size. The marine clam *Venerupis philippinarum* was exposed to the suspension of fragments and fiber-shaped PET MPs with different size (<20 µm, Fragment S; 45 µm–75 µm, Fragment M; >150 µm, Fragment L; 200 µm–400 µm, Fiber S; 3 mm, Fiber L) in the range of 0.0005 mg/L to 100 mg/L. The results showed that to gain insights into the mechanism of PET-induced toxic effects, reactive oxygen species (ROS) contents, the activities of superoxide dismutase (SOD) and acetylcholinestesase (AChE) in the gill and the digestive gland were measured. Both two different types (fragments or fibres) of PET MPs did not cause mortality at the tested concentrations over 96 h. However, the exposure to each different-shaped PET MP significantly increased ROS levels in all tested concentrations compared to control value. Generally, increasing oxidative stress to ROS also caused increased SOD enzyme activity. The AChE activities in the gill showed significant increase after exposure to fragment-shaped PET MPs. There was no significant difference in AChE activity in the gill and the digestive gland exposed to fiber-shaped PET MPs. This work will provide empirical evidence of the toxicity of PET MPs to better understand the effects of MPs in aquatic organisms.

1.09.P-Mo088 The Effect of Dioctyl Terephthalate on Biofilm Formation of Plastic-Degrading Bacterium *Rhodococcus ruber* on PVC Film
***Dana Fahad Mohamed**[1], Abhrajyoti Tarafdar[2] and Jung-Hwan Kwon[2], (1)Environmental Science and Ecological Engineering, Korea University, Korea, Republic of (South), (2)Korea University, Korea, Republic of (South)*
Phthalate esters are the most widely used plasticizers and were found to have an annual consumption of over 30 million tons in the year 2017. However, because many phthalates are the cause behind reproduction and developmental toxicity, their use is gradually being phased out. The European Union (EU) has introduced dioctyl terephthalate (DOTP) as a less toxic nonphthalate alternative for the widely used di-(2-ethylhexyl) phthalate (DEHP). Presently, other than studies on humans and rats, there are no data available on the biodegradation and toxicity of DOTP on microbes. Therefore, this study aims to discover the metabolic pathway and toxicity of DOTP upon internalization by *Rhodococcus ruber.* The metabolic pathway was found by analysis of media containing PVC plastic with 0.1% DOTP using an Orbitrap mass spectrometer. Biodegradation of DOTP had similar metabolites which were found in the degradation of DEHP with a final product of benzoic acid. The toxicity was found by determining oxidative stress when exposed to different concentrations of DOTP (1% −10% v/v) in PVC plastic using the CellROX™ Green Reagent and Hoechst 33342. Oxidative stress was apparent even from 1% v/v DOTP in the plastic.

1.09.P-Mo089 Survival and Reproduction Effects of Four Microplastics on *Ceratophysella denticulata*, *Folsomia candida*, *Heteromurus nitidus,* and *Sinella curviseta*
***Sam van van Loon**[1] and Cornelis A.M. van Gestel[2], (1)Vrije Universiteit Amsterdam, Amsterdam Institute for Life and Environment (A-LIFE), Netherlands, (2)Amsterdam Institute for Life and Environment (A-LIFE), Vrije University Amsterdam, Netherlands*
An estimated 467 kt of soil contamination is caused by agricultural plastics annually. Plastics that end up in the soil break down into secondary microplastics (MPs). Not much is known about the effects these MPs have on soil functioning and organisms residing in the soil. To evaluate these effects and properly assess the risk they pose to the environment, experimental data are needed on the effects MPs have on the survival and reproduction of model organisms. This research aimed to assess the toxicity of four MP types derived from commonly used agricultural plastics to different Collembola species, representing an important and highly diverse class of soil living arthropods. Starch-PBAT blend MPs were produced from both virgin mulching films as well as mulching films that were artificially aged by mechanical recycling. In addition, MPs were made from linear low-density polyethylene (LLDPE) virgin mulching films and low-density polyethylene (LDPE) MPs that underwent the same mechanical recycling process as the starch-PBAT blend MPs. Four Collembola species were used: *Ceratophysella denticulata, Folsomia candida, Heteromurus nitidus,* and *Sinella curviseta.* The use of these four species ensures the inclusion of epedaphic, euedaphic, and hemiedaphic species, as well as sexually reproducing and parthenogenetic Collembola. Each of the species was exposed using Lufa 2.2 spiked with the MPs at nine concentrations: 0.0016, 0.008, 0.04, 0.2, 1, 2, 3, 4, and 5% (w/w dry soil). Eight controls were included, while all treatments had five replicates. Tests were started with 20 age synchronized (40–43 –d-old) adults of the sexually reproducing species, while for the parthenogenetic *F. candida* 10 adults were used per test jar. All species were exposed for three weeks, except for *C. denticulata*, since the eggs of this species can take up to two weeks to hatch, asking for a four-week exposure period. No significant effects of starch-PBAT blend MPs from virgin PBAT films have been observed in *F. candida* or *S. curviseta* at any of the tested concentrations. The analyses of the samples from this study are ongoing, and results will be presented at the meeting in May 2023.

1.09.P-Mo090 Toxicological Interaction of Microplastic and Polyaromatic Hydrocarbons on Macrophyte
***Hoi Shing Lo**[1], Betty Chaumet[2], Stefano Bonaglia[3], Anna Sobek[2] and Elena Gorokhova[1], (1)Department of Environmental Science, Stockholm University, Sweden, (2)Environmental Science, Stockholm University, Sweden, (3)Gothenburg University, Sweden*
The potential effect of microplastic has been investigated in various organisms yet such a study on macrophyte is relatively scarce. Direct contact of plastic particles on plants was found to exert impacts on growth rate primarily due to shading, while the chemicals related to the plastic may also cause negative effects. To elucidate the interactions between toxic chemicals, plastic, and macrophyte, we designed an exposure system containing microplastic, polyaromatic hydrocarbons (PAHs) contaminated sediment, and duckweed *Lemna minor*. This system creates agitation; therefore the contaminated sediment could be suspended in the water column to interact with microplastic and plants. After exposure, the PAHs partitioning between these components will be analyzed. We hypothesize that the microplastic can contribute to the transfer of PAHs from sediment to the plants thereby causing stronger toxic effects. Growth inhibition and relevant sublethal biomarkers including antioxidant capacity/oxidative stress will also be assessed. This study will provide insight on the potential toxic effects of microplastic for both particle and chemical effects on macrophytes.

1.09.P-Mo091 Combined Toxic Effects of Cadmium and Environmental Microplastics in *Aphanius fasciatus* (Pisces, Cyprinodontidae)
***Benjamin Pina**[1], Kaouthar Kessabi[2], Amira Abbassi[2], Samar Lahmar[2], Marta Casado[3], Mohamed Banni[4] and Imed Messaoudi[2], (1)Environmental Chemistry, Spanish Research Council (CSIC), Institute of Environmental Assessment and Water Research*

(IDAEA), Spain, (2)Laboratory of Genetic, Biodiversity and Valorization of Bioresources, University of Monastir, Higher Institute of Biotechnology, Tunisia, (3)Department of Environmental Chemistry, Spanish Research Council (CSIC), Institute of Environmental Assessment and Water Research (IDAEA), Spain, (4)Laboratory of Biochemistry and Environmental Toxicology, Higher Institute of Agronomy, Tunisia
Microplastics (MPs), plastic particles smaller than 5 mm in diameter, have received extensive attention as new environmental pollutants with still unexplored potential ecological risks. In this study we investigated the effects of cadmium (Cd) and environmental MPs in the marine killifish *Aphanius fasciatus*, both separately and in combination. Female individuals were exposed to Cd and/or MPs for 21 d, and the subsequent effects were monitored by a combination of biochemical, histological, and molecular toxicity markers. Exposure to Cd, but not to MPs, increased metallothionein content and mellothionein gene MTA mRNA levels both in liver and gills. On the contrary, we observed a significant oxidative stress response at histological, enzymatic, and gene expression levels to both toxicants in both tissues, particularly in gills, but not very weak evidence for the interaction between the two effectors. Finally, exposure to both MPs and Cd induced spinal deformities, although bone composition was only altered by the latter, and MTA mRNA bone levels only differed from controls in the doubly exposed samples. Our results indicate a major effect of MPs on gills at different organizational levels, and suggest a possible, if mild, capacity for enhancing the toxic effects of heavy metals.

1.09.P-Mo092 Are Polyethylene and Polystyrene Microparticles Capable to Disrupt the Intestinal Function of Rainbow Trout?

Nikola Hodkovicova[1], *Aneta Hollerová*[1,2], *Denisa Medková*[2] *and Martin Faldyna*[1], *(1)Department of Infectious Diseases and Preventive Medicine, Veterinary Research Institute, Czech Republic, (2)Department of Animal Protection and Welfare & Veterinary Public Health, University of Veterinary Sciences Brno, Czech Republic*
Polyethylene (PE) and polystyrene (PS), the main polymer polluters of the aquatic environment, were tested to achieve information about their potential toxicity for intestinal tracts of freshwater fish. A study was done with rainbow trout (*Oncorhynchus mykiss*) as a model organism, while the PE (46.6 ± 11.3 µm) and PS (52.5 ± 11.5 µm) were submitted to fish in commercial feed pellets for six weeks. Both PE and PS were tested in the same concentration doses – 0.5%, 2%, and 5% of the feed/day. Our study aimed to characterise PE and PS effects on the gut microbiota alterations and gene expression changes in intestinal tissue.

In regard to microbiota, we observed higher diversity of bacteria species in the control group compared to groups exposed to both tested microplastics. Moreover, in the case of PE the amount of bacteria decreased in concentration manner also. The lower diversity of bacteria phyla in gut is a sign of dysbiosis and is associated to outbreak of fish diseases. In our study, the *Firmicutes* and *Fusobacteria* were the most abundant phyla of all; their mutual ratio, however, was affected by the PE and PS exposure. Both these phyla are producers of short-chain fatty acids that regulate the energy metabolism, improve intestinal integrity, and support gut reparation. Analysis of gene expression showed significant changes of carrier family 9 member A1b (*slc9a1b*), ghrelin/obestatin prepropeptide (*ghrl*), and transferrin-a (*tfa)* gene expression mainly in the highest (5%) tested concentration. Both *slc9a1* and *ghrl* interact with the immune system and cytokine release. Moreover, *slc9a1b* is involved in pH regulation and sodium proton antiporter activity, and *ghrl* has an appetite-stimulating effect and induces reactive oxygen species (ROS) production. Additionally, *tfa* is participating in iron ion binding and maintaining of homeostasis and alterations at mRNA expression level may potentially provoke the ROS release in intestine.

With respect to the results obtained so far, it is clear that microplastics submitted orally may affect the function of the digestive tract, immune system, and induce oxidative stress. As plastics in microsizes are known to be a serious threat to the aquatic biota with yet not completely described consequences, these alterations in intestinal function might predict that the negative effects of polymers can be expected at the level of the digestive tract as well.

1.09.P-Mo093 Do Polystyrene Microparticles Affect the Early-Life Stages of Zebrafish (*Danio rerio*)?

Aneta Hollerová[1,2], *Denisa Medková*[3,4], *Pavla Lakdawala*[2], *Nikola Hodkovicova*[1], *Jana Blahova*[2] *and Martin Faldyna*[1], *(1)Department of Infectious Diseases and Preventive Medicine, Veterinary Research Institute, Czech Republic, (2)Department of Animal Protection and Welfare and Veterinary Public Health, University of Veterinary Sciences Brno, Czech Republic, (3)Department of Zoology, Fisheries, Hydrobiology and Apiculture, Mendel University, Czech Republic, (4)Department of Animal Protection and Welfare and Veterinary Public Health, Mendel University, Czech Republic*
Plastic waste pollution is considered one of the biggest problems facing our planet, which is caused mainly by an excessive use of this material, its high resistance in the environment and poor waste management. Under mechanical and biological degradation, plastics can be broken down into smaller fragments. Microplastics (<5 mm; MPs) have been discovered in the bodies of various organisms, across all trophic levels of the aquatic environment. Although many studies have focused on the impact of MPs on aquatic organisms, only a small number of them study the effect of MPs on early developmental stages of fish. The tested organism zebrafish (*Danio rerio*) has been widely used as an emerging disease model to investigate human genetics and early-stage development due to its high similarity with the human genome and in addition, zebrafish embryos are transparent, making it possible to reveal a disorder or malformation caused by exposure to MPs.

In our study, the effect of polystyrene microspheres (50 µm) on zebrafish embryos was tested in three concentrations – 0.01 g/L, 0.1 g/L, and 1 g/L for 96 h with 18 eggs of zebrafish per each concentration. The plates were kept in a temperature-controlled test environment (26°C) with a photoperiod of 12 h light/12 h dark. Testing solutions were replaced every day to make sure that the test concentrations remained their nominal values. During the test, each plate was checked for coagulation of fertilized eggs, lack of somite formation, lack of detachment of tail-bud from the yolk sac, lack of the heartbeat, hatching rate, and developmental malformations. After 96 h exposure, eight replicates were created from each test group, with each sample containing 10 mg of embryos to subsequent PCR analysis of selected genes and proteomic to the systematic identification and quantification of selected proteins. The significant changes at tested concentrations were compared to the control group, without microplastic addition.

1.09.P-Mo094 Automated Quantification of Fluorescence Signals for Apoptosis and Necrosis in Bivalve Hemocytes (*Mytilus edulis*) using Fiji/ImageJ as a Proxy for *in vitro* Toxicity Assessment

Jenevieve Hara[1], *Sébastjen Schoenaers*[2], *Maaike Vercauteren, PhD*[3], *Colin Janssen*[4], *Ronny Blust*[5], *Jana Asselman*[6] *and Raewyn M. Town*[5], *(1)ECOSPHERE, Department of Biology, University of Antwerp, Belgium, (2)University of Antwerp, Belgium, (3)GhEnToxLab, Ghent University (UGent), Ghent, Belgium, (4)Laboratory for Environmental Toxicology (GhEnToxLab), Ghent University (UGent), Ghent, Belgium, (5)ECOSPHERE, University of Antwerpen, Antwerpen, Belgium, (6)Blue Growth Research Lab, Ghent University (UGent), Ghent, Belgium*

Hemocytes are responsible for cell-mediated immunity in bivalve mollusks. Apoptosis and necrosis (cellular death) are part of the integral cellular processes that influence essential physiological functions, including cellular immunity. It has been established that the physicochemical properties of micro- and nanoplastic particles (MPs/NPs) can directly affect cellular uptake mechanisms and immunotoxicity. However, the standardized method for systematic analysis of sensitive cellular-level endpoints induced by MPs/NPs exposure is still lacking. Hence, this study aims to validate and apply a microscopy-based method for evaluating the induction of apoptosis/necrosis in bivalve hemocytes as a proxy for micro- and nanoplastic toxicity assessment. The *in vitro* assay was carried out via a dual staining approach using an apoptosis detection kit (Biovision) and by the complementary application of confocal microscopy and ImageJ, an open-source image processing program. To ensure the validity and sensitivity of the automated quantification of fluorescence signals for viable, apoptotic, and necrotic cells, the output generated by the automated method was compared with manual and flow cytometry-based quantification methods. Results revealed that, with proper optimization of settings, the automated quantification method is a reliable and reproducible method that uses open-source software for image analysis, suitable for large-scale image quantities, and is applicable to evaluate the induction of apoptosis in fluorescent images of various cell types.

1.09.P-Mo095 Toxicity Assessment of Used and Pristine Cigarette Filter Microplastics and Their Leachates to *Daphnia magna*

Victor Carrasco Navarro, *Su'ad Musse and Jussi Kukkonen, University of Eastern Finland, Finland*

Littering is one of the main causes of plastic contamination in the environment and it may cause the production of microplastics (MPs) under several conditions. Microplastics are a very complex group of contaminants where sizes, type of polymer, and additives, among other factors, may influence their toxicity. Cellulose acetate is one polymer widely used in cigarette filters (CF) and one of the most prevalent sources of littering and MPs.

In our study, the toxicity of used and pristine CF microplastics and their leachates was assessed using the water crustacean *Daphnia magna*. *Daphnia* species inhabit very diverse water bodies and are a key prey species of planktivorous fish and other larger invertebrates, which highlights their importance in aquatic ecosystems.

The leachates were prepared by shaking a suspension of CF (80 g L^{-1}) in artificial freshwater 2.5 mM in Ca^{2+} and Mg^{2+} for 15d at 160 rpm. Following that, the suspension was filtered (0.22 µm pore size membranes) and the resulting leachate was considered as pure, 100% leachate. Dilutions to 5, 2.5, 1, 0.5, 0.25, 0.125, and 0.025% were used as the concentration range. Furthermore, we cryogrinded both pristine and used cigarette filters previously cut in smaller pieces (~ 20 mg) by pestle and mortar after cooling the materials with liquid N_2. The obtained microplastic particles were used to prepare suspensions at concentrations of 4, 2, 0.8, 0.4, 0.2, 0.1, and 0.02 g L^{-1}, equivalent to the concentrations used in the leachate tests.
Magna neonates (<24 h old) were added to experimental vessels with 10 ml of the experimental waters at the concentrations mentioned above. Mobility of the organisms was monitored after 24 h and 48 h after a gentle shake of the vessels. The results were used to build dose response curves and obtain EC_{xx} values.
The results indicated that only the particles and leachates from the used CF were toxic at the concentrations used. The CF particles were more toxic than the leachates (EC50 values of 0.29 and 0.38 g L^{-1} at 48 h, respectively). Also, the particles caused a significant immobility already after 24 h of exposure compared to the leachates.

Overall, this study points at the toxicity caused by CF to freshwater ecosystems at relatively low concentrations. While recognising that the values found to cause significant toxicity would be hard to reach in large water bodies, we speculate that populations of organisms living in small ponds or puddles of water may be at risk if littering of CF continues.

1.09.P-Mo096 Assessing the Effects of Car Tire Additives to a Marine Amphipod Using Behavioural Studies

Henry Ebele Obanya, *Fay Couceiro and Alex Ford, University of Portsmouth, United Kingdom*

Behaviour in ecotoxicology is expanding as it provides a link between the biochemical and physiological effects of environmental contaminants. This has been facilitated by advancements in computational automaton and the increased prevalence of behavioural modulating compounds in the environment. The main aim of this study is to assess the effects of car tire additive compound, 2-mercapto benzithiazole (2-MBT) on the behaviours of model crustaceans, *Gammarus pulex*. A developed assay on a Zantiks unit was used to measure locomotion as a kind of behaviour associated with stress on the invertebrate. The Gammarids were exposed to environmentally relevant concentrations (100 µg/L, 1 µg/L, 0.1 µg/L, 0.01 µg/L) of the car tire additive compound (MBT). Exposure to this compound had significant impacts on the behaviour of these Gammarids. The animals moved rapidly when light came on after 2 min, but they got slower with time. There was a significant difference found in the mean distance moved between day 7 and 14. The movement of Gammarids was affected over time with most effect found in 100 µg/L. The results obtained showed that 2-MBT affected the locomotion behaviour of the Gammarids after 7 d and 14 d even at environmentally relevant concentrations. This may then mean that the presence of these compounds in the environment may affect their behaviour in the wild as impaired locomotion can hinder their capacity to escape predation, alter reproduction, and generally affect population

1.09.P-Mo097 Effects of Three Micro- and Nanoplastics Under Weathering Conditions on Messenger and Long Noncoding RNA Expression in the Inland Silverside (*Menidia beryllina*)

Sara J. Hutton[1,2]*, Samreen Siddiqui*[1]*, Erin Anderson*[1]*, Stacey L. Harper*[1] *and Susanne M. Brander*[3]*, (1)Oregon State University, (2)GSI Environmental, Inc., (3)Department of Fisheries, Wildlife, and Conservation Sciences, Oregon State University*

Micro- and nanoplastics (MNPs) are the result of widespread plastic pollution which has become an environmental pollutant of great concern. As plastics break down into smaller fragments the addition of weathering processes can further aid in degradation as well as alter the toxicity of the particles. However, MNP toxicity is still poorly understood and the potential mechanisms of toxicity for this class of compounds have yet to be fully explained. Additionally, how toxicity may be altered following weathering processes is even less well studied. Therefore, to better understand the potential differences in mechanisms of toxicity across MNP types, shapes, sizes, and weathering processes we have exposed the Inland Silverside (*Menidia beryllina)* to three different MNP types: tire particles (TP) and polylactic acid (PLA) at both micro- and nanosize fractions and polyester microfibers (MFs) in the microsize fraction to both weathered and unweathered forms. Micro- and nanoplastics were weathered for 72 h with exposure to UV A, B, and C while being constantly shaken in saltwater. Organisms were exposed to either weathered or unweathered particles for 21 d. Following the exposure, RNA was extracted and is currently in the process of being sequenced for both messenger and long noncoding RNA (mRNA and lncRNA, respectively). Following sequencing, bioinformatic analysis will be used to determine differentially expressed genes. mRNA will inform on the gene expression of the organisms following chronic exposure which will allow for an assessment of differentially expressed gene pathways. lncRNA play essential biological roles and are additionally important in development of diseases, the analysis of which will also provide insights into the potential epigenetic effects of MNPs. Here, we present our results which show that weathering increases or decreases toxicity may be dependent on polymer type. These data will provide a necessary comparative assessment of multiple MNP types to better understand the relative toxicity of these contaminants. Additionally, this will be the first assessment of lncRNA in the Inland Silverside, a commonly used model species in both research and regulatory testing.

1.09.P-Mo098 Immunophysiological Impact of Exposure to Polyethylene Terephthalate Microparticles on Rockfish *Sebastes schlegelii*

Kwang-Min Choi[1]*, Seong Hee Mun*[1]*, Dongju Shin*[2]*, Youmi Choi*[2] *and Jee hyun Jung*[2]*, (1)Korea Institute of Ocean Science and Technology (KIOST), Korea, Republic of (South), (2)Risk Assessment Research Center, Korea Institute of Ocean Science and Technology, Korea, Republic of (South)*

Microplastics (MPs) are widely detected across marine ecosystems and thus are recognized as a global problem. They are known as potential harmful factors in the marine environment, but the study of toxic pathway on their ecological impact dependent on exposure concentration is still lacking. In this study, we evaluated the toxic effects of MPs on rockfish (*Sebastes schlegelii*), which are widely distributed along the coast of South Korea. The exposure size of MP was divided into three fragment types including 0–20 µm, 45–75 µm, and >150 µm from polyethylene terephthalate (PET). After 48 h of exposure to 0.4 g/L of MPs, cytotoxicity was measured using Annexin V, propidium iodide staining, and flow cytometry. Two advanced ’omics analyses, transcriptomics and metabolomics, were also conducted to clarify to toxic pathway. Differentially expressed gene derivation and validation were analyzed for transcriptome functional interpretation and component analysis. The group exposed to the smallest MP size (0–20 µm) showed the increased leukocyte apoptosis, and the phagocytic activity, measured using flow cytometry, revealed that leukocyte phagocytic activity of all exposed groups increased compared to that of the control group. Supporting the exposure response mechanism of the rockfish revealed by metabolomic analysis, correlation analysis confirmed the metabolomic changes. Our results can be used as reference data for evaluating effects caused by PET exposure and might be useful for identifying the correlation between toxic effects and physiological functional characteristics in marine fish after exposure to MPs.

1.09.P-Mo099 Are *Daphnia* More Sensitive to Weathered or Pristine Microplastics Derived from Common Consumer Products?

Bettie Cormier[1]*, Manon Perrier*[1]*, Lisbet Sorensen*[2]*, Andy Booth*[3] *and Martin Wagner*[1]*, (1)Norwegian University of Science & Technology (NTNU), Norway, (2)SINTEF, Norway, (3)Climate and Environment, SINTEF, Norway*

A large body of research has established that microplastics (MP) are ubiquitous pollutants that can be hazardous for some species. To date, MP research has focused primarily on using commercially available pristine test materials that are often spherical and made of polystyrene, due to a lack of environmentally relevant reference materials. In the current study (REVEAL project), we investigated the toxicity of pristine and partially aged irregular-shaped MP produced from common consumer products. To obtain different materials (shape, size, polymer), two common plastic products – textile fibers and shopping bags – were selected. Fibers were made of polyester, polyamide, or polyacrylonitrile, and wool was used as natural reference fiber. For polyethylene (PE) shopping bags, we used virgin and recycled PE to investigate the influence of recycled materials on degradation and toxicity. Plastic products were cut into small pieces (<1 cm), cryomilled (6770 Freezer/Mill), and then sieved (<63 µm) prior to use in toxicity testing. Approximately half of the particles were then exposed in a UVC chamber for 20 d to simulate an accelerated photodegradation of the particles and generate chemical changes to the surface. All MP types were characterized before (pristine) and after (weathered) photodegradation using scanning electron microscopy (SEM) images, micro-Fourier transform infrared (µFTIR) (carbonyl index; chemical changes), and coulter counter (shift in size distributions). Yellowing and loss of color provided visual evidence that material weathering had occurred, while an increase of carbonyl index was observed for some polymers. *Daphnia magna*, a sensitive water flea, was selected for the toxicity study. The organisms were exposed to the different MP following a standard test (OECD 211 - *D. magna* reproduction test). Reproduction, survival, growth, and O_2 consumption were the assessed endpoints. This study contributes to gaining a better understanding of the toxicity of weathered MP research, as well as of recycled and pristine plastics. Furthermore, the production of weathered irregular-shaped particles (film and fibers) is of great interest in MP research because of the environmental relevance compared to pristine spherical materials. More information on reference materials used can be found in the presentation "Production and analysis methods for pristine and degraded microplastic and nanoplastic reference materials," session 3.28.

1.09.P-Mo100 Embryotoxic and Neurobehavioural Effects of Nanoplastics on the Early Life Stage in Zebrafish

Xiaoyu Duan[1]*, Mohamed Helal Seda*[2] *and Elvis Genbo Xu*[3]*, (1)Department of Biology, University of Southern Denmark, Denmark, (2)Biology, University of Southern Denmark, Denmark, (3)University of Southern Denmark, Denmark*

Nanoplastics (NPs) have attracted global attention due to their potential ecological and health impacts. Previous ecotoxicological studies have reported nanoplastic toxicity in various aquatic organisms but there is still limited understanding of how different nanoplastics affect embryonic development and early life stage behaviours. Here, we investigated the embryonic and neurobehavioural effects of polystyrene nanoplastics (PS-NPs) in different sizes (50 nm to 1 µm) and with different charges (amino-modified PS-NP and carboxyl-modified PS-NP) on early-stage zebrafish. Zebrafish embryos were exposed to PS-NPs (0.1 to 10 ppm) from 2 to 120 h postfertilization. The dose-responsive toxicological assessment included mortality, hatching, deformities, locomotor activities (distance, velocity, rotation, and active time), and biochemical and transcriptomic responses. The results showed that nanoplastic exposures did not affect mortality, hatching rate, or deformities but significantly decreased locomotor activities. RNA-Seq and bioinformatical analyses predicted and characterised the key biological processes and pathways affected by different nanoplastic exposures. These findings provide new insights into the size- and surface-charge-dependent sublethal toxicity of nanoplastics and highlight the challenge of assessing the ecological risks of nanoplastics due to the great complexity of nanoplastic mixtures in the environment.

1.09.P-Mo101 Effects of Plastic on the Reproductive Behaviour of the Freshwater Snail *Biomphalaria Glabrata*: An Invertebrate *in vivo* Study

Linda Prähauser*, Robin Friedrich, Nevena Lakic, Karoline Schweitzer, Christoph Olscher, Xavier Monforte Vila, Barbara Gepp, DI and Elisabeth Simboeck, University of Applied Sciences Technikum Wien, Austria*

Plastic has been an increasingly important omnipresent material with versatile properties and diverse applications since the 1950s. However, its long life and decomposition into microplastics, and its various additives cause significant environmental pollution with growing scientific and public health concerns. Risk assessment of microplastic pollution is highly demanded, however, and often includes animal testing.

In this study, we investigated the putative effects of conventional (high density polyethylene) and biodegradable plastic bags (based on corn starch) on the aquatic system, using the freshwater snail *B. glabrata*. In comparison to vertebrates, invertebrate study systems are less regulated and do not need approval by an ethical commission. Nevertheless, efforts are done to keep invertebrate research ethical. Therefore, all experiments were planned carefully and highest attention was paid to avoid any suffering. In addition, a noninvasive assay was chosen to investigate the reproduction behaviour of adult snails.

Snails were exposed to pieces of conventional and biodegradable plastic bags, as well as to leachates of the two plastic bags, which potentially contain harmful substances. The reproduction behaviour was monitored by counting the number of laid egg clutches. Our results demonstrate that the reproductive behaviour of *B. glabrata* was influenced by plastic; however the increased clutch production was possibly not affected by leached chemicals but rather by other factors such as the surface area of the plastic or the amount of plastic pieces. Although further experiments are needed to gain more information on the impact of plastic on aquatic organisms, our study demonstrates that *B. glabrata* is an appropriate *in vivo* invertebrate test system for ecotoxicological risk assessment.

1.09.P-Mo102 Behavioural Toxicity of Conventional vs Biobased and Marine Recycled Polymers in European Perch and Netted Dog Whelk

Christopher Liechti*, Azora König Kardgar, Darragh Doyle and Bethanie Carney Almroth, University of Gothenburg, Sweden*

Microplastic is everywhere, from the beaches to the depths of the seafloor. These small plastic particles are challenging organisms and communities in a variety of different ways. By virtue of their small size, microplastics are ingested by many species, which may have adverse particle and mechanical effects. In addition, microplastics contain thousands of chemicals, which are either added during production, or which sorb to the plastics upon entering the environment. These chemicals may leach from the plastics and into the surrounding water/organisms, with the potential for additional adverse outcomes.

While much work has been done on the physiological side of toxicology, less has been done to assess the behavioural effects of exposure to plastic and its associated chemicals. Behaviour is comprised of internal stimuli and external stimuli and how these are combined to what is happening in the environment. Changes in behaviour may be detrimental to individuals and populations by interfering with chemical cues related to feeding, reproduction, or predator avoidance.

In this study, changes in behaviour will be investigated in two organisms. Firstly, a chronic exposure of juvenile European Perch (*Perca fluviatilis*) will be exposed to microplastic particles via ingestion over a six-month period. The first will be fed a mixture of conventional microplastics and biobased microplastics. Classical behavioural tests will be carried out on the perch to assess changes to behaviour. The tests will include response to a novel object, locomotion, predator avoidance, and conspecific recognition. The second study species is the Netted Dog Whelk (*Tritia reticulata*). This species will be exposed to 2% w/v chemical leachate from recycled marine plastic for two months. Predator-avoidance behaviour and response to food cues will be measured in snails exposed to either leachate or control. In addition, the snails will be assessed for the presence of imposex.

1.09.P-Mo103 Toxic Effect of Polypropylene Loaded with Fluoxetine on *Daphnia Magna*: Adsorption and Desorption Mechanisms of Fluoxetine on Three Microplastic Types

Diana Souza Moura*[1], *Carlos J. Pestana[1], Colin F. Moffat[1], Nikoletta Gkoulemani[2], Jianing Hui[2], John T. S. Irvine[2] and Linda A. Lawton[1], (1)Robert Gordon University, United Kingdom, (2)University of St Andrews, United Kingdom

Water quality is an increasing global environmental concern. An indicator of poor water quality is the presence of micropollutants. Pollutants, including microplastics, are commonly detected throughout freshwater and marine aquatic systems. There is an ever-developing recognition that microplastics can act as a vector for micropollutants when co-occurring and that loaded-microplastics can become integrated to food webs. This study evaluated the adsorption / desorption of the antidepressant fluoxetine with three virgin and three aged microplastic types widely reported in the freshwater environment. Microparticles of polypropylene (PP), polyamide (PA), and polyvinyl chloride (PVC) with average particle sizes of less than 33 µm were acquired commercially and artificially aged in the laboratory using a xenon arc weathering instrument (Suntest XLS+, AMETEK Inc., USA). The effect of aging microplastics on the adsorption of fluoxetine onto PP (15-100 µg/mL), PA (1-15 µg/mL), and PVC (1-15 µg/mL), followed by the desorption from the microplastics, was evaluated. Results showed similar adsorption by virgin and aged PP (83-98%), while no desorption was observed. On the other hand, fluoxetine adsorbed more to aged PA (25-68%) and PVC (38-90%) when compared to virgin PA (24-55%) and PVC (33-83%). Both virgin and aged particles of PA and PVC desorbed up to 20% of the fluoxetine from microplastics after 24 h at 25 °C. To evaluate whether microplastics loaded with fluoxetine can act as a vector for fluoxetine entering the food chain, an ecotoxicity experiment with *Daphnia magna* neonates was performed using Daphtoxkit F (Microbiotest, BE). The investigation was conducted to evaluate five treatments each containing a total of 20 neonates. After 48 h, *Daphnia magna* demonstrated ingestion of PP under all treatments where microplastic was included. However, the ingestion of microplastics did not appear to affect the mobility / survival of the organisms in the microplastic control (100 µg/mL plastic) and fluoxetine-loaded microplastic (50 µg/mL plastic). Toxic effects were observed in the treatments containing fluoxetine either in solution or loaded onto microplastics. Out of 20 daphnids, five were dead / immobilised when in a solution with only fluoxetine (1 µg/mL), and six were dead / immobilised when in a solution with fluoxetine-loaded microplastic (100 µg/mL plastic). The results indicate that microplastic can enter the food chain and act as a vector for pollutants.

1.09.P-Mo104 Elucidating the Human Health Hazards of Inhaled MicroNanoPlastics in Particulate Matter Using Advanced *in vitro* Approaches

*Lewis James Hodgetts[1], Eric Auyang[2], Olivia Whittle-Wright[1], Kirsty Meldrum[1], Joshua Bateman[1], Joseph M Levermore[2], Ulla Birgitte Vogel[3], **Stephanie Wright**[2], Shareen H Doak[1] and Martin J.D Clift[1], (1)In Vitro Toxicology Group, Swansea University, United Kingdom, (2)School of Public Health, Imperial College London, United Kingdom, (3)National Research Centre for the Working Environment, Copenhagen, Denmark*

MicroNanoPlastics (MNPs) are formed by the biological, chemical, or mechanical degradation of plastics. Research has targeted the environmental impacts of MNPs, however the human health hazard of MNPs is largely unknown. Surgical face masks are a prevalent source of MNP exposure to humans, notably during the SARS-CoV-2 pandemic. These masks contain a high plastic content, specifically polypropylene (PP) and are known to shed MNPs. Respirable (<5 µm diameter) samples of commercial PP powder (Goonvean Fibres Ltd.), and face masks were prepared using cryomilling and cryotome slicing. Two mask samples were prepared, consisting of either all three filter layers, or just the innermost layer, and were analysed using Pyrolysis-Comprehensive-Two-Dimensional GCMS (+LECO ChromaTOF Tile) for composition, and via Zetasizer for Dynamic Light Scattering (size distribution) and Zeta Potential (surface charge). To assess MNP human impact, type-II lung epithelial cells (NCI-H441) were cultured at the air-liquid interface (ALI) and exposed to carbon black (CB) (Printex© 90), as a positive particle control, and the PP samples via aerosol (Vitrocell Cloud12) with deposited concentrations of 0.5, 1.0, and 2.0 µg/cm^2. Cell cultures were then postincubated at 37°C, 5% CO_2 for 24 h. Alongside acellular deposition, particle, and cellular morphology (electron microscopy) assessed endpoints of cell viability (trypan blue exclusion), barrier integrity (blue dextran), (pro-)inflammatory response (IL-1β/IL-6/IL-8), oxidative stress (*SOD-1*), and genotoxicity (mononucleate micronucleus) were conducted. A decreased cell viability was observed following exposure to commercial PP and full mask samples, concomitantly with an increase in all (pro-)inflammatory mediators assessed. However, these changes were only significant at 2.0 µg/cm^2, in contrast to CB, which was significantly increased between each concentration. Further, initial genotoxicity assessment suggests a minor increase to micronucleus formation for both exposure samples. Thus, data suggest that aerosolised MNPs may instigate a hazardous response *in vitro*, though the mechanisms associated with this remain under investigation. In advancement of this approach, a co-exposure of aerosolised MNPs ± (standardised) indoor and outdoor particulate matter (e.g., NIST 2584 and 1649b) upon a co-culture lung model (NCI-H441 + d-THP-1), cultured at the relevant *in vivo* ratio for the lower human lung, for 4 and 24 hr is currently ongoing.

1.09.P-Mo105 Detection and Quantification of Micro- and Nanoplastics in Olfactory Bulb Tissue: A Neurodegenerative Disease Association Study

Ayesha Babbrah[1]*, Melanie Engstrom Newell*[1]*, Raj Rathnam*[1]*, Katherine B. Henke*[2]*, Erin M. Driver*[2]*, Devin A Bowes*[1] *and Rolf Halden*[1]*, (1)Arizona State University, (2)Center for Environmental Health Engineering, Arizona State University*

The ubiquity of micro-/nanoplastics (MNPs; 100 nm - 5mm and <100 nm, respectively) in the environment has incentivized exploration into the neurodegenerative impacts of chronic plastic exposure. There is growing concern for the distribution of MNPs in vital organs, leading to neurotoxicity, disease (e.g., cancer, renal, cardiovascular), oxidative stress, and other serious health consequences. The olfactory region of the brain is of particular interest due to its demonstrated ability to transfer neurodegenerative disease (NDD) causing agents (e.g., BMAA) to the brain via the olfactory pathway. Existing studies have observed the role of environmental toxin exposure on olfactory bulb dysfunction; however more are needed to examine specific impacts on the human brain and blood-brain barrier (BBB). This study aimed to identify and quantify concentrations of MP (BPA/TPA) monomers and plasticizers (phthalates) in postmortem olfactory bulb tissue by LC-MS/MS analysis. We hypothesized that 1) inhaled MNPs can utilize the olfactory pathway to access brain tissue, and 2) there will be significantly higher (95% CI) quantities of MPs in patients with neurodegenerative diseases compared to healthy individuals. The olfactory nerve, referred to as cranial nerve 1 (CN1), was sampled from human postmortem brain donors with documented occupational and/or residential exposure to plastic contaminants. CN1 biospecimens include donors with neurodegeneration pathologies (n = 12), as well as unaffected controls (n = 3) spanning 20 to 80 years of age. Donor selection criteria are based upon occupational and residential histories, and samples are accompanied by de-identified patient data. Tissue samples have undergone digestion, depolymerization, solid phase extraction, and elution procedures prior to LC-MS/MS analysis and quantification by isotope dilution. Identification of MNPs in the brain would be indicative of olfactory pathway absorption and could suggest a linkage between neurotoxicity and plastic exposure. The method utilized for detection of plastics in brain tissue has the potential to link MNP concentration with neurodegeneration, provided patient metadata and additional analysis to quantify neurotoxicity (e.g., single-nucleus transcriptomics, RNA sequencing). Based on the concentration of nanoplastics reported in this study, further qualitative assessment could be used to understand the neurological impact of plastic exposure.

1.09.P-Mo106 Combined Rffects of Nanoplastics and Benzo[*a*]pyrene in Human Colon Adenocarcinoma Cells

Joana Antunes[1]*, Paula Sobral*[2]*,* ***Marta Martins***[3] *and Vasco Branco*[4]*, (1)MARE - Marine and Environmental Sciences Centre, Portugal, (2)MARE - Marine and Environmental Sciences Centre | ARNET - Aquatic Research Network Associate Laboratory, NOVA School of Science and Technology, University of Lisbon, Portugal, (3)MARE - Marine and Environmental Sciences Centre, NOVA School of Science and Technology, Portugal, (4)Research Institute for Medicines (iMed.Ulisboa), Faculty of Pharmacy, Universidade de Lisboa, Portugal*

Nanoplastics (NP) and Polycyclic Aromatic Hydrocarbons (PAHs) are known to individually pose risks to environmental and human health. Interaction effects are not known, but this is a relevant issue since NP knowingly adsorb pollutants from the environment.

In this study, we propose to assess the effects of the mixture of NPs and a well-known PAH, the benzo[*a*]pyrene in HT29 cells (human colon adenocarcinoma cell line). First, cellular viability (MTT assay) was evaluated exposing HT29 cells to five different concentrations of polystyrene NP (25, 50, 100, 200, and 500 $g.ml^{-1}$) with 25, 50, and 100 nm of diameter and B[*a*]P (1, 5, 25, 50, and 100 µM) individually, for 24, 48, and 72 h. Secondly, several biomarkers related with the detoxification mechanisms of B[*a*]P, like 7-ethoxyresorufin O-deethylase (EROD), glutathione-S-transferase (GST) activities and glutathione levels (reduced [GSH] and oxidized [GSSG] forms) were afterwards analysed in cellular lysates exposed to 500 $g.ml^{-1}$ of NP and two B[*a*]P concentrations (5 and 50 µM) individually and in mixture.

The results revealed that larger NP particles (100 nm) yielded higher cytotoxicity than smaller plastics. The cytotoxicity increased with time of exposure to both contaminants. Results showed higher EROD activity in cells exposed to NP (with and without B[*a*]P). Contrary to expected, cells exposed to NP and B[*a*]P mixtures showed lower EROD activity comparing to NP individual contamination. This can occur due to surface interactions decreasing B[*a*]P accessibility. On the other hand, GST activity increased with the increase of B[*a*]P concentration and in exposure containing the mixture of both contaminants (B[*a*]P and NP), pointing to increased conjugation of metabolites.

The results highlighted the complex nature of the interactions between NP and B[*a*]P .

1.09.P-Mo107 Study of the Bioavailable Fraction of Metals Derived from Polylactic Acid (PLA) Microplastics

Javier Terán Baamonde[1]*, Alatzne Carlosena Zubieta*[1]*, Rosa M Soto Ferreiro*[1]*, Elia Alonso Rodríguez*[2] *and* ***Soledad Muniategui-Lorenzo***[1]*, (1)Universidade da Coruña, Spain, (2)University of A Coruña, Spain*

The production of degradable polymers is rising considerably in recent years seeking to replace nondegradable polymers and to solve many of the widely known environmental problems arising from their use.

Polylactic acid (PLA) is considered one of the most commercially promising bioplastics, due to its wide availability, tunability, and lower production cost compared to other biodegradable polymers. It is derived from renewable sources (sugar and starch) from which lactides are obtained, followed by a conventional polymerization process. In this step, a high amount of metallic catalyst is required, such as lead, tin, zinc ,or aluminum, which can remain as impurities in the final product.

On the other hand, although PLA is compostable, it can remain in the marine environment for up to 1000 years, generating a great amount of microplastics that can enter the food chain.

In this framework, it would be necessary to assess the potential risk derived from the metals presented in bioplastics such as PLA. Then, metal contents in PLA samples were tested in the present study, observing the elevated Sn concentration (ca. 25 µg/g). Moreover, bioavailable metallic fraction was assessed by using an *in vitro* human digestion procedure, following the *in vitro* unified BARGE Method. This method simulates the human digestive procedure using synthetic digestive fluids (saliva, gastric, duodenal, and bile) and, in this work, a dializing membrane step was included to estimate the possible metallic diffusion transport into the simulated blood fluid. This allows discerning between the bioaccessible (BARGE Method) and bioavailable fractions.

1.09.PC Micro (Nano)Plastics: Occurrence, Fate, Uptake, and Mechanistic Approaches to Understand Their Risk for the Environment and Human Health

1.09.P-Mo052 Modelling Environmental Microplastic Fate and Exposure
Yvette Agnes Maria Mellink[1], *Merel Kooi*[1], *Joris T.K. Quik*[2] *and Albert A. Koelmans*[1], *(1)Wageningen University & Research, Netherlands, (2)National Institute for Public Health and the Environment (RIVM), Netherlands*
Exposure assessment is the basis of risk assessment for microplastic particles (MP). Since small microplastic and nanoplastic particles are almost impossible to detect, and their concentrations can only be estimated by interpolating in time and space, retrospective risk assessments must rely on modelling. This requires a holistic modelling approach, linking sources, transport, fate, and exposure of MP. In this research, we will develop and validate a range of microplastic transport and fate models, encompassing different spatial and temporal scales. The first step will be to develop a harmonized microplastic emission model, followed by the development of a 'unit world' multimedia model. Microplastic fluxes generated by this multimedia model will serve as input for a detailed spatiotemporal river transport model. While previous models were usually parameterized to simulate only the behaviour of monodisperse spherical microplastic particles, we will apply new approaches using probability density functions (PDFs). Using these PDFs we will be able to capture the full multidimensionality and diversity of environmentally relevant MP as they exist in nature. Modelled MP-PDFs can then be tuned to threshold effect concentrations to characterize ecological risks in environmental systems. The toolset presented enables us to prospectively assess risks for decades to come.

1.09.V Micro (Nano)Plastics: Occurrence, Fate, Uptake, and Mechanistic Approaches to Understand Their Risk for the Environment and Human Health

1.09.V-01 Accumulation in Soft Body, Histological Alternation, and Cytotoxicity Caused by Exposures to Two types of Microplastics in the Mediterranean Mussel (*Mytilus galloprovincialis*)
Won-Seok Kim[1], *Ji-Won Park*[1], *Kiyun Park*[2], *Byoung-San Moon*[3] *and Ihn-Sil Kwak*[1], *(1)Department of Ocean Integrated Science, Chonnam National University, Yeosu, Korea, Republic of (South), (2)Fisheries Science Institute, Chonnam National University, Yeosu, Korea, Republic of (South), (3)Department of Biotechnology, Chonnam National University, Yeosu, Korea, Republic of (South)*
Plastics enter the ocean through various routes and are decomposed through physicochemical reactions such as waves, ultraviolet, temperature, and pH. Due to this reaction, various sizes and shapes of microplastics (MPs) and nanoplastics (NPs) are formed, which easily accumulate in the organism body and cause toxic effects. In the study, we investigated the effects of exposures to two types (spherical and fiber) of MPs on Mediterranean mussel (*Mytilus galloprovincialis*). To do this, we observed biological and physiological responses including survival rate, number of MPs accumulation in the soft body, and histological structures on *M. galloprovincialis* exposed to each MP type. The survival rate decreased on *M. galloprovincialis* following exposures to two types of MPs as a dose-time dependent manner. It is a direct toxic effect of exposed MPs. Especially, a significant decrease of the survival rate was observed on *M. galloprovincialis* exposed to the fiber type, suggesting that it has higher toxicity than the spherical type. As a result of MPs accumulation in the soft body, accumulation of spherical MP decreased until the 7 days, but a sharp increase of the MP particles observed on *M. galloprovincialis* body at 21 days. However, body accumulation of fiber type tended to increase throughout the exposure periods. The exposure to two types of MPs induced alterations of histological structures including increased width of gill filament in the gill tissue of *M. galloprovincialis*. We also observed the cytotoxic signals in gill tissues of all exposed groups as a time-dependent trend using terminal deoxynucleotidyl transferase dUTP nick end labeling (TUNEL). These results suggest that exposures through two types of MPs induced different accumulation sensitivities on *M. galloprovincialis* body and were directly related to survival changes. Moreover, observation of histological alterations in gill tissues by inductions of cytotoxicity is a good tool to assessing MPs pollutions in aquatic environment.

1.09.V-02 Leaching of Microplastic Constituents in Aqueous Medium; Aquatic Toxicity on Marine and Freshwater Organisms
Josipa Papac Zjacic[1], *Marin Kovačić*[1], *Hrvoje Kušić*[1], *Zlata Hrnjak Murgić*[2], *Dionysios D. Dionysiou*[3] *and Ana Lončarić Božić*[1], *(1)University of Zagreb, Croatia, (2)University of Zagreb Faculty of Chemical Engineering and Technology, Croatia, (3)Environmental Engineering and Science Program, University of Cincinnati, Cincinnati, OH*
Sources of microplastic (MP) in the environment are various including inefficient wastewater treatment plants, and stormwater runoff. Also, everyday activities that produce municipal plastic waste due to unregulated waste management end up in the aquatic environment which with time can be degraded and fragmented into MP particles. Due to its shape and size, MP can easily enter the food chain and cause negative effects on the organisms. Also, it is important to notice that in atmospheric conditions waste

polymer material as well as MP can release additives that are mostly residue from the synthesis or even can be produced in the process of recycling.
The aim of this study was to investigate the qualitative content and aquatic toxicity of samples during the leaching process. For that purpose pristine and photooxidative (UV) aged polyethylene terephthalate (PET) bottles were exposed to the enhanced atmospheric conditions. In leaching tests, using pristine and aged MP, the concentration of bisphenol A (BPA) in the aqueous phase was monitored using High-Performance Liquid Chromatography Analysis. Heavy metal concentration was monitored using Inductively Coupled Plasma Mass Spectrometry. Acute toxicity bioassays were performed with the freshwater microalgae *Pseudokirchneriella subcapitata (Selenastrum capricornutum)* and the crustacean *Daphnia magna* as well as marine bioluminiscent bacteria *Vibrio fischeri*, according to standard procedures (ISO).

Obtained results indicate that the fragmentation of PET bottles is enhanced for pristine PET bottles in terms of a higher percentage of smaller particles. Leachates that are released from both pristine and aged PET samples were BPA and antimony. The release of antimony was much lower from the UV-aged sample. In general, presence of leached constituents enhances overall toxicity effects in comparison with the samples that consisted of only MP particles.
These results will serve as preliminary study for the further investigation of microplastic behaviour in the aquatic environment and the goal is to step forward to the more complex environmentally relevant samples which are considered as a mixture of microplastics and other pollutants.

1.09.V-03 Influence of Photooxidative Aging on the Aquatic Toxicity of Microplastic Tested on Freshwater Organisms
Josipa Papac Zjacic[1]*, Bruno Grassl*[2]*, Hrvoje Kušić*[1]*, Zlata Hrnjak Murgić*[3]*, Dionysios D. Dionysiou*[4] *and Ana Lončarić Božić*[1]*, (1)University of Zagreb, Croatia, (2)University de Pau et des Pays de lAdour, France, (3)University of Zagreb Faculty of Chemical Engineering and Technology, Croatia, (4)Environmental Engineering and Science Program, University of Cincinnati, Cincinnati, OH*
Everyday life conveniences and activities such as washing clothing made of synthetic fibers, tire wear, and plastic packaging break down in the environment may serve as an abundant source of microplastic (MP). There is plenty of evidence that microplastic is a problem due to its shape, size, and concentration and the fact that it can easily enter the food chain which causes negative impacts on human health and the environment. An important aspect of this problem is also the fact that microplastic and other contaminants of emerging concern (CEC) present in water can interact, in terms of the adsorption of CEC onto the MP surface. The adverse effect of MP in water is therefore influenced by factors affecting adsorption capacity: particle size, specific surface area, hydrophobicity, and polarity of MP as well as CEC.

The aim of this study was to investigate the aquatic toxicity of pristine and photooxidative (UV) aged microplastics and pesticide atrazine samples after the sorption. For that purpose, we investigated the impact of UV aging on polyethylene terephthalate (PET) bottles and correlated it with surface properties. Polyethylene terephthalate was inspected for morphology changes using Scanning Electron Microscopy and Fourier Transformation Infrared Spectroscopy. The specific surface was investigated by using Brunauer-Emmet-Teller Analyzer to determine the adsorption capacity of MP. The fragmentation of PET bottles into microplastic particles has also been investigated. In adsorption tests, using pristine and aged PET MP, the concentration of atrazine in the aqueous phase was monitored using High-Performance Liquid Chromatography Analysis. Aquatic toxicity samples were assessed by exposing freshwater organisms to the aqueous dispersion of pristine and aged MP, without and with adsorbed pollutants. Acute toxicity bioassays were performed with the microalgae *Pseudokirchneriella subcapitata (Selenastrum capricornutum)* and the crustacean *Daphnia magna* according to standard procedures (ISO).

Obtained results indicated that UV aging resulted in changes in PET bottle morphology and structure. Carboxyl groups are confirmation of surface degradation. The adsorption capacity of MP increases with a higher aging degree. Adsorption capacity is decreasing with an aging degree. Toxicity is increasing with the complexity of samples but decreases with the aging degree. Mixture (MP and CEC) confirmed higher toxicity in comparison to the individual components.

1.10 Nanoparticle Biological Interactions and Their Responses

1.10.P-We001 Intracellular Measurement of Dissolved Metals and Localization of Metal Nanoparticles using X-ray Spectroscopy Techniques
Matteo Minghetti[1]*, William Dudefoi*[2]*, Yanqui Luo*[3]*, Si Chen*[3] *and Jeff Catalano*[4]*, (1)Oklahoma State University, (2)Environmental Toxicology, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Dübendorf, Switzerland, (3)Advanced Photon Source, Argonne National Laboratory, (4)Washington University in St. Louis*
Intracellular dissolution of metal nanoparticles (NPs) and speciation of dissolved metal species relates to cellular toxicity and bioreactivity. While it is possible to predict the chemical transformations of metals and metal NPs in the extracellular environment, intracellular chemical transformations are more challenging to predict. X-ray absorption spectroscopy (XAS) is optimally suited for the nondestructive determination of the speciation of metals in situ. Moreover, imaging of intracellular metal and metal nanoparticle can be achieved by X-ray fluorescence microscopy (XRF). The intracellular fate of NPs might have important toxicological implications, but it remains poorly understood. In this study we used an intestinal cell line from rainbow trout (*Oncorhynchus mykiss*), the RTgutGC. We used the RTgutGC cells and XRF to determine the intracellular localization and concentration of essential trace metals in cells exposed to silver and titanium dioxide NPs. Cell monolayers were exposed to nontoxic and toxic concentrations of silver nitrate and silver and titanium dioxide NPs. After exposure, cells were washed and

then fixed chemically or cryogenically. To determine the intracellular NPs' localization, a subset of samples was measured using 3D tomography. In a parallel set of samples metal intracellular concentration was measured by ICP-MS. The comparison of metal quantification by XRF and ICP-MS in RTgutGC cells showed a remarkably similar concentration of trace metals. X-ray fluorescence imaging of cells exposed to silver nitrate showed a reduced nuclear size confirming previous imaging data. Cells exposed to silver and titanium dioxide NPs accumulated nanoaggregates intracellularly. Remarkably, titanium dioxide NP aggregates showed a significant increase in the trace metals iron and zinc suggesting that these metals could sorb onto the NP surface. The 3D tomography data demonstrated that both silver and titanium NPs can translocate to the cell nucleus. Although technically challenging, XRF imaging is a very powerful technique and can be used to accurately map intracellular metal concentrations. Although titanium dioxide NPs are not acutely toxic their sorption properties might result in disruption of essential trace metal metabolism. The nuclear translocation of silver and titanium dioxide NPs is alarming but could also be exploited for certain applications.

1.10.P-We002 Size and Shape-Dependent Interactions of Lipid-Coated Silver Nanoparticles: An Improved Mechanistic Understanding Through Model Cell Membranes and *in vivo* Toxicity

Stacey L. Harper[1]*, Citlali N. Lira*[1]*, Andrew Carpenter*[1]*, Paul Nguyen*[1]*, Joe Baio*[1]*, Bryan J. Harper*[2] *and Marilyn Mackiewicz*[1]*, (1)Oregon State University, (2)Environmental & Molecular Toxicology, Oregon State University*

The wide applicability and versatility of silver nanoparticles (AgNPs) has led to an increased demand for optimized AgNPs with tuned physical, optical, and chemical properties for various industrial and biomedical applications. Specifically, biocompatible and stable AgNPs with minimal impact on human health and the environment are of significant interest. It is well-known that the physical, optical, and catalytic properties of AgNPs are strongly influenced by their size, shape, and surface properties. While *in vitro* and *in vivo* studies of AgNP uptake have provided a wealth of knowledge regarding the mechanism and efficiency of AgNP uptake, distribution, and toxicity, many of these studies cannot disentangle the contribution of silver ions to these processes or effects.

Our approach was to systematically study a series of engineered AgNPs that are shielded from dissolution, detailing their interactions with i) biomimetic lipid monolayers and their ii) uptake and effects *in vivo*. Well-studied biomimetic lipid monolayers have been employed to assess the interactions of biomolecules or NPs with a lipid monolayer. Sum Frequency Generation (SFG) vibrational spectroscopy can detect the adsorption and orientation of biomolecules at submicromolar concentrations and can directly identify interactions between NPs and model cell membranes with molecular resolution. For these studies, we synthesized a size and shape series of AgNPs coated with robust and tightly packed lipid bilayer composed of sodium oleate (SOA), hydrogenated phosphatidylcholine (HPC), and hexanethiol (HT).

Combining *in vivo* toxicity studies with SFG spectroscopy and model membranes we were able to elucidate our gap in knowledge in understanding of how NP shape and size influence interactions without the confounding effect of ionic Ag. We observed differences in toxicity related to both the size and shape of AgNPs without the confounding factor of dissolved Ag ions being present. Zebrafish exhibited hyperactive spontaneous movement from the AgNP exposures and a unique caudal fin malformation was observed in both the AgNS and the AgNPL. This work demonstrates the utility of *in vitro* evaluations with biomimetic models combined with *in vivo* testing to move toward mechanistic understanding of biomaterial interaction. This study further supports the need for moving towards mechanistic evaluations of nanomaterial technology to inform rational design, hazard, and application.

1.10.P-We003 Assessment of Multiple Stressors: Combined Effects from Exposure to Silver Nanoparticles or Zinc-Oxide Nanoparticles with the Pathogen *Klebsiella Pneumoniae* in *Caenorhabditis Elegans*

Jarad Cochran[1]*, Jason Unrine*[1] *and Olga V. Tsyusko*[2]*, (1)University of Kentucky, (2)Plant and Soil Sciences, University of Kentucky*

Nanoparticles (NP), such as AgNP and ZnONP, are rapidly being incorporated into agricultural settings as precision herbicides and pesticides. To assess the potential toxicity of these NP, model organisms are exposed to NP as a single stressor, but in nature, organisms are affected by multiple sources of stress, including infections, which might exacerbate or mitigate negative effects of NP exposure. To expand our understanding of the environmental consequences of released NP, this project examined the combined effects of AgNP or ZnONP on *Caenorhabditis elegans* infected with a common pathogen, *Klebsiella pneumoniae*. To determine effects of single stressors on reproduction, nematodes were exposed to AgNP or ZnONP while being fed nonpathogenic bacteria. Nematodes were also fed *K. pneumoniae* without the presence of NP. All exposure treatments decreased reproduction in nematodes. To assess effects of combined stressors, *C. elegans* were exposed to EC_{30} concentrations of AgNP or ZnONP along with the pathogen. Exposure to both AgNP and *K. pneumoniae* resulted in reproduction that was not significantly different compared to single stressors exposures. However, combined exposure to Zn treatments and *K. pneumoniae* resulted in reproduction that was not significantly different from controls. Further experiments aimed to determine mechanisms of the antagonistic effects in Zn treatments. Mitigation of the pathogen effects by ionic or particulate forms of Zn is partially explained by the estimates of the colony forming units (CFU) of *K. pneumoniae* within treated nematodes. The nematodes exposed to ZnONP had significantly lower CFU compared to nematodes only exposed to *K. pneumoniae*. Pathogen biofilm formation after Zn exposure was also assessed. Results showed that *K. pneumoniae* produces biofilm, even in the presence of Zn (ion controls or ZnONP); however, Zn exposure significantly lowered biofilm production. Taken together, our results suggest Zn exposure decreases *K. pneumoniae* ability to form biofilms in host intestines, yet mechanisms of reduction of host Zn toxicity by pathogen exposure remain unknown. To elucidate molecular pathways that are involved in the observed antagonistic effects, transcriptomic data from nematodes exposed to Zn and *K. pneumoniae* is currently being analyzed.

1.10.T-01 Bionano Interactions: A Key to Mechanistic Understanding of Nanoparticle Toxicity

Vladimir Lobaskin[1]*, Ian Rouse*[1]*, Julia Subbotina*[2]*, Konstantinos Kotsis*[3]*, Anais Colibaba*[3] *and Parinaz Mosadeghi Amini*[2]*, (1)School of Physics, University College Dublin, Ireland, (2)Physics, University College Dublin, Ireland, (3)University College Dublin, Ireland*

The new paradigm in the assessment of toxicity of nanomaterials relies on a mechanistic understanding of the organism's response to an exposure to foreign materials from the initial, molecular level interactions to signaling and regulatory cascades. Such detailed information is often missing as only downstream events of adverse outcome pathways (AOP) are registered. Physics-based molecular modelling could provide such information, which can, in its turn, serve to generate the data for a development of quantitative structure-activity relationships between the nanomaterial properties and the key events of the AOPs and prediction of toxicity for new materials. Recently, a significant progress has been made in development of multiscale physics-based models of bionano interactions designed to fill the gaps in description of the toxicity mechanisms. Here, we present a methodology to quantify the essential interactions at the bionano interface using multiscale modelling, which can be used in combination with the AOP analysis to build mechanism-based predictive schemes for toxicity assessments. We introduce a set of new, advanced descriptors of the nanomaterials, which refer to their ability to bind biomolecules and trigger the pathways via the molecular initiating events. We also present a suite of open-source software tools to evaluate the interactions of biomolecules with arbitrary nanomaterials and predict the binding affinity and content of biomolecular corona for those materials. We demonstrate the predictive power of the *in silico* methods and novel descriptors by modelling various *in vitro* and *in vivo* biological endpoints.

1.10.T-02 Mechanistic Insight for Microbiota-Inclusive Nanotoxicology: Metabolite Corona and TLR2 Signaling

Bregje Brinkmann[1]*, Bjørn Koch*[2]*, Ankush Singhal*[3]*, Agur Sevink*[3]*, Lisette Neeft*[2]*, Willie Peijnenburg*[2] *and Martina G. Vijver*[2]*, (1)Environmental Biology, Leiden University, Institute of Environmental Sciences, Netherlands, (2)Leiden University, Leiden, Netherlands, (3)Leiden Institute of Chemistry, Leiden University, Leiden, Netherlands*

Recent progress in the nanosafety field revealed the importance of interactions between hosts and their associated microbiota to nanotoxicity. Mechanistically, microbiota-dependent nanomaterial toxicity has mainly been related to nanoparticle-induced dysbiosis, that is, to changes in the composition of host-associated microbiota that have detrimental consequences to host physiology (e.g., causing colitis or obesity). Conversely, nanoparticles have also been found to cure dysbiosis in plants and animals, thereby improving crop yield, preventing diarrhea in cattle, and inhibiting dental caries formation. In this presentation, I will introduce two other mechanisms that govern microbiota-dependent nanomaterial toxicity. The first of these mechanisms, is the adsorption of microbial metabolites onto the surface of nanomaterials, potentially affecting the identity and colloidal stability of nanoparticles as influenced by the biocorona. By constructing quantitative structure-activity relationship models, we predicted the adsorption affinities for 60 microbial metabolites to 13 metal and 6 carbon nanomaterials. Correlations of these predictions with surface interaction descriptions revealed key interaction types that drive the adsorption of microbial metabolites to nanomaterials. Using molecular dynamics simulations, we obtained excellent support for these interaction types, and moreover showed how flexible metabolites can gain stability on the nanomaterial surface via conformational changes. The second microbiota-dependent toxicity mechanism that we investigated, is the recognition of microbiota by Toll-like receptors (TLRs), potentially modulating the immune response of microbially-colonized hosts to immunotoxic nanomaterials. We studied this by comparing the sensitivity of wildtype zebrafish larvae, to that of mutants for TLR2, and TLR2-adaptor proteins (TIRAP and MyD88), to immunotoxic silver nanoparticles (nAg). This revealed that, exclusively under microbially colonized conditions, mutants for TLR2, and for one of its adaptor proteins (TIRAP), were more sensitive to nAg than their wildtype siblings. This indicates that TIRAP-dependent TLR2 signaling can protect hosts against immunotoxic nanoparticles. Based on common extrapolation strategies for nanotoxicology, I will present how this insight into these two microbiota-dependent toxicity mechanisms can contribute to more accurate predictions of nanomaterial safety for human and environmental health.

1.10.T-04 Investigating the Impact of Environmental Transformation of Nanomaterials on Their Fate of Nanomaterials Using Isotopic Enrichment and a pilot Wastewater Treatment Plant

Sebastian Kuehr[1]*, Johannes Raths*[2]*, Brian Sinnet*[2]*, Marco Kipf*[2]*, Rebekha Moore*[3]*, Gloria Young*[3]*, Mark Rehkamper*[3]*, Karl Andreas Jensen*[4]*, Ralph A Sperling*[5]*, Andy Booth*[6]*, Ralf Kaegi*[2] *and Anastasia Georgantzopoulou*[1]*, (1)Norwegian Institute for Water Research (NIVA), Norway, (2)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Dübendorf, Switzerland, (3)Imperial College London, United Kingdom, (4)Norwegian University of Life Sciences (NMBU), Norway, (5)Fraunhofer IMM - Institute for Microengineering and Microsystems, Mainz, Germany, (6)Climate and Environment, SINTEF, Norway*

An increasing number of consumer products, such as cosmetics, textiles, and nanomedicines contain engineered nanomaterials (ENMs). Engineered nanomaterials can end up in wastewater from where they are removed quite efficiently to the sludge by wastewater treatment plants (WWTPs). Most ENMs are chemically and physically transformed in wastewater, they can still potentially have effects on aquatic organisms and their dissolvable metals still appear to be bioavailable. However, only a few studies have investigated transformed ENMs. To date, most existing studies on ENMs bioavailability or accumulation were performed with pristine ENMs and/or the studies were conducted with artificial wastewater to simulate the transformation processes in WWTP. In addition, most investigations used unreasonably high ENM concentrations. The aim of this study is to investigate the fate of ENMs in WWTPs and the impact of the environmental transformation processes that occur in WWTPs at realistic ENM concentrations through the use of stable isotope labelling technique.

To this end, isotopically enriched ENMs (^{109}Ag and ^{68}ZnO) were synthesized and used. This allows ENM tracing and detection at low concentrations in complex matrices, even against the high background levels of elements present in WWTP matrices. To investigate the fate of the ENMs within the WWTP system, a pilot WWTP that operated with municipal wastewater was used.

The produced WWTP matrices (effluent and digested sludge) containing the enriched transformed ENMs were employed in exposure tests with the benthic amphipod *Hyalella azteca*, which was previously used in various studies on the bioaccumulation of ENMs, also in combination with WWTP matrices. Data derived from body burden measurements were then used to compare the availability of the respective metals from ENMs that passed through the WWTP. ^{109}Ag and ^{68}ZnO from ENMs that passed through the WWTP or were exposed with WWTP matrices (e.g., spiked to control effluent) showed a strongly reduced availability compared to their pristine counterparts. In contrast, the accumulation for non-enriched Au ENMs (also studied) was higher for ENMs that passed the WWTP. The experiments hence show that lab scale pilot WWTPs can be used to investigate the fate of ENMs in WWTPs and that the use of isotopically enriched ENMs allows monitoring of ENMs even at low and environmentally relevant concentrations.

1.10.P Nanoparticle Biological Interactions and Their Responses

1.10.P-We004 Potential Issues Specific to *in vitro* Toxicity Tests of Cellulose Nanofibers

***Akihiro Moriyama**, Isamu Ogura and Katsuhide Fujita, National Institute of Advanced Industrial Science and Technology (AIST), Japan*

Cellulose nanofibers (also called cellulose nanofibrils or nanofibrillated cellulose; CNFs) are a natural material consisting of a soft and long structure originating from wood or plants. These materials have low weight, high tensile strength, and a low thermal expansion coefficient. Various applications have been proposed to take advantage of these unique features. However, the introduction of new materials into the market requires thorough safety studies to be conducted. Recently, toxicity testing using cultured cells has attracted attention as a safety assessment that does not rely on experimental animals. Recent literature regarding CNF cytotoxicity tests was reviewed and the current toxicity assessment state surveyed. In the literature, a variety of cell lines and CNF exposure concentrations were found and selected. Furthermore, the cytotoxicity test results differed and were not necessarily consistent. Numerous examined reports had not evaluated endotoxin/microbial contamination or CNF interaction with the culture medium used in the tests. The following potential specific issues involved in CNF *in vitro* tests were discussed: (1) endotoxin contamination, (2) microbial contamination, (3) culture medium component adsorption to CNFs, and (4) changes in aggregation/agglomeration and CNF dispersion states resulting from culture medium components. In this presentation, the available measurement methods and solutions for these issues will be discussed. Addressing these points will lead to a better understanding of cellular effects of CNFa and safer CNF development.

1.10.P-We005 The Importance of a Comprehensive Toxicity Assessment of Nanopesticides in the Environment: Comparing Toxic Effects of Tebuconazole in Different Formulations on the Nematode *C. elegans*

***Mahleh Eghbalinejad**[1], Sebastian Hoess[2] and Jakub Hofman[1], (1)RECETOX, Masaryk University, Czech Republic, (2)Ecossa, Starnberg, Germany*

Nanopesticides (NPs) are considered less environmentally harmful formulations compared to existing conventional plant production products, able to control better the exposure of pests, reduce the total amount of pesticides consumed, and increase the environmental balance in agriculture. However, like any other new materials, these new nanoformulations of pesticides also need to be evaluated very carefully for their possible environmental risks prior to reaching the market. Nematodes are the most abundant and species-rich soil metazoans and are key drivers of soil functioning. The nematode *C. elegans* is used as a test organism with sublethal endpoints to assess chemical toxicity in water and soil. This invertebrate is used as a model due to its advantages which fill the gap between in vitro and in vivo tests, in addition to the simplicity, accuracy, repeatability, and low cost of the experiments. We tested the toxicity of two different NPs with polymer and lipid nanocarriers encapsulating fungicide tebuconazole (TBZ) as the active ingredient and a commercial TBZ formulation to *C. elegans* in different TBZ concentrations in the aquatic matrix. Additionally, the nanocarriers without TBZ were also used to assess their toxicity on *C. elegans*. We designed tests based on worst case scenario, so the nematodes were exposed to maximum released TBZ into the media after 48 h. Both tested NPs showed similar toxicity. However, experiments with the pure carriers revealed that the higher toxicity of NLC-TBZ was mainly due to stronger effects of NLC- compared to PCL-carriers, suggesting mixture toxicity of nanoparticles and active ingredient. Overall, these *in vivo* tests highlight that comprehensive toxicity testing of NPs is required to allow a reliable risk assessment.

1.10.P-We006 Size- and Concentration-Dependent Disturbance in Algal Metabolism Induced by nTiO2 Exposure

***Vera Slaveykova**[1], Wei Liu[1], Mengting Li[1], Arturo Keller[2] and Weiwei Li[2], (1)University of Geneva, Switzerland, (2)University of California, Santa Barbara*

The present work aims to fill an important knowledge gap regarding the metabolic perturbations induced by engineered nanomaterials on phytoplankton species. More specifically the goal is to decipher the metabolic perturbations in green alga *Chlamydomonas reinhardtii* induced by exposure to $nTiO_2$ materials and to explore if size- and concentration-dependences of the observed effects exists. To this end, green alga *C. reinhardtii*, grown in 4xTAP medium was exposed to increasing concentrations

(2 to 200 mg L^{-1}) of $nTiO_2$ with primary sizes of 5, 15, and 20 nm for 72 h. The effects of $nTiO_2$ on the algal growth, oxidative stress, membrane permeability, and photosynthetic activity were determined. In parallel, the stability of $nTiO_2$ suspensions in exposure media was followed by measuring hydrodynamic size distributions and Z-potential, as well as the sedimentation rates of $nTiO_2$. The metabolic perturbations in *C. reinhardtii* exposed to $nTiO_2$ of different sizes and concentrations were determined by liquid chromatography mass spectrometry. Transcriptomic responses of *C. reinhardtii* exposed to $nTiO_2$ were assessed using NanoString nCounter Technologies. Experiments with unexposed controls were also performed. The results revealed that despite the important aggregation and sedimentation, the exposure to increasing concentrations of $nTiO_2$ with primary sizes of 5, 15, or 20 nm altered significantly the abundance of metabolites involved in various pathways corresponding to amino acid, nucleotides, fatty acids, TCA, and antioxidant metabolism. Most of the responsive metabolites were common for the all treatments; however the intensity of the response and the existence or not of concentration- and nanoparticle primary size-dependences differed among the treatments. The metabolomics results correlate well with the transcriptomics and physiological results and confirmed that oxidative stress is a major toxicity mechanism for $nTiO_2$ exposure. The implications of the obtained results for the assessment of the toxicity and tolerance responses in phytoplankton and for enabling a discovery of sensitive markers for early warning are discussed.

1.10.P-We007 Sublethal Effects of Polysterene Nanoplastics on Freshwater Organisms
Maria Catarino[1], Sofia Azevedo[1], Ivone Pinheiro[1], Patricia Taladriz-Blanco[2], Laura Rodriguez-Lorenzo[3], Ana Vieira[1], Marilia Barreiros dos Santos[1] and ***Begoña Espina**[1]*, *(1)International Iberian Nanotechnology Laboratory, Portugal, (2)Water Quality, International Iberian Nanotechnology Laboratory, Portugal, (3)Water Quality Group, International Iberian Nanotechnology Laboratory (INL), Portugal*
The global accumulation of micro and nanoplastics is a growing concern for the environmental and human health. While the toxicity of macro and micro-sized plastics is relatively well studied, toxicity of nanoplastics is largely uncharacterized. This study investigated the possible size-related effects of 100 and 200 nm polystyrene nanoparticle (PS-NPs) standards using cyanobacteria *Microcystis aeruginosa* and *Danio rerio* zebrafish as model organisms evaluating, not only mortality or growth inhibition, but also structural modifications, PS-NPs interactions with the organisms (SEM), and impact on toxin biosynthesis or availability (microcystin quantification by ELISA). To make possible the comparison and reusability of the data reported, standard testing guidelines TG201 and TG236 were employed for ecotoxicity assays and the stability of the PS-NPs dispersion in the test media was always characterized (DLS, ɜ-potential and NTA).

No apparent acute toxicity was registered between the two PS-NPs in the model organisms; however results demonstrate that both PS-NPs have an influence on *M. aeruginosa* toxin microcystin availability in water, being different for both sizes. Additionally, an unprecedented structural modification on zebrafish embryonic development in response to both PS-NPs at the highest concentration tested (100 mg/L) was confirmed; the appearance of highly elongated neuromasts.

1.10.P-We008 Exposure Scenarios During Aging of Titanium Dioxide Nanomaterials Affect Dimethoate Toxicity in *Daphnia*
***Rajdeep Roy**[1]*, *Mukhtar Bashir[1], Verena Christina Schreiner[1], Ralf Schulz[2] and Mirco Bundschuh[1], (1)iES Landau, University of Kaiserslautern-Landau (RPTU), Germany, (2)iES Landau, Institute for Environmental Sciences, University of Kaiserslautern-Landau (RPTU), Germany*
Titanium dioxide nanomaterials (nano-TiO_2) are frequently used in consumer products (e.g., cosmetics, cleaning agents, filters, food, etc.) and are consequently released into freshwater systems via wastewater treatment plants. Furthermore, insecticides may enter freshwater ecosystems via runoff from agricultural fields. During their aquatic life cycle, nano-TiO_2 may interact with co-existing insecticides, simultaneously undergoing aging processes (over time) and may alter the toxicity of insecticides towards nontarget organisms. The effect sizes of these interactions may also be regulated by environmental factors, including natural organic matter (NOM) and ultraviolet (UV) radiation. The present study aimed at assessing the impact of NOM, UV radiation, and nano-TiO_2 over time (aging) on the toxicity of the insecticide dimethoate using a factorial test design. The test design involved two levels of NOM (0 versus 8 mg/L TOC), two levels of UV radiation (0 (dark) versus 18 ±1 W/m^2 (8 h UV: 16 h dark cycle)), three nano-TiO_2 levels (0.0, 0.6 and 3.0 mg/L), four aging durations (0, 1, 3, and 6 days) and seven nominal dimethoate concentrations (ranging from 0 – 64 mg/L). Eventually, the ecotoxicity of the aged medium was assessed using *Daphnia magna* as a model organism. The results showed that the presence of nano-TiO_2 (irrespective of its concentration, NOM, and UV radiation levels) significantly mitigates dimethoate toxicity by a factor of 2 relative to an unaged dimethoate solution in absence of nano-TiO_2. Upon aging in the darkness, these effect sizes did not exceed a factor of 3 after 6 days of aging. Contrary, after 6 days of aging in presence of UV, NOM, and nano-TiO_2, dimethoate toxicity was reduced up to 5-fold. While other environmental factors may additionally influence the interaction of nano-TiO_2 and dimethoate, it is evident from this study that the presence of both NOM and UV radiation along with higher aging duration assist this nanomaterial in mitigating dimethoate-induced toxicity.

1.10.P-We009 The Use of an *ex vivo* Gut Sac Technique to Determine the Uptake of Nanogold in the Gastrointestinal Tract of *Clarias gariepinus* (African Sharptooth Catfish)
***Mikayla Oosthuizen**[1]*, *Victor Wepener[2] and Armagh Hugh Mclaughlin Cook[3], (1)North West University (Potchefstroom Campus), South Africa, (2)Water Research Group, Unit for Environmental Sciences and Management, North-West University, South Africa, (3)School of Biological Sciences, North-West University, South Africa*
Nanotechnology is a rapidly growing science with increasing application in the field of nanomedicine. Nanogold is commonly used engineered nanomaterial (ENM) in drug delivery and has received special attention due to its unique properties. There is

however a risk of ecological exposure to these materials as a result of unintended releases into the environment. It therefore becomes essential to evaluate the behaviour, biodistribution, and bioaccumulation of these ENMs. The gastrointestinal tract is an important exposure pathway for ENMs in fish and this study made use of the *ex vivo* gut sac methodology to evaluate the uptake of nanogold and its metal equivalent in the African sharptooth catfish (*Clarias gariepinus*). Gut sacs were prepared and exposed to 1 mg/L nanogold and ionic gold for a period of 96 h. The gold concentrations in different sections of the GIT (mucosa and serosa of the stomach, anterior- mid and posterior intestine) were determined using ICP-MS. Significantly higher gold concentrations (compared to the control) were present in all regions of the GIT following exposure to ionic gold indicating uptake of gold. With the exception of the mid- and anterior intestine mucosa, no gold was detected following exposure to nanogold. The presence of gold particles was verified using CytoViva darkfield imaging. It is likely due to the particles becoming entrapped in the mucosa rather than actual uptake. In contrast, ionic gold accumulated in the muscularis suggesting the transepithelial transport. The gut sac method successfully demonstrated that there was not uptake of nanogold through the GIT of the African sharptooth catfish.

1.10.P-We010 Understanding the Impact of Nanoparticle Charge on Algae-Nano Interactions Using Functionalized Carbon Dots and Morphological Data

Emma McKeel[1], *Hye-In Kim*[2], *Suji Jun*[2], *Juan Pablo Giraldo*[2] *and Rebecca Klaper*[3], *(1)School of Freshwater Sciences, University of Wisconsin, Milwaukee, (2)University of California, Riverside, (3)University of Wisconsin, Milwaukee*

Nanoparticle surface charge is a critical factor influencing the interactions of nanomaterials and biological systems. Understanding the role charge plays in these interactions is key to understanding the ecological risks of nanoparticle exposure and informing sustainable nanoparticle design. In this study, the impact of nanoparticle surface charge on nano-algae interactions was investigated, using carbon dots (CDs) functionalized with polymers to have positive, negative, or neutral surface charge and the freshwater algae *Raphidocelis subcapitata* as models. Morphological impacts on green algae were investigated utilizing high-throughput fluorescence microscopy. Results indicate that positively charged CDs are most toxic to green algae, but that CDs with negative or neutral charge still induce sublethal impacts on algae. Specifically, morphological data suggests that exposure to negatively charged CDs leads to increased neutral lipid droplet formation. These lipid droplets are produced primarily when algal cells undergo stress. However, the mechanism by which functionalized CDs assert toxicity is still unclear. Further linking of morphological traits to outcomes such as toxicity can inform sustainable nanoparticle design.

1.10.P-We011 Natural Compounds, Metal Complexes, Nanoencapsulation, Release into The Environment

Joao Batista Fernandes[1], *Sean dos Santos Araújo*[2] *and Artur da Silva Cruz SR*[2], *(1)Chemistry, Federal University of Sao Carlos (UFSCar), Sao Carlos, Brazil, (2)Quimica, Universidade Federal de São Carlos, São Carlos, Brazil*

The world supply of agricultural products and the control of disease transmission by insects are highly significant. Pest ants are one of the main problems for Brazilian agriculture, causing enormous damage to agribusiness. *Aedes aegypti* is responsible for transmitting dengue, yellow fever, chikungunya and zica virus in the world. New chemical and biological techniques are being developed specially to reduce costs, the amount of insecticides applied and release into the environment. Studies to control ants and *Aedes aegypti* without contaminating the environment have been carried out by the natural products group and its collaborators with significant results, such as tests to determine the toxicity in *Brachydanio rerio* of the insecticides obtained, or nanoencapsulations to stabilize the active compounds and reduce the amount used, and obtaining complexes of natural products with metals to increase the insecticidal action and reduce the amount applied. In these studies, compounds from different classes of plants and co-cultures were obtained, such as flavonoids, coumarins, terpenes, chalcones, anthraquinones and chromone were the most active as insecticides, fungicides and bactericides, and many of which were complexed with metals.

1.10.P-We012 Ecotoxicity Assessment of Dust from Inorganic Aerogel Mats

Analuisa Rubalcaba[1], *Veronica Di Battista*[2], ***Lars Skjolding***[3], *Wendel Wohlleben*[2] *and Anders Baun*[4], *(1)DTU Environment, Denmark, (2)BASF SE, Germany, (3)Technical University of Denmark (DTU), Lyngby, Denmark, (4)Department of Environmental and Resource Engineering, Technical University of Denmark (DTU), Lyngby, Denmark*

European Union initiatives are developing and integrating 'green' practices to promote a toxic-free environment from the early stages of product development. Given the novelty of some materials, challenges are being faced in the assessment of advanced materials that are safer for us as well as for the environment from their design until their end-of-life stages, and still achieve the required performance. Examples of such materials are inorganic aerogels, who have emerged as key components of innovative and high-performance insulating mats, starting to replace conventional alternatives in the construction field.

One of their main advantages related to sustainability is their low thermal conductivity (less than 0.02 W/mK), compared to 0.025 - 0.040 W/mK seen in conventional benchmarks. This enables lower energy consumption and cost savings from heating and cooling of indoor air, leading to more efficient and sustainable cities. Yet very little is known about the potential exposure scenario for the environment at the end of life, during demolition and disposal. This can lead to potential risks to surface water organisms, if any of the components or their degradation products should be bioaccumulating, or persistent, or toxic or mobile.

To our knowledge, no previous ecotoxicity studies have been conducted for dust released from aerogel materials. Hence, here we investigate the potential environmental effect of three commercial silica-based and fibre-supported aerogel mats. The dust released aerogel particles were obtained from studies conducted by the H2020 HARMLESS project (GA 953183), with sizes ranging from submicron to micron particles. The environmental exposure was assessed through ecotoxicity testing of the aerogel particles in aquatic media. *Daphnia magna* 48 h immobilisation test and freshwater alga 72 h growth inhibition test were conducted following OECD guidelines. Our findings suggest that inorganic aerogel particles show non-significant toxic response on *D. magna* and *Pseuodokirchneriella subcapitata*, indicating no adverse effects on aquatic environment.

1.10.P-We013 Do Coatings on Copper Oxide Nanomaterials Impact Their Fate and Effects in Soil?
*Jessica Velicogna[1], Dina Schwertfeger[1], David Kennedy[2] and **Juliska Princz**[3], (1)Environment and Climate Change Canada, Canada, (2)National Research Council of Canada, Ottawa, ON, Canada, (3)Environment and Climate Change Canada, Ottawa, Canada*
Metal oxide nanomaterials can be found in an increasing variety of applications and are frequently engineered with coatings to improve their stability, dispersability and resistance to weathering or, to provide functionalized surfaces for specific applications. As the production and use of these engineered nanomaterials increase, so does concern over their fate in the environment. There is mounting evidence that the effects of metallic nanomaterials on soil dwelling organisms can be attributed to the release of metal ions. However, it is unclear if this relationship is maintained when the nanomaterials are coated. This research examined the fate and effects of three differently coated (polyvinylprrolidone (PVP), mineral oil (MO) or stearic acid (SA)) copper oxide nanomaterials (CuO NM) (25-55 nm) in a field soil. Soil was spiked at CuO concentrations ranging from 4-1000 mg kg^{-1} and used to assess effects on earthworm (*Eisenia andrei*) reproduction. Additionally, soils were sampled over five months to determine the fate of the coated CuO NM through the measurement of available Cu^{2+}. Results were compared to previous studies that looked at the fate and effects of uncoated CuO NM and $CuSO_4$ (as a soluble Cu form). Fewer juvenile *E. andrei* were produced in soils with MO coated CuO (EC50: 37 (6-241) mg kg^{-1}) compared to the PVP and SA coated NM, which had a similar response (EC50: 79 (53-118) and 84 (25-283) mg kg^{-1}, respectively). Generally, the soils with coated CuO NM had a greater effect on juvenile production compared to the uncoated CuO NM and $CuSO_4$ spiked soils. The amount of available Cu^{2+} measured in the spiked soils could not explain the differences in toxicity observed among the three coatings, suggesting an effect of the coatings or a nano-specific effect. In aged soils, pHs decreased between day 0 and 1 month and the largest increase in measured available Cu^{2+} occurred in this first month of aging with the exception of the MO CuO, for which large increases in available Cu^{2+} extended to 2 months of aging. After 2 months of aging, the Cu^{2+} activity stabilized in all coated CuO NM. The data collected in this study will provide important insights to risk assessors for read-across potential as they evaluate differently coated metallic NM.

1.10.P-We014 Using Novel Multiplexed Algal Cytological Imaging Assay and Machine Learning to Predict the Phytotoxic Mode of Action of LiCoO2 Nanomaterials to the Green Algae *Raphidocelis subcapitata*
***Eric Ostovich**[1], Austin Henke[2], Robert Hamers[3] and Rebecca Klaper[1], (1)University of Wisconsin, Milwaukee, (2)Chemistry, University of Wisconsin, Madison, (3)University of Wisconsin, Madison*
With copious engineered nanomaterials found in the environment and commerce, it may not be feasible to study them all using conventional toxicological methods. And with a lack of toxicity data, there is a need for more nontargeted, high-throughput profiling assays that can characterize biological activity and predict modes of action (MoA's). In recent years, phenotypic profiling has shown its ability to provide rich sources of data for interrogating biochemical perturbations as the phenotype of a cell is extremely sensitive and strongly influenced by factors such as metabolism, genetic state, and environmental cues. Additionally, it has been shown that specific biochemical perturbations deliver equally as specific phenotypic profiles, and therefore any subset of phenotypic features that deviate from that of healthy cells can serve as a fingerprint to characterize biological activity. Furthermore, when comparing the fingerprint of novel compounds to that of compounds with established MoA's, the probable MoA of these novel compounds can then be identified.

In this experiment, a novel multiplexed algal cytological imaging (MACI) assay was used to investigate the impacts of the mixed metal oxide nanomaterial, $LiCoO_2$ (LCO), to *Raphidocelis subcapitata*. LCO is largely used as a cathode material in lithium-ion batteries, and with annual productions at high quantities of environmental significance while also lacking infrastructure for recycling and disposal, there is a high potential for environmental release of this material. This is concerning as LCO contains metals with high reactivity and known inherent toxicity. Thus, it will be important to understand how LCO interacts with environmentally relevant organisms, like green algae.

MACI, a high-throughput phenotypic profiling assay, was used to visualize different organelles and obtain a large number of phenotypic features at the resolution of a single-cell. Different sub-cellular structures of *R. subcapitata*, including chloroplasts, neutral lipid droplets, and nuclei, were analyzed in response to LCO exposure. Statistical differences in each structure were observed between treated and non-treated samples, as well as in the overall phenotypic profile, thus exemplifying the ability of MACI to characterize bioactivities in response to nanomaterials. Lastly artificial neural networks were employed to predict the probable phytotoxic MoA of LCO using compounds with established MoA's as a training/reference set.

1.10.P-We015 Compositional Turnover in Macroinvertebrate- and Zooplankton Communities in Response to a Controlled-Release Nano-TiO2-Coated Formulation of Carbendazim and its Constituents in Freshwater Mesocosms
***Tom Adrianus Pieter Nederstigt**[1], Willie Peijnenburg[2], Bode Bode[3], Maarten Schrama[3], Ruud Van Ommen[4] and Martina G. Vijver[5], (1)Institute for Environmental Sciences, Leiden University, Institute of Environmental Sciences, Netherlands, (2)National Institute for Public Health and the Environment (RIVM), Netherlands, (3)CML, Leiden University, Leiden, Netherlands, (4)Department of Chemical Engineering, Technical University Delft, Netherlands, (5)Leiden University, Leiden, Netherlands*
The implementation of nanocarriers is increasingly proposed as a means to reduce pesticide translocation to nontarget sites. The scientific basis to substantiate the intended reduced environmental impact of nanocarrier-based pesticides has however remained marginal to date, and concerns have been raised regarding potential direct- and indirect toxicity associated with the

(unintentional) release of nanocarrier-based pesticides to the environment. We report the findings of a long-term mesocosm experiment in which we assessed impacts of a novel controlled-release pesticide formulation (i.e., nano-TiO_2-coated carbendazim) and its individual- and combined constituents (i.e., nano-sized TiO_2 and carbendazim) on naturally established freshwater macroinvertebrate and zooplankton communities. Pronounced effects of all applied stressors were observed on a variety of taxonomy- and function-based community parameters, and impacts were most pronounced in carbendazim-including treatments. Our findings demonstrate that 1) when released to nontarget sites, nanocarrier-based pesticides may not necessarily differ in impacts from their active ingredient, and that 2) current environmental concentrations of $nTiO_2$ may impact zooplankton populations and communities.

1.10.P-We016 Toxicity of the New Emerging Nanomaterials LDH and MoS2 to Aquatic Organisms: First Results from the Project SCANNER

Ailbhe Macken[1]*, Adam Lillicrap*[1]*, Sebastian Kuehr*[1]*, Samantha Martins*[2]*, Anastasia Georgantzopoulou*[1] *and Tania Gomes*[1]*, (1)Norwegian Institute for Water Research (NIVA), Norway, (2)Ecotoxicology and Risk Assessment, Norwegian Institute for Water Research (NIVA), Norway*

SCANNER is a 4-year collaborative project between India and Norway focusing on the development of tools for hazard and risk assessment of new emerging Nanomaterials (NMs). Initially, the partners identified two NMs of interest, Layered double hydroxides (LDH) and Molybdenum disulphide (MoS_2). The Indian partners were responsible for synthesizing the NMs and supplying them to the partners to be used in *in vitro* and *in vivo* studies to understand the impacts on human health (India) and the environment (Norway). SCANNER aims to conduct controlled exposure experiments to obtain detailed knowledge on the mode of action (MoA) and effects of NMs under realistic environmental conditions (on humans, freshwater (FW) and marine species). Charactisation of behavior of NMs in various exposure media is conducted alongside the various assays. A battery of effect-based tools from cells (both human and fish) to organism level (e.g., copepods, mussels, oysters, chironomids, amphipods, zebra fish embryos (FET)) are being applied to assess MoA and to identify new effect biomarkers. The bioavailability, uptake and transport mechanisms of NMs will also be studied (cell, tissue and organism level). The data generated will be integrated into a hazard and risk assessment approach that can be used for NMs. Results to date indicate little or no observed toxicity at realistic environmental concentrations. Results from the FET tests (with LDH) indicated small effects in survival at concentrations from 1.25-50 mg/L and effects on hatching at 6.25-50 mg/L. No effects were observed at 100 mg/L. For MoS_2 there was no hatching of embryos at 100 mg/L, decreased hatching at 50 mg/L and malformations observed at 1.25mg/L. For the developmental assays with *Tisbe battagliai* exposed to LDH, there were significant developmental delays and mortalities at 25-100 mg/L. For MoS_2 there were mortalities at high concentrations (50 and 100 mg/L) but this may have been caused by a shading effect of the particles or clumping of the algae, limiting the food availability for the developing nauplii. Significant differences were observed between the behavior of MoS_2 in FW media compared to seawater. Based on the results so far, MoS_2 and LDH are not acutely toxic at low concentrations and effects were only observed at concentrations unlikely to be found in the environment. The next stage of the project will focus on lower concentrations of NMs to look at sublethal and chronic effects in the various systems.

1.10.P-We017 Evaluation of the ecotoxic potential of graphene oxide in *Xenopus laevis* tadpoles

Lauris Evariste[1]*, Laura Lagier*[2]*, Antoine Mottier*[2]*, Emmanuel Flahaut*[3]*, Maïalen Barret*[2]*, Eric Pinelli*[2]*, Laury Gauthier*[2] *and Florence Mouchet*[2]*, (1)ECOLAB UMR5245 CNRS UPS INPT, Toulouse, France, (2)UMR5245 CNRS-UT3-INPT laboratoire Ecologie Fonctionnelle et Environnement, France, (3)CIRIMAT UMR CNRS 5085 UPS INPT, France*

Due to their unique properties, the production of graphene-based nanomaterials (GBMs) including graphene oxide (GO) is growing worldwide to develop new applications. This raises the question of the potential consequences of their release in the aquatic environment. The aim of this work is to assess the ecotoxicological potential of GO using the amphibian, *Xenopus laevis*, as biological model. For this purpose, standardized *in vivo* studies were conducted to evaluate on the one hand the effect of GO on larval growth and related pathways including alterations of the gut microbial communities as well as potential endocrine disruption using respectively 16S sequencing and T3-induced amphibian metamorphosis assay. Larval growth inhibition following exposure to doses ranging from 0.05 to 10 mg/L was shown to be driven by GO surface area while alterations of the gut microbiota structure through an increase of the Firmicutes/Bacteroidetes ratio, a marker of metabolic diorders, might contribute to the observed effects, with no involvement of endocrine disruption. On the other hand, genotoxic potential was assessed through measurement of micronucleated erythrocyte occurrence. Targeted gene expression quantification in qPCR coupled to nanomaterial thermal reduction and characterization allowed to demonstrate which oxygen-containing functional groups are involved in the ROS-mediated induction of genotoxic effects by GO. The obtained results allowed to decipher toxic pathways involved in the physiological alterations of *X. laevis* tadpoles following exposure to GO and to propose a “safer-by-design” approach to mitigate GO toxicity.

1.10.P-We018 Toxicokinetics and Bio-Distribution of Gold Engineered Nanomaterials in the African Sharptooth Catfish

Armagh Hugh Mclaughlin Cook[1]*, Tarryn Lee Botha*[2,3] *and Victor Wepener*[3]*, (1)School of Biological Sciences, North-West University, South Africa, (2)University of South Africa, Institute for Nanotechnology and Water Sustainability, College of Science, Engineering and Technology, South Africa, (3)Water Research Group, North-West University, South Africa*

Nanotechnology provides a promising tool in the manipulation of engineered nanomaterials (ENMs) which can be used for applications in medical treatment. Nanogold (nAu) is used in targeted drug delivery, while gold chloride ($HAuCl_4$) is used as a precursor for the synthesis of nAu. The increased use, production, and disposal of nano-enabled products increases the potential risk, particularly to aquatic life. Fish are dependent on aquatic habitats, and water bodies act as a sink for pollutants therefore waterborne exposure is inevitable. Due to the limited knowledge on the absorption, distribution, metabolism, and excretion

(ADME) of nAu, and $HAuCl_4$ in fish, further investigation is warranted. To determine the tissue-uptake rate of the metal salt and metal ENM a 24 h waterborne exposure to nAu and $HAuCl_4$, at 1 mg/L Au each, were independently conducted using adult African sharptooth catfish (*Clarias gariepinus*). Using a systematic approach, the experimental data was used to understand ENM toxicokinetics, crucial to risk assessment. To gain insight into ENM toxicokinetics, a blood-flow limited physiologically based pharmacokinetic (PBPK) model was modified to simulate and compare the ADME of nAu, and $HAuCl_4$ in catfish. The PBPK model describes the ADME of nAu, and $HAuCl_4$, in the gill, air-breathing organ, liver, kidney, and muscle tissues. The model was calibrated using data from both literature such as cardiac output, and experimentation such as organ weights. Chemical-specific parameters were estimated by fitting the model to the experimental data. The model adequately (root mean square < 0.5) predicted the datasets on an organ-level, by simulating the Au ADME in the gill, air-breathing organ, kidney, liver, and muscle tissues, indicative of reliable predictive capability. Simulation results indicate parameters related to ENM-specificity and animal physiology have a profound influence on dose-uptake metrics. Since the physiological effects will depend greatly on the compartmentalization within each specific organ, this study warrants a focus on the cellular and sub-cellular ADME of ENMs in fish. This will permit further model development, and optimization to improve the model's predictive capacity and accuracy.

1.10.P-We019 *In Silico* Prediction of the Nanoparticle – Biomolecule Corona
Ian Rouse *and Vladimir Lobaskin, School of Physics, University College Dublin, Ireland*
The bioactivity, adverse outcomes, and eventual fate of a nanoparticle (NP) in biological environments are known to be mediated through the existence and content of a corona of adsorbed proteins, metabolites, and other small organic molecules acquired by the NP from the surrounding medium. Information about the content of the corona for a given NP in a certain biological environment is therefore key for the prediction of potential toxic outcomes, yet obtaining it remains a highly challenging task due to the necessity to scale up from individual molecules adsorbing within microseconds to the long-term corona formation over the course of hours but also due to extreme diversity of the organic content of biological and environmental liquids. Here, we present a multiscale computational method for the prediction of the NP corona content from first principles without experimental input. We perform atomistic molecular dynamics simulations to obtain interaction potentials between common biomolecular fragments and inorganic NP surfaces and use a machine-learning approach to extend this initial set to a much greater range of small molecules and surfaces, potentially applicable to arbitrary combinations of molecules and surfaces. These potentials are employed in the UnitedAtom (UA) framework to produce orientation-specific adsorption energies of proteins and metabolites to the NP of interest, taking into account the size, shape, surface charge, and chemical composition of the NP. In turn, these adsorption energies are converted to adsorption and desorption rate constants used as input to a random sequential adsorption model of the corona formation. Our methodology takes into account not only the individual affinity of biomolecules towards the NP but also the area occupied by adsorbates and their concentration in the bulk medium, allowing for a more physically realistic model of corona formation. The procedure has recently been validated by comparison to the corona obtained experimentally for silica NPs immersed in a multicomponent protein solution, finding good agreement and confirming the overall validity of our approach.

1.10.P-We020 Metabolomic, Physiological, and Behavioural Responses of the Freshwater Shrimp, *Caridina africana*, Following Exposure to Nanodiamonds and Copper oxide
Nichole Sasha-lee Donough[1]*, Victor Wepener*[1] *and Tarryn Lee Botha*[1,2]*, (1)Water Research Group, North-West University, South Africa, (2)University of South Africa, Institute for Nanotechnology and Water Sustainability, College of Science, Engineering and Technology, South Africa*
Nanomaterials are the building blocks for nanotechnology, which has gained momentum within the science community, especially in the medical field. Examples of such nanomaterials include nanodiamonds and copper oxide. The effects that these two nanoparticles may exert on crustaceans, such as shrimp, are not well documented. *Caridina* is a freshwater crustacean and is a relatively sensitive species, which makes them suitable for ecotoxicity testing. Chronic bioassays were conducted on *Caridina africana* for 96 h. Treatment groups were spiked with sublethal concentrations of nanodiamond – LC_{10} and LC_{20} (0.98 mg/L and 1.97 mg/L) and copper oxide – LC_{10} and LC_{20} (0.97 mg/L and 1.94 mg/L). Following 96 h exposure, shrimp from different treatments were randomly selected for metabolic, physiological (heart rate and respiration rate) and behaviour assessment. For the heart and respiration rates, shrimp were either placed under a microscope and a 10-second video was recorded, or in a Loligo respiration chamber to analyze their respiration rate. At least five individuals per treatment were transferred to a 12-well plate and placed in a Noldus Daniovision and behaviour was recorded for 30 min alternating between a light and dark cycle every 5 min. For metabolomics, shrimps were snap frozen in liquid nitrogen. Following extraction, untargeted metabolomic profiles were determined using LC-MSMS techniques. Only the heart rate of copper oxide LC_{10} and LC_{20} exposures decreased when compared to both the control and the nanodiamond treatment groups. Respiration rate increased with increasing nanodiamond concentrations, but with copper oxide there was an increase in the respiration rate at the LC_{10} exposure followed by a decrease at the higher LC_{20} concentration. Behaviour responses were more pronounced in the copper oxide exposure groups, and this is accompanied by distinct metabolic profile changes. The effect of copper from the copper oxide nanoparticles is likely the reason for the more negative response of the shrimps to copper oxide materials, while the differences in response to nanodiamonds is attributed to the greater agglomeration rate and physical disturbance effects at the higher exposure concentration.

1.10.P-We021 Evaluation of the Relative Hydrophobicity/Hydrophilicity of Metal and Metal Oxide Nanoparticles
Anais Colibaba[1]*, Konstantinos Kotsis*[1] *and Vladimir Lobaskin*[2]*, (1)University College Dublin, Ireland, (2)School of Physics, University College Dublin, Ireland*
The impact of hydrophobicity on the fate and toxic potency of nanomaterials is a well-established observation. The hydrophobicity affects most of all the uptake rates of nanoparticles into cells and has a considerable effect on their overall

toxicity. Highly hydrophilic compounds exhibit low cell uptake rates due to their repulsion from the headgroups of the membrane lipids. Highly hydrophobic particles are also poorly uptaken because they are insoluble in the water-based cytoplasm. To be effectively uptaken by the cells, nanoparticles must exhibit a certain hydrophilicity/hydrophobicity balance to be able to cross the membrane and then remain soluble in the cytoplasm. A good measure of the relative hydrophilicity/hydrophobicity is the enthalpy of immersion which is the enthalpy change associated with the immersion of a solute in a liquid. Here we quantify the relative hydrophilicity/hydrophobicity of a nanomaterial as a function of relative enthalpies of immersion of that slab of nanomaterial in water and in octanol, respectively, to represent its behaviour in aqueous and lipid phases. We employed the GROMACS molecular dynamics package to evaluate the immersion enthalpy of 7 metal oxides and of 17 metals samples with three different surfaces each in octanol and in water. Furthermore, we used the force field and unit lattice cell descriptors of each nanomaterial slab as input data to train a neural network model to predict the immersion enthalpy values or a robust ranking thereof. We created an ensemble of neural network models that were trained and validated on various samples of the molecular dynamics dataset. On average, when comparing the calculated immersion enthalpies versus the neural network predicted ones, we obtained correlation coefficients R2 higher than 0.95 and a Kendall-Tau ranking coefficient higher than 0.9. With the present method, we are able to accurately predict the rankings of various materials' relative hydrophilicity/hydrophobicity using simple molecular interaction and geometric descriptors. Thus, we demonstrate that information on the ranking of materials in terms of their relative hydrophilicity/hydrophobicity can be obtained from first principles using commonly accessible descriptors, thus eliminating the reliance on lengthy molecular dynamics simulations and possibly experimental input.

1.10.P-We022 Considering Matrix Effects in the Assessment of Environmental Safety for Engineered Nanomaterials and Nano-Enabled Products

Emily Eagles[1]*, Amaia Green Etxabe*[1]*, Fie Rubner-Petersen*[1]*, Claus Svendsen*[1]*, David J Spurgeon*[1]*, Sarah Thacker*[1]*, Jasmine Pullen*[1]*, Magda Blosi*[2]*, Anna Costa*[2]*, David Burrueco Subira*[3] *and Elma Lahive*[1]*, (1)UK Centre for Ecology & Hydrology (UKCEH), United Kingdom, (2)National Research Council (CNR), Italy, (3)LEITAT Technological Center, Spain*

Engineered nanomaterials (ENMs) are often manufactured with a chelating agent to enhance the stability or functionality of the ENMs. This ENM functionality is important to the overall design and manufacture of nano-enabled products (NEPs). In this case study, textiles are coated with silver (Ag) ENMs synthesised with two different chelating agents (quaternized hydroxyethyl cellulose and curcumin) to provide an antibacterial function to the textiles. When considering the NEP safety, the potential ecotoxicological effects of an ENM and NEPs need to be addressed, considering firstly the relative toxicity of the ENMs; secondly, whether toxicity originates from the core particle, the chelating agent or the NEP matrix; and finally, whether there are interactions which may alter toxicity compared to that predicted from the toxicity of the individual components. For soil organisms, exposure to ENMs may occur as a result of direct addition or as constituents of industrial and domestic waste materials and sewage sludge - applied to soil as a conditioner. The aim of this study was to compare the fate and toxicity of Ag ENMs developed as part of a safe-by-design approach for NEPs, to a soil organism in environmentally relevant media. We consider the fate and effects of the ENM together with the chelating agents (alone and in combination) on a model soil species, the annelid *Enchytraeus crypticus*, using acute toxicity tests, with survival monitored through time during the 96h test period. The exposures were performed in media representative of soil pore water (both synthetic and extracted soil pore water). Finally, the overall NEP will be considered by performing tests with coated textile fibres to establish whether differences in the ENMs will finally be important to the overall safety of the NEP.

1.10.P-We023 Multiscale Modelling of Milk Proteins Interaction with Iron Surfaces

Parinaz Mosadeghi Amini[1]*, Julia Subbotina*[1] *and Vladimir Lobaskin*[2]*, (1)Physics, University College Dublin, Ireland, (2)School of Physics, University College Dublin, Ireland*

Understanding interactions occurring between biomolecules and the inorganic materials at the interfaces is important for understanding various phenomena, e.g., formation of protein corona of nanoparticles (NP), fouling of metallic surfaces, biomedical nanoformulations, or in food con tact applications (storage, dairy industry, packaging, etc.). Milk fouling and the role of proteins aggregation on heat exchangers and therefore contamination problem has been studied recently to reduce the cost of cleaning and increase the quality of milk products. Herein we present the preliminary results on the study of the interaction of bovine milk proteins with iron metallic surface. Selected metal represents the bulk of one of the most common materials used in the food industry, and bovine milk represents one of the most common sources of proteins in the human diet. By calculating the adsorption energies of the bovine milk proteins with the substrate we quantify the adsorption strength at different conditions and rank proteins by adsorption affinity. The results are expected to correlate with the probability of fouling. Protein adsorption energies were predicted by applying United Atoms (UA) multiscale approach, in which protein and the NP are represented in a coarse-grained (CG) way. The NP is structured as the metallic slab with the uniform density, while the protein is constructed as the rigid body via a "one-bead-per-amino acid" representation. The total interaction of the whole protein with the NP was calculated additively, via individual terms corresponding to each amino acid (AA). The total UA interaction potential between NP and AA is modelled with different resolution at different surface-surface separation distances. This requires parametrisation of the AA-NP potential term at short distances (<1.2 nm) via potential of mean force (PMF) profiles obtained with all-atom AWT-Metadynamics simulations (GROMACS/Plumed). Obtained PMFs were used to predict adsorption energies of the proteins with the UA method at the next step. The coordinates of protein structures (820 in total) were predicted computationally by i-TASSER software from corresponding sequences.

Obtained information on protein adsorption affinities was further utilized for building a statistical (nanoQSAR/ANN) and adsorption kinetics (AN) model, which can predict protein binding affini
ties and the corona composition to zero-valent iron surfaces directly from the protein sequence and NP descriptors.

1.10.P-We024 Impact of Storage Conditions on Silver Nanoparticle Stability for Toxicity Studies Using spICP-MS
Sebastian Kuehr*, Kuria Ndungu and Anastasia Georgantzopoulou, Norwegian Institute for Water Research (NIVA), Norway*
Single particle Inductively Coupled Plasma-Mass Spectrometry (spICP-MS) is an important analytical method for the detection, characterization and quantification of nanomaterials (NMs) in aqueous samples.

SpICP-MS is increasingly being used to study the ecotoxicity and fate of NMs. However, protocols for determining NM concentrations in different media, including tissue, are still being developed. To date, there is little systematic data on how sample storage can impact the characteristics of NMs in aqueous samples. The influence of storage on the quality of NM measurement is important because samples are usually preserved for varying lengths of time and temperature prior to spICP-MS analysis. It is thus unclear how storage conditions affect the quality of NM measurements.

We studied the effect of sample storage conditions using two types of silver nanoparticle (AgNP) suspensions in both MQ water and filtered natural seawater: citrate-stabilized and PVP coated AgNP. We tested the effect of storage duration (1, 7 and 28 days) at four temperatures (21°C, 4°C, -20°C, and -80°C) in the absence of light with spICP-MS.

We observed a strong decrease (approx. -80%) in particle concentration over the storage period for citrate-stabilized AgNP in both MQ and seawater. On the contrary, the concentration of Ag NP in MQ water at 4 and 21°C increased over time (up to +50%). The concentration of PVP-coated AgNP show the same trends, but to a much lesser extent. A slight decrease of particle size over time at all temperatures was observed for citrate-stabilized AgNP suspensions in MQ water. There was however no discernible change in particle size for seawater suspensions over time. The calculated median sizes show a larger standard deviation for the citrate-stabilized particles in seawater than for the particles in MQ water. Also for the PVP coated AgNP no clear trend in change in particle size was observed, regardless of the medium, storage or temperature. Again, the standard deviation for the calculated median sizes of the particles were higher in seawater than in MQ water.

Our data show that the particle concentration of citrate-stabilized AgNP in MQ water is better preserved for up to four weeks when they are stored at 4 or 21°C, but for seawater a storage at -80°C is recommended compared to storage at sub-zero temperatures. The same applies to PVP coated AgNP, which are more stable over time in terms of particle concentration than the citrate-stabilized AgNP.

1.11 Novel Methods and Approaches for Assessing Effluents, Chemicals Toxicity and Surface Water to Support Regulations

1.11.T-01 DECIDE - An Ecotoxicological Assessment System for Rivers
Delia Lara Hof[1]*, Thomas Bing*[2]*, Klaus Peter Ebke*[2]*, Sebastian Heß*[3]*, Jörg Oehlmann*[1]*, Andrea Sundermann*[3] *and Matthias Oetken*[1]*, (1)Aquatic Ecotoxicology, Goethe University Frankfurt, Frankfurt am Main, Germany, (2)MESOCOSM GmbH, Institut für Gewässerschutz, Germany, (3)Section River Ecosystem Managment, Senckenberg Society for Nature Research, Germany*
Due to various anthropogenic pressures, surface waters are negatively affected worldwide. In particular, chemical pollution and morphological degradation endanger the ecosystem functions they provide. In Germany, 9.2 % of surface waters achieve the required good ecological status, according to the European Water Framework Directive (WFD). Effective management can counteract the progressive degradation of water bodies and achieve improvements. However, knowledge about the respective main causes on site is indispensable.

In the DECIDE project, an innovative system solution for water management practice is developed as the basis for sustainable water management. For this purpose, an ecotoxicological and WFD-compliant evaluation system will be developed to prioritize water management measures. In practice, the assessment system will help to decide whether chemical pollution or deficient water body structures are the main cause of failing to achieve good ecological status. Effect-based assessment methods are used to determine the "ecotoxicological status class" as an additional parameter.

In 2021 and 2022, the *Hessian Ried* was investigated, which is of great importance as a drinking water resource for the Rhine-Main metropolitan region. At a total of 30 sampling sites, the structural and ecological status was recorded according to existing assessment methods. Ecotoxicological effects were detected on both *in vivo* and *in vitro* levels. After chronic exposure, the snail *Potamopyrgus antipodarum* and the crustacean *Gammarus fossarum* showed significant effects compared to uncontaminated reference sites. At the *in vitro* level, mutagenic, endocrine and dioxin-like effects, as well as baseline toxicity were detected. Furthermore, laboratory and field experiments were performed to detect possible phytotoxic effects. Subsequently, ecotoxicological status classes were determined for all sampling sites. By comparing the ecotoxicological status class with the hydromorphological quality, the contribution of the chemical pollution at a sampling site for failure to achieve the good ecological status can now be estimated more precisely.

1.11.T-02 Application of Real-Time Biological Early Warning Systems in Wastewater Treatment Plants: A New Opportunity to Monitor Changing Wastewater Composition?

*Ali Kizgin[1], Danina Schmidt[1], Adriano Joss[2], Juliane Hollender[3], Eberhard Morgenroth[4], Cornelia Kienle[5] and **Miriam Langer**[6], (1)Ecotox Center Eawag-EPFL, Dübendorf, Switzerland, (2)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Dübendorf, Switzerland, (3)Environmental Chemistry, Environmental Chemistry, Eawag, Swiss Federal Institute of Aquatic Science and Technology, Dübendorf, Switzerland, (4)ETH Zürich, Zürich, Switzerland, (5)Ecotox Centre, Switzerland, (6)University of Applied Sciences and Arts Northwestern Switzerland - FHNW, Switzerland*

Wastewater treatment plants (WWTPs) are a major source of micropollutants to surface waters. Currently, their chemical or biological monitoring is realised by using grab or composite samples, which provides only snapshots of the current wastewater composition. Especially in WWTPs with industrial input, the wastewater composition can be highly variable and a continuous assessment would be advantageous, but very labour and cost intensive. A promising concept is automated real-time biological early warning systems (BEWS), where living organisms are constantly exposed to the water and an alarm is triggered if the organism's responses exceed a harmful threshold of acute toxicity. Currently, BEWS are established for drinking water and surface water but are seldom applied to monitor wastewater. This study demonstrates that a battery of BEWS using algae, water flea, and gammarids can be adapted for wastewater surveillance. For continuous low-maintenance operation, a back-washable membrane filtration system is indispensable for adequate preparation of treated wastewater. Only minor deviations in the reaction of the organisms towards treated and filtered wastewater compared to surface waters were detected. After spiking treated wastewater with two concentrations of the model compounds diuron, chlorpyrifos methyl, and sertraline, the organisms in the different BEWS showed clear responses depending on the respective compound, concentration and mode of action. Immediate effects on photosynthetic activity of algae were detected for diuron exposure, and strong behavioural changes in water flea and gammarids after exposure with chlorpyrifos methyl or sertraline were observed, which triggered automated alarms. Different types of data analysis were applied to extract more information out of the specific behavioural traits, than only provided by the vendors algorithms. To investigate whether behavioural movement changes can be linked to impact other endpoints, the effects on feeding activity of G. pulex were evaluated and results indicated significant differences between the exposures. Overall, these findings provide an important basis indicating that BEWS have the potential to act as alarm systems for pollution events in the wastewater sector.

1.11.T-03 Considerations for the Use of Behavioral Endpoints and Methods as a Line of Evidence in Regulatory Toxicity Testing

*Alexandra Steele[1] and **William L. Goodfellow**[2], (1)Exponent Inc., (2)Ecological and Biological Sciences, Exponent Inc.*

Regulatory toxicity studies traditionally use endpoints such as mortality, growth, and reproduction. While these traditional endpoints provide reliable evidence in toxicity testing and provide a connection to toxicity effects on populations, interest in use of behavioral endpoints in toxicity testing has been growing. This interest is driven by the sensitivity, technical developments creating increasingly automated frameworks to measure behavior, and the potential to offer evidence on the mode of action of chemical contaminants provided by behavioral toxicity tests. Aquatic organisms have developed specific mechanisms such as identifying prey, avoiding predators, sexual displays, homing behaviors, etc.; all important behaviors in maintaining a functioning ecosystem. Chemicals in the environment can impact aquatic organisms by disrupting or masking these necessary behaviors. Behavioral endpoints can also provide a connection to population level processes depending on the behavioral measures used. These characteristics of behavioral studies can provide supporting lines of evidence when identifying events of toxicity, however the usefulness of these measures is dependent on several factors including the appropriateness of the test organism selected, the behavioral endpoint used, and how the endpoint relates to a population-level effect. This presentation will discuss how current regulations define the use of behavioral endpoints and population level effects and will also explore strategies for using behavioral measures in toxicity testing and provide examples of behavioral toxicity testing data with comparisons to traditional toxicity test measures.

1.11.T-04 Effect-Directed Analysis of a Complex Mixture of Polyaromatic Compounds from Contaminated Soil using Bioassays and Zebrafish Embryos (*Danio rerio*)

***Greta Nilen**[1], Maria Larsson[2] and Steffen H. Keiter[3], (1)MTM, Orebro University, Örebro, Sweden, (2)School of Science and Technology, Orebro University, Örebro, Sweden, (3)Orebro University, MTM Research Centre, Sweden*

In the environment, organisms are exposed to a wide range of pollutants in complex mixtures. Over the last decade, numerous frameworks have been established to consider the potential mixture effects in regulatory decision-making processes. Commonly, the specific composition of complex environmental mixtures is unknown, and one approach to study them is to use effect-directed analysis (EDA), combining fractionation, bioassays, and targeted and non-targeted chemical analysis. Polyaromatic compounds (PACs) are widespread environmental contaminants, that have been detected in high concentrations in environmental samples. Only 16 polycyclic aromatic hydrocarbons (PAHs) are listed as priority pollutants by the US EPA and are regularly monitored. However, more attention has been drawn to the alkylated PAHs (alkyl-PAHs) and heterocyclic aromatic compounds (NSO-PACs) since they can be more toxic than the parent PAHs. In the present study, zebrafish embryos and *in vitro* bioassays were used to investigate the behavioral and molecular effects of an extract from a soil sample collected at a former gasworks site in Sweden. Four different CALUX® assays were used to evaluate aryl hydrocarbon receptor (AhR) activation (DR-CALUX and PAH-CALUX), estrogen receptor activation (ERα-CALUX), and androgen receptor inhibition (anti-AR-CALUX) of the soil extract. The zebrafish behavior was measured as larvae movement during exposure to interchanging light and dark periods. In addition, the response to mechanical stimuli was recorded using a tapping device. Quantitative gene expression analyses were conducted on a set of 36 selected genes that are known to be directly linked to certain adverse outcomes. The complex mixture caused hyperactivity in darkness and hypoactivity in light. The larvae were also hypoactive after the mechanical stimuli. The qPCR analysis showed that 15 genes were differentially regulated. For instance, one gene connected to eye pigmentation (*opn1sw1*) was downregulated and a gene involved in heart failure (*fpgs*) was upregulated. In addition, the extract gave a significant response in three bioassays (ERα-, DR-, and PAH-CALUX). To identify drivers of the toxicity the extract was fractionated, and thirteen out of 96 fractions were active at 120 hpf. The observed effects were mortality, lack of blood circulation, unhatched embryos, and edemas. In the last step of this study, the compounds in the active fractions will be identified.

1.11.T-05 Combined Use of Transcriptomics and Proteomics as an Evaluation Tool of Environmental Toxicity in a Beluga Whale (*Delphinapterus leucas*) Population Highly Exposed to Contaminants
Antoine Etienne Simond[1], *Véronique Lesage*[2], *Jonathan Verreault*[3], *Lisa Loseto*[4], *Magali Houde*[5], *Ashley Elliott*[4], *Marie Noel*[6] *and Tanya Brown*[4], *(1)Simon Fraser University, Canada, (2)Maurice Lamontagne Institute, Fisheries and Oceans Canada, Canada, (3)University of Quebec at Montréal, Canada, (4)Fisheries and Oceans Canada, Winnipeg, Canada, (5)Environment and Climate Change Canada, Canada, (6)Ocean Wise Conservation Association, Canada*
The St. Lawrence Estuary (SLE) beluga whale (*Delphinapterus leucas*) population in Canada is endangered. It has been postulated that exposure to elevated concentrations of polychlorinated biphenyls (PCBs), chlorinated pesticides, polybrominated diphenyl ethers (PBDEs), and emerging halogenated flame retardants (HFR) might be contributing to the decline of this population. Recently, concentrations of PCBs, chlorinated pesticides, and emerging HFRs in SLE male beluga blubber were shown to correlate with skin transcript levels of genes coding for nuclear receptors and proteins involved in the regulation of thyroid and steroid hormones as well as the metabolism of xenobiotics. A growing number of studies investigating contaminant exposure-related effects in cetaceans rely on "*omics*" methods such as transcriptomics or proteomics, as these approaches require small amounts of tissue and provide a maximum of biological information. To improve our understanding of the impacts of contaminant exposure on the health of SLE belugas and the mechanisms of toxicity involved, we compared transcriptomic and proteomic skin profiles between adult male belugas from the SLE and a reference population (Eastern Beaufort Sea, Canada). Being exposed to dramatically different levels of contaminants the evaluation of transcript and protein profiles will allow to shed some light on specific genes, proteins and pathways affected by the exposure to organic contaminants. Total RNAs and proteins were isolated from skin samples of adult male belugas from the SLE (n = 39) and Eastern Beaufort Sea (n = 34). Skin was also used to determine carbon and nitrogen stable isotope ratios, and PCBs, PBDEs and emerging flame retardants were measured in blubber. RNA sequencing and proteomics analysis allowed the identification of 21 646 unique gene transcripts and 6152 proteins. A total of 3676 genes and 128 proteins were upregulated, and 1418 genes and 113 proteins were downregulated in SLE belugas compared to the reference population. Ongoing work will characterize the functional profile of differentially expressed genes and proteins to understand the biological implications of contaminant exposure, and potential biomarkers of contaminant exposure will be suggested. The combined use of transcriptomics and proteomics is a promising tool for wildlife ecotoxicology research and has the potential to significantly improve the risk evaluation of organic contaminant exposure in wildlife populations.

1.11.P Novel Methods and Approaches for Assessing Effluents, Chemicals Toxicity and Surface Water to Support Regulations

1.11.P-Tu032 Predicting the Impacts of Chemical Pollutants on Animal Groups
Marcus Michelangeli[1,2], *Jake Martin*[1], *Noa Pinter-Wollman*[3], *Erin McCallum*[1], *Christos Ioannou*[4], *Michael Grant Bertram*[1] *and Tomas Brodin*[1], *(1)Wildlife, Fish and Environmental Studies, Swedish University of Agricultural Sciences (SLU), Sweden, (2)School of Biological Sciences, Monash University, Australia, (3)Ecology and Evolutionary Biology, Univesity of California, Los Angeles, (4)School of Biological Sciences, University of Bristol, United Kingdom*
Chemical pollution is among the fastest-growing agents of global change. Synthetic chemicals with diverse modes-of-action are being detected in the tissues of wildlife and pervade entire food webs. Although such pollutants can elicit a range of sublethal effects on individual organisms, research on how chemical pollutants affect animal groups is severely lacking. This is a critical oversight because many animals engage in social interactions over their lifetime and live within highly structured societies or form loosely structured social groups. These animals coordinate their behaviours with others to provide protection against predation, gain reproductive opportunties, find food, and reduce energy expenditure. Here, we present a framework that outlines how chemical contaminants could disrupt behavioural processes that are instrumental in the emergence and self-organisation of animal groups. We provide a roadmap for prioritising the study of chemical pollutants within the context of sociality and highlight important methodological advancements for future research. Integrating animal sociality and collective behaviour into ecotoxicity studies is particularly important in light of recent evidence that behavioural endpoints are largely ignored in chemical risk assessments when not linked to population or higher-order ecological outcomes. Thus, our framework provides an important guide for researchers and practicitioners to predict how chemical stressors will likely affect the emergence, organisation, and function of animal social groups.

1.11.P-Tu033 A Rapid Approach to Characterise the Photosynthetic Efficiency and Growth Inhibition of a Marine Microalgae Exposed to Metal Mixtures
Chloe Eastabrook[1], *Li Xie*[2], *You Song*[2], *Knut Erik Tollefsen*[2] *and Gary Stephen Caldwell*[1], *(1)Newcastle University, United Kingdom, (2)Norwegian Institute for Water Research (NIVA), Norway*
Marine algae are under threat from increased chemical (including metals) and nutrient run-off. Due to their trophic position and

need to utilise trace metals for biochemical processes, microalgae are often considered as the first target of metal toxicity. To better inform risk assessments and develop more holistic impact considerations, combined toxicity assessment to characterise the joint effects of mixtures is needed. However, mixture toxicity studies can be difficult to conduct, with resource, time, and financial limitations. These can be mitigated with a Design of Experiments approach, including Definitive Screening Design (DSD), which can determine main effect drivers and second-order effects ($P < 0.05$). Using DSD and rapid stress assessments, such as pulse amplitude modulated fluorometry (PAM), could be useful in combined toxicity assessments with microalgae, macroalgae and plants. Using the microalgae *Tetraselmis suecica*, this study conducted a rapid combined toxicity assessment for the metals copper, nickel, and zinc. Growth was measured over 7 days of exposure, alongside the impacts on photosynthetic performance using an Imaging PAM. IPAM samples were dark adapted and parameters measured, including photochemical (qP) and non-photochemical quenching (qN and NPQ), effective photosystem II quantum yield (YII) and electron transfer rate (ETR). By using a rapid assessment tool to measure photosynthetic stress and a DSD mixture design, we found that metal mixtures affected algal photosynthesis photochemistry and inhibited growth. All three metals were identified as main effect drivers reducing *T. suecica* growth, with metal interactions between all metal combinations. The F_v/F_m fluorescence analysis demonstrated that copper was the main effect driver and there were no interactions with the other metals. For light acclimated parameters, copper was the only main effect driver within the mixture for qN, NPQ, qP, YII and ETR, with interactions between copper with nickel and zinc for YII and ETR. These trends in chlorophyll fluorescence parameters suggests that the light harvesting capacity of PSII was downregulated during metal exposure and photoinhibition was occurring, in turn limiting photosynthetic efficiency and growth rates. As most mixture studies focus on the adverse effects (e.g., growth), this study provides evidence for and a demonstration of how DSD can be used to enhance mechanistic understanding of combined toxicity of metals in microalgae.

1.11.P-Tu034 Standardization of a Short-Term Chronic Method using *Daphnia magna*

***James M. Lazorchak**[1], Sarah Kadlec[2], Alex Kascak[3], David Mount[2], Correne Jenson[2], Will Backe[2], Sarah Goodrich[4], Leah Glimsdal[5], Russ Hockett[2], Abigail Johnson[6] and Teresa J Norberg-King[7], (1)Office of Research and Development, US Environmental Protection Agency, (2)US Environmental Protection Agency, (3)Pegasus c/o US EPA Cincinnati, (4)Pegasus c/o US EPA ORD Cincinnati, (5)Integrated Biosciences Graduate Program, University of Minnesota, (6)AgriLife Research, Texas A&M University, (7)King Creek Environmental*

In 2009, US EPA published development and validation of a *Daphnia magna* 4-d survival and growth test method in ET&C. This method is now being standardized so that it can potentially be used as another short-term chronic test in the National Discharge Elimination System (NPDES) permitting process for whole effluent toxicity testing and other regulatory assessments. Two ORD laboratories (Duluth, MN; Cincinnati, OH) have conducted additional testing to optimize method performance, followed by 4-d standardization studies to evaluate method variability and reproducibility using reference toxicants. The standardization studies consisted of triplicate tests conducted by both laboratories, with three toxicants: ammonia, zinc, and diazinon. Each toxicant was also tested using a 7-d chronic *Ceriodaphnia dubia* test for comparison. For ammonia, intra-laboratory variation in IC25 values for *D. magna* weight was relatively low (CV = 17%, 27%, for Duluth and Cincinnati, respectively), but there was an apparent difference in toxicant sensitivity between laboratories, with IC25 values of 24 to 33 mg/L as N for Duluth, and from 49 to 84 mg/L as N for Cincinnati. For diazinon, CVs were also low = 25% and 7% (Cincinnati and Duluth, respectively), but the IC25 values were higher for Duluth (0.63-1.01 µg/L) than Cincinnati (0.38-0.43 µg/L). *C. dubia* results for diazinon were similar for both labs (0.20 and 0.17 µg/L). For zinc, Duluth's IC25s ranged from 78.8-114 µg/L while Cincinnati's two tests were 110 & 143 µg/L. *C. dubia* results for zinc were 38 µg/L for Duluth and 103 µg/L for Cincinnati. Reasons for the differences between the labs in apparent sensitivity are under investigation, but may be due to differences in test solution pH or potential differences in culture methods, stock genetics and algal food preparation procedures. A *post hoc* power analysis was done to quantify the relationship between number of replicates and statistical power to detect differences between experimental treatments. Future method standardization work will include evaluation of whole effluents with both species.

1.11.P-Tu035 *Hydra viridissima* as Model to Study the Toxicity of Environmental Contaminants: A Case Study with Metals

***Miguel Oliveira**[1], Ana Rita Santos[2], Isabel Lopes[1] and Cátia Venâncio[3], (1)University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Aveiro, Portugal, (2)Department of Biology, University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Portugal, (3)University of Coimbra, Portugal*

Anthropogenic activities are globally increasing the concentration of contaminants such as metals in the environment, particularly in the freshwater environment, thus leading to significant effects at population, community, and ecosystem levels. Therefore, cost-effective tools for continuous monitoring of these contaminants must be pursued. In this sense, hydras can be a valuable biological model that may provide rapid information on the toxicity of a substance/particle, easily recognizable by potential morphological and behavioural changes. Accordingly, the present study aimed to assess the toxicity of three metals (copper, zinc, and cadmium) focusing on lethality, morphological changes, and feeding rate of the freshwater cnidarian *Hydra viridissima* after a 96-h exposure period. A set of metal concentrations (copper 0.09-1 mg/L, zinc 0.24-2.77 mg/L, and cadmium 0.14-1.57 mg/L) was prepared by successive dilutions of the metals' stock solutions in hydra medium. Organisms were checked every 24 h for mortality and morphological alterations. The feeding behaviour was also assessed after 96 h exposure. The lethality data allowed the estimation of the median lethal concentrations (96 h-LC_{50}) which allow the toxicity ranking as copper > cadmium > zinc. *H. viridissima* mortality was detected after the 96-h exposure period at concentrations equal or higher than 0.667 mg/L, reaching 100% at the highest concentrations tested for each metal. Regarding malformations, more than half of the organisms presented shortened body and/or tentacles. In the post-exposure feeding assay, hydras exposed to intermediate concentrations (0.138 and

0.207 mg Cd/L; 0.243 and 0.364 mg Zn/L) displayed a trend to ingest more prey than controls, although only significantly in the zinc treatments. Overall, *H. viridissima* sensitivity to metal exposure strongly supports its use in the assessment of waterborne contaminants based on a wide range of endpoints. In addition, deriving up to date toxicity values based on these organisms may be important for setting more conservative benchmarks.

1.11.P-Tu036 Environmental Levels of Carbaryl Impair Zebrafish Larvae Behavior: The Potential Role of ADRA2B and HTR2B

*Demetrio Raldua[1], Melissa Diogo Faria[2], Marina Bellot[3], **Juliette Bedrossiantz**[2], Jonathan Ricardo Rosas-Ramirez[4], Eva Prats[5], Natalia Reyero[6], Cristian Gómez-Canela[7], Jordi Mestres[8], Xavier Rovira[9], Carlos Barata Dr[10], Amadeu Llebaria[9] and Leobardo Manuel Gómez-Oliván[11], (1)Environmental Toxicology, Spanish Research Council (CSIC), Institute of Environmental Assessment and Water Research (IDAEA), Spain, (2)Environmental Toxicology, IDAEA-CSIC, Spain, (3)University Ramon Llull IQS, Spain, (4)Laboratorio de Toxicología Ambiental, Universidad Autónoma del Estado de México, Mexico, (5)CID-CSIC, Spain, (6)U.S. Army Engineer Research and Development Center (ERDC), (7)School of Engineering, Institut Químic de Sarrià-Universitat Ramon Llull, Spain, (8)Chemotargets, Spain, (9)IQAC-CSIC, Spain, (10)Spanish Research Council (CSIC), Institute of Environmental Assessment and Water Research (IDAEA), Spain, (11)Autonomous University of the State of Mexico, Mexico*

The insecticide carbaryl is commonly found in nondirectly exposed freshwater ecosystems at ng/L concentrations, below its NOEC for acetylcholinesterase (AChE) inhibition reported for different fish species. Therefore, environmental levels of carbaryl are commonly considered safe for fish communities. In this study, we showed that after only 24 h of exposure to environmental concentrations of carbaryl (0.066-660 ng/L), zebrafish larvae exhibit impairments in essential behaviors. Interestingly, the observed behavioral effects induced by carbaryl were acetylcholinesterase-independent. To elucidate the molecular initiating event that resulted in the observed behavioral effects, *in silico* predictions were followed by *in vitro* validation. We identified two target proteins that potentially interacted with carbaryl, the α2B adrenoceptor (ADRA2B) and the serotonin 2B receptor (HTR2B). Using a pharmacological approach, we then tested the hypothesis that carbaryl had antagonistic interactions with both receptors. Similar to yohimbine and SB204741, which are prototypic antagonists of ADRA2B and HTR2B, respectively, carbaryl increased the heart rate of zebrafish larvae. When we compared the behavioral effects of a 24-h exposure to these pharmacological antagonists with those of carbaryl, a high degree of similarity was found. These results strongly suggest that antagonism of both ADRA2B and HTR2B is the molecular initiating event leading to the observed behavioral effects in zebrafish larvae exposed for 24 h to environmentally relevant levels of carbaryl.

1.11.P-Tu037 Pull-Down Assay as a Novel Approach for the Identification of Compounds Interfering with Thyroid Hormone Signalling in Complex Environmental Mixtures

***Petra Mikusova**[1], Ludek Sehnal[1], Zuzana Tousova[1], Jan Kuta[2], Garry Codling[3], Roman Grabic[4] and Klara Hilscherova[1], (1)RECETOX, Masaryk University, Czech Republic, (2)Recetox, RECETOX, Masaryk University, Czech Republic, (3)University of Saskatchewan, Canada, (4)University of South Bohemia in Ceske Budejovice, Faculty of Fisheries and Protection of Waters, Czech Republic*

Plasma protein transthyretin (TTR) plays an important role in transport of thyroid hormones (T3 and T4) in vertebrates. Some environmental pollutants can compete with natural TTR ligands, which may disrupt TTR binding and thyroid hormone transport and lead to neuro/developmental and metabolic disorders. Little is known regarding the ability of chemicals occurring in aquatic environment to bind to the TTR protein. Our results indicate that complex environmental mixtures associated with discharges from waste-water treatment plants can elicit such effect, but the effect drivers are unknown.

Here, we present one of the solutions of this problem, a novel method based on an interaction of the TTR with its ligands, called pull-down assay. Recombinant TTR is prepared by inserting TTR sequence into plasmid and expressed in *E. coli*. The purified recombinant TTR is incubated with prioritized extracts of environmental water samples (EwS), leading to the potential binding of TTR ligands to TTR protein. The complex is bound to magnetic Ni^{2+} affinity resin via Histidine tag added into TTR sequence. Magnetic particles with bound protein-ligand complex are attached to the surface of the reaction tube using a magnetic holder and the washing steps lead to the displacement of unbound chemicals. The complex is then eluted with an imidazole solution. TTR is denatured with solvent with the ligands released into the solution. The identification of the ligands is performed via non-target MS analysis on LC-Orbitrap and confirmed with target MS analysis. The potential ligands can be identified using library searches and are further tested for their activity in TTR binding bioassay. Finally, the contribution of the identified compounds (e.g., diclofenac and its metabolites) to previously reported endocrine-disrupting potency (TTR binding) of the EwS can be characterized.

1.11.P-Tu038 The Use of Heart Rate Monitors to Determine the Effects of Environmental Stressors in the Common Shore Crab (*Carcinus Maenas*)

***Emily Price**[1], Alex Ford[1] and Christopher Nicolai Roterman[2], (1)University of Portsmouth, United Kingdom, (2)Marine Biology, University of Portsmouth, United Kingdom*

Wearable technologies have advanced substantially in the human fitness and health field and offer huge potential for the monitoring of wildlife. In this study, we aimed to determine the utility of wearable fitness watches as a noninvasive method to monitor the health of crabs. Traditional methods examining the physiology of decapod crustaceans have used wired approaches which are invasive and logically challenging for environmental toxicology. The objective of the study was to determine whether over-the-counter fitness watches could be utilised to monitor heart rate in a decapod crustacean (Common shore crab, *Carcinus maenus*). The accuracy and reliability of these devices are being explored through a series of ongoing experiments using temperature and cardio stimulants. Results so far indicate that fitness watches can detect crab heartbeats through the carapace at rates equivalent to former studies with some clear peaks through handling stress. While there is still considerable optimisation required and the determination of baseline data, these preliminary results point huge potential in this approach to in vivo studies in the laboratory or in situ monitoring in the environment.

1.11.P-Tu039 Sperm Quality Assessment in *Ficopomatus enigmaticus* (Fauvel, 1923): Effects of Selected Organic and Inorganic Chemicals Across Salinity Levels

***Alessia Cuccaro*[1]*, Lucia De Marchi[2], Matteo Oliva[2], Matilde Vieira Sanches[1], Rosa Freitas[3], Gianfranca Monni[4], Valentina Casu[4], Vincenzo Miragliotta[4] and Carlo Pretti[4], (1)University of Aveiro, Aveiro, Portugal, (2)Interuniversity Consortium of Marine Biology and Applied Ecology "G. Bacci", Italy, (3)Department of Biology & CESAM, University of Aveiro, Aveiro, Portugal, (4)University of Pisa, Italy*

Contamination by organic and inorganic compounds remains one of the most complex problems in both brackish and marine environments, causing potential implications for the reproductive success and survival of several broadcast spawners. Particularly, aquatic contamination by trace elements, polycyclic aromatic hydrocarbons (PAHs), and surfactants is known to be of critical environmental concern due to their high environmental concentrations, persistence and toxicity in different organisms. *Ficopomatus enigmaticus* is a filter-feeding tubeworm polychaete, well adapted to brackish water conditions, for which the reliability to be used as a candidate model organism for ecotoxicological purposes has been already described. Although most studies were focused on polychaete juvenile and adults, few have been devoted to compounds effects on sperms. Spermiotoxic impact caused by environmental pollutants could lead to transmission of damage to offspring and, in turn, potential implications for reproductive capacity and population preservation. Therefore, the present study investigated the putative impact of five trace elements (zinc, copper, cadmium, arsenic and lead), one surfactant (sodium dodecyl sulfate,SDS) and one PAH (benzo(a)pyrene) on *F. enigmaticus* sperm quality across salinity variations. Sperms were exposed *in vitro* to different contaminant concentrations under four salinity levels and effects on sperm function were assessed in terms of oxidative stress, membrane integrity, viability, and DNA damage. Results showed that sperm impairments induced by organic contaminants were more evident than those induced by inorganic ones, with the largest effects exerted by SDS. When both stressors act in combination, variations in biomarker responses were observed. Specifically, due to salinity influence on physio-chemical speciation of inorganic compounds, major impairments were detected at the higher and lower salinity levels. With respect to organic compounds, because of direct interference of salinity on contaminant toxicity, higher salinity levels enhance their concentration-dependent effects. Overall, the high tolerance showed by *F. enigmaticus* sperms to salinity variations confirms the use of this species as promising organism for an early assessment of marine/brackish water pollution. The present study provides the effectiveness of fluorometric/photometric methods as integrative or alternative endpoints to investigate the spermiotoxicity potential of pollutants.

1.11.P-Tu040 Effect-Based Monitoring Tools Reveal that Chemical Pollution Counteracts the Restoration Success of Streams

***Sarah Hörchner*[1]*, Ariane Moulinec[2], Andrea Sundermann[2], Klaus Peter Ebke[3], Thomas Bing[3], Jörg Oehlmann[1] and Matthias Oetken[1], (1)Aquatic Ecotoxicology, Goethe University Frankfurt, Frankfurt am Main, Germany, (2)Section River Ecosystem Managment, Senckenberg Society for Nature Research, Germany, (3)MESOCOSM GmbH, Institut für Gewässerschutz, Germany*

In 2027, the third planning cycle of the European Union Water Framework Directive (WFD) ends and still more than 90 % of German surface waters do not meet its objectives. The main drivers causing degradation of aquatic ecosystems are the presence of contaminants, morphological degradation and high nutrient loading. However, current monitoring methods make it difficult to predict if the poor status of water bodies is due to chemical pollution or morphological degradation. Moreover, recent studies have shown that in rivers with a high proportion of treated wastewater, hydromorphological restoration was not only unsuccessful in improving ecological status, but that the restored sections had higher toxicities than the unrestored reference sections of the same river. Effect-based methods (EBMs) can function as scientifically sound and target-oriented monitoring tools to get a better insight into the pollutants and mechanisms underlying the observed effects. Given this background, the present study aims to use EBMs at organismic and sub-organismic levels to better assess five restored streams and their associated non-restored reference site in Hesse (Germany). We aim to determine whether water pollution or structural deficits are the main causes of the failure to achieve good ecological status.

For this purpose, we performed various *in vitro* tests on water and sediment samples, such as recombinant yeast reporter gene assays for estrogenic, androgenic and dioxin-like activity, Microtox assay for baseline toxicity, Ames fluctuation assay for mutagenicity and AREc32 test for oxidative stress response. Additionally, *in vivo* data on reproductive toxicity using *Potamopyrgus antipodarum* were obtained and further *in vivo* testing using *Hyalella azteca* and fish embryos (*Danio rerio*).

Considering the age of the restoration measures carried out on our sampling sites (approx. 20 years old), we did not expect strong differences between the non-restored reference site and the restored site. Applied EBMs revealed toxic activities in water and sediment samples. So far, the preliminary results do not indicate a clear correlation between toxicity and the morphological condition of the sampling sites. Accordingly, the present findings suggest that the pollutant load counteracts the restoration success. In future studies, more recent restoration projects (approx. 2-5 years old) will be investigated expecting to find higher toxicity in restored river sections.

1.11.P-Tu041 Is Olive Oil Value Chain an Environmental Risk? Ecological Quality Evaluation of Tua River (Portugal) and Multitrophic Toxicity Assessment

***Silvana Teixeira Costa*[1]*, Fernando Miranda[2], Fernando Teixeira[2], Aya Zidouh[2], Conceição Fernandes[3], Luis Dias[3], Amílcar*

Teixeira[3] and Zulimar Hernandez[1], (1)MORE- Laboratório Colaborativo Montanhas de Investigação, Portugal, (2)Instituto Politécnico de Bragança, Portugal, (3)CIMO - Centro de Investigação de Montanha, Instituto Politécnico de Bragança, Portugal
Portugal is amongst the main producers of olive oil worldwide, where Trás-os-Montes e Alto Douro region is the second national producer. The last two decades were marked by the technological transition in the olive oil industry, responsible for the generation of a by-product called olive pomace (>75% water content). Currently, almost all olive pomace generated in this region is processed in a single outdated industry for the extraction of oil for further refining and sold as edible oil. During this process, olive mill wastewaters (OMWW) are produced, which are stored in high volume and open-air lagoons. Although it is known that olive pomace is phytotoxic due to its high organic load, deeper knowledge is necessary on how OMWW can impact habitat's integrity, namely freshwater ecosystems.

Therefore, eight sampling sites along Tua River (Douro basin) and tributaries were seasonally monitored for a year (2021-2022), following standardized procedures defined by the Water Framework Directive. Environmental data were registered, considering water physicochemical (common metrics and specific pollutants), hydromorphological (River Habitat Survey) and biological (fish and invertebrates) elements. Moreover, to understand the toxicant role of OMWW, crustacean *Daphnia magna* and mussel *Unio delphinus* were chosen as bioindicators organisms. Organisms were used to perform acute and chronic exposures, respectively. Assessments were performed following standardized procedures (24 h Immobilisation test, metabolic capacity, antioxidant responses -catalase and superoxide dismutase- and lipid peroxidation).

When comparing the obtained results, sites located downstream of oil extraction industries showed a significant decrease on the water quality and aquatic habitats. Several ecological metrics and multivariate analyses detected the ecological impact of the effluent. Additionally, the conducted 24 h LD50 assays revealed that the doses required to cause the death, of at least 50% of the tested population, is equivalent to 0.873% (v/v) of OMWW. The increase of reactive oxygen species may have triggered the antioxidant enzymes that, though ineffective, led to increased metabolic rates.

The present research highlights the impact of olive industry upon surrounding ecosystems and the importance to develop ecologic solutions to treat OMWW, reducing its toxicity and, therefore, promoting biodiversity conservation.

1.11.P-Tu042 Ecotoxicological Evaluation of Effluents Originated by the University Hospital, UFSC , Florianópolis – SC, BRAZIL.

Carlos H.L. Soares[1]*, Ivana Eunice Baptista[2], Claus T Pich[2] and Mateus V Machado[2], (1)Biochemistry, Universidade Federal de Santa Catarina, Brazil, (2)Biochemistry, Federal University of Santa Catarina, Brazil*
Hospital effluents are considered potentially hazardous pollutants. Thus, we sought to characterize the effluent from the University hospital in the city of Florianópolis-SC, through physical-chemical and ecotoxicological tests. Physico-chemical analyzes of the parameters ammonia, nitrate, phosphate, total phenols and gas chromatography, and acute ecotoxicological tests in different concentrations with organisms of different trophic levels (*S. subispicatus, D. magna, Artemia* sp.*, D. rerio, L. sativa,* and *A. cepa*). Characteristics of fresh sewage were identified through chromatography and relationships between the concentrations found in the physical-chemical tests and the behaviors of the models tested in the bioassays. In the acute tests, stimulation of the algal growth rate was found in most of the concentrations tested with *S. subispicatus* and in some of the tested points, interference from the low levels of phosphate where there was no growth and the high level of nitrate and ammonia where inhibition occurred. Total growth of *L. sativa* was stimulated in most concentrations and where there was no growth, ammonia values were high. Inhibition of apical growth of *A. cepa* roots was observed in most concentrations; however where nitrate levels were lower, the roots grew equal to the control. Toxicity to *Artemia* sp. mainly in concentrations where the ammonia levels were higher. Mortalities, deformations and morphological delays occurred in the models of *D. rerio*, where the values of ammonia and nitrate were higher, the mortalities were also higher. No changes or mortality were recorded in the concentrations tested with *D. magna*, whose model is one of the main test organisms used as a reference in current Brazilian legislation.

1.11.P-Tu043 Physicochemical and Toxicological Characterization of Samples from Water Sources Neighboring Rice Plantations

Carlos H.L. Soares[1] *and Ivana Eunice Baptista[2], (1)Biochemistry, Universidade Federal de Santa Catarina, Brazil, (2)Biochemistry, Federal University of Santa Catarina, Brazil*
The southern region of Brazil is dominated by wetlands, which are attractive ecosystems for irrigated rice production and accounted for 68% of national rice production in 2021. This type of farming is generally practiced in the vicinity of water sources, and requires intensive use of chemical inputs resulting in serious risk of water contamination. For these studies were chosen two sites in Cachoeira do Sul river (nº 3 and 4), from which the water is pumped to the management of the rice fields. By recycling, these sites get back the water and wastes. Next to these two sites in the same river, another site was sampled (No. 5). In this case it is directly in contact with the culture of rice through a pale of communication. To define a possible site to be used as a reference site, without contamination, another sampling site (No. 7 - Table 1) was chosen for its crystal clear water, thus without the turbidity of the others, caused by the aforementioned recirculation. This site has no contact with the rice fields. A water sample was also taken directly from a framework of growing rice (No. 1 - Table 1) in a nearby area, however, without direct communication with the sites mentioned above. The samples were collected in November 2008, during the rice cultivation period and therefore the application of pesticides on crops. Ecotoxicological tests were performed using a microalgae (*Scenedesmus subspicatus*), microcrustacean (*Daphnia magna*) and *Danio rerio* embryos. Analyses of water samples were performed by GC/MS. The results obtained showed medium-high toxicity for microalgae and microcrustaceans and slight toxicity for *Danio*

rerio embryos. Chromatographic analyses detected the presence of bentazone, as the main herbicide, in concentrations of 150 µg – 450 µg, glyphosate, 80 µg -110 µg, carbofuram 20 µg to 60 µg, and the insecticide quinalphos, 110 µg.

1.11.P-Tu044 Haloacetonitriles React with Proteins via Three Distinct Reaction Pathways

***Kirsten Yeung**[1], Pranav Nair[2] and Hui Peng[1], (1)University of Toronto, Canada, (2)Chemistry, University of Toronto, Canada*

Disinfection by-products (DBPs) are formed in disinfected/sanitized water which have been correlated with incidences of disease such as bladder cancer and adverse pregnancy outcomes. Disinfection by-products are a large portion of the human exposome and thus are prioritized for human health regulations. There are >700 DBPs discovered, however the DBP drivers of toxicity and their mechanisms of action within the cell are unknown. Recently, haloacetonitriles (HANs) have been highlighted as an emerging DBP with stronger toxicity than regulated DBPs. This talk will elucidate the toxicity mechanism of HANs, including monoHANs and polyHANs, by investigating their reactivity with human proteome. Unexpectedly, despite the 'simple' structures of HANs, three distinct reaction pathways were observed which led to differing toxicity of HANs depending on the type and number of halogens. Both substitution and addition reaction pathways will be discussed, the latter of which is a novel pathway never reported for DBPs. Cytotoxicity and oxidative stress bioassays were employed to determine the ability of various HANs to induce toxic effects and the role of each HAN's preferential reaction pathway in predicting harmful effects in the human cell. Activity based protein profiling (ABPP) was used to image *in vitro* HAN adduction effects on protein thiols in human cells. Finally, this project involves the use of OMICs by incubating HANs *in vitro* in human embryonic kidney (HEK293) cells which are pertinent to the exposure of DBPs. Proteomics will be used to elucidate the specific HAN-attacked proteins and the dominant HAN reaction mechanism *in vitro* thus elucidating the dominant pathway reaction pathway and prioritizing HANs using their chemical reactivity. This talk will reveal the underlying chemical pathways in which HANs react with thiol proteins and the importance of fundamental chemistry in assessing water toxicity.

1.11.P-Tu045 Using Tissue Residue-Based Effects Concentrations in Setting Sediment Guidelines for Dioxin-Like Compounds

***Therese M. Manning**[1] and Graeme E. Batley[2], (1)Environmental Risk Sciences (enRiskS) Pty Ltd, Carlingford, NSW, Australia, (2) Centre for Environmental Contaminants Research, CSIRO Land and Water, Kirrawee, New South Wales, Australia*Setting sediment guidelines for chemicals that bioaccumulate, such as dioxin-like chemicals, can be problematic. Guidance for deriving such guidelines encourages the use of sediment toxicity tests or the use of field data; however, these methods do not work well with chemical groups like the dioxin-like compounds.

Sediment ecotoxicity data are almost nonexistent for dioxin-like compounds. Field data predominantly address effects on invertebrates which are not the most sensitive organisms for this chemical group. Research to understand the ecotoxicity of this group of chemicals for aquatic organisms has identified that the most sensitive organism type is fish – particularly the early life stages and effects concentrations based on tissue residues provide more robust endpoints.

To assess the suitability of these sediments for ocean disposal, a defensible sediment quality guideline value (SQGV) for dioxin-like compounds, expressed as pg toxic equivalent (TEQ)fish/g dry weight, was required and work was undertaken to review the basis of existing guidelines.

The findings showed that there were too many uncertainties associated with a value derived using effects data from field studies for this chemical group. A similar issue was associated with values based on equilibrium partitioning from sediment to pore water, largely associated with the wide range of reported sediment:water partition coefficients.

A tissue residue approach was identified based on equilibrium partitioning between sediment and organisms determined using tissue concentrations in fish, the most sensitive aquatic biota, and biota: sediment accumulation factors. The calculation of an appropriate SQGV used data for dioxin-like compounds in both fish and sediments from Sydney Harbor. A conservative SQGV for dioxin-like compounds of 70 pg TEQ/g dry weight was deemed to be adequately protective of biota that might be exposed to these contaminants in sediments.

1.11.P-Tu046 Role of Alkylated Polycyclic Aromatic Hydrocarbons in Mixture Toxicity from a Legacy Creosote Site

***Ian Moran**[1], Robyn Leigh Tanguay[1], Katrina M Waters[2] and Kim Anderson[1], (1)Oregon State University, (2)Pacific Northwest National Laboratory*

Creosote is a pesticide used to preserve wood products. Derived from distillation of coal tar, creosote is a complex mixture containing mostly polycyclic aromatic hydrocarbons (PAHs) and their derivatives. Alkylated PAHs are abundant constituents of creosote and many petroleum products and are known to become enriched relative to their respective parents through weathering. Less is known about the toxicity of alkylated PAHs than their parent compounds. Despite this, alkylated PAHs have been shown to contribute substantially to the toxicity of PAH mixtures in the environment. The goal of this study is to understand the contribution of alkylated PAHs to the toxicity of a complex, weathered mixture from a legacy creosote site. This study utilizes low density polyethylene passive samplers deployed at a former wood treatment facility to accumulate freely dissolved organics in the surface water. Passive sampler extracts are analyzed by gas chromatography - tandem mass spectrometry for parent and alkylated PAHs. To assess toxicity, embryonic zebrafish are exposed to passive sampler extracts in 96-well plates and are observed at 24 and 120 h postfertilization for a suite of behavioral and morphological endpoints. A year-long sampling campaign at the site has shown substantial variability in chemical abundance and toxicity with sum PAH concentrations in two adjacent months varying by greater than a factor of two and LC50 values varying by a similar magnitude. Alkylated PAHs constituted the majority of measured PAHs in all samples (83-89%). Ongoing work seeks to determine the drivers of toxicity and the role of alkylated PAHs by fractionation of field collected mixtures through effect-directed analysis. Fractionation by gel permeation chromatography revealed that three fractions together recapitulated the toxicity of the whole mixture. The fraction containing alkylated PAHs caused the majority of the toxicity while the fraction containing many unsubstituted PAHs caused less than 10% mortality. A third unidentified fraction caused high incidence of notochord malformation in zebrafish at low concentrations. While further toxicant confirmation is necessary, these results suggest that highly abundant alkylated naphthalenes and phenanthrenes are responsible for driving toxicity rather than the routinely monitored parent PAHs. Understanding the role of alkylated PAHs can inform remediation efforts and improve our ability to protect human health and water quality.

1.11.P-Tu047 Estrogenic Effects on Wastewater Receiving Bodies; an EDA Approach Using YES Bioassays in the Basque Country

Belen Gonzalez-Gaya[1]*, Carlos Triviño*[2]*, Irene Beltran de Heredia*[3]*, Naroa Lopez*[4]*, Nestor Etxebarria*[5]*, Maitane Olivares*[6]*, Olatz Zuloaga*[6]*, Ailette Prieto*[6] *and Estilita Ruiz Romera*[5]*, (1)ESTACION MARINA DE PLENTZIA. UPV/EHU, Spain, (2)Estacion Marina de Plentzia (EHU/UPV), (3)Plentzia Marine Station of Basque Country University (EHU/UPV), Spain, (4)Analytical Chemistry, EHU/UPV, Leioa, Spain, (5)University of the Basque Country (UPV/EHU), Spain, (6)Analytical Chemistry, University of the Basque Country (UPV/EHU), Spain*

The scientific community is recently evaluating the fate and distribution of contaminants of emerging concern in aquatic ecosystems receiving wastewater treatment plants (WWTP) effluents. Those latter accumulate housing and industrial wastewaters and are not always able to degrade compounds such as personal care products and pharmaceuticals (PCPPs) or consumption chemicals (additives, detergents, PFAS, plasticizers, etc.) which are delivered into rivers and marine waters with an unpredictable effect in the aquatic ecosystems. Among the undesired effects in wild biota, endocrine disruption is of particular concern.
Within this context, an effect-directed analysis approach (EDA) was implemented in the Urola river basin in the Basque Country, north Spain. It is impacted by the Zuringoain WWTP that gathers wastewater from 3 municipalities and the Zumarraga hospital, being the hospital water the 2 % of the total river flow during summer season. Two concurrent high volume samples (50 L) of the WWTP effluent and the river area where the effluent impacts were taken in low water period (Sept 2022) using a large volume solid-phase extraction device loaded with a triphasic cartridge (Chromabond HR-X (Macherey-Nagel), Sepra ZT-WAX and Sepra ZT-WCX (Phenomenex)). Both were fractionated by means of preparative chromatography onto a C18 column into 18 sub fractions, and tested for potential estrogenic activity using the A-YES (yeast estrogenic screening) bioassay. Estrogenic fractions will be further fractionated onto an aminopropyl column and subsequentially biotested. A suspect screening approach will be used for the tentative identification of the isolated compounds in the active fractions with their confirmation via target analysis (≈300 compounds) on a Thermo Scientific Dionex UltiMate 3000 UHPLC coupled to a Thermo Scientific Q Exactive Focus Orbitrap MS for xenobiotics. Moreover, an UHPLC system Agilent 1290 Infinity II coupled to an Agilent 6430 triple quadrupole mass spectrometer will be used for the target analysis of 16 hormones.
The comparison of the identified compounds in the river and in WWTP effluent will point to the missing information regarding the potential estrogenic chemicals and their fate and relevancy once delivered in the basin.

1.11.V Novel Methods and Approaches for Assessing Effluents, Chemicals Toxicity and Surface Water to Support Regulations

1.11.V-01 Assessment of Behavioral Responses in the Freshwater Mussel *Sinanodonta woodiana* to Exposure to Six Model Contaminants

Konstantina Efstathia Drainas[1]*, Sebastian Beggel*[2] *and Juergen Geist*[2]*, (1)School of Life Sciences, Technical University of Munich (TUM), Germany, (2)School of Life Sciences, Technical University of Munich, Aquatic Systems Biology Unit, Germany*

Behavioral biomarkers are considered sensitive tools to assess the impact of contaminants in organisms in a direct and ecologically relevant way, yet the use of such markers in freshwater mussels is still in its infancy. High frequency noninvasive (HFNI) valvometers on mussels are a good example for an application of such biosensors which allow continuous monitoring of gaping and filtration behavior. Due to their sedentary lifestyle and as filter-feeders, mussels are specifically sensitive to changes in the ambient water matrix and are therefore ideal sentinels for potentially harmful conditions.

For the application of such biosensors it is necessary to assess potential responses to different substance classes and to interpret which behavioral patterns are meaningful for the determination of sensitivity thresholds. Therefore, we examined the sensitivity of mussels' valve gaping behavior towards six selected contaminants in the ambient water by simulating pulse exposure scenarios in a laboratory setup.

As model stressors, we selected substances with different modes of action, namely microplastics, salt, copper, diclofenac, α-cypermethrin, and phenanthrene. Reactions of the freshwater mussel *Sinanodonta woodiana* (n_{total} = 94) were recorded within 1 week experiments using Hall sensor-based HFNI valvometry. In a flow-through system, we simulated the contamination of running waters in the form of a short-term substance-peak, covering environmentally relevant as well as extreme concentrations of each substance.

The results indicate a substance-specific behavioral reaction of the mussels after short-term exposure, with immediate and delayed effects. These first results are based on state-of-the-art statistical comparison of simple measures such as count and duration of opening/closing the shells. We currently advance the analysis by AI and machine learning-based methods to improve this promising new approach for early detection of potentially hazardous substances in the water.

1.12 The Use of 'Omic Tools to Assess the Impact of Mixture Toxicity

1.12.T-01 Linking Reproductive and Metabolic Disruption After Exposure to Novel Flame Retardants: An i*n vitro* Approach

Chander Kant Negi[1]*, Lola Bajard*[1] *and Ludek Blaha*[2]*, (1)RECETOX, Masaryk University, Czech Republic, (2)RECETOX, RECETOX, Masaryk University, Czech Republic*

Organophosphorus flame retardants (OPFRs) are widely used in several indoor and outdoor products as substitutes for polybrominated diphenyl ethers. The presence of OPFRs has been noted in various environmental matrices and biological samples, which indicates possible human exposure. The present study aims to evaluate the effects of OPFRs on human cell culture (monolayer and 3D spheroids) to characterize the toxicological effects and potential mechanisms through morphological, transcriptional, and biochemical assays. To evaluate the potential endocrine-related adverse reproductive effects (adrenal steroidogenesis), we further used the human adrenocortical cell culture (H295R).

Our findings suggest that the aromatic (aryl-) OPFRs, i.e., tricresyl phosphate (TMPP), triphenyl phosphate (TPHP), 2-ethylhexyl diphenyl phosphate (EHDPP), and the chlorinated OPFR, tris(1,3-dichloropropan-2-yl) phosphate (TDCIPP) induced the lipid accumulation in human liver cell culture by altering the expression of genes encoding for hepatic lipogenesis and mitochondrial dysfunction. Available data from ToxCast and *in silico* analysis suggested pregnane X receptor (PXR) and peroxisome proliferator-activated receptor-gamma (PPARγ) as potential molecular initiating events. Moreover, EHDPP-mediated dysregulation of hepatic lipidome was also observed in human 3D hepatospheroids. Dysregulation in several lipid classes, including sterol lipids (cholesterol esters), sphingolipids (dihydroceramide, hexosylceramide, ceramide, sphingomyelin), glycerolipids (triglycerides), glycerophospholipids, and fatty acyls were noted along with alteration in several genes involved in lipid homeostasis. Potential effects on oxidative homeostasis were also noted. The H295R cells exposed to EHDPP showed altered production of hormones, including progesterone, androstenedione, and cortisol along with the enhanced expression of several corticosteroidogenic genes. Intracellular lipid assay identified EHDPP-mediated disruption of lipid profile in H295R cells as evidenced by reduced total cholesterol ester, sphingolipids, and increased phospholipids and triglycerides species, indicating connections between OPFR-induced metabolic and reproductive pathologies.

In summary, our study identified several OPFRs as potential risk factors for endocrine-related reproductive and metabolic pathologies that are of increasing importance due to the risk of occupational or cumulative environmental exposure to humans.

1.12.T-02 Using 'Omic' Data to Predict Chemical Sensitivity Across Terrestrial Invertebrates: Progress and Challenges

Stephen James Short[1]*, Alex Robinson*[2]*, David J Spurgeon*[2]*, Claire Badder*[2]*, Amaia Green Etxabe*[2]*, Emily Eagles*[2] *and Peter Kille*[3]*, (1)Pollution, UK Centre for Ecology & Hydrology (UKCEH), United Kingdom, (2)UK Centre for Ecology & Hydrology (UKCEH), United Kingdom, (3)Cardiff University, United Kingdom*

Some terrestrial invertebrate groups are declining, with toxicant exposure thought to be an important driver. Using 'omic' data to predict differential species sensitivity (DSS) to toxicants, as well as vulnerabilities to chemical interactions, represents a cost-effective way to help flag species vulnerable to specific chemicals (and their combinations). However, this ambition requires uncovering the molecular mechanisms that underlie DSS, as well as determining the extent critical mechanistic differences between species can be extrapolated from readily available 'omic' data. We have used an approach that compares and scores genes/gene families pertinent to species sensitivity across three omic levels – (i) genomic (the presence/absence/functional domain sequence), (ii) basal gene expression (i.e., the level of expression in unexposed animals), and (iii) the responsive expression capacity (the extent and speed of omic response once exposed). 'Pertinent' in this case includes toxicant receptor genes (target and off-target), xeno-metabolic pathways, damage repair/mitigation systems and genes associated with genome responsive capacity (e.g., epigenetic regulator genes). Correlating such data with chemical sensitivity across terrestrial invertebrates identifies mechanistic insights into the basis of DSS, suggesting an under-appreciated role for off-target receptors, as well as confirming the role of xeno-metabolic complexity in determining a species' vulnerability to synergistic chemical interactions. This work is now expanding to correlating a species' 'responsome', i.e., the differential, and multi-dimensional, capacities of species to respond to toxicant-induced stress. Scoring a species' omic 'responsome' offers a rapid approach to quantify deep evolutionary divergences between species, as the score reflects differences in life-cycle, diet, reproductive strategy, regenerative ability, as well as a species' likelihood of experiencing unpredictable environmental extremes. Furthermore, given that many of the most problematic contaminants generate toxicity largely via non-specific modes of action, we suggest the 'responsome' represents a critical predictive factor that could augment current risk assessment. We hope that our approach and findings will support efforts towards combining omics with other appropriate data (e.g., ecological, phenotypic, and ecotoxicological) to identify vulnerable terrestrial invertebrates.

1.12.T-03 Effect of Wastewater Treatment Plant Discharge in a Norwegian Fjord to Juvenile Atlantic Cod (*Gadus morhua*) Brain Transcriptome

Jason Tyler Magnuson[1]*, Magne O. Sydnes*[1]*,* ***Daniel Schlenk***[2] *and Daniela Maria Pampanin*[1]*, (1)University of Stavanger, Norway, (2)Environmental Sciences, University of California, Riverside*

The release of pharmaceuticals and personal care products (PPCPs) into the aquatic environment from runoff, aquaculture, and effluent from wastewater treatment plants (WWTPs) may threaten the health of aquatic organisms. To better understand the input and movement of PPCPs from a predominant, regional WWTP into the Stavanger fjord and potential toxicity to an environmentally and economically important fish species, a dose related Risk and Effect Assessment Model (DREAM) was used to track the dispersion of complex chemical mixtures from the discharge plume. This model was used to select locations within the fjord to monitor the movement of the discharge and assess potential toxicity to Atlantic cod (*Gadus morhua*). Fish were caged at three sites for four weeks within the fjord. Brains were dissected from male and female individuals and transcriptomic profiling assessed, with differentially expressed genes presented relative to a reference location, site 1. The top predicted canonical pathways in male Atlantic cod caged at the site closest to the WWTP discharge, site 2, were involved in estrogen, glucocorticoid, and aryl hydrocarbon receptor signaling pathways, with disease and functions related to impaired growth of genital organs and neural cell proliferation, as determined through pathway analysis software. PPARα/RXRα activation, neuroinflammation signaling pathway, and glucocorticoid receptor signaling were among the top predicted canonical pathways in male fish caged at the site furthest from the WWTP discharge, site 3, with disease and functions involved in the transport of molecules and central nervous system inflammation. Top predicted canonical pathways in female Atlantic cod caged at site 1 were involved in CREB signaling in neurons and axonal guidance signaling, with motor dysfunction/movement disorder and hyperactivity among the top disease and functions altered. Synaptogenesis signaling pathway and glucocorticoid receptor signaling were among the top predicted canonical pathways in female fish caged at site 2, with disease and functions involved in the formation of intermediate filaments and dissociation of neurofilaments. These data indicate that PPCPs in the proximity of the WWTP discharge are dispersed from the plume into rearing habitats for native fish species and compounds present in the discharge have multiple targets within the brain that impair motor neuron function and induce estrogenic effects.

1.12.T-04 Earthworms Facing Pesticide Residues in Agricultural Landscapes
***Audrey Barranger*[1]**, *Romain Georges[2], Benjamin Andrieux[2], Olivier Delhomme[3], Maurice MILLET[3], Florent Lafay[4], Emmanuelle Vulliet[5], Gaëlle Daniele[4] and Françoise Binet[2], (1)CCEM, IFREMER, France, (2)UMR CNRS 6553 ECOBIO, University of Rennes 1, France, (3)UMR CNRS ICPEES 7515, University of Strasbourg, France, (4)UMR CNRS ISA 5280, University of Lyon 1, France, (5)Institut des Sciences Analytiques, UMR 5280, France*
Although agricultural soils are the main entry of pesticides, spatio-temporal and large-scale monitoring studies on soil and fauna contamination are still very rare, especially on currently used pesticides. There is consequently a lack of knowledge on the dynamics and fate of the pesticide contamination in agricultural landscapes. Research objectives of this study were threefold: 1) Characterize the multiresidual contamination of soils by pesticides and establish the spatio-temporal patterns of contamination according to agricultural soil management; 2) Analyze how earthworm's exposure is related to the soil pesticide contamination and 3) Assess how soil agricultural management differentially affects earthworms communities. Adopting a synchronic approach, 27 French agricultural fields were sampled (9 permanent meadows, 9 conventional fields and 9 organic fields), out of which 6 cropped fields were four time monitored through a diachronic approach. Both soil and earthworms were sampled and analysed. Multi-class pesticides (73 selected pesticides) and glyphosate and its metabolites have been determined concomitantly by LC-MS/MS. In soil, a total of 50 pesticides were detected in conventional fields, 35 in organic fields and 18 in meadows. Glyphosate and AMPA were found in all samples, including permanent meadows corroborating its ubiquity in the environment. Atrazine, Epoxiconazole and Fluxapyroxad were the most detected molecules apart from Glyphosate and AMPA. In earthworms**,** a total of 32 pesticides were detected from conventional fields, 16 in organic fields and 10 in meadows. High concentrations of Metolachlore ESA, Imidacloprid, AMPA and Glyphosate were found in earthworm tissues. Multivariate analyses will allow us to discriminate and assess the relative contribution of each agricultural and environmental variables (agronomical properties, farming practices, soil properties, inorganic pollution) in addition to the soil contamination by the pesticides that may explain the composition and structure of earthworm communities. This study showed that earthworms faced a cocktail of several chemicals at high concentrations in their natural environment. It thus raises important concerns about the effect of these residual pesticides on non-target soil organisms and how soil fauna may cope with that residual contamination in the future. Our observations advocate for more investigations on the evolutionary responses of soil biota to pesticide pollution.

1.12.T-05 Effects of Mixtures of Herbicides on Soil Functions
***Isabel García*[1,2]**, *Vera Silva[3], Paula Harkes[3], Foskea Raevel[3], Rima Osman[3], Oscar Bentancur[4], Grisel Fernandez[4] and Violette Geissen[3], (1)CENUR Litoral Norte, CENUR Litoral Norte, Universidad de la Republica, Uruguay, (2)Environmental Sciences Group, Wageningen University & Research, Netherlands, (3)Soil Physics & Land Management Group, Wageningen University & Research, Netherlands, (4)Facultad de Agronomía, Universidad de la República, Uruguay*
Despite the intensive and widespread use of pesticides, assessing environmental risks of mixtures on soils remains highly challenging. In this study, we used a mesocosm set-up to evaluate the effect of increasing doses of a commonly used herbicide scheme on biological nitrogen fixation and mycorrhization, and its relation with plant growth. This work aims to contribute to a more comprehensive environmental risk assessment of herbicides, by including more realistic test conditions and non-traditional endpoints.

The pot experiment was conducted inside a fine-meshed tunnel outdoors and lasted 100 days. The mixtures of herbicides were applied in two moments. On day 1 we applied glyphosate + dicamba + clethodim, and 30 days later, we applied S-metolachlor + flumioxazin. Four different concentrations were tested: 0 (control), 0.5, 1, and 2 times the recommended dose of the individual herbicides, referred to as D0, D0.5, D1, and D2 respectively. Each treatment had 10 replicates, but plants were harvested taking five random replicates in the vegetative stage (V4) and the remaining five plants in the reproductive stage (R3). Soybean seeds inoculated with *Bradyrhizobium japonicum* were sown on day 35. On each time point, plant biomass, number, colour, and dry mass of nodules were registered. AMF were stained and the presence of hyphae, arbuscules, and vesicles was quantified.

In V4 stage, significant reduction effects were observed at higher herbicide doses on plant biomass, total mycorrhizal colonization and arbuscules, and nodules dry mass. In R3 stage treatments showed no significant differences in plant biomass and arbuscules colonisation. However, by the reproductive stage, D2 presented lower total colonisation than the control, and lower nodule dry mass than all the treatments. The number of nodules was not statistically different among treatments in V4, but by the R3 stage, D0.5 showed a higher number of nodules than D2. In V4 stage, vesicle formation showed significant differences and values were lower at D1 and D2 than at D0.5, but not different from the control. By R3, D2 was the only treatment that presented significantly less vesicle formation than the control.

Overall, the effects of mixtures of herbicides had a marked effect on soybean plant biomass and the symbiotic endpoints analysed in the first stages of the plant. The highest dose tested presented effects on the symbiotic process that could not be reverted by the reproductive stage.

1.12.P The Use of 'Omic Tools to Assess the Impact of Mixture Toxicity

1.12.P-Th068 Metabolomics to Study the Impact of Diazepam and Irbesartan on Glass Eels (*Anguilla Anguilla*) and the Differences in their Migratory Phenotypes

***Iker Alvarez**[1], Valérie Bolliet[2], Naroa Lopez[3,4], Maitane Olivares[5], Mathilde Monperrus[6] and Nestor Etxebarria[1], (1)University of the Basque Country (UPV/EHU), Spain, (2)UMR ECOBIOP INRA - Université de Pau, France, (3)Analytical Chemistry, EHU/UPV, Leioa, Spain, (4)Plentzia Marine Station of Basque Country University (EHU/UPV), Spain, (5)Analytical Chemistry, University of the Basque Country (UPV/EHU), Spain, (6)Université de Pau et des Pays de l'Adour, France*

Since glass eels (*Anguilla anguilla*) are continuously exposed to contamination throughout their migratory journey through the estuaries, to a certain extent the fall in the population of this endangered species may be due to this exposure, which is especially acute in estuaries under high urban pressure. Metabolomics was used in this study to assess the effects of the previously selected contaminants, diazepam, and irbesartan, on glass eels. An exposure experiment to diazepam, irbesartan, and their mixture was carried out over 7 days followed by 7 days of depuration phase. After exposure, glass eels were individually killed using a lethal bath of anaesthesia, and then an unbiased sample extraction method was used to extract separately the polar metabolome and the lipidome. The polar metabolome was submitted to targeted and non-targeted analysis, whereas for the lipidome only the nontargeted analysis was carried out. A combined strategy using partial least squares discriminant analysis and statistical analysis (ANOVA, *t*-test, and fold-change analysis) was used to identify the metabolites altered in the exposed groups with respect to the control group. The results of the polar metabolome analysis revealed that glass eels exposed to diazepam-irbesartan mixture were the most impacted ones, with altered levels for 11 metabolites, some of them belonging to the energetic metabolism, which was confirmed to be sensitive to these contaminants. Additionally, seven lipids were also found dysregulated after exposure to the mixture. In the same vein, the same metabolomics approach was also used to find the differences in the metabolic profile of the two behavioural phenotypes of glass eels (migrants and nonmigrants). Nonmigrant glass eels showed lower overall metabolic values than migrant glass eels, and the lipidome analysis also showed alterations in the levels of eight cholesterol esters. These two findings offer new research perspectives to explain this facultative migration of glass eels and confirm the suitability of metabolomics in attempting to explain the differences between migrant and nonmigrant glass eels.

1.12.P-Th069 Oxidative Markers in Pulmonary Cells Exposed to Different Fractions of PM2.5-0.3 Collected from Urban, Traffic, andIndustrial Sites in Northern France

***Anthony Verdin**[1], Lamia Moufarrej[2], Fabrice Cazier[3], Dominique Courcot[4] and Frédéric Ledoux[4], (1)UCEIV, University of the Littoral Opal Coast, France, (2)Uceiv, Université du Littoral Côte d'Opale, France, (3)CCM, Université du Littoral Côte d'Opale, France, (4)Unité de Chimie Environnementale et Interactions sur le Vivant, UCEIV UR4492, FR CNRS 3417, University of Littoral Côte d'Opale (ULCO), France*

The aim of this work was to study the relationship between the chemical composition of $PM_{2.5\text{-}0.3}$ collected from different influences and their oxidative stress potency. Thus $PM_{2.5\text{-}0.3}$ were collected from three different sites (urban, road traffic, and industrial) in the North of France, and were then chemically characterized for major and minor chemical species. Four different fractions ($PM_{2.5\text{-}0.3}$, organic extract, water soluble extract, and nonextractable matter) were prepared for each of the three samples. After pulmonary cells exposure to 24 µg/cm^2 of $PM_{2.5\text{-}0.3}$ or PM-equivalent extracts (i.e., organic extract, water soluble extract, and non-extractable matter), oxidative stress was studied by quantifying ROS accumulation in cells, oxidative damage to proteins (carbonylated proteins), cell membrane alteration (8-isoprostane) and DNA damages (8-OHdG). PM was capable of inducing severe ROS overproduction and caused damage to proteins at higher levels than other fractions. Higher cell membrane and DNA damages were found with PM and organic extracts from the urban site. Correlation analysis showed that ROS concentrations were correlated with carbonylated proteins, DNA damages and membrane alteration while principal component analysis (PCA) showed a correlation between the amount of ROS in cells and the 8-isoprostane and carbonylated proteins. The results of classification confirmed the ability of PM to induce the highest damage to proteins and cell membrane.

1.12.P-Th070 Identification of Adverse Outcome Pathway (AOP) Relevant to Diesel Particulate Matter (DPM) Using Transcriptomics and Comparative Toxicogenomics Database Integrative Approach

***Yongmin Jung**, Jaeseong Jeong and Jinhee Choi, School of Environmental Engineering, University of Seoul, Seoul, Korea,*

Republic of (South)
Diesel Particulate Matter (DPM) is one of the major harmful mixtures and is well known to cause respiratory diseases such as lung cancer, pulmonary fibrosis, and asthma. However, due to the lack and limitations of mechanism-based research in mixture toxicity, it is challenging to establish a toxicity pathway. In this paper, we proposed a potential adverse outcome pathway (AOP) of DPM by integrating omics data with the Comparative Toxicogenomics Database (CTD) and AOP wiki. First, to discover Molecular Initiating Event, we screened the activity of transcription factors according to DPM exposure and confirmed that it induces activation of Aryl Hydrocarbon Receptor. In addition, differently expressed genes (DEGs) in time-dependent were discovered using transcriptomics data and 288 pathways were identified through Reactome analysis. In CTD analysis for discovering potential diseases through DEGs, 7 respiratory diseases were identified. In another, 32 respiratory diseases were found by searching CTD for diseases related to Particulate Matter (PM). Transcriptomics and CTD integrative approach revealed lung cancer and related 1210 CGPD tetramers. Through overlapping CGPD tetramers and toxicity pathways, 79 pathways and 146 phenotypes were identified, which were clustered into 11 key events in the AOP wiki. Putative AOP leading to lung cancer was then constructed. Among the 15 Key Event Relationships (KER) between these events, 10 were in the AOP Wiki and 5 were newly discovered. This study presented an approach in combination with CTD, AOP wiki, and omics in developing qualitative AOP as a case study of DPM. In addition, as a future study, we plan to establish a quantitative AOP using the dose-response relationship of omics and apply it to risk assessment.

1.12.P-Th071 Particulate Pollution in Lebanon: *In-vitr*o Evaluation of PM Organic Extractable Matter in Human pulmonary Cells

Malak Chwaikani[1], Ghidaa Badran[1], ***Anthony Verdin[2]****, Imane Abbas[3], Mohamed Roumie[3], Jean-Marc Loguidice[4], Dominique Courcot[5], Guillaume Garcon[4] and Frédéric Ledoux[5], (1)Uceiv, Université du Littoral Côte d'Opale, France, (2)UCEIV, University of the Littoral Opal Coast, France, (3)Lebanese Atomic Energy Commission, NCSR, Lebanon, (4)University of Lille, France, (5)Unité de Chimie Environnementale et Interactions sur le Vivant, UCEIV UR4492, FR CNRS 3417, University of Littoral Côte d'Opale (ULCO), France*
Nowadays, air-pollution-derived fine particulate matter ($PM_{2.5}$) is fully acknowledged to be a significant public health problem. $PM_{2.5}$ generally corresponds to a complex mixture of both inorganic (e.g., metals, ions) and organic (e.g. ,polycyclic aromatic hydrocarbons, pesticides, dioxins) chemical and biological components (e.g., pollen, fungi). The critical role of the $PM_{2.5}$ organic extractable matter (OEM) in the observed adverse health effects is still fragmented. The objective of this study was to investigate the toxicological effects of OEM prepared from $PM_{2.5\text{-}0.3}$ and quasi-ultrafine particles $PM_{0.3}$ collected in the south of Lebanon, on normal human bronchial epithelial cells (BEAS-2B).

The chemical characterization revealed the presence of a wide range of organic chemicals, notably PAHs, Nitrated-PAHs (N-PAHs), and Oxygenated-PAHs (O-PAHs), Dioxins and Furans. Exposure of BEAS-2B cells to OEM revealed decreases in ATP activities and increases in LDH levels, especially after exposure to the quasi-ultrafine particles OEM. In agreement with the high concentrations of PAH in OEM, CYP1A1 and CYP1B1 showed a high transcription level in cells supporting the activation of the AhR signaling pathway, especially after cells exposure to $OEM_{0.3}$. Consequently, genotoxic effects occurred in BEAS-2B cells with cell survival events and cell cycle deregulation, as supported by alterations of the protein expression of pP53, total P21, pH2AX, total MDM-2, pCHK-1 pCHK-1 and 2. Given the original data reported in this preliminary study, future complementary works are also needed to better decipher the critical role of $OEM_{0.3}$ and the activation of processes involved in autophagy, mitophagy, and/or cell senescence.

1.12.P-Th072 Use of Transcriptomic Points of Departure (tPODs) to Assess Toxicity of Oil in Early Life Stage Atlantic Cod

Jessica Head[1]*, Eléna Legrand[2], Emily Boulanger[1], Nil Basu[3] and Benjamin Patrick de Jourdan[4], (1)Faculty of Agricultural and Environmental Sciences, McGill University, Canada, (2)Stantec, Canada, (3)McGill University, Canada, (4)Huntsman Marine Science Centre, Canada*
Transcriptomics dose-response analysis (TDRA) is a promising approach for predicting the *in vivo* toxicity of environmental contaminants from transcriptomics data. TDRA has potential applications to the field of environmental risk assessment, but has seldom been used in the context of environmental mixtures. Here, we apply TDRA to early life stage Atlantic cod (*Gadus morhua*) exposed to two different types of oil; ultra low sulfur fuel oil (ULSFO) and cold lake blend diluted bitumen (CLB). Co-larvae (~200 degree days) were exposed to seawater control or water accommodated fractions (WAFs) made using variable loadings (0.01, 0.1, 1, 10, 25 g/L) of each oil for 24 h . Concentrations of polycyclic aromatic hydrocarbons (PAHs) and other organic chemicals were measured in water using analytical techniques. Whole larvae were flash-frozen in pools of five and preserved for RNASequencing. Quality control, trimming, and quantification were performed on RNAseq data using EcoOmicsAnalyst. Subsequent steps were performed on ExpressAnalyst which included filtration of low variance, low abundance, and unannotated genes, log2-counts per million (logCPM) normalization, and differential expression analysis using EdgeR. Differentially expressed genes (DEGs) were identified with an FDR adjusted *p*-value of 0.05 and log2-fold change (log2FC) of 1. Transcriptomic points of departure (tPODs) were calculated for each oil type using FastBMD. The ULSFO d CLB oils each contained a distinct complex mixture of PAHs that increased with oil loading. At equal oil loadings the ULSFO exposed cod was associated with greater mortality than the CLB exposed cod. Many genes were dysregulated by both oil types, but a greater number of DEGs were detected in ULFSO (1349) than CLB (530) -treated samples. Many DEGs were associated with aryl hydrocarbon receptor signalling. Gene level tPODs were calculated for 624 and 222 genes in the ULSFO and CLB samples, respectively. The tPOD mode for ULFSO and CLB were 0.034 and 0.18 g/L, respectively, suggesting a good

concordance between tPODs and apical outcomes. Overall, *in vivo* endpoints, chemical analysis, tPODs, and DEGs all suggested that the ULSFO oil was more acutely toxic to ELS fish. Ongoing analysis is investigating pathway level tPODs. This work helps to highlight the potential of TDRA for evaluating the toxicity of environmental mixtures.

1.12.P-Th073 Chemicals in Plastic Food Packaging Activate Cell Surface Receptors

Molly McPartland[1]*, Sarah Stevens*[2]*, Ingrid Gisnås Vardeberg*[2]*, Johannes Völker*[3] *and Martin Wagner*[2]*, (1)Biology, Norwegian University of Science & Technology (NTNU), Norway, (2)Norwegian University of Science & Technology (NTNU), Norway, (3)IES Ltd, Switzerland*

Plastics have a wide variety of uses, including the packaging of foodstuff and beverages. As plastics contain complex chemical mixtures that can leach into such food and drink, plastic food packaging is, thus, a relevant source of human exposure to synthetic chemicals. GPCRs are interesting targets for plastic chemicals because they are the largest class of cell surface receptor and are central regulators in most cellular processes. Further, GPCR deregulation and dysfunction is linked to a multitude of diseases which is underscored by the fact that they are targeted by more than one third of all prescribed pharmaceuticals. In this work, we report activation across 132 GPCRs by bisphenol A (BPA), diethyl phthalate (DEP), triphenol phosphate (TPP), and three mixtures of the chemicals extracted from 14 plastic food contact materials. We demonstrate that plastic chemicals activate adenosine 1 (ADORA1), melatonin 1 (MTNR1A), melatonin 2 (MTNR1B), and melanocortin 3 (MC3R) receptors which have previously remained largely undescribed as targets for plastic chemicals. We further demonstrate that specific polyvinyl chloride and polyurethane plastic products contain MTNR1A and ADORA1 agonists. However, generalized concentration addition modelling indicates the presence of antagonism, synergism, and competitive antagonism within each mixture. We attempted to identify specific active chemicals within our mixture by docking all identified compounds against three crystal structures of MTNR1A and ADORA1. Finally, to understand the biological implications of our work, we performed a gene ontology analysis to identify commonality between MTNR1A, MTNR1B, MC3R, and ADORA1. The most prominent, shared biological processes function to align circadian and rhythmic behaviors, thereby indicating plastic chemicals may also act as circadian disrupting chemicals. Considering our continued and increasing production and usage of plastics, our results demonstrate the necessity of continued research to identify active chemicals, downstream effects, and their overall contribution to non – communicable diseases.

1.12.P-Th074 Investigation of Benzotriazole Toxicity in Rainbow Trout Larvae (*Oncorhynchus mykiss*) using the Transcriptomics Point of Departure Approach

Andreas Eriksson[1]*, Justin Dubiel*[1]*, Emily Mertens*[1]*, Jackie Zhou*[1]*, Zhe Lu*[2] *and Steve Wiseman*[1]*, (1)University of Lethbridge, Canada, (2)University of Québec À Rimouski, Canada*

Benzotriazole UV stabilizers (BUVS), which are a class of chemicals added to plastics as to increase their resistance to degradation by ultraviolet irradiation, are persistent and ubiquitous pollutants of aquatic strata. Detected at concentrations, *in situ*, ranging from a few nanograms per liter of water to several microgram per gram sediment and soil, even in pristine locations; BUVS are known to bioaccumulate and potentially bio-magnify in organisms and throughout the food web, respectively.

Toxicologically, BUVS can agonise and antagonise a wide array of biological functions, including a potential for endocrine disruption, impaired liver function and altered histopathology, activation of aryl-hydrocarbon receptor 2 mediated xenobiotic metabolism, as well as causing altered iron metabolism. The latter is believed to be related to increased oxidative stress.
In our ongoing study, we are aiming to assess the impact of two BUVS, UV327 and UV328, on early-life stages of rainbow trout (*Oncorhynchus mykiss*). Freshly fertilized eggs have been microinjected with serial doses of UV327 or UV328 and are being reared until complete yolk sac absorption. Upcoming termination of the assay, subsets of larvae will be used to assess a variety of apical endpoints (developmental malformations, histology) and for RNAseq. The objective is to identify apical and transcriptomic points-of-departure (aPOD and tPOD, repsectively); that is, to identify doses at which the selected BUVs induce a shift in the whole-body tPOD and aPOD of exposed rainbow trout embryos. Subsequent data can then be utilized by environmental risk assessors to identify safe environmental concentrations, as demonstrated by several tPOD studies.

1.12.P-Th075 Developing a Bioindicator Yoolbox for Monitoring the Tisk of Plant Protection Product Residues in Soil

Gilda Federica Dell'Ambrogio[1]*, Jean Mathieu Renaud*[1]*, Sophie Campiche*[2]*, Mireia Marti-Roura*[1]*, Alena Tierbach*[1] *and Benoit J.D. Ferrari*[1]*, (1)Swiss Centre for Applied Ecotoxicology, Switzerland, (2)Envibiosoil, Gollion, Switzerland*

Soils contain complex networks of organisms which provide critical ecological functions allowing the balance, maintenance and resilience of the soil ecosystem. In agricultural soils, the functions performed by soil organisms play a critical role in maintaining soil fertility. However, agricultural soils can contain a range of plant protection product (PPP) residues, which can disrupt soil functions and soil fertility. To protect soil organisms and their functions, it is important to establish a toolbox of bioindicators to assess the impact of PPP residues on soil fertility.

The selection of a toolbox of bioindicators consisted of multiple steps. First, the actors (i.e., soil organisms) with a role in ecological soil functions supporting soil fertility were identified, based on key scientific references, using an ecosystem service framework to harmonize the information. Then, actors were ranked by their degree of connectiveness to different ecological processes and the relative importance of ecosystem services to soil fertility, as perceived by different stakeholders involved. The final scoring of the actors is the weighted (by stakeholder importance) connectiveness of organisms to processes and consequently ecological soil functions.

Bioindicator tools will be selected for the highest scoring actors, from available standardized guidelines or well-established test methods. The selection of the most appropriate methods will be performed in consultation with international experts for each key actor group, based on the applicability, cost and quality of data generated for each method. In addition to "ready to use" methods, experts will be inquired on promising methods that require future developments. The final toolbox selection aims to include both laboratory (ecotoxicological) and field (ecological) indicators.

In next steps, the bioindicator toolbox will be experimentally tested in pilot studies. Pilot studies aim at further refining the toolbox, establishing the sampling experimental design and developing normal operating ranges for bioindicators. Establishing normal operating ranges is critical to discriminate the effects of PPP residues from natural variability within a monitoring scheme.

1.12.P-Th076 Proposal for the Validation Process of the Methodology for the Quantitative Analysis of Microorganisms
*Josep Antoni Aguilar-Alberola, **Carmen Gimeno** and Adrian Martinez, Eurofins Trialcamp, Spain*
A large part of the studies for the validation process of the methodology for the quantitative analysis of microorganisms are based on the SANTE/2020/12830, Rev. 1 (2021). However, this guidance, as indicated by itself, is not intended for biological agents. Despite this, due to the lack of specific guidelines to carry out these studies, the methodology described in this poster is based on the principles indicated in SANTE, but adapted to the peculiarities of microbiology. The main reason for this is that the microbiological analysis is direct and does not depend on the signal of a detector as happens for chemical products.

The peculiarities associated with the storage of samples are also considered, since, in most cases, there are no methodologies described for the preservation of samples that contain microorganisms, whereas the stabilization and preservation methods for chemical products are known (in most cases by freezing) that allow the storage of samples for their later analysis.
A very important point to take into account in microbiology are the reproducibility conditions during the analysis of the samples, while aspects such as linearity and LOD are not really important. Furthermore, due to the intrinsic variability of microbiological methods, parameters such as the allowable recovery range, as well as specificity, must be reviewed and adapted. The matrix effect also deserves special mention, since, in microbiology, this effect may not simply be affecting its detection, but rather the viability of the microorganism.

1.12.P-Th077 Evaluation of the Effects of a Sequential Application of Plant Protection Products on Soil Microbes and Free-Living Nematodes in a Field Experiment
***Camilla Drocco**[1], Anja Coors[1], Marion Devers-Lamrani[2], Saúl Fernandes[3], Fabrice Martin-Laurent[2], Bernhard Förster[1], Aymé Spor[2], Clémence Thiour-Mauprivez[2] and Liyan Xie[4], (1)ECT Oekotoxikologie GmbH, Floersheim am Main, Germany, (2)INRAE, Institut Agro, Université de Bourgogne, Université de Bourgogne Franche-Comté, Agroecologie, France, (3)Amsterdam Institute for Life and Environment (A-LIFE), Section Ecology & Evolution, Vrije University Amsterdam, Netherlands, (4)Aarhus University, Denmark*
Plant protection products are sprayed in conventional agriculture and integrated pest management to ensure an adequate production of food and fibers. During the growth cycle of a crop, several different plant protection products (PPPs) are usually applied, in combination or separately. Such sequential applications of PPPs result in a mixture of residues of active ingredients (a.i.) in the soil. The residues of a.i. are then dispersed in the environment and can reach nontarget organisms in the soil, including soil microbial communities, and may affect ecosystem services supported by these communities. This mixture scenario, rather frequent, has rarely been addressed experimentally. In this regard, the EFSA (European Food Safety Authority) recently published a scientific opinion (2017) inciting to include more soil microbe-mediated processes in environmental risk assessments of agrochemicals. In addition, PPPs could also affect free-living nematodes, a soil health indicator that is not well studied yet.

The objective of this study was therefore to evaluate the effect of the sequential application of PPPs on soil microbial community structure and functioning, and on free-living nematode abundance. To do so, triplicated plots in the field were treated either with an herbicidal PPP (150 g/ha clopyralid), an insecticidal PPP (75 g/ha cypermethrin), a fungicidal PPP (250 g/ha pyraclostrobin), or their sequential mixture at 1x or 10x the agronomical dose. Sequential applications were done one week apart from each other, and plots were sampled one day before the respective applications and day 7 and 28 after applications. Control and mixture plots were sampled at every timepoint over the 45 days. The ecotoxicological impact was evaluated on bacterial and fungal communities' diversity and structure using sequencing of 16S rDNA and ITS gene amplicons, and on the abundance of nematode.

We hypothesized that the mixture resulting from the sequential application of PPPs, especially at the highest dose applied, would have a stronger impact the structural and functional endpoints than the sequential application of PPPs. The results from this work will provide new knowledge and insights for the scientific community and may help fill the regulatory gaps on the assessment of risk of PPPs mixture for in soil living organisms.

1.12.P-Th078 Differing Sensitivity of *Folsomia candida* and *Encytraeus crypticus* to Pesticides and their Mixtures
***Emily Eagles**[1], Stephen James Short[2], Sylvain Bart[3], Alex Robinson[1], Kevin Noort[1], Fie Rubner-Petersen[1], Elma Lahive[1], Peter Kille[4] and David J Spurgeon[1], (1)UK Centre for Ecology & Hydrology (UKCEH), United Kingdom, (2)Pollution, UK Centre for Ecology & Hydrology (UKCEH), United Kingdom, (3)Ministère de l'Écologie, du Développement durable, des Transports et du Logement, France, (4)Cardiff University, United Kingdom*
In agricultural environments soil organisms are often exposed to mixtures of pesticides. Understanding and assessing mixture exposures requires consideration of the potential interactive effects of chemicals. In combination chemicals may have differing

toxicity to what is expected if synergistic or antagonistic interactions occur. Here, two soil detritivores were considered in acute pesticide toxicity assays, first in single chemical exposures then in binary mixtures, to assess the mixture effects and any differences between species toxicity. Juvenile *Folsomia candida* and adult *Enchytraeus crypticus* were exposed to pesticides; Azoxystrobin, Chlorothalonil, Clothianidin, Cypermethrin, Imidacloprid and Prochloraz (and selected mixtures of these), with survival monitored through time. This allowed for toxicokinetic (TK) - toxicodynamic (TD) models, the General Unified Threshold model for Survival (GUTS), to be used to predict the effects of mixture exposures through time which were compared with the observed survival data. The two species showed differing sensitivity to the tested pesticides, in the single chemical exposures, with the highest sensitivity being to Imidacloprid for *F. candida* and Cypermethrin for *E. crypticus*. Mixture studies showed within a binary exposure both synergism and antagonism may occur, varying with dose and time. Therefore, chemical combinations cannot always simply be labelled as synergistic or antagonistic. The TK and TD traits of each species may contribute to the differing species sensitivity seen here. Our ongoing studies are considering these, TKs - through uptake rates measured via radiolabelled pesticide exposures, and TDs – by using molecular analysis of pesticide target receptors.

1.12.P-Th079 Assessment of the Oxidative Potential of Fine Particles $PM_{2.5}$ According to their emission sources

Anthony Verdin[1]*, Yamina Allouche*[2]*, Marc Fadel*[3]*, Frédéric Ledoux*[3] *and Dominique Courcot*[3]*, (1)UCEIV, University of the Littoral Opal Coast, France, (2)Uceiv, Université du Littoral Côte d'Opale, France, (3)Unité de Chimie Environnementale et Interactions sur le Vivant, UCEIV UR4492, FR CNRS 3417, University of Littoral Côte d'Opale (ULCO), France*

Fine particulate matter ($PM_{2.5}$) present in the atmosphere are the subject of considerable attention from the scientific community and public authorities because of their proven impacts on climate and health. $PM_{2.5}$ form a complex mixture of chemical compounds that can differ according to emission sources. To implement effective air quality management policies, a better knowledge of the sources that contribute to the concentration of air pollutants as well as the assessment of their respective effects on health is necessary.

The objective of this study is to estimate the oxidative potential associated with the sources of fine particles that contribute to the ambient concentrations of $PM_{2.5}$ in the Dunkirk area, located in the North of France.

$PM_{2.5}$ were collected on four sites influenced by urban, road traffic, industrial and rural emissions. $PM_{2.5}$ from all four sites were chemically characterized, notably for the quantification of metal(oid)s, water-soluble ions, total carbon, and water-soluble organic compounds (Water-Soluble Organic Carbon (WSOC), Humic-Like Substances (HULIS), carboxylic acid, sugars, quinones as well as Polycyclic Aromatic Hydrocarbons (PAHs).

Oxidative potential has been evaluated by acellular tests, namely the ascorbic acid assay (OP-AA) and the dithiothretol assay (OP-DTT). These methods were chosen because they are easy to use, inexpensive, have high repeatability, and are complementary because they are not sensitive to the same chemical species and particle sources.

1.12.P-Th080 Differential Gene Expression of Freshwater Macroinvertebrates Exposed to Pesticide Mixtures: A Pilot Study in Agriculture Areas in Southern Sweden

Pedro A. Inostroza*, Sameer Hassan, Henrik Aronsson and Thomas Backhaus, University of Gothenburg, Sweden*

The expansion and intensification of agriculture activities and consequently the associated pesticide pollution remain one of the most important human stressors to aquatic ecosystems worldwide. Pesticides are designed to interact with specific pests' target sites and disrupt their biological pathways, which ultimately will lead to reduce their abundances. Unfortunately, pesticides end up in nearby water bodies forming pesticide mixtures and affecting, in the same manner, nontarget organisms' pathways reducing their ecological functions and/or eventually their biodiversity. Aquatic benthic invertebrate fauna represents one of the Biological Quality Elements, which is used to determine the Ecological status of surface water bodies according to the EU Water Framework Directive. They are therefore extensively used as biological indicators to assess water quality. Nevertheless, a thorough understanding of the adverse biological consequences of pesticide mixtures at the pathways level under real exposure conditions is still absent. There is not a standard approach defined to unveil such effects and most of the evidence available is based on single gene assessment. In this study, an RNA-based-sequencing (transcriptomic) approach was applied to shredder invertebrate *Gammarus pulex* populations to face the mentioned challenge. Nontargeted gene assessment provides evidence of expected chemical-target site interactions but also allows the identification of novel pathways under chemical stress. Our results suggest an overall significant downregulation of invertebrate genes exposed to pesticide mixtures in small streams. We did also rank differentially expressed genes in order to generate a comparative expression map between invertebrate population living in stressed streams and reference conditions (low human impacts). Finally, a pathways enrichment analysis allowed us to identify classes of genes being over-represented under pesticide mixture stress and link these responses to particular pesticide groups.

1.12.P-Th081 Effect of Pesticide Residue Mixtures on *Lumbricus rubellus*: The SPRINT Approach

Kayode Jegede[1]*,* ***Fanrong Meng***[2]*, Paula S. Tourinho*[3]*, Jakub Hofman*[3] *and Violette Geissen*[2]*, (1)Soil Physics and Land Management, Wageningen University & Research, Netherlands, (2)Wageningen University & Research, Netherlands, (3)RECETOX, Masaryk University, Czech Republic*

The risk assessment of pesticides have been based on single pesticides, which is not reflective of the reality. In realistic scenarios, pesticides are found in the environment as mixtures, therefore risk assessment of pesticides should be based on mixtures. Moreover, toxicity tests used for risk assessment have been based on the use of one or few standardized species, e.g., *Eisenia fetida*, which may not represent ecological realism. It is in this knowledge that our study also assessed pesticide mixtures on a native earthworm species, *Lumbricus rubellus*. For this study, 11 case study sites - CSS (10 European and 1 South American) representing all EU biogeographical zones and eight (n =8) main cropping systems. From the pesticide residue analysis of each CSS, five pesticides were prioritized as mixtures specific for each CSS. The mixture toxicity of the five pesticides were then assessed in a dose-response experimental design at environmentally relevant concentrations - measured environmental concentrations (MEC), EFSA predicted environmental concentration (PEC) and five times PEC (5 x PEC) and control (no pesticides) for the eleven CSS. The toxicity of the pesticides varied across the CSS with some significant effect observed at levels below PEC in some CSS and some CSS did not show any effect of the pesticides at all concentrations tested. The results are relevant for risk assessment of pesticide mixtures in EU representative of cropping systems and biogeographical zones, using an important soil ecological receptor native to Europe.

1.12.P-Th082 Compare the Effects of Different Mixture Pesticides on Earthworm

***Fanrong Meng**, Wageningen University & Research, Netherlands*

Increased use of pesticides has also resulted in the bio-accumulation and diffusion of pesticides and/or their metabolites in soil, water, and atmosphere which may eventually pose threats to environment and human health. Due to the ecosystem function of earthworms in the soil, they are often exposed to pesticides and are sensitive. Therefore, earthworms are selected as bioindicator species for contamination in the soil. Although most studies including the current regulations and legislations are mainly focused on single contaminants, it is apparent that the pesticides that occur in agricultural fields are mixtures instead of a single contaminant. Apart from additive effects, the interactions of agrichemicals can be synergistic, or antagonistic, which is largely unknown. This current study assessed pesticide residues of arable soils in 10 EU member states, which are the Netherlands, Czech Republic, France, Portugal, Switzerland, Slovenia, Croatia, Denmark, Italy, and Spain. Based on their detected frequency and concentration, different mixtures made up of five pesticides each were selected for assessing the toxic effects of pesticides at environmentally relevant concentrations on soil ecosystem. Toxicity tests with these pesticide mixtures, following standardized test guideline with earthworms (*Eisenia Fetida*), were conducted. We hope the results can fill some knowledge gap between current single pesticide test and complexity of the in-situ soil situation.

1.12.P-Th084 Bottom-up Proteomics Analysis for Adduction of the Broad Spectrum Herbicide Atrazine to Mammalian Histone Proteins

*Shaogang Chu[1] and **Robert J. Letcher**[2], (1)Environment Canada, Canada, (2)Science and Technology Branch, Environment and Climate Change Canada, Canada*

Chemical pollution remains a poorly understood human-driven environmental change, and the impact is largely unknown for humans exposed to mixtures of over 350 000 chemicals registered for industrial use. Proteins are the direct mediators of cellular processes and (potential) targets of chemical contaminants. There is estimated to be 20 000 proteins in the human proteome. Proteins can covalently adduct at active amino acid residues with endogenous or exogenous chemicals including drugs, pesticides or their metabolites. Longer term research has demonstrated that these protein-adducts might lead to multiple health issues. Therefore, identification of xenobiotics adducted to key proteins and identification of the sites of adduction within the protein are important for a better understanding of events underlying diseases and chemically induced adverse reactions. Xenobiotics can react with multiple proteins at multiple sites and identification and characterization of adducted proteins are complicated by analytical challenges. Atrazine (2-chloro-4-[ethylamino]-6-[isopropylamino]-1, 3, 5-triazine) and is commonly and mainly used for control of broadleaf and grassy weeds. Histones are the major proteinaceous component of chromatin in eukaryotic cells and an important part of the epigenome. However, to our knowledge, there has been no research on the formation of atrazine adducts with histone. In this study, a bottom-up proteomics analysis method was optimized and applied to identify histone adduction by atrazine *in vitro.* Whole histones of calf thymus or human histone H3.3 were incubated with atrazine. After solvent-based protein precipitation, the protein was digested by trypsin /Glu-C and the resulting peptides were analyzed by high-performance liquid chromatography–tandem high resolution mass spectrometry (UHPLC-MS/MS). The resulting tryptic/Glu-C peptide of DTNLCAIHAK from calf thymus or human H3.3 was identified with an accurate mass shift of +179.117 Da in atrazine incubated samples. A chemical group with elemental composition of $C_8H_{13}N_5$ (179.1171 Da) from atrazine adducted with calf thymus or human histone H3.3. MS/MS analysis confirmed that the adduction position was at its cysteine110 residue. Time and concentration dependent assays also confirmed the formation of histone H3.3 covalent adduct with atrazine *in vitro*. Thus, the potential exists that atrazine adduction may lead to the alteration of histones that subsequently disturbs their normal function.

1.13 Towards a One Health Approach to Integrating Human Toxicology, Ecotoxicology and Ecological Impacts of PFAS and Related Chemicals

1.13.P-Th085 Lessons Learned: Considerations for PFAS Field Sampling Design

***Sara J. Hutton**, Kenia Whitehead, Janet Anderson and Philip E Goodrum, GSI Environmental, Inc.*

Per- and polyfluoroalkyl substances (PFAS) have emerged as contaminants of concern across an increasing number of sites undergoing remediation. The diversity of PFAS chemical characteristics combined with varying environmental factors has created a unique set of challenges in estimating and understanding how these compounds bioaccumulate in different systems. Literature values for chemical-specific bioaccumulation factors (BAFs) range by several orders of magnitude across different sites and taxa and between laboratory and field study conditions. We examine how abiotic factors can improve predictive models of fish tissue concentrations, and whether sampling designs can be optimized to better describe the key factors that explain variability. In addition, there is ongoing debate regarding the science supporting different regulatory approaches to PFAS mixtures, ranging from treating all PFAS as a single chemical class to evaluating specific chemical groups or individual compounds. We examine possible limitations to the single class approach given the variability in PFAS uptake and toxicity. Field sampling occurred in freshwater streams and included analysis of sediment, surface water, aquatic vegetation, macroinvertebrates, and fish for various PFAS compounds. Fish data include various trout, perch, bluegill, and bass species. For our analysis for risk assessment, we explored the associations between abiotic conditions (i.e., pH, conductivity, temperature, hardness, and dissolved/total organic carbon) and BAFs. The results from our study indicate that PFAS uptake in fish is mediated via direct and indirect pathways from sediment and surface water to organisms. Our analyses highlight the complex pathways of PFAS from abiotic media into fish and indicates BAF/BSAF ratios alone may not be sufficient to predict fish tissue concentrations from surface water and sediment. Variability in data between field sites emphasizes the need to design sampling methods with the intent of capturing a wide net to account for variables influencing BAF/BSAFs. Examples of confounding variables include 1) differences in sampling whole body vs. fillet tissue and 2) abiotic factors that influence bioaccumulation, here we found conductivity to be important when predicting PFOS concentrations in fish at our site.

1.13.P-Th086 Exposure and Adverse Effects of PFAS in Resident Passerine Birds Breeding Nearby a Perfluoropolymer Plant

Marco Parolini[1]*, Sara Valsecchi*[2]*, Michelangelo Morganti*[2]*, Beatrice De Felice*[1]*, Marianna Rusconi*[2]*, Maria Teresa Palumbo*[2]*, Diego Rubolini*[1] *and Stefano Polesello*[2]*, (1)University of Milan, Italy, (2)Water Research Institute - Italian National Research Council IRSA-CNR, Italy*

Per- and polyfluoroalkyl substances (PFAS) encompass a large, heterogeneous group of chemicals of potential concern to human and environmental health. Among PFAS, in recent years the attention has been focused on emerging, short-chain compounds, which are expected to be less persistent, bioaccumulative and toxic, but more used and discharged in the environment, than their legacy, long-chain relatives. Whilst the information on the occurrence, the fate and the potential toxicity of some legacy PFAS is consolidated, there is a lack of knowledge for emerging PFAS. The present study aimed at monitoring the occurrence and adverse effects of legacy and emerging PFAS mixture nearby a perfluoropolymer plant (PFP) located in the Western sector of the Po River valley (Northwestern Italy). The presence of legacy and emerging PFAS was measured in the eggs of two resident species, the European starling (*Sturnus vulgaris*) and the Great tit (*Parus major*), breeding in nest-boxes located nearby the PFP. The adverse effects, in terms of the onset of an oxidative stress condition, were assessed on blood sample of nestlings of the same species. The concentrations of both legacy and emerging PFAS measured in the eggs from nest-boxes located nearby the PFP were higher compared to those from a control site. Accordingly, a modulation of antioxidant defenses and an increase in lipid peroxidation levels were noted in *S. vulgaris* nestlings born nearby the PFP compared to conspecifics from the control area. Our results showed that the exposure to environmental mixture of PFAS nearby a PFP can induce adverse effects on free-living organisms, suggesting the necessity of field studies to assess the risk of these emerging compounds.

1.13.P-Th087 Pre- and Postnatal Exposure to Per- and Polyfluoroalkyl Compounds (PFAS). Unravelling the Early Exposure to “the Forever Cemicals”.

Anne San Román Martínez[1]*, Nestor Etxebarria*[2]*,* ***Belen Gonzalez-Gaya***[3]*, Amaia Irizar*[4] *and Eunate Abilleira*[5]*, (1)Dept. Analytical Chemistry, Epidemiology and Public Health, University of Basque Country, IIS Biodonostia, Spain, (2)University of the Basque Country (UPV/EHU), Spain, (3)ESTACION MARINA DE PLENTZIA. UPV/EHU, Spain, (4)Epidemiology and Public Health, University of Basque Country, Spain, (5)Epidemiology and Public Health, University of Basque Country, IIS Biodonostia, Spain*

The presence of per- and polyfluoroalkyl substances (PFAS) in numerous types of samples represents a latent threat to human health and for the environment. In fact, these compounds are frequently found in human serum samples and this presence has been associated with various physical alterations and behavioral difficulties in children and teenagers. However, the association between health problems and the exposure to PFAS is often inconsistent, challenging the assessment of chronic exposure.

In this work, we want to evaluate the bioaccumulation of PFAS through the analysis of plasma samples (n = 498) in children of various ages (4, 8, and 12 years) and three origin cohorts from Spain (Gipuzkoa, Sabadell, and Valencia). Moreover, the links of a chronic exposure to these compounds by the drinking water supply will be assessed by analyzing actual occurrence of PFAS in those cohort areas as well as the different behavior impairments.

To this end, a targeted instrumental analysis method for the quantification of the largest possible number of PFAS in both plasma and water samples through High Performance Liquid Chromatography coupled to High Resolution Mass Spectrometer (HPLC-HRMS) has been optimized. Moreover, different extraction protocols specific for each matrix have been tested to establish the most adequate procedure for each case, making a complete validation of the selected method.

In this sense, the presence of these compounds in plasma samples has been studied and the different statistical approaches will give us a new perspective about the early exposure profiles in plasma of children and teenagers. Also, drinking water analyses will give us information about PFAS levels at one of the most relevant exposure sources.

1.13.T-01 Macroinvertebrate Community Responses to PFAS Pollution: Identification of Threshold Body Burdens

Cara Byns[1]*, Thimo Groffen*[2] *and Lieven Bervoets*[2]*, (1)Universiteit Antwerpen, Antwerpen, Belgium, (2)University of Antwerp, Belgium*

The pollution of perfluorinated alkyl substances (PFAS) in aquatic environments is a worldwide environmental concern with complex regulatory challenges. Today, most scientific studies focus on the distribution and bioaccumulation of PFAS while the ecological impact of PFAS contamination on aquatic communities is less studied. This lack of understanding goes along with a lack of regulatory measures such as the derivation and implementation of suitable quality standards (QS). In Europe, biota and environmental quality standards have only been set for a limited amount of PFAS, while more than 4000 different compounds are produced. Moreover, the current biota quality standard (BQS) for PFOS was derived for the protection of human health and secondary poisoning of top predators. Therefore, the derived BQS might not be adequate for the protection of aquatic communities.

To study the impact of PFAS on a community level, we assessed the macroinvertebrate community structure from 35 rivers and streams across Flanders, Belgium. Aquatic macroinvertebrate communities can reflect the cumulative impact of short- and long-term pollution events because some taxa are more sensitive to pollution than others. At each site, accumulated PFAS concentrations were measured in the biotic (invertebrates) and abiotic environment (water and sediment). Additionally, physicochemical water and sediment properties such as pH, conductivity, cation exchange capacity, clay content, and total organic carbon (TOC) were assessed. The main aim of this research is to study the relationship between the accumulated PFAS levels and the invertebrate community structure to derive threshold body burdens that are protective of aquatic communities. To assess the community structure the multimetric index of Flanders (MMIF) was used. Secondly, we aim to evaluate the existing QS for biota, sediment and water by comparing them with the derived thresholds from this research. Lastly, we aim to study the relationship between PFAS in the biotic and abiotic environment and the influence of physicochemical properties on this relationship.

1.13.T-02 Acute Toxicity of Seven Perfluoroalkyl Substances (PFAS) in *Daphnia magna* and *Raphidocelis subcapitata*
Edoardo Pietropoli[1]*, Marianna Pauletto*[2]*, Martina Zanella*[2]*, Valentina Simonato*[2]*, Mery Giantin*[2]*, Marco De Liguoro*[2] *and Mauro Dacasto*[2]*, (1)Comparative Biomedicine and Food Science, University of Padua, Italy, (2)University of Padua, Italy*
Among environmental pollutants of emerging concern, perfluoroalkyl substances (PFASs) are one of the classes of compounds most in the spotlight. Currently, there are few or as yet unknown effects that PFAS emissions may cause on aquatic ecosystems. Among the thousands of known PFASs, this research project evaluated the toxicity of several compounds that are normally found in the environment. Some of them are well-known compounds, such as PFOA and PFNA, while others are considered to be replacement compounds for new-generation PFASs, such as PFHpA, PFHxA, PFBA, PFBS, and GenX. As the Environmental Protection Agency is constantly seeking updated toxicological data to assess the toxicological framework of PFASs, this study provides toxicity data on two aquatic trophic levels. PFAS toxicity was evaluated on *Daphnia magna* according to the OECD 202 test and on *Raphidocelis subcapitata* according to the US-EPA OCSPP 850.4500: Algal Toxicity test. Among the two species, it was generally observed that algae are more sensitive to PFAS than daphnia. In fact, the EC_{50} value for the compound under analysis was lower for algae (EC_{50} mg/L: PFNA, 90.5; PFOA, 45.54; PFHpA, 385.98; PFHxA, 957.42; PFBA, 30.03; PFBS, 105.8; GenX, 738.0) than the Daphnids (EC_{50} mg/L: PFNA, 187.5; PFOA, 705.9; PFHpA, >1000; PFHxA, >1000; PFBA, >1000; PFBS, >1000; GenX, 785.7). These data suggest that the alga *Raphidocelis subcapitata* is more sensitive to these molecules than *Daphnia magna*. As noted by previous research, PFASs can impair the photosynthetic system, causing downstream alteration of cell duplication and inhibition of algal growth. Since it appears that *Daphnia* is not the most sensitive organism to these molecules in acute exposure, this does not mean that these compounds cannot cause reproductive and growth damage in chronic exposure. In fact, it has been observed that following the organisms for another ten days after acute exposure the toxicity is more severe than that observed at 48 h of exposure, confirming the delayed toxicity. These data will be crucial to better understand the real impact of these molecules on the environment. In addition, they will be useful in laying the groundwork for further research on the chronic toxicity of PFASs and their possible interaction in mixtures.

1.13.T-03 Per- and Polyfluoroalkyl substances (PFAS) Exposure Dysregulates Neural Activity, Exacerbates Microglial Injury Responses, and Sensitizes Larval Zebrafish to the Convulsant Pentylenetetrazole
Jessica Plavicki[1]*, Shannon E Paquette*[2]*, Manuel A Camarillo*[2]*, Chloe Wray*[2]*, Katherine Manz*[2]*, Dana Biechele-Speziale*[2]*, Nathan Martin*[2] *and Kurt Pennell*[2]*, (1)70 Ship Street, (2)Brown University*
Per- and polyfluoroalkyl substances (PFAS) are global contaminants that are classified as presumed immune hazards due to their adverse effects on adaptive immunity. However, comparatively little is known about how PFAS exposure affects the innate immune system. Microglia, the innate immune cells of the brain, are essential for responding to pathogens and injury, and also play critical roles in shaping brain development and homeostasis. Our prior work using zebrafish demonstrated developmental exposure to perfluorooctane sulfonate (PFOS) produces an activated microglial morphology and results in the upregulation of *p2ry12*, a G-coupled protein receptor involved in microglial activation and migration. Perfluorooctane sulfonate-induced microglial activation resulted in a heightened microglial response to brain injury, which could be rescued by using optogenetics to drive microglia toward a homeostatic state. We found the PFOS exposure increased neural activity and that the neuronal signaling environment modulated microglial activation state. Optogenetic silencing of the neurons was sufficient to normalize the microglial morphology and response to injury in PFOS exposed larvae. To further examine the relationship between immunotoxic PFAS congeners and neuron-microglial communication, we exposed zebrafish larvae to perfluorooctanoic acid (PFOA), an 8-carbon PFAS with a carboxylic functional group. Exposure to PFOA did not alter microglial responses to injury or the neuronal signaling environment, suggesting PFAS congeners have differential effects on neural activity. Consistent with this interpretation, we found perfluorohexane sulphonic acid (PFHxS), but not perfluorobutane sulfonic acid (PFBS) increased brain activity. Given that PFOS and PFHxS heightened neural activity, we next asked whether low level exposure to PFOS (2 uM) or a mixture of PFAS sensitized zebrafish larvae to the GABAA receptor antagonist and convulsant, pentylenetetrazole (PTZ). Exposed larvae were incubated in subthreshold concentrations of PTZ that do not elicit seizures in control larvae. Behavioral assays revealed a differential response to PTZ in larvae exposed to the PFOS (2uM) or a PFAS mixture that contains equal proportions of PFOS,

PFHxS, PFBS, GenX, and PFOA at a concentration of 1 uM/congener. We are currently performing electrophysiological recordings in PFAS-exposed larvae both with and without subthreshold concentration of PTZ to better understand the impact of PFAS exposure on neural systems.

1.13.T-04 Neurotoxicity of Novel Perfluoroalkyl Ether Carboxylic Acids (PFECAs) in Earthworms (*Eisenia foetida*)

Davide Rotondo[1], Davide Gualandris[1], Marcello Manfredi[2], Candida Lorusso[1], Antonio Calisi[1] and ***Francesco Dondero**[3]*, *(1)Department of Science and Technological Innovation, Università del Piemonte Orientale, Italy, (2)Department of Translational Medicine, Università del Piemonte Orientale, Italy, (3)Department of Science and Technological Innovation, Università del Piemonte Orientale, Alessandria, Italy*

New generation PFASs often incorporate one or more ether groups into their chemical structure for the purpose of reducing environmental persistence and potential bioaccumulation in biota. However very little is known about their toxicological properties and for this reason they are also called poor-data PFAS.

In the nematode PFAS (sensu strictu PFOS) neurotoxicity is mediated by mitochondrial impairment and superoxide stress. Using Perfluorooctanoic acid (PFOA) as a reference compound, we investigated the neurotoxic effects of three novel perfluoroalkyl ether carboxylic acids (PFECAs) with carbon chain between C4-C6 (PF3MOPrA, PF4MOBA, HFPO-DA) in the terrestrial oligochaetes *Eisenia foetida* exposed by means of the filter paper test (OECD Test.207).

Acetylcholinesterase (ACHE) activity was measured in earthworm tissues extract (SN10) obtained from animals exposed for 72 h to PFOA or each PFECA congener in a range of 0.6-229 microM. PFOA elicited an overall increase of ACHE activity with some characteristics of hormesis suggesting potential anticholinergic effects. PF3MOPrA and PF4MOBA showed a similar trend, while a moderate threshold inhibition was observed for HFPO-DA.
SOD activity was also evaluated by means of in gel assay. Preliminary results seem to indicate a dose dependent increase of enzyme activity in tissue protein extracts of PFOA and PFECAs.
To confirm the development of neurotoxicity triggered by PFAS neurotransmitter measurement is ongoing by means of a targeted LC-MS approach in a UHPLC Vanquish system coupled with an Orbitrap Q-Exactive Plus, identifying and quantifying more than forty molecules and precursors such as GABA, melatonin, serotonine, TMAO, acetylcholine, tryptophan, indols, dopamine.
A set of behavioural tests will complete the neurotoxicological assessment to classify the hazard of next generation PFAS.

1.13.P Towards a One Health Approach to Integrating Human Toxicology, Ecotoxicology and Ecological Impacts of PFAS and Related Chemicals

1.13.P-Th089 Towards an Integrated Approach for Testing and Assessment of PFAS – Integration of Experimental and Computational Approaches, from Literature and Developed within SCENARIOS

***Iseult Lynch**[1]*, *Panagiotis D. Kolokathis[2], Konstantinos D. Papavasileiou[2], Georgia Melagraki[3], Eva Junque[4], Peng Zhang[1], Tiziano Verri[5], Tommaso Serchi[6], Francesco Dondero[7] and Antreas Afantitis[8], (1)University of Birmingham, United Kingdom, (2)Department of ChemoInformatics, NovaMechanics MIKE, Greece, (3)Chemoinformatics, Entelos Institute, Larnaca, Cyprus, (4)University of Birmingham, Birmingham, United Kingdom, (5)Università del Salento, Italy, (6)Luxembourg Institute of Science and Technology (LIST), Luxembourg, (7)Department of Science and Technological Innovation (DISIT), Università del Piemonte Orientale, Italy, (8)NovaMechanics Ltd., Cyprus*

Per- and polyfluorinated alkyl substances (PFASs) are a large, complex group of manufactured chemicals with widespread use in aerospace, automotive, construction, and electronics industries. The OECD estimated that >4000 PFASs have been produced and used in a broad range of industrial and consumer applications. However, little is known about the potential hazards (e.g., bioactivity, bioaccumulation, and toxicity) of most PFASs, and the vast majority of data on the health effects of PFAS family chemicals have been done on just a handful of chemicals. Thus, for the vast majority of PFAS compounds there is insufficient data on hazard (or exposure) on which to make a risk assessment as to their safety for use in consumer products.

SCENARIOS is developing a computational approach to expand and extend the long-term toxicity assessment and risk assessment methods that have been applied for the well-studied PFAS members to members that are currently non-regulated PFAS, or for which there is very limited experimental data. The initally developed workflow contains modelling and data analysis components that can be adjusted to the available data in each case ('omics, *in vitro*, or *in vivo*), and is formulated as an Integrated Approaches to Testing and Assessment (IATA) for risk assessment of PFAS. In due course the approach will also be applied to PFAS congener mixtures, enhancing and enabling a one health approach to environmental and human health protection.

Here we present the first iteration of the IATA, which has been applied to a set of 34 data-poor PFAS molecules as the basis for the extension to the models to data-poor PFAS candidates, based on the k Nearest neighbour (kNN) approach. KNN is an instance-based (lazy) method that predicts the dependent variable based on the distance of the k (k = 1, 2, 3, …) nearest neighbours. Based on binding data to transthyretin (TTR) a key membrane transport protein, cytochrome P450 1a, a protein involved in the biotransformation of chemicals in the liver, and 1,2-dioleoyl-sn-glycero-3-phosphocholine (DOPC) the major component of the lipid bilayer, a set of QSAR models based on protein / lipid binding, bioavailability, and toxicity was established, and the experimental validation of the predictive power of the models was confirmed experimentally. The integration of the various models, supplemented by machine learning models from the literature, into a first version of an overall IATA for risk assessment of PFAS will be presented.

1.13.P-Th090 Toxicological Assessment of PFAS in Embryonic Zebrafish Cells and its Implications for Human Health
Eva Junque[1]*, Tiziano Verri*[2] *and Iseult Lynch*[3]*, (1)University of Birmingham, Birmingham, United Kingdom, (2)Università del Salento, Italy, (3)University of Birmingham, United Kingdom*
Per- and polyfluoroalkyl substances (PFAS) persist in the environment, bioaccumulate through the food web, and are toxic for humans. This class of chemicals is very broad and only a few members are well studied, leading to gaps in knowledge and limited risk assessment. To overcome this, alternative test systems are needed to enable screening of a wider range of PFAS chemicals and extrapolation of knowledge from data-rich PFAS to data-poor ones. Adverse Outcome Pathways (AOPs) are an emerging approach to organise molecular, cellular, and whole organism toxicity information in order to link from an initial exposure and molecular initiating event through a set of key events to an adverse outcome. Thus, other chemicals that trigger similar key events are likely to lead to the same adverse outcome, reducing the need for animal testing.

Here, we present results from a literature screening of PFAS toxicity and its organisation into an AOP, and building on this, toxicity screening data on a suite of 34 PFAS chemicals utilising a zebrafish embryonic cell model (ZF4), which is a suitable model to explore chemical toxicity in the aquatic environment and for extrapolation of effects in human beings. The suite of endpoints assessed includes cell viability, membrane permeability, oxidative stress induction, upregulation of multidrug resistance protein 4 and multiresistance-associated protein 1, and expression of glutathione S-transferase and cytochrome P450 1A associated with PFAS biotransformation. ZF4 cells were cultured in a DMEM/F12 supplemented with 1% penicillin and streptomycin at 28 °C and saturated with 5% CO_2 in a humidified atmosphere. Cells were exposed to three different environmental concentrations of each PFAS with three replicates. Dose-response curves were established, and modes of action and biotransformation assessed.

Based on the screening results, 10 PFAS will be selected for more detailed mechanistic studies in zebrafish, which will be exposed in semistatic conditions at environmental PFAS concentrations and sampled at regular intervals. For each sampling, several organs will be inspected for abnormalities and PFAS content will be evaluated via biodistribution studies and used to establish a zebrafish PBPK model for environmental risk assessment providing a maximum residue level which will help the authorities in determining the global regulatory PFAS levels.

1.13.P-Th091 Perfluorooctanesulfonic Acid Induced Seizurogenic Effect in Zebraifh Larvae
Il woo Kim*, Eun Ki Min and Kitae Kim, Seoul National University of Science and Technology, Korea, Republic of (South)*
While the developmental neurotoxicity of perfluorooctane sulfonate (PFOS) has been reported, its seizurogenic potential has not been investigated. Behavior assessment was conducted in zebrafish larvae exposed to PFOS at concentrations of 0, 0.1, 1, 5, 10, and 20 μM. Changes in electrophysiological signals and in the concentration of 20 neurochemicals were measured. Behavior assessment revealed that PFOS altered larval behaviors and significantly increased the counts and duration of bursting (an irregular high-speed movement). Electrophysiological analysis showed that the number of seizure-like events and duration of seizure-like signals were significantly increased, corresponding to results observed using pentylenetetrazol as a positive seizurogenic agent. The outbreak of seizures detected via abnormal electrophysiological signals was confirmed by the increased expression of c-fos and bdnf, which are typical seizure-related genes. Analysis of neurochemicals indicated that PFOS dysregulated overall neurotransmission systems, and aberrant endogenous concentrations of various neurochemicals in the amino acid, cholinergic, dopaminergic, serotonergic and kynurenergic, and GABAergic systems were associated with seizure-like behavior and signals. This study, the first to demonstrate that exposure to PFOS provokes a seizurogenic effect in developing zebrafish larvae, should stimulate further research on the association between PFOS exposure and neurodevelopmental toxicity or neurological disorders.

1.13.P-Th092 Integration of Multi-Omics Reveals the Analogous Developmental Neurotoxicity Mechanisms Between PFBS and PFOS in Zebrafish
Eun Ki Min *and Kitae Kim, Seoul National University of Science and Technology, Korea, Republic of (South)*
The differential biomolecular mechanisms between legacy per- and polyfluoroalkyl substances (PFAS) and their short-chained alternatives were studied at the same concentrations, which hampers our understanding of the potency of alternatives. We therefore compared the commonalities of PFBS and PFOS with profiled biomolecules of zebrafish larvae such as transcripts, proteins, and metabolites. PFBS showed approximately 700 times lower developmental toxicity than PFOS based on the benchmark dose (BMD) of embryonic mortality. Although the toxic potency was different, larval neurobehavior patterns were similar; hyperactivity was observed at the same ratio of lower concentrations on a BMD_5, and constant larval movement was observed at higher concentrations. Biomolecular profiles from individual omics analysis also indicated the similarities between PFBS and PFOS in oxidative stress, immune response, lipid metabolism, and energy metabolism. Knowledge-based integration of multi-omics was further applied to better understand the neurotoxicity of PFBS and PFOS. The integrated multi-omics analysis revealed the commonality in enriched pathways affected by both PFBS and PFOS such as dysregulation of various signaling pathways, lipids metabolism, amino acid metabolism, and oxidative response. In particular, the biomolecular mechanism that underlies the similar neurotoxicity of PFOS and PFBS was closely interlinked, including calcium signaling pathway, primary bile acid biosynthesis, and peroxisome. These findings demonstrated that integrated multi-omics is useful to explore neurotoxicity of PFAS alternatives as well as PFBS could be an alternative of PFOS because of low neurotoxicity in developing zebrafish embryos. However, the similarly dysregulated biomolecular mechanisms suggested that the potential risk of PFBS should also be carefully managed.

1.13.P-Th093 Identifying Bioactive Per- and Polyfluoroalkyl Substances (PFAS) from a Diverse Library and Their Mode of Action in Zebrafish

Lindsey St Mary[1]*, Yvonne Rericha*[1]*, Lisa Truong*[1]*, Michael T Simonich*[1]*, Ryan S McClure*[2] *and Robyn Leigh Tanguay*[1]*,*
(1)Oregon State University, (2)Pacific Northwest National Laboratory

Per- and polyfluoroalkyl substances (PFAS) are a structurally diverse class of chemicals of particular interest due to their impacts on both environmental and human health. Toxicological data are only available for a small number of the thousands of PFAS on the global market, and even fewer PFAS with transcriptomic information. A more complete understanding of PFAS hazard potential and modes of action by which PFAS induce toxicity is needed. We assessed the developmental toxicity of a structurally diverse PFAS library in zebrafish and conducted a transcriptomic investigation of bioactive compounds to fill this data gap. We screened two libraries: 139 PFAS stocks procured from the US EPA and 25 PFAS obtained directly from manufacturers (144 unique structures). Embryonic zebrafish were statically exposed in 96-well plates to 0.015-100 µM PFAS from 6 to 120 h postfertilization (hpf), and 10 morphological endpoints were evaluated (n = 36). Fifteen PFAS, which included those with sulfonic acid, sulfonamide, diacrylate, and diol substituents, induced morphological effect(s) in at least 80% of the test population and were selected for subsequent transcriptomic interrogation. Exposures were conducted at the concentrations that induced 80% effect (EC_{80}) by 120 hpf for each PFAS, sampling at 48 hpf (n = 4 pools of 10 embryos), before observable effects. We utilized Lexogen QuantSeq 3' FWD mRNA-Seq library preparation and performed NextSeq mRNA sequencing which found differential expressed gene (DEG) counts from 0 to 3,715. Internal concentrations of PFAS were then measured to determine if differing uptake resolved the disparate DEG counts across the compounds. We identified high internal concentrations of PFAS at 120 hpf which indicated the possibility of differentiated uptake at other developmental stages and/or that the availability of biological targets occurs later in development. Finally, we measured gene expression changes across different life stages between 72-120 hpf for the chemicals that produced few DEGs at 48 hpf despite their production of robust 120 hpf phenotypes. Collectively, this study identified a subset of bioactive PFAS and their resulting gene expression perturbations across diverse chemical structures in a single *in vivo* system. These findings begin to elucidate the differential actions of individual PFAs in biological systems for improved regulatory decision-making.

1.13.P-Th094 Effects of PFAS Exposure on Telomere Length in Resident Passerine Birds Breeding Nearby a Perfluoropolymer Plant

Marco Parolini[1]*, Sara Valsecchi*[2]*, Michelangelo Morganti*[2]*, Beatrice De Felice*[1]*, Marianna Rusconi*[2]*, Maria Teresa Palumbo*[2] *and Stefano Polesello*[2]*, (1)University of Milan, Italy, (2)Water Research Institute - Italian National Research Council IRSA-CNR, Italy*

Telomeres are noncoding DNA repeats located at the end of eukaryotic chromosomes that play a key role in ensuring genomic stability. Although telomere length progressively shortens over individual lifespan with advancing age, the rate of telomere shortening can accelerate as a consequence of diverse environmental stressors. Among these, the exposure to environmental contaminants can contribute to the modulation of telomere length or dynamics. The present study aimed at investigating the effects due to the exposure to legacy and emerging per- and polyfluoroalkyl substances (PFAS) on telomere length of two bird species, the European starling (*Sturnus vulgaris*) and the Great tit (*Parus major*), living nearby a perfluoropolymer plant (PFP). In 2022, nest boxes were placed nearby a PFP located in the Western sector of the Po River valley (Northwestern Italy), as well as in control area. The first laid egg from each nest box was collected to estimate the maternally transferred amount of PFAS. A blood sample was collected from all the nestlings growing in the nest boxes and telomere length was measured through a real time PCR method. Previous correlative studies returned contrasting results on the relationships between the concentrations of PFAS and the telomere length in adults and nestlings of bird species sampled in remote areas. Thus, the preliminary results of the present study, performed nearby a PFP with high levels of PFAS contamination, allow to shed light on the relationships between the levels of both legacy and emerging PFAS, and telomere length in free-living birds.

1.13.P-Th095 Impact of PFAS on Lipid Accumulation and Cholesterol Homeostasis in the Human Hepatocarcinoma Cell Line HepaRG

Faezeh Sadrabadihaghighi[1]*, Thorsten Buhrke*[2] *and Albert Braeuning*[2]*, (1)Food Safety, German Federal Institute for Risk Assessment (BfR), Berlin, Germany, (2)German Federal Institute for Risk Assessment (BfR), Berlin, Germany*

Per- and polyfluoroalkyl substances (PFAS) are a large family of synthetic chemicals that are used for numerous consumer products with water- and dirt-repellent properties. Due to their extraordinary stability they are resistant to thermal, chemical, and biological degradation and, therefore, persist in the environment. Some PFAS such as perfluorooctanoic acid (PFOA) and perfluorooctanesulfonic acid (PFOS) are toxicologically well characterized. Exposure to PFAS has been associated with several adverse health effects in humans such as increased serum cholesterol levels. As PFOA and PFOS are continuously replaced by alternative PFAS in the industrial applications, this study aims to characterize the impact of these PFOA and PFOS replacements on lipid accumulation and cholesterol homeostasis in human liver cells.

The human hepatocarcinoma cell line HepaRG was selected as in vitro model for human hepatocytes. In addition to PFOA and PFOS, we selected perfluorohexanoic acid (PFHxA), perfluorohexanesulfonic acid (PFHxS), perfluorobutanoic acid (PFBA), perfluorobutanesulfonic acid (PFBS), perfluorononanoic acid (PFNA), perfluorodecanoic acid (PFDA), and two next generation PFOA replacements (GenX and ADONA) for in vitro testing. The steatotic potential of the 10 selected PFAS in HepaRG cells was examined using the AdipoRed assay to determine intracellular triglyceride accumulation. To examine the cholestatic potential of PFAS, we employed an *in vitro* assay that is based on the observation that in the presence of high bile acid concentrations cholestatic compounds are cytotoxic already at lower concentrations compared to their cytotoxicity in the absence of bile acids.

In the AdipoRed assay, the selected PFAS induced no significant increase in triglyceride accumulation except for a slight increase for some PFAS at the respective highest noncytotoxic test concentration that was statistically significant in some cases. Regarding the experiments on the cholestatic potential, two well-known cholestatic drugs (cyclosporine A and nefazodone) clearly showed increased cytotoxicity in the presence of high bile acid concentrations. In contrast, cytotoxicity induced by the selected PFAS was independent of the presence or absence of bile acids. From our *in vitro* data we conclude that the selected PFAS neither induce triglyceride accumulation nor possess a cholestatic potential in HepaRG cells at concentrations that are relevant for human exposure scenarios.

1.13.P-Th096 Toxicity Mechanisms of Legacy and Novel Sulphonated Perfluoroalkyl and Polyfluoroalkyl Substances (PFAS)

Emma Arnesdotter[1]*, Naila Rajabli*[1]*, Charlotte Stoffels*[1]*, Chiara Leo*[2]*, Dario Greco*[3]*, Francesco Dondero*[4]*, Arno Gutleb*[1] *and Tommaso Serchi*[1]*, (1)Luxembourg Institute of Science and Technology (LIST), Luxembourg, (2)Genetica e Biologia Srl, Polo d'innovazione di Genomica, Italy, (3)Tampere University, Finland, (4)Department of Science and Technological Innovation (DISIT), Università del Piemonte Orientale, Italy*

Per- and polyfluoroalkyl substances (PFAS) are highly complex synthetic compounds used in several products and industrial processes (fluoropolymers, semiconductors, textile, chrome plating, chloro alkali, etc.). PFAS are mobile, omnipresent in the environment and extremely persistent. Although the toxicological implications of human exposure to certain (legacy) PFAS are well-studied, data on alternative/next generation PFAS are still very limited. Thus, collecting experimental toxicity information of such poor-data PFAS is of high importance.

The high serum-binding of PFAS congeners may influence their cytotoxic activity. Therefore, the influence of foetal bovine serum (FBS) and bovine serum albumin (BSA) on the cytotoxic activity of one legacy (Perfluorooctanesulfonic acid – PFOS, CAS number 2795-39-3) and seven poor-data PFAS belonging to the sulphonic acid series (CAS numbers: 3871-99-6; 763051-92-9; 29311-67-9; 2706-91-4; 375-92-8; 70755-50-9; 749836-20-2; 113507-82-7) was investigated. Two epithelial barrier *in vitro* models, i.e., A549 cells and a differentiated co-culture of Caco-2 HTB-37 and HT-29 MTX cells was exposed to the compounds in the presence of zero, low (1%) and high (10%) FBS, or BSA (1 mg/mL). Cells exposed to PFOS in the presence of BSA displayed an increased susceptibility to cytotoxicity than cells exposed in the presence of any or no level of FBS. This was observed for some, but not all, alternative PFAS. In contrast, cells exposed to 8:2 Cl-PFESA with no or low FBS tolerated a lesser concentration than cells exposed in high FBS or BSA. Also, a large discrepancy in sensitivity between the cellular models was observed, with the intestinal epithelium being the less sensitive system. This could in part be attributed to the models' inherent properties, yet it warrants further investigations into the specific toxicity mechanisms in different organ systems.

Future studies encompass the use of advanced *in vitro* 3D models (intestinal barrier, alveolar barrier, and skin) and single-cell transcriptomics. The results will inform on potential apical effects that can be measured in high throughput assays, and so contributing to a testing toolbox to improve and address the hazard of PFAS exposure to human health and ultimately, facilitate read-across actions between legacy and poor-data congeners.

1.13.P-Th097 Investigation of PFASs Interactions with Biomolecular Model Systems Powered by the Enalos Asclepios KNIME Nodes

Panagiotis D. Kolokathis[1,2]*, Konstantinos D. Papavasileiou*[1,3]*, Peng Zhang*[4]*, Marco De Gennaro*[5]*, Georgia Melagraki*[6]*,* ***Francesco Dondero***[7]*, Tiziano Verri*[8]*, Iseult Lynch*[4,9]*, Antreas Afantitis*[1,2,6] *and Amilcare Barca*[8]*, (1)Department of ChemoInformatics, NovaMechanics MIKE, Greece, (2)NovaMechanics Ltd., Cyprus, (3)2Department of ChemoInformatics, NovaMechanics Ltd., Cyprus, (4)University of Birmingham, United Kingdom, (5)Department of Biological and Environmental Sciences and technologies, Università del Salento, Italy, (6)Entelos Institute, Larnaca, Cyprus, (7)Department of Science and Technological Innovation, Università del Piemonte Orientale, Alessandria, Italy, (8)Università del Salento, Italy, (9)Entelos Institute, Birmingham, United Kingdom*

Per- and polyfluoroalkyl Substances (PFASs) are present in a wide variety of industrial processes and consumer products, the majority of which having unknown hazardous potential in terms of bioactivity, bioaccumulation, and toxicity. Understanding of their physical and chemical properties and how these determine their biological and toxicological effects is of great importance and will enable the prediction of their interaction properties, without the necessity of performing extensive empirical testing (and thus with a reduction of costs and need for *in vivo* testing). In this respect, the design of a comprehensive *in silico* study for the elucidation of the interaction mechanisms of PFAS molecules with biomolecular systems is necessary, especially those for PFAS for which limited experimental data is currently available. To this end, a plasma transport protein and a cellular membrane model are utilized, i.e., transthyretin (TTR) and the 1,2-dioleoyl-sn-glycero-3-phosphocholine (DOPC) lipid bilayer, respectively, as interaction targets. TTR is a transport protein present in human, mammalian, and fish plasma that transports the thyroid hormone thyroxine (T4) and retinol to the liver. TTR has a dimer of dimers quaternary structure (55kDa MW, 508 residues, ~4,065 atoms). DOPC membrane consists of lipids, each of which has a hydrophilic head oriented to the exterior and two hydrophobic tails oriented to the interior of the bilayer. The ability of PFASs to interact with biomolecules such as TTR and lipid bilayers is of great importance, since these molecules enable PFAS transport within the body. Understanding PFASs interactions with biomolecular systems may enable minimisation of their toxicity by designing alternative compounds that interact less and are thus less bioavailable. Our methodological approach involves using the Enalos Asclepios KNIME pipeline to perform molecular docking and fully atomistic molecular dynamics (MD) simulations on a panel of preselected PFAS molecules, some of which have existing experimental data and some that are data-poor, for which the predictions will then be validated experimentally to confirm their interactions. The findings of this project are expected to assist toward understanding the interactions and transport mechanisms of PFASs in living organisms, thus allowing rational design modifications to minimise their environmental and toxicological impact and design alternative molecules with improved features.

1.13.P-Th098 *In vitro* Examination of Molecular Toxicity Mechanisms of Alternative (Poly-)Ether Per- and Polyfluoroalkyl Substances

***Wiebke Alker**, Thorsten Buhrke and Albert Braeuning, German Federal Institute for Risk Assessment (BfR), Berlin, Germany*

The use of many legacy per- and polyfluoroalkyl substances (PFAS) is being reduced due to their high persistence and hazardous effects. Thus, alternative PFAS are increasingly used for numerous industrial applications, while at the same time there is no or only few data on their toxicity.

The project aims at examining the molecular toxicity mechanisms of alternative PFAS with a focus on the subgroup of mono- and polyether PFAS, with both linear and branched structures. A number of perfluoroalkyl sulfonic acids (PFSA) and perfluoroalkyl carboxylic acids (PFCA) including the well-characterized perfluorooctanesulfonic acid (PFOS) and perfluorooctanoic acid (PFOA) were also included in the list of in total 34 different PFAS compounds that were selected for *in vitro* testing in the present study. The human cell line HepaRG was chosen as a model to study potential hepatotoxic effects of PFAS *in vitro*. Here we present data on the cytotoxic effects of the 34 PFAS in HepaRG cells and on the activation of the peroxisome proliferator-activated receptor alpha (PPARα), whose activation has been attributed to hepatotoxic effects of PFOS and PFOA in rodents.

Most monoether PFAS were less cytotoxic to HepaRG cells than PFOA and PFOS, whereas some linear and branched polyether PFAS displayed a higher cytotoxicity than the legacy PFAS. For most of the selected PFAS, PPARα activation was only observed at concentrations close to the cytotoxicity level of the respective compound. However, some PFAS (e.g., 2,3,3,3-tetrafluoro-2-(heptafluoropropoxy)propanoic acid (HFPO-DA) and perfluoro-4-methoxybutanoic acid) activated PPARα already at concentrations much lower than their cytotoxicity levels, indicating that some PFAS may induce stronger effects at this particular receptor than PFOA or PFOS, although being less cytotoxic.

The *in vitro* data can be used to calculate benchmark concentrations and derive points of departure for specific cellular and molecular endpoints. A comparison of these data with those of the well-characterized PFOA and PFOS will support risk characterization of the poor-data PFAS examined in the present study.

1.13.V Towards a One Health Approach to Integrating Human Toxicology, Ecotoxicology and Ecological Impacts of PFAS and Related Chemicals

1.13.V-01 Developing an Easily Accessible Repository of PBK Models for PFAS

***Periklis Tsiros**, Eleni Strompoula, Vassilis Minadakis and Haralambos Sarimveis, National Technical University of Athens, Greece*

Physiologically based kinetic (PBK) models are a key component in both human and environmental risk assessment workflows. Used in a forward dosimetry mode, they can convert external exposure into internal organ burdens, while reverse dosimetry can estimate the external exposure that leads to a witnessed concentration at the tissue level. PBK models for per- and polyfluoroalkyl substances (PFAS) are invaluable tools for investigating the persistence and impact of this class of chemical substances in humans and other species. Ease of access and use of PBK models for PFAS can potentially accelerate the process of risk characterisation. We have developed a framework based on R (Python under development) for uploading and exposing PBK models as fully documented, ready-to-use web services through the Jaqpot platform, thus making them also available through the SCENARIOS cloud platform. Using this framework, we have replicated and exposed several PBK models for PFAS that have been published in literature, so that they can be used by nontechnical end-users. Clients in various programming languages (R, Python, Java, etc.) allow remote use of the models and easy integration in computational pipelines. Our goal is to continuously update the existing list of PFAS-related PBK models on Jaqpot, as long as new models emerge, so that these models can reach a wider audience, increasing their applicability.

1.13.V-02 Systematic Developmental Toxicity Assessment of a Structurally Diverse Library of 139 PFAS in Zebrafish

***Michael T. Simonich**[1], Lisa Truong[1], Yvonne Rericha[1], Preethi Thunga[2], Skylar Marvel[2], Jennifer Field[1], Dunping Cao[1], David Reif[3] and Robyn Leigh Tanguay[1], (1)Oregon State University, (2)North Carolina State University, (3)National Institute for Environmental Studies (NIES)*

Per- and polyfluoroalkyl substances (PFAS) are widely used chemicals with very limited human health data relative to the diversity of structures manufactured. To help fill this data gap, an extensive *in vivo* developmental toxicity screen was performed for 139 PFAS provided by the US EPA. Dechorionated embryonic zebrafish were exposed to 10 nominal water concentrations of PFAS (0.015 - 100 µM) from 6-120 h postfertilization (hpf). The embryos were assayed for embryonic photomotor response (EPR), larval photomotor response (LPR), and 13 morphological endpoints. A total of 49 PFAS (35%) were bioactive in one or more assays (11 altered EPR, 25 altered LPR, and 31 altered morphology). Perfluorooctanesulfonamide (FOSA) was the only structure that was bioactive in all 3 assays, while Perfluorodecanoic acid (PFDA) was the most potent teratogen. Low PFAS volatility was associated with developmental toxicity ($p<0.01$), but no association was detected between bioactivity and five other physicochemical parameters. The bioactive PFAS were enriched for 6 supergroup chemotypes. The 14 most bioactive PFAS plus the previously untested Nafion byproduct 2, an emerging next gen PFAS of concern, were selected for transcriptomic investigation. We sought to phenotypically anchor the transcriptional changes, thus the EC_{80} for each PFAS was used as the exposure concentration and embryos were sampled at 48 hpf. GO analysis identified both common and unique biological processes enriched by structurally diverse PFAS including protein folding, regulation of peptidase activity, disrupted peptide biosynthetic and metabolic processes, translation, neuron development and differentiation, and sensory system and visual system development. Many of the most significantly enriched processes were related to nervous system, brain, and neuron development. The results illustrate the power of a multidimensional *in vivo* platform to assess developmental toxicity of diverse PFAS and to accelerate PFAS safety research.

1.13.V-03 Cytotoxicity of Ether Perfluoro Carboxylic Acid PFAS Congeners in Earthworm Granulocytes
Antonio Calisi[1], Davide Gualandris[1], Candida Lorusso[1], Davide Rotondo[1] and ***Francesco Dondero****[2], (1)Department of Science and Technological Innovation, Università del Piemonte Orientale, Italy, (2)Department of Science and Technological Innovation (DISIT), Università del Piemonte Orientale, Italy*
Soil pollution has enormously increased in the last decades. From different type of pollutants per- and polyfluoroalkyl substances (PFAS) are found in the soil due to their various industrial uses (e.g., anti-fire foams, fluoropolymer resins such as Teflon; separation processes; textiles; cosmetics) and their high persistence. Most emerging PFAS congeners do not have toxicity data that would allow an environmental assessment. Biological approaches to soil monitoring, such as the measurement of biochemical and cellular responses to pollutants (i.e., biomarkers) on organisms living in the soil, have become of major importance for the assessment of the quality of soil. The aim of this work was to investigate the effect of these substances from an ecotoxicological point of view on nontarget species, using PFAS as a reference standard. For this purpose, our study focused on assessing the potential cytotoxicity and genotoxicity of four different PFAS congeners (PFOA, HFPO-DA, PF4MOBA, PF3MOPrA) on immune system cells (coelomocytes) of sexually mature earthworm *Eisenia foetida* in a range concentration of 0.6-229 microM. Toxicity tests were carried out according to OECD Test No 207 (by filter paper test) to assess the cytotoxic and genotoxic effect in earthworms coemolocytes. Coelomocytes were collected from the coelomatic fluid using an insulin syringe prefilled with 0.25 ml saline solution. Coelomocytes morphometric alterations were determined by Diff quick staining; oxidative stress alterations and micronuclei frequency were determined respectively by H2DCFDA staining for ROS and DAPI coupled with fluorescence microscopy. Results showed significant alteration of the investigated patterns. An increased enlargement of granulocytes was usually observed in exposed earthworms with respect to control group. A hormetic pattern was observed. The enlargement was quantified by measuring the area of 2D digitalised granulocyte images. A decrease of oxidative burst and an increase of micronuclei frequency were also seen. Further investigation of impaired cell-mediated immune function is ongoing. The results of this study will lead to the construction of an ecotoxicological database on numerous alternative PFAS congeners allowing a weight of evidence risk assessment analysis of these substances. These data can contribute to regulation and restriction of PFAS at national and European level.

1.14 Using New Approach Methods to Move from Descriptive to Mechanistic Ecotoxicology

1.14.P-We025 Targeted Phosphoproteomics Reveals the mTOR Pathway Dynamics and its Role in Growth Regulation in the Zebrafish PAC2 Cells
Nikolai Huwa*, Rene Schonenberger and Ksenia J Groh, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Dübendorf, Switzerland*
Environmental assessment of chemicals frequently uses fish growth as a chronic toxicity endpoint, and alternative methods to replace this animal test are urgently needed. Previously, it was demonstrated that measurement of proliferation of fish cells cultured *in vitro*, in conjunction with toxicokinetic modelling, could be used to predict impacts of pesticides on fish growth *in vivo*. However, the molecular mechanisms underlying chemical effects on fish cells growth remain poorly understood. We here focus on the mechanistic target of rapamycin (mTOR) pathway, which is known to regulate cell growth and proliferation in mammals. Since the mTOR pathway activity is regulated by protein phosphorylation, it has been traditionally studied by antibody-based assays. However, suitable antibodies are often lacking for nonmammalian species. Moreover, antibody-based methods do not allow monitoring multiple pathway targets simultaneously. To overcome this challenge, we developed an alternative approach using mass spectrometry-based targeted (phospho-)proteomics, first applied in the zebrafish (*Danio rerio*) PAC2 cell line model. Our method currently allows monitoring changes in protein abundance and phosphorylation of 15 protein targets along the mTOR pathway, represented by 31 unique peptides, and provides insights into several checkpoints involved in regulating cell growth and proliferation. We used it to illuminate the mTOR pathway dynamics at different growth phases of zebrafish PAC2 cell cultures and are currently working on investigating the responses to pharmacological modulators of the mTOR activity, as well as to selected chemicals known to affect fish growth *in vivo.* These experiments will expand our knowledge about the mTOR signalling and growth regulation in fish cells, as well as its role in mediating chemical-induced effects on fish growth.

1.14.P-We026 Combination of Computational New Approach Methods for Enhancing Evidence of Biological Pathway Conservation Across Species
Peter Schumann*[1], Carlie LaLone[2], Claudia Rivetti[3], Jade Houghton[4], Geoffrey Hodges[3], Bruno Campos[4] and Maria Blanco-Rubio[3], (1)School of Freshwater Science, University of Wisconsin, Milwaukee, (2)Office of Research and Development, Great Lakes Toxicology and Ecology Division, US Environmental Protection Agency, (3)Unilever - Safety and Environmental Assurance Centre (SEAC), United Kingdom, (4)Unilever, United Kingdom*

There is a need for new approach methodologies (NAMs) in chemical risk assessment to help mitigate the ethical and resource burdens of animal-based toxicity testing. With the amount of nonanimal-based methods, approaches, and tools already in existence it is worth investigating how these NAMs can be combined to advance understanding of toxicity. In this case, the value of combining two computational tools, Sequence Alignment to Predict Across Species Susceptibility (SeqAPASS) and Genes to Pathways – Species Conservation Analysis (G2P-SCAN) was investigated in relation to supporting cross-species evaluations for predicting chemical susceptibility. G2P-SCAN was used to efficiently gather biological pathway information using gene inputs that represented known molecular targets of chemicals of interest. Network analyses were leveraged with adverse outcome pathway (AOP) information to aid in the prioritization of these mapped pathways. The proteins that comprised these prioritized pathways were then used as a basis for cross-species extrapolation or hypothesis generation for chemical susceptibility using SeqAPASS. In this report, this analysis was described by highlighting the results from three molecular targets: PPARA, ESR1, and GABRA1. The utility and challenges of this combined computational approach were demonstrated. Overall, the weight of evidence to support cross-species susceptibility predictions was enhanced by using biological pathway information. The information gained through this computational approach could ultimately inform chemical risk assessments by enhancing cross-species predictions of chemical susceptibility and potentially by expanding the biologically plausible taxonomic domain of applicability (tDOA) of relevant AOPs.

1.14.P-We027 NAMs in REACH – A Regulatory and Policy Level Perspective

Georg Streck, *European Commission - DG GROW, Brussels, Belgium*

The main aim of the presentation is to provide a perspective from a regulatory and policy level on how NAMs can be used today in a legislation, reflecting about what is needed to enhance the use of NAMs and where further scientific developments are required. The focus of this contribution is on the EU Regulation REACH.

The presentation is structured in four points:

(1) Opportunities and requirements for using NAMs – current framework: REACH allows already the use of NAMs. Several conditions are attached to their use, inter alia:

- Equivalence of information: NAMs replacing existing information requirements have to provide the information that is requested by the legislation.
- Confidence in NAMs: Regulators need to be able to judge whether the NAM fulfils the information requirement.
- Legal certainty: Registrants should be able to rely on that the use of a specific NAM will satisfy the legal requirements.
- Economic and proportionality considerations

Furthermore, NAMs are used to support, e.g., read-across, grouping and categorisation of chemicals. The presentation will provide examples.

(2) Future developments: The presentation will reflect about future developments that increase the use of NAMs on a short-term (e.g., revision of REACH) and a longer-term timeframe,

(3) Research needs: The presentation will outline research needs. For several endpoints it is still challenging to use NAMs, e.g., for complex human health endpoints.

(4) From science to legislation – or from legislation to research: The last part of the presentation is inspired by discussions the author had at the last SETAC meeting in Copenhagen. Those discussions revealed that academic researchers sometimes have the perception that NAMs developed by them are not taken up by regulators or decision makers. At the same time, regulators and the policy level identify and communicate via different channels needs for scientific developments, but might not always reach the academic research community. The presentation includes a section on possibilities to foster the information exchange between researchers, regulators and the policy level.

1.14.T-01 Enhancing the Quantitative Understanding of an Adverse Outcome Pathway Network for Mitochondrial Dysfunction Using i*n vitro* and *in silico* New Approach Methodologies

Maria T. Hultman[1], *Yang Cao*[2], *Prem Chand*[3], *Thomas Rundberget*[1], *Maria Christou*[4] *and You Song*[1], *(1)Norwegian Institute for Water Research (NIVA), Norway, (2)Clinical Epidemiology and Biostatistics, Orebro University, Örebro, Sweden, (3)Ecotoxicology and risk assessment, Norwegian Institute for Water Research (NIVA), Norway, (4)Norwegian Insitute for Water Research, Norway*

Mitochondria are the energy warehouses in eukaryotes. A wide range of chemicals can affect mitochondrial energetic functions. Uncoupling of oxidative phosphorylation (OXPHOS) is one of the most common modes of action of mitochondria toxicants leading to adverse effects of regulatory concern (e.g., growth inhibition). By aligning the adverse outcome pathway (AOP) concept and the 3Rs principles, this study aims to use new approach methodologies (NAMs) to support the development of a quantitative AOP network (qAOPN) and a tiered animal alternative testing strategy for cost-efficient hazard assessment of mitochondrial uncouplers. The AOPN linking mitochondrial uncoupling to growth inhibition in eukaryotes is currently under active development (OECD AOP project 1.92), with one of the linear AOPs being endorsed by WPHA/WNT (https://aopwiki.org/aops/263). To quantify key events (KEs) in this AOPN, a suite of high-throughput *in vitro* bioassays was conducted with the zebrafish liver (ZF-L) cell-line, after a time-course exposure (2, 6, 12, 24, 48, and 72 h) to nine concentrations (0.001–100 μM) of the model uncoupler carbonyl cyanide m-chlorophenyl hydrazone (CCCP). The KEs measured include: mitochondrial membrane potential (MMP), ATP level, calcium signalling, cytotoxicity (metabolic activity and cell membrane integrity), and cell proliferation. In addition, chemical analysis was performed of CCCP in the cells and exposure media. Temporal and concentration dependent responses of ZF-L cells to CCCP were observed for the KEs of interest as early as 2 h of exposure. The uptake and metabolism of the different CCCP concentrations corresponded well to the temporal effect response observed in the cells. The most sensitive and responsive (2 h) KE was uncoupling of OXPHOS as indicated by decreased MMP. A decrease in ATP was observed after 6 h of exposure, followed by a clear concentration-dependent decrease in cell proliferation. There was no apparent change in cytosolic calcium signalling until 6-12 h of exposure. A slight increase in cell death was also observed when exposure duration increased. The data were further used to construct quantitative KE relationships in an AOPN. The coefficients for molecular initiating- and several of the key events were statistically significant in the AOPN. This study has demonstrated the use of NAMs for qAOPN development. Current work has supplied novel causal knowledge and a new workflow for qAOPN construction for future studies.

1.14.T-02 AOP-Based Evidence from Chicken Embryos and the Chicken Hepatic LMH Cell Line that Bisphenol A and Ethinyl Estradiol Induce Dysregulation of Bile Acid Homeostasis in Birds

Tasnia Sharin[1]*, Doug Crump*[2] *and Jason O'Brien*[3]*, (1)Ecotoxicology and Wildlife Health Division, Environment and Climate Change Canada, Ottawa, Canada, (2)Ecotoxicology and Wildlife Health Division, Environment and Climate Change Canada, National Wildlife Research Centre, Ottawa, Canada, (3)Environment and Climate Change Canada, Canada*

Bile acids play an important in cholesterol metabolism and secretion of endogenous and xenobiotic compounds. Concentration of bile acid is tightly regulated by nuclear receptors and transporters. One adverse outcome pathway (AOP #27, https://aopwiki.org/aops/27) documents how inhibition of the bile salt export pump (BSEP) can interfere with bile acid homeostasis and lead to cholestasis. Previous studies have found that environmental chemicals can impair bile acid homeostasis and cause cholestasis in birds. In the present study we measure several endpoints along the BSEP inhibition AOP following exposure to BPA and EE2 in two avian model systems 1) an early life stage model, the chicken embryo, and 2) an *in vitro* model, immortalized chicken hepatic cells, LMH, cultured as spheroids. The objectives were 1) to determine if BPA and EE2 are probable inducers of liver cholestasis in birds, based on AOP-based evidence, and 2) investigate if spheroid LMH cells could be a suitable model to screen for cholestasis-inducing chemicals for avian toxicity testing. Embryos were exposed via egg injection prior to incubation and data were collected at two developmental stages, mid-incubation (embryonic day [ED] 11) and term (ED20). Changes in expression of bile acid genes and bile acid concentrations were measured at both time points. Morphometric measurements were recorded at ED20. LMH spheroids were treated with BPA and EE2 for 8, 24, and 48 h. Changes in gene expression were evaluated at all three time points and bile acid concentration at 24 and 48 h. Both BPA and EE2 resulted in modulation of bile acid genes, including downregulation of BSEP, in mid-incubation livers and LMH spheroids at 24 h. The magnitude of change in gene expression was greater in mid-incubation livers and LMH spheroids at 24 h compared to term livers and LMH spheroids at 48 h. BPA and EE2 increased bile acid concentration in term livers and LMH spheroids at 48 h. Exposure to BPA (50 µg/g) and EE2 (25 and 50µg/g) significantly decreased gallbladder mass and increased liver mass in ED20 embryos. In summary, we found that BPA and EE2 downregulated BSEP mRNA expression, and increased bile acid levels in hepatocytes. Based on the BSEP AOP, this evidence suggests that these compounds could induce cholestasis in birds. Further, these results suggest that LMH cells cultured as 3D spheroids may be a suitable in vitro model to screen chemicals that impair bile acid homeostasis.

1.14.T-03 Evaluation of Thyroid Hormone System Disrupting Potential of Resorcinol in Fish Using an AOP-Based Approach

Imke Van Dingenen[1]*, Emma Andersen*[2]*, Jiri Novak*[3]*, Monica Christiansen*[2]*, Ann-Cathrin Haigis*[1]*, Sina Volz*[2]*, Brett R Blackwell*[4]*, Emma Stacy*[4]*, Daniel L. Villeneuve*[4]*, Lucia Vergauwen*[1]*, Klara Hilscherova*[3]*, Henrik Holbech*[5] *and Dries Knapen*[1]*, (1)University of Antwerp, Belgium, (2)Syddansk University, Denmark, (3)RECETOX, Masaryk University, Czech Republic, (4)US Environmental Protection Agency, (5)University of Southern Denmark, Denmark*

An increasing number of pollutants are reported to interfere with the thyroid hormone system, raising concerns for both human and environmental health. Recently, resorcinol was brought up as a substance of very high concern due to thyroid hormone system disruption (THSD). It is used for a variety of purposes, such as applications in the rubber industry, but also as a substance in pharmaceuticals. There is *in vitro* evidence that resorcinol can inhibit thyroperoxidase (TPO), an enzyme crucial in thyroid hormone (THs) synthesis. Furthermore, resorcinol exposure has been linked to hypothyroidism in humans. Evidence linking the compound to THSD in the environment is currently lacking. In the current study, the TSHD potential of resorcinol *in vitro* and *in vivo*, in the zebrafish embryo model, was assessed using the adverse outcome (AOP) conceptual framework. AOPs linking THSD to impaired swim bladder inflation and eye development in fish have been previously developed. *In vitro* data were gathered to predict the possible molecular initiating events (MIEs), and confirmed that resorcinol is a TPO inhibitor. Additionally, resorcinol was identified to be a thyroid receptor (TR) antagonist and a transthyretin (TTR) displacer. TH levels were assessed following resorcinol exposure in zebrafish embryos. Whole-body thyroxine (T4), the main synthetised TH, levels were significantly reduced, showing that resorcinol is capable of inhibiting TPO in vivo. Resorcinol exposure significantly impaired swim bladder inflation. T4 supplementation could not rescue the effect on the swim bladder, showing that this effect is not a result of TPO inhibition, and is likely attributable to one of the other identified THSD mechanisms, such as TR antagonism and TTR displacement. Swimming performance in embryos with uninflated swim bladders was significantly impaired and the effect depended on the resorcinol concentration. Additional analyses, including gene transcription analysis and eye histology, are being performed, which will aid in further elucidating the effect of resorcinol both on the thyroid hormone system and THSD-related endpoints *in vivo*. The current study is valuable for the development of THSD screening methods, as it illustrates how an AOP-based approach can be used to consider the contributions of multiple mechanisms when evaluating the THSD potential of a chemical.
The contents of this abstract neither constitute, nor necessarily reflect, US EPA policy.

1.14.T-04 Unraveling Molecular Mechanisms of Alkyl Sulfonic Acid PFAS-Dependent Hyperactivity in Larval Zebrafish Using Gene-Editing

Sebastian Gutsfeld[1]*, Leah Wehmas*[2]*, Ifeoluwa Omoyeni*[1]*, Nicole Schweiger*[1]*, David Leuthold*[1]*, Paul Michaelis*[1]*, Gi-Mick Wu*[1]*, Xia Meng Howey*[2]*, Wibke Busch*[1]*, Shaza Gaballah*[2]*, Nils Kluver*[1]*, Stefan Scholz*[1] *and Tamara Tal*[1]*, (1)Chemicals in the Environment Research Section, Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany, (2)US Environmental Protection Agency*

Per- and polyfluorinated alkyl substances (PFAS) are a diverse class of synthetic chemicals widely used in industrial manufacturing. We previously showed that exposure to alkyl sulfonic acid PFAS (perfluorooctanesulfonic acid (PFOS) or perfluorohexanesulfonic acid (PFHxS)) caused dark-phase hyperactivity in larval zebrafish. To confirm that PFAS-dependent behavioral effects result from a developmental perturbation, swimming behavior was assessed in 5-day post fertilization (dpf) larvae following either developmental (1-4 dpf) or acute (5 dpf) exposure to 0.43-7.86 µM PFOS, 7.87-120 µM PFHxS, or 0.4% dimethyl sulfoxide (DMSO). Relative to DMSO, dark phase hyperactivity occurred both developmentally and acutely in PFAS-exposed larvae. In contrast, visual startle response hyperactivity only occurred following developmental exposure. A wash-out study was performed where developmental exposure to PFOS or PFHxS from 1-4 dpf triggered irreversible concentration-dependent visual startle response hyperactivity at 5-8 dpf. Peroxisome proliferator-activated receptors (ppara, ppard, pparg) were identified as putative upstream regulators. To test the hypothesis that ppars are required for PFAS-dependent visual startle response hyperactivity, CRISPR/Cas9-based gene editing was used to knockdown pparaa/ab, pparda/db, or pparg at day 0. Knockdown larvae were exposed to 7.86 µM PFOS, 80 µM PFHxS, or 0.4% DMSO from 1-4 dpf and locomotor activity was assessed at 5 dpf. pparaa/ab or pparg knockdown did not affect the ability of PFOS or PFHxS to provoke visual startle response hyperactivity. In contrast, pparda/db knockdown blunted PFOS and PFHxS-dependent hyperactivity as compared to the exposed negative control. Orthogonal confirmation using the ppard antagonist GSK3787 confirmed that ppard is required for PFOS-dependent visual startle hyperactivity. This work identified two distinct phenomena. One, exposure to PFOS or PFHxS causes acute and transient dark-phase hyperactivity. Two, developmental, but not acute, exposure to the same chemicals triggers persistent visual startle response hyperactivity that requires the activity of ppard. Taken together, we identified a novel adverse outcome pathway for hyperactivity in the visual startle response elicited by structurally similar PFAS. More broadly, this work shows how gene editing can be used for rapid hypothesis testing in larval zebrafish.

1.14.P Using New Approach Methods to Move from Descriptive to Mechanistic Ecotoxicology

1.14.P-We028 *In vitro* Screening of UV-Stabilizers and UVFilters: Cytotoxicity, CYP1A Activity, and mRNA Expression in an Immortalized Embryonic Double-Crested Cormorant Cell Line

Tasnia Sharin[1]*, Ramela Koumrouyan*[2]*, Doug Crump*[3] *and Jessica Head*[2]*, (1)Ecotoxicology and Wildlife Health Division, Environment and Climate Change Canada, Ottawa, Canada, (2)Faculty of Agricultural and Environmental Sciences, McGill University, Canada, (3)Ecotoxicology and Wildlife Health Division, Environment and Climate Change Canada, National Wildlife Research Centre, Ottawa, Canada*

Ultraviolet (UV) stabilizers and UV filters are added to industrial and personal care products to absorb UV rays and prevent photooxidation. Some of these compounds have been listed as substances of concern by the European Chemical Agency due to their persistence in the environment and large production volume. UV stabilizers and UV filters have been detected in a range of environmental matrices, including high trophic level bird species (e.g., double-crested cormorant). Little is known about the toxicological properties of these compounds, especially in birds. Previously, we established and characterized an immortalized embryonic double-crested cormorant hepatic cell line, DCH22, for chemical screening. In the present study, DCH22 cells, cultured as 3-dimensional (3D) spheroids, were exposed to four UV stabilizers (UV-328, UV-329, UV-9, UV-P) and a UV filter (BP-3) at nominal concentrations of 0.1 to 1000 µM to determine cell viability, CYP1A activity and changes in mRNA expression. Cell viability and CYP1A activity were measured using intracellular ATP concentration and ethoxyresorufin-*O*-deethylase (EROD) activity. A customized species-specific PCR array, EcoToxChip, comprising 384 genes, will be used to determine changes in mRNA expression. The UV stabilizers and UV filter elicited similar effects on cell viability with LC50 values ranging from 145 to 208 µM. UV-P and BP-3 exposure resulted in a concentration-dependent increase in CYP1A activity with BP3 inducing a greater response than UV-P. UV-328 and UV-329 did not induce CYP1A activity in DCH22 spheroids. Concentration-dependent (0.1 to 100 µM) changes in mRNA expression will be evaluated for the five compounds and the dose-response modelling program PROAST (RIVM) will be used to determine benchmark doses. The CYP1A activity and gene expression data will provide information on the mechanism of toxicity for each chemical. Given the increased use and prevalence of these compounds, these findings will generate much needed toxicity data in a wildlife avian species.

1.14.P-We029 Directional Reactive Model Predicting *in silico* Ligand-Aryl Hydrocarbon Receptor Activity

Taewoo Kim[1]*, Junghyun Lee*[2]*, Bong Oh Kwon*[3]*, Seongjin Hong*[4]*, Changkeun Lee*[2]*, Keun Hwa Chae*[5]*, John Giesy*[6]*, Gap Soo Chang*[6] *and Jong Seong Khim*[2]*, (1)Seoul National University of Science and Technology, Korea, Republic of (South), (2)School of Earth and Environmental Sciences & Research Institute of Oceanography, Seoul National University of Science and Technology, Korea, Republic of (South), (3)Kunsan National University, Korea, Republic of (South), (4)Department of Marine Environmental Science, Chungnam National University, Daejeon, Korea, Republic of (South), (5)Korea Institute of Science and Technology, Korea, Republic of (South), (6)University of Saskatchewan, Canada*

The protein receptor as a transcription factor mediates the enzyme regulation and determines how the cells in organism adapt drugs or metabolize xenobiotics. Since the activation of receptors is a ligand-specific and cell-type specific process, understanding of how the physicochemical factors configure the environment for ligand-receptor binding is a key to predictive assessment of drug efficacy or toxicity of environmental pollutants. Here we show that the binding affinity of homologues of chrysene to the aryl hydrocarbon receptor is dominantly influenced by dipole moment-aligned reaction of ligands with charge states of amino acids forming the AhR. We propose the directional reactivity factor as a mechanistic prediction indicator linking molecular ligand-receptor binding to in vitro toxicity. The DRF accurately estimated toxic potency of a set of similarly structured polycyclic aromatic hydrocarbons, as confirmed by H4IIE-*luc* bioassay.

There are several "new findings" from the present work:

- This study is the first to apply a novel approach, based on mechanistic prediction of binding of ligands to their respective protein receptors, by calculating physicochemical properties in PAHs and their binding to the AhR. Of note is the interpretation and utilization of their properties of this class of toxicants that were not clear to date.
- The present article summarizes limitations of current models to predict toxic potencies of similarly structured chemicals, either drugs or contaminants and presents a novel model and perspective for more accurate prediction of binding of drugs or contaminants to receptors. The expansion and development of this model not only raised new and challenging topics in approaches to predict toxicity of contaminants, but also can help improve other existing models.
- This is the first approach to assess interactions between toxicants and receptors based on interplay of physicochemical properties as determined by the first principles calculation and validated by use of synchrotron-radiation X-ray spectroscopy. Using this novel method, it will be possible to classify species-specific toxic potencies of chemicals in different environments.

Our experiment-free first principles approach provides an analytical framework for predicting molecular bioactivity in silico and complements conventional observation-based bioassays.

1.14.P-We030 Development of Adverse Outcome Pathway Network Based on Molecular Initiating Event Identification Using Molecular Docking Simulation: A Case Study with Additive Chemicals in Plastics

***Kimoon Na**, Jaeseong Jeong and Jinhee Choi, School of Environmental Engineering, University of Seoul, Seoul, Korea, Republic of (South)*

Computational molecular docking simulations can rapid screening of numerous chemicals by predicting which ligands bind to target proteins, and discover molecular initiating events (MIEs) in an Adverse Outcome Pathway (AOP) framework. There is an increased need to identify potential toxicity of additive chemicals in plastics. In this study, (1) AOP networks (AOPNs) with nuclear receptors as MIEs were developed using the Comparative Toxicogenomics Database (CTD), and (2) additive chemicals in plastics were prioritized through molecular docking simulations for potential MIEs. From this, (3) we developed an approach to identify the potential AOP based on CTD and molecular docking simulation. A focus was made on EDC-relevant nuclear receptors related response. As stepwise, the largest EDC-relevant AOPN associated with nuclear receptors was compiled from the AOP Wiki, consisting of 19 Key Events (KEs), 5 AOPs, and 2 Adverse Outcomes. Potential biomarkers were derived by combining the known diseases and toxicity mechanisms of each receptor and each ligand using CTD. We generated 947 CGPD tetramers for "Carcinoma, Hepatocellular" associated with 3 genes (PPARG, FXR, and LXRB), and 4 CGPD tetramers for "adenoma, the liver cell" associated with a gene (CAR). Collectively, we identified the strengthened MIE related to CAR and the potential MIEs related to PPARG, FXR, and LXRB. Molecular docking analysis was performed using 223 plastic additives on 17 human nuclear receptors. According to the binding affinity values, plastic additives were prioritized as potential MIEs of nuclear receptors by type of use. These results highlight the applicability of molecular docking to screen priority chemicals as well as the identification of toxicity mechanisms of potentially hazardous chemicals. The approach proposed in this study is expected to provide insight into toxicity mechanisms and chemical-gene interactions in chemical risk assessment.

1.14.P-We031 One Substance, One Assessment – Unachievable Ambition or an Opportunity for NAMs Not to be Missed?

***Samuel K Maynard**[1], Natalie Burden[2], Charlotte Elston[3], Thomas Hutchinson[4], Michelle Booth[5] and Audrey Pearson[6], (1)Global Sustainability, Astrazeneca UK Ltd, United Kingdom, (2)NC3Rs, London, United Kingdom, (3)Syngenta, United Kingdom, (4)R&D Global Safety Assurance, Reckitt, United Kingdom, (5)Product Safety, Syngenta, United Kingdom, (6)Environment Agency (England), Bristol, United Kingdom*

As a part of the EU's Zero Pollution Strategy within the Chemicals Strategy for Sustainability there is a proposal for the implementation of a "One Substance, One Assessment" approach. Such an aim is ambitious given the divergence of regulatory frameworks, data requirements, exposure scenarios and underpinning guidance in the various sectors under which a chemical may be registered for different uses (e.g., general chemicals, biocides, pesticides, pharmaceuticals etc).

All forms of risk assessment should start with problem formulation as a central principle acknowledged for over 30 years. The current package of *in vivo* ecotoxicology studies is a group of test methods designed to generate data to answer a problem that has generically been formulated by the predefined protection goals, surrogate receptors and sector specific associated guidance. In practice the problem formulation is rarely revisited in the risk assessment in a defined manner. As a consequence, many nonanimal methods or New Approach Methodologies (NAMs) proposed for use in risk assessment tend to focus on, or are judged as, direct replacement of *in vivo* testing, rather than centering on the aspects of the 'problem' they can define or address.

When considering NAMs it is important to revisit the problem formulation phase of the risk assessment. This clarifies what information can be provided by NAMs to address the case specific problem – thereby contributing to an overall reduction in the vertebrate testing burden. Here we present a more chemical-specific problem formulation that can drive the robust implementation of NAMs within risk assessment. Leveraging problem formulation to drive the early generation of nonanimal data and NAMs (e.g., physical chemical properties, environmental fate as well as *in vitro* and *in silico* approaches) enables the design of substance specific approaches (i.e., meeting the objective of the One Substance, One Assessment ambition) whilst reducing our reliance on *in vivo* vertebrate testing.

This concept will demonstrate how building on well-established principles of risk assessment, can enable modern scientific technology and techniques to deliver the better use of NAMs providing robust environmental safety assessments.

1.14.P-We032 Exploring the Taxonomic Domain of Applicability (tDOA) of Thyroid Hormone System Disruption using the Adverse Outcome Pathway Framework

Ann-Cathrin Haigis[1], Carlie LaLone[2], Daniel L. Villeneuve[3], Jason O'Brien[4], Dries Knapen[1] and ***Lucia Vergauwen****[1], (1)University of Antwerp, Belgium, (2)Office of Research and Development, Great Lakes Toxicology and Ecology Division, US Environmental Protection Agency, (3)US Environmental Protection Agency, (4)Environment and Climate Change Canada, Canada*

Multiple studies have associated chemical exposures with endocrine disruption, and specifically thyroid hormone system disruption (THSD), in humans and wildlife. Current regulatory efforts focus on developing fast and efficient screening methods to identify thyroid hormone system disrupting compounds in the environment. These efforts comprise the substitution of animal-based assays, mainly rodent studies, by new approach methodologies (NAMs) such as zebrafish or amphibian embryo assays and thus increase future needs for cross-species extrapolation. Adverse outcome pathways (AOPs) can support this need by providing causal linkages from molecular initiating events (MIEs; describing the interaction between a chemical and a molecular target) to adverse outcomes (AOs; on individual or population level) via key events (KEs; describing measurable, altered biological states).

Different AOPs for THSD have been developed which are, in most cases, applicable to a single taxon. They do, however, share multiple KEs and thus form a THSD AOP network that connects, e.g., AOPs developed in fish with AOPs described in mammals. Making use of this network, we evaluated whether paths leading, for example, to impaired learning and memory in mammals, are potentially applicable to other vertebrate taxa. In doing so, we aimed to identify paths with a high potential for cross-species extrapolation that could further support the development of tailored, alternative (non-mammalian) test methods.

Assessing the taxonomic domain of applicability (tDOA) of MIEs and AOs in the THSD network was achieved by means of a literature study. In this study a special focus was on the link between MIEs and AOs with altered thyroid hormone levels as these present key elements in the THSD network, linking almost all AOPs with each other. Our meta-analysis suggests that a majority of MIEs is applicable across taxa. Further, we found that paths in the network leading, for example, to adverse neurodevelopmental outcomes, possess a high potential for cross-species applicability, while paths leading to thyroid cancer are most likely applicable to rats only. Based on this analysis we are now able to prioritise paths suitable for cross-species extrapolation and highlight the potential of using data from non-mammalian vertebrate classes to predict THSD-induced effects in mammals, including humans, and vice versa.

1.14.P-We033 Application of ’Omics for Identification of Mode of Action-Specific Molecular Fingerprints and Protein Biomarkers Induced by the Fungicide Carbendazim in Zebrafish Embryos

Fatma Marghany*[1], Steve Uwa Ayobahan[2], Hannes Armin Reinwald[3], Christoph Schaefers[4], Henner Hollert[5] and Sebastian Eilebrecht[3], (1)Eco'n' OMICS Attract group, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany, (2)Fraunhofer Attract Eco'n'OMICs, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany, (3)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany, (4)Ecotoxicology, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany, (5)Evolutionary Ecology & Environmental Toxicology, Goethe University Frankfurt, Frankfurt am Main, Germany*

Chemical substances, including fungicides, that are introduced to the ecosystem in a targeted manner can adversely affect nontarget organisms inhabiting the ecosystem. Currently, regulatory agencies mandate a series of studies to evaluate environmental side effects, including analysis of bioaccumulation, environmental fate and toxicity in various model organisms. However, these studies do not capture the early cellular responses to the chemical stressors at the molecular level. The application of recent OMICs technologies enables sensitive and global identification of molecular changes at the level of RNA (transcriptomics) and proteins (proteomics). According to the 2022 FRAC (Fungicide Resistance Action Committee) classification, Carbendazim is classified as an inhibitor of the cytoskeleton and motor proteins synthesis in fungi. The aim of this work was to predict the early responses induced by Carbendazim in zebrafish embryos in terms of changes in gene expression supported by proteomic profiling of the same sample. Zebrafish embryos were exposed to sublethal concentrations of carbendazim for 96 h followed by simultaneous RNA and protein extraction from the respective samples. To further analyse effects induced by carbendazim in transcriptomic and proteomic profiles, RNA-Seq (transcriptome) and mass spectrometry-based proteomics (proteome) analysis were applied. The resulting molecular fingerprints and protein biomarkers will provide the basis for developing a mode of action (MoA)-specific screening approach for active substance precursors under development as well as for monitoring environmental samples to detect early responses to environmental contaminants. In-depth knowledge of molecular changes induced by active substances with different MoA and linkage to phenotypic and population effects will significantly facilitate the classification of active substances in terms of their environmental side effects.

1.14.P-We034 Exploring the Molecular Basis of Transient versus Persistent Neurotoxic Effects Using a Multi-Omics Approach in the Zebrafish Model

***Ksenia J. Groh**, Melissa von Wyl, Severin Ammann, Rene Schonenberger and Colette MichÃ¨le vom Berg, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Dübendorf, Switzerland*

Neurotoxicity occurs when exposure to toxic substances alters the normal functioning of the nervous system. A common way of assessing functional significance of changes in the nervous system is the measurement of an organism's behavioral output, as this reflects the combined action of neuronal, neuroendocrine, and neuromuscular signals. Behavior assessment in early life stages of zebrafish *Danio rerio* is time- and cost-effective, due to its small body size, well-developed testing methodology, and commercial availability of relevant instrumentation. However, it remains unclear, to what extent the observed behavioral effects reflect specific changes in the nervous system, and whether these alterations are transient or irreversible. Therefore, to investigate mechanistic links that could help in the interpretation of behavioral observations, we analyzed zebrafish larvae behavior concomitantly with molecular, cellular and structural changes in the nervous system. For this, zebrafish larvae are exposed to a set of neurotoxic substances and then depurated in clean water to assess recovery potential. We measured (i) functional changes through behavior assessment, (ii) cellular and structural changes such as synaptic connections, neuronal fibers, and muscular structure by using immunohistochemical markers and (iii) molecular changes by transcriptomics, proteomics and metabolomics focused on molecules relevant to the functioning of nervous system, such as selected receptors, enzymes and neurotransmitters. Previously, we demonstrated that most insecticide-induced behavioral changes in zebrafish larvae are of transient nature, even in the presence of concomitant structural changes in motorneuron outgrowth or muscles. We have now investigated the persistence of behavioral changes upon exposure to other neuroactive/neurotoxic chemicals (e.g., the opioid fentanyl citrate, the serotonin receptor agonist buspirone and the plastic chemical bisphenol A) and found that most behavioral effects partially or fully recovered as well, albeit at different rates. With the currently ongoing molecular analyzes we aim to identify molecular markers that could be predictive of transiency or persistency of neurotoxic effects. These insights will aid interpretation of test results obtained in zebrafish behavior assays and will be used to explore whether and how to include behavioral testing into hazard assessment of neurotoxic substances.

1.14.P-We035 Molecular Signature of Thyroid Hormone System Disrupting Chemicals

*Rikke Poulsen[1], Yanis Zekri[2], Romain Guyot[2], Frederic Flamant[3], **Henrik Holbech**[4] and Martin Hansen[5], (1)Environmental Science, Aarhus University, Denmark, (2)École Normale Supérieure de Lyon, France, (3)Ecole Normale Superieure de Lyon, France, (4)University of Southern Denmark, Denmark, (5)Aarhus University, Denmark*

Endocrine disrupting chemicals pose a threat to both humans and wildlife. The hypothalamic-pituitary-thyroid axis has been identified as an area with large knowledge gaps and insufficient test guidelines, not at least when it comes to early life stages. Aiming to evaluate and discover molecular key events for thyroid hormone system disruption, we used targeted quantification of 12 thyroid hormones (TH) and metabolites as well as untargeted metabolomics to investigate the molecular fingerprint of one model- and three suspected thyroid hormone system disrupting chemicals (THSDC). Propylthiouracil (PTU) is an antithyroid drug used to treat hyperthyroidism, which has been extensively used as a model THSDC. The brominated flame retardant tetrabromobisphenol-A (TBBPA), and the two pesticides pyraclostrobin and amitrole are compounds that have shown thyroid activity either *in vitro* or in *in vivo* experiments with other vertebrate species. To target the perinatal life stage, pregnant C57bl/6 mice were exposed from gestational day 7 to postnatal day 14, resulting in *in utero* and lactational exposure of the pups. Blood was then sampled from both mothers and pups and enriched for analysis in the targeted and non-targeted workflow.

TH metabolism was significantly affected by PTU, amitrole, and pyrachlostrobin, but not TBBPA. Interestingly the effects on the TH pathway were not similar across compounds. For instance, thyroxine (T4) and 3,3′,5′-triiodothyronine (rT3) were decreased by PTU but increased by pyrachlostrobin in both mothers and pups. Iodothyronine (T1) was decreased by PTU in mothers but increased by amitrole. Metabolomics analyses detected more than 10 000 endogenous metabolites in mothers and pups. Analyses are currently ongoing, but at least 6 metabolites were found to be significantly affected by both amitrole, pyraclostrobin and PTU in pups. These biomolecules are potential new quantifiable key events for determining thyroid hormone system disruption at the perinatal life stage. The results show that THSDCs may have different underlying mechanisms of toxicity and affect for instance thyroid hormone metabolic pathways at different points. This underlines the importance of not only looking at the most commonly measured thyroid hormones T3 and T4. Untargeted metabolomics is furthermore a valuable technique in identifying new approach methods to expand the repertoire of key event used to assess THSDC

1.14.P-We036 Does the Zebrafish Microbiome Bioactivate PFOS Precursors?

***Sebastian Gutsfeld**, Nicole Schweiger, Gabriel de Macedo, Heidrun Paschke, Qiuoguo Fu, Nils Kluver, Ulisses Nunes da Rocha and Tamara Tal, Chemicals in the Environment Research Section, Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany*

Chemical exposure can alter host-associated microbiomes. In turn, host-associated microbiomes harbor the capacity to modify chemical structures and form biotransformation products. Whether these changes cause adverse effects at the level of the host remains an open question. We previously showed that exposure to PFOS evokes hyperactivity in 5-day postfertilization (dpf) zebrafish. Although PFOS has been phased out of use, it has been replaced by larger, branched PFAS that are widely detected in the environment and can undergo biotransformation to form PFOS. We hypothesized that, similar to 5 dpf zebrafish, PFOS-dependent hyperactivity occurs in older larvae and that the microbiome can bioactivate PFOS precursors to generate the active metabolite PFOS. To test our hypothesis, zebrafish embryos were exposed to PFOS (0.28-5 μM), the PFOS precursors N-EtFOSA (0.07-1.25 μM) or PFOSAmS (0.83-15 μM), or 0.1% DMSO from 5-6 dpf. Chemical was removed at 7 dpf and swimming behavior was assessed at 8 dpf using a light-dark transition test. Similar to 5 dpf larvae, exposure to PFOS resulted in light- and dark-phase and visual startle response hyperactivity at 8 dpf. In contrast, exposure to N-EtFOSA or PFOSAmS triggered light- and dark-phase and visual startle response hypoactivity. Concentrations of the PFOS precursors and the metabolite PFOS were analyzed using liquid chromatography coupled to tandem mass spectrometry (LC-MS/MS) for target quantification. To identify the enrichment of microorganisms that harbor the potential to biotransform N-EtFOSA or PFOSAmS into PFOS, gut dissections were performed in 8 dpf larvae exposed to 5 µM PFOS, 0.7 µM N-EtFOSA, 8.4 µM PFOSAmS, or 0.1% DMSO and used for 16S rRNA gene amplicon sequencing and metagenomic sequencing to describe changes in community structure. These results show that larval exposure to PFAS compounds results in different phenotypic outcomes. Future work will pair the developed analytical approach with metagenomic sequencing to identify species-specific enzymes that are capable of bioactivating PFAS precursors to form PFOS. Collectively, this work seeks to address the degree to which the host-associated microbiome bioactivates widely occurring environmental chemicals.

1.14.P-We037 A New Approach Methodology (NAM) for Risk Assessment of SSbD Nanomaterials Based on Adverse Outcome Pathways Approach, Real Exposure Scenarios and Relevant Hazard Testing

Rossella Bengalli[1]*, Maurizio Gualtieri*[2]*, Giulia Motta*[2]*, Melissa Saibene*[2]*, Joan Cabellos*[3]*, Franco Belosi*[4]*, Marie Carriere*[5]*, Anna Costa*[6] *and Paride Mantecca*[2]*, (1)Earth and Environmental Sciences, University of Milano-Bicocca, Italy, (2)University of Milano-Bicocca, Italy, (3)LEITAT Technological Center, Spain, (4)National Research Council of Italy, Institute of Atmospheric Sciences and Climate (CNR-ISAC), Bologna, Italy, (5)Univ. Grenoble Grenoble Alpes, CEA, CNRS, IRIG-SyMMES, CIBEST, Grenoble, France, (6)National Research Council (CNR), Italy*

The use of new approach methodologies (NAMs) for the hazard assessment of chemicals, including nanoparticles (NPs) and nano-enabled products (NEPs), is rapidly increasing, due also to the request of the European Commission to promote new tools for the development of safe and sustainable by design (SSbD) materials. NAMs include *in silico*, *in vitro* and adverse outcome pathways (AOPs) testing strategies as alternative methods to animal testing. In this work, we provided a NAMs-based framework for the risk assessment of NPs, designed according to SSbD approach. The NAM we propose integrate the AOP perspective, real human exposure assessment and novel hazard testing approaches. First, NPs were assessed for their safety: NPs physicochemical properties were linked to the mechanistic aspects of their biological outcomes, using A549 human lung cells as target systems (Tier 1, *molecular*, and Tier 2, *cellular*, level of a given AOP). Comparative *in vitro* cytotoxicity tests were performed to define and measure representative biomarkers of key events (KE) along possible NPs-driven AOPs, with oxidative stress, inflammatory and genotoxic pathways being the main players. For realistic exposure scenarios, particulate matter (PM) mass concentration data from environmental monitoring campaign at a manufacturing site, during an industrial process to produce NEPs of interest, were gathered. Aerosol measurements (e.g., NPs size, concentrations, and effective density in air), were then used as inputs to calculate the alveolar retained doses through MPPD modelling. The MPPD doses, were then translated in real occupational monthly or yearly human exposure doses and then tested in an *in vitro* co-culture model representative of the lung alveolar space (A549 + THP1-derived macrophages cells). Exposures were performed at the air liquid interface (ALI), using the Vitrocell® Cloud α-12 system, to mimic actual inhalation and deposition of the NPs at the manufacturing site. Preliminary hazard endpoints evaluated were cell viability and inflammatory responses. This integrated approach represents a NAM that integrates a procedure to calculate the exposure doses for humans and the potential hazard resulting from the exposure in vitro complex models (Tier 3 according to AOPs). The results obtained, due to the application of NAMs, allow for more reliable and realistic interpretation of the hazard of new SSbD nanomaterials.

1.14.P-We038 Development of Potential Adverse Outcome Pathway for Neurotoxicity From Toxicogenomics Data Using Benchmark Dose Modeling Approach: Case Study on Valproic Acid

Jaeseong Jeong*, Kimoon Na and Jinhee Choi, School of Environmental Engineering, University of Seoul, Seoul, Korea, Republic of (South)*

Benchmark Dose (BMD) is a value calculated by a statistical method from a dose-response model and represents a certain level of pre-determined effect compared to the control group. valproic acid (VPA) is a drug used to treat epilepsy and bipolar disorder. Although rare, side effects such as spina bifida and neural tube obstruction may occur. Recent studies have shown that VPA affects cell growth, differentiation, apoptosis, and immunogenicity. In this study, by using human and rat ’omics data for VPA collected from Open TG-GATEs, an open toxicgenomics database, BMD values were analyzed to determine the key event (KE) and its sensitivity to develop quantitative adverse outcome pathway (AOP). Differentially expressed genes (DEGs) were analyzed from ’omics data using BMDExpress and Ingenuity Pathway Analysis (IPA), and major toxicity pathways were identified through toxicity pathway analysis based on DEGs. Then, BMD values were calculated and mapped onto DEGs and pathways to identify the important processes initiated at these values. Disease and phenotype data were collected from the AOP Wiki, Comparative Toxicogenmic Database (CTD, http://ctdbase.org/), and literature review to build the AOP. Finally, we suggest an AOP for neurotoxicity based on toxicogenomics data using benchmark dose modeling approach. This study showed the use of ’omics data in AOP development and the possibility of using BMD in quantitative AOP development.

Track 2: Ecotoxicology Becomes Stress Ecology: From Populations to Ecosystems and Landscapes

2.01 Advantages of Using Lab and Field Collected Invertebrates and *in situ* Studies in Ecotoxicology: Challenges and Opportunities

2.01.P-Th099 Environmental Concentrations of Carbaryl and Fenitrothion Alter Highly Conserved Biological Responses: From *D. magna* to Fish Species

Juliette Bedrossiantz[1], *Melissa Diogo Faria*[1], *Eva Prats*[2], *Carlos Barata*[3], *Jérôme Cachot* [4] *and Demetrio Raldua*[5], *(1)Environmental Toxicology, IDAEA-CSIC, Spain, (2)CID-CSIC, Spain, (3)Spanish Research Council (CSIC), Institute of Environmental Assessment and Water Research (IDAEA), Spain, (4)EPOC, University of Bordeaux-CNRS, France, (5)Environmental Toxicology, Spanish Research Council (CSIC), Institute of Environmental Assessment and Water Research (IDAEA), Spain*

Carbaryl and fenitrothion are two insecticides sharing a common mode of action, the inhibition of the acetylcholinesterase (AChE) activity. Their use is now regulated or banned in different countries, and the environmental levels of both compounds in aquatic ecosystems have decreased to the range of pg/L to ng/L. As these concentrations are below the non-observed-adverse-effect concentrations (NOAEC) for AChE inhibition reported for both compounds in aquatic organisms, there is a general agreement that the current levels of these two chemicals are safe for aquatic organisms. In this study we have exposed *Daphnia magna* and two fish species, zebrafish and medaka, to concentrations of carbaryl and fenitrothion under their NOAECs for 24-h, and the effects on heart rate (HR), basal locomotor activity (BLA), visual motor response (VMR), startle response (SR) and its habituation have been evaluated. Both pesticides increased the HR in the three selected model organisms, although the intensity of this effect was chemical-, concentration- and organism-dependent. The exposure to both pesticides also led to a decrease in BLA and an increase in VMR in all three species, although this effect was only significant in zebrafish larvae. For SR and its habituation, the response profile was more species- and concentration-specific. The results presented in this manuscript demonstrate that concentrations of carbaryl and fenitrothion well below their respective NOAECs induce tachycardia and the impairment of ecologically relevant behaviors in phylogenetically distinct aquatic model organisms, both invertebrates and vertebrates, emphasizing the need to include this range of concentrations in the environmental risk assessment.

2.01.P-Th100 Establishment of Chronic Toxicity Testing with *Cloeon Dipterum* Including Transcriptomics-Based Molecular Profiling

Kirsten Germing[1], *Maria Vogt*[1], *Lena Kosak*[2] *and Sebastian Eilebrecht*[1], *(1)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany, (2)Ecotoxicology, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany*

Aquatic larvae of the so-called EPT-taxa are frequently exposed to multiple contaminants and are shown to be highly sensitive. In Europe we are still lacking standardized test systems with more sensitive species, particular for chronic tests. We adapted a test system for chronic toxicity tests with the lentic mayfly species *Cloeon dipterum* and included transcriptomics-based molecular profiling.

Two chronic toxicity tests with field-collected larvae in an early development stage were performed; in both tests, Fipronil was used as test item in environmentally relevant concentrations (0.037 – 0.60 µg/L). The tests were conducted in glass beakers under conditions of standing water. During the tests, the grazing larvae were fed with *Navicula* grown on small tiles and carrots. The exposure was semistatic and test solutions and food were replaced twice a week. At each media renewal the development stages of the larvae were determined. As endpoints the larval development throughout the test, emergence and mortality were examined. In each test the concentration of Fipronil was determined by LC-MS/MS.

The long-term exposure test was conducted until all individuals had emerged or died (38 days). Emerged female individuals were sampled for further transcriptomic analysis. For the sublethal endpoint larval development statistical evaluations were performed for several time points. After a test duration of 7 days an EC50 of 0.70 mg/L was determined. For this test transcriptomics revealed no significantly differentially expressed genes when comparing treatments and control. Based on these results, we decided to repeat the test with an adapted test design.

The short-term exposure test was conducted for 7 days and transcriptomic analysis was performed with the larvae. For the endpoint larval development an EC10 of 0.029 mg/L was determined. Indeed, with this test setup, significantly differentially expressed genes (DEGs) were detected in the larvae using transcriptomics. We observed a concentration-dependent increase in the numbers of DEGs as well as strong positive correlation for their expression changes when comparing the different exposure concentrations.

We established a system for chronic toxicity tests with the lentic mayfly species *C. dipterum* successfully. Larval development was pointed out as an appropriate endpoint. Furthermore, transcriptomics were successfully applied to this model organism observing concentration-dependent gene expression changes.

2.01.P-Th101 Uncovering Metabolic Disturbances in Chitin Metabolism after Exposure to Teflubenzuron and Linking Them to Phenotypical Effects in *Daphnia magna*

Simon Schmid[1], *Diana Ilyaskina*[2], *Marja Lamoree*[3], *Pim Leonards*[4] *and Knut Erik Tollefsen*[1], *(1)Norwegian Institute for Water Research (NIVA), Norway, (2)Amsterdam Institute for Life and Environment (A-LIFE), Section Environment & Health, Vrije University Amsterdam, Netherlands, (3)A-Life, Vrije University Amsterdam, Netherlands, (4)Vrije University Amsterdam, Netherlands*

In order to grow, reproduce, and survive, arthropods need to shed their cuticle (exoskeleton) periodically through molting. In order to molt, arthropods depend on the formation of a new, larger cuticle stable to support muscular contractions during the molting process. As chitin is a major constituent of the arthropod cuticle, its synthesis is crucial and has been exploited as a target for control of unwanted arthropods by development of compounds such as chitin synthesis inhibitors (CSIs). We investigated the effects of the chitin synthesis inhibitor teflubenzuron (TEF) on selected metabolites of the chitin biosynthesis – and degradation pathway, as well as on molting and associated mortality. We aimed to identify responsive metabolites in the pathway and find possible metabolic markers to predict adverse phenotypical effects. To achieve our objectives, we exposed *Daphnia magna* to TEF (0.1-8 µg/L) for 48 h. After 24 h of exposure, we sampled *D. magna* for subsequent metabolite extraction and quantitative LC/MS analysis of 6 selected metabolites involved in chitin synthesis- and degradation.

We observed a dose dependent decrease in Trehalose (Tre) and increase in Glucose (Glc) levels, as well as nonmonotonic responses of Glucosamine (GlcN) and *N*-Acetylglucosamine (GlcNAc). The observed 24 h benchmark dose concentrations (BMCs, based on zSD Benchmark response) for the change in Tre, Glc, and GlcNAc (0.19, 0.53, and 0.44 µg/L, respectively), were found to be lower than both 24 h and 48 h BMCs for molting (2.64 and 2.63 µg/L, respectively) and survival (3.16 and 0.95 µg/L, respectively), indicating that metabolic modifications occurred prior to and at lower concentrations of TEF than adverse phenotypical (apical) effects. Alteration in levels of metabolites involved in both chitin synthesis and degradation suggest that multiple pathways, that are key to chitin synthesis and ultimately chitin integrity, are affected by exposure to TEF. In summary, quantified carbohydrates involved in chitin synthesis and degradation were found to be more sensitive endpoints than phenotypical effects and establish themselves earlier than the onset of molting disturbances or mortality.

2.01.T-01 The Population Development of Splash Pool Organisms under Copper and Predation Risk Exposure in Field Conditions

Jan Heuschele[1]*, Torben Lode*[2]*, Hilde Bruserud*[1]*, Trym Røil Dingstad*[3]*, Solveig Brochmann*[2] *and Katrine Borga*[2]*, (1)Department of Biosciences, University of Oslo, Norway, (2)University of Oslo, Norway, (3)Department of Biosciences,, University of Oslo, Norway*

In nature, organisms must cope with multiple biotic and abiotic stressors and anthropogenic contaminants. Copepods are one of the most abundant organisms and a crucial link in the aquatic food web. Especially coastal copepods are exposed to anthropogenic stressors such as copper. Copper (Cu) is an essential metal, but it becomes toxic at elevated concentrations and is used as a biocide in agriculture and as an antifoulant in aquaculture.

Natural factors can alter organisms' responses to contaminants. Predation risk affects population dynamics and interferes with their responses to Cu. Copepods often contain the carotenoid pigment astaxanthin – an antioxidant that lessens the impact of Cu, but increases the risk of visual predation. Contaminants' toxicity also depends on the physicochemical environment. In the intertidal and spray zone, conditions vary from optimal to hostile. Intertidal organisms, such as the harpacticoid copepod *Tigriopus brevicornis*, are adapted to cope with such extreme environments. Despite their hardiness, we saw potentiating effects of predation risk on copper effects on development in the lab, even at sub-lethal Cu concentrations. Here we tested whether these findings were detectable in a realistic field setting. We initiated 36 outdoor mesocosms and exposed them to predation risk (fish kairomones), Cu (10 µg L^{-1}), combined, and control. Each month, we quantified the population composition and size of copepods and other mesocosm inhabitants, and measured copepod's pigmentation and stable isotope composition.

Treatments had weak effects on the copepod population but a positive effect on nonbiting chironomids, which seem to thrive in the combined stressor treatment. In addition to the treatments, all inhabitants experienced high and fluctuating temperatures and salinities. Despite these extreme conditions, copepods were more pigmented with kairomones but not in combination with Cu. Our study shows the importance of studying contaminant effects in an environmentally realistic setting. Natural factors can interfere with and potentially mask long-term contaminant exposure's effects. However, even if temperature and salinity effects might be a more immediate threat to coastal copepod populations due to the ongoing climate crisis, natural and anthropogenic stressors are still detectable in natural populations and potentially influence the ability of copepods and other organisms to establish stable populations.

2.01.T-02 The Impact of the Anti-Sea Lice Chemotherapeutant, Hydrogen Peroxide, on Three Nontarget Crustacean Species

Rosa Helena Escobar Lux*, Aoife Parsons, Ann-Lisbeth Agnalt and Ole Bent Samuelsen, Havforskningsinstituttet/Institute of Marine Research, Norway*

The expansion of Atlantic salmon aquaculture in Norway has raised concerns about its impact on the marine environment, including negative effects on wild salmonid populations, the release of nutrients and chemical pollutants, as well as the spread of parasites such as the sea lice. To control the sea lice infestations in the salmonid farms, strict regulations have been put in place. To comply with these regulations, the industry has relied on chemotherapeutants. Hydrogen peroxide (H_2O_2) as a delousing agent, has the potential to negatively impact other species other than sea lice. Wild nontarget populations, living in the vicinity of aquaculture facilities, are especially at risk. Moreover, there is a growing need to carry out toxicity studies of the delousing chemotherapeutants on species that are ecologically relevant for the salmon producing nations. The aim of the study was to assess the acute toxicity of H_2O_2 to three important marine crustaceans of the Norwegian coast: the copepods *Calanus* spp., the Northern krill (*Meganyctiphanes norvegica*), and the European lobster (*Homarus gammarus*).
Though H_2O_2 has long been labeled as the most environmentally friendly topical treatment for treating sea lice infestations on salmonid farms, this study has shown that recommended H_2O_2 concentrations are lethal to nontarget crustaceans. Our results demonstrate that H_2O_2 was acutely toxic *Calanus* spp., *H. gammarus* and *M. norvegica*. We observed that lethal effects occurred

at concentrations well below recommended treatment concentrations. We have identified the keystone krill species, *M. norvegica*, as the most sensitive crustacean to H_2O_2 of tested so far. Sublethal effects were observed immediately after the 1 h exposure. Our behavioral results suggest that *Calanus* spp., the dominant component of the North Atlantic zooplankton communities, will be more susceptible to predation due to impairment of their escape response as a result of the paralysis induced by H_2O_2 at concentrations equivalent to 1% of the recommended treatment. And the behavior parameters linked with the shelter seeking behavior of the *H. gammarus* juveniles were negatively affected at concentrations low as 5% of the recommended treatment. The survival of newly settled lobsters depends on the ability to avoid predators and rapidly find a shelter. Young lobsters that reside in the vicinity of salmon farms treating with H_2O_2, may therefore be at a higher risk of predation.

2.01.T-03 Transcriptomic Comparison of Lab and Field Based Enchytraeids for Toxicity Testing
***Alex Robinson**[1], Stephen James Short[2], David J Spurgeon[1], Elma Lahive[1], Emily Eagles[1], Peter Kille[3] and Sylvain Bart[4], (1)UK Centre for Ecology & Hydrology (UKCEH), United Kingdom, (2)Pollution, UK Centre for Ecology & Hydrology (UKCEH), United Kingdom, (3)Cardiff University, United Kingdom, (4)Ministère de l'Écologie, du Développement durable, des Transports et du Logement, France*
Organisms are exposed to a wide range of toxicants in the environment and due to the number of species it is impossible to perform chemical risk assessments for all, so model organisms are used. Given the array of toxicants, high-throughput systems using lab cultured species are needed. Many laboratory test species are highly inbred, so may differ genetically to their wild counterparts, so it is important to compare their responses to wild animals.
Annelids fill vital ecosystem functions so earthworms are a key OECD test organism. Enchytraeids can provide similar data over a much shorter timespan. Unlike earthworms, where a realistic population can be field collected, enchytraeids for toxicity testing are reared in artificial culture conditions, hence responses may be very different. Are results from lab experiments due to transcriptomally “lazy worms”?
The effect of environment was compared using transcriptomes prepared from worms taken directly from 1) artificial culture, 2) after exposure in aquatic media, 3) having acclimated for 2 weeks in soil. Very minor differences were seen in the expression of genes relevant to toxicological response
While rearing or exposure conditions may not affect transcriptional profiles of worms, are these cultures representative of the wider population?
A transcriptome atlas has been generated of field collected *E. albidus* and the expression of toxicologically pertinent genes and the expression patterns are being compared with closely related (99% across CO1 genes) individuals from inbred cultures.
Given the transcriptomic validation, high throughput aquatic testing was used for 12 commonly used agrochemicals in *E. crypticus*. The transcriptomic responses to a selection of these chemicals (and their mixtures) are being analysed across a highly resolved time-series, revealing mechanistic insights into toxicity.

Overall, rearing conditions do not appear to have a major impact on the transcriptomic output *of E. crypticus*. Wild *E. albidus* are transcriptomally similar to culture for toxicologically pertinent genes. This means inbred lab cultures of enchytraeids, amenable to high-throughput exposure systems, are a good model for soil dwelling annelids. Our research suggests combining these systems and transcriptomics will allow a mechanistic understanding to help predict agrochemical sensitivity across annelids.

2.01.T-04 The Effects of Dexmedetomidine on the Behaviour of Crustaceans: Lab to Field Approach
*Susanne Vogeler[1], Elea Giraud[2], Daniela Famoso[2], Matthew Parker[3], Samuel Robson[2] and **Alex Ford**[2], (1)School of Biological Science, University of Portsmouth, United Kingdom, (2)University of Portsmouth, United Kingdom, (3)University of Surrey, United Kingdom*
Dexmedetomidine is an α2-adrenergic receptor agonist and was originally authorised as a human/veterinary sedative but is now an active ingredient in antifouling paint for boats. In crustaceans it is known to bind to octopamine receptors, which like other neurohormones, cascade to control many biological functions including behaviour. The aim of this study was to determine whether exposure to Dexmedetomidine can alter the behaviour of marine amphipods (*Echinogammarus marinus*) and juvenile crabs (*Carcinus maenus*) under laboratory conditions using both Zantiks and Daniovision behavioural analysis. Amphipod specimens were exposed between 0.1 and 100µg/L with behaviour recorded over several (1-3) days and (1-2) weeks and compared to controls and octopamine exposed individuals. Exposure significantly increased activity vs controls in both amphipods and crabs interesting non-monotonic concentration effects observed. We then set out to determine whether these results could be replicated in the field using acoustic telemetry in large adult *C. maenus* were exposed to Dexmedetomidine and octopamine and tagged and released into a saline lake. The field experiment is ongoing but the results of which will be presented representing the first acoustic telemetry project with crabs looking into the behavioural effects of an environmental contaminant.

2.01.P Advantages of Using Lab and Field Collected Invertebrates and in Situ Studies in Ecotoxicology: Challenges and Opportunities

2.01.P-Th102 The Amphipod *Gammarus pulex* Thrives in Polluted Habitats but Genetic Diversity is Affected
*Vid Svara[1], Martin Krauss[2], Stefan G. Michalski[3], Tobias Schulze[2], Stephan Geuchen[4], Rolf Altenburger[4], Werner Brack[5] and **Till Luckenbach**[4], (1)UNESCO Chair for Sustainable Management of Conservation Areas, IT & Engineering, Carinthia University of Applied Sciences, Austria, (2)Department of EffectDirected Analysis, Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany, (3)Department of Community Ecology, Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany, (4)Department of Bioanalytical Ecotoxicology, Helmholtz Center for Environmental Research (UFZ), Leipzig,*

Germany, (5)Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany
The freshwater amphipod *Gammarus pulex* Linnaeus, 1758 occurs in both pristine and anthropogenically polluted sections of European rivers. Applying population genetics approaches, we addressed the question, whether *G. pulex* is impacted by a selective effect of ecotoxicologically relevant anthropogenic organic micropollutants (AOM) in polluted field sites. We performed a regional scale study with *G. pulex* sampled at differently polluted sites at six rivers in central Germany. The *G. pulex* genetic population structure was analyzed by genotyping 16 microsatellite markers and by comparisons of individual DNA sequences of a segment of the mitochondrial cytochrome oxidase I (COI) gene. In parallel, AOM contamination levels and their toxicity potentials at the sampling sites were determined by measuring an array of AOM in water and amphipod tissue samples. Genetic data indicated intact gene flow within the rivers; a separation of genetically differently adapted *G. pulex* subpopulations by chemical water contaminants was not indicated. However, there was a clear trend of reduced genetic diversity of *G. pulex* from sites with higher AOM levels. Tissue levels of AOM in *G. pulex* were found to depend on AOM levels at the respective sampling sites, with higher AOM tissue levels and accordingly higher chemical toxicity potentials in individuals from the more polluted sites. As indicated by a lab experiment with the model toxicant imidacloprid toxic susceptibility of *G. pulex* for adverse chemical effects was higher when individuals were from a sampling site with increased AOM water and tissue levels. Although *G. pulex* can be abundant in river stretches with high AOM levels our studies, comprising population genetics, chemical analysis and toxicological approaches, show that *G. pulex* is affected by AOM: 1) Continuous exposure to certain AOM levels in the species' habitat leads to an increase of its toxicological sensitivity on the individual scale; 2) AOM caused reduced genetic diversity on the population scale. Reduced genetic diversity and increased sensitivity may lead to a reduction of species resilience to further stressors in its habitat.

2.01.P-Th103 Effects of Artificial Light at Night on Two Freshwater Invertebrates
Diana Campos[1]*, Ana Luísa Machado*[1]*, Bruna Silva*[2]*, Filipa Veiga*[2]*, Isabel Lopes*[1] *and João L.T. Pestana*[1]*, (1)University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Aveiro, Portugal, (2)University of Aveiro, Department of Biology, Aveiro, Portugal*
Light pollution is one of the emerging environmental concerns. ALAN has been expanding worldwide, and it is expected to increase continuously, in the upcoming years, according to IUCN. Artificial light at night (ALAN) leads to changes in natural light timing, intensity, and spectrum. Consequently, human health and biodiversity have been threatened since the day/night light cycle plays a crucial role in living organisms' behavioural and physiological processes. In fact, ALAN, namely from white LEDs that emit a wavelength peak in the blue range, is associated with the suppression of nocturnal melatonin production. Melatonin, the time-keeping hormone, regulates biological rhythms and an array of physiological processes and has been appointed as a key sensitive response to ALAN in many organisms. We present work aimed to assess the effects of ALAN on the life history traits of two freshwater invertebrates: the insect *Chironomus riparius* and the planarian *Girardia tigrina*. This work also aimed to understand the potential role of the hormone melatonin as mediator of light pollution effects.
For that*, C. riparius* were exposed for 28 d to three light regimes (control, i.e., dark nights) and two relevant levels of ALAN (1, 10 lux during the night period), in the absence and presence of exogenous melatonin (1 μM). Larval growth, development time, and imagoes body weight were analysed. *G. tigrina* were exposed for 10 days to the same treatments. After exposure, behavioural endpoints (feeding and locomotion) and cephalic regeneration after decapitation (blastema length, photoreceptors, and auricle formation) were evaluated.

Results show that exposure to ALAN led to delayed emergence of *C. riparius* (significantly for females) and altered males imagoes size. Concerning *G. tigrina,* exposure to ALAN caused a delay in head regeneration, with no clear effects in behaviour. Results also indicate that exogenous melatonin could help mitigate the ALAN-elicited effects suggesting that ALAN might affect its production in aquatic invertebrates. However, further studies are needed to clarify this and ongoing experimental work is evaluating biochemical responses (e.g., energy metabolism and oxidative stress/damage). Results suggest that low, environmentally relevant intensities of ALAN could affect the life history traits of freshwater invertebrates, potentially leading to adverse population-level effects.

2.01.P-Th104 Broadening the Perspective of Environmental Stress in Aquatic Ecosystems due to Contamination: An Approach using the Habitat Selection Response Based on a Cost-Benefits Balance
María del Pilar Gonzalez Muñoz[1]*, Andrea Cordero*[2]*, David Salvatierra*[2]*, Mohammed Islam*[2,3]*, Helmut Stremmel*[4]*, Lucía Herrera*[5]*, Eloisa Ramos-Rodriguez*[6]*, Gema Parra*[7] *and Cristiano Araújo*[2]*, (1)Instituto de Ciencias Marinas de Andalucía, Spain, (2)Institute of Marine Sciences of Andalusia (CSIC), Spain, (3)Faculty of Fisheries, Sylhet Agricultural University, Bangladesh, (4)Ruhr University Bochum, Germany, (5)Environmental and Food Safety Research Group of the University of Valencia (SAMA-UV), Spain, (6)University of Granada, Spain, (7)University of Jaén, Spain*
If it is assumed that mobile organisms move to look for food, a safe habitat, to mate or to avoid predators, why is the same not expected to occur when they are confronted by contamination? What would happen if we looked at the effects of contamination from another perspective, by broadening the way that toxicity is assessed? From a wider conceptual perspective, some particularities that can condition the responses of organisms to contamination should be considered: (i) are organisms able to escape from contaminants thus avoiding their toxic effects? (ii) what is the role of contamination in organisms' habitat selection processes? The aim of this work is to show, firstly, evidences of the role of contaminants in the organisms' decision to stay in or avoid an ecosystem and, secondly, how a nonforced approach could be integrated to the forced exposure approach to understand the balance of cost-benefits performed by organisms when a contaminated habitat is selected. In addition, we will show the different nonforced multicompartmented exposure systems that have been developed at different spatial scales (mini- and

mesocosms) to simulate spatially connected heterogeneous contamination scenarios (methodological advance). Our recent data show that contamination by the agrochemicals chlopyrifos and terbuthylazine at 10 µg/L was not very aversive to *Daphnia magna*; however, in mixture they considerably prevented the colonization response (even at 0.01 µg/L). In a cost-benefits study, copper showed to be aversive to the freshwater shrimp *Atyaephyra desmarestii*, but when simultaneously confronted to contamination, risk of predation, and presence of shelters, shrimps made an environmental analysis moving toward moderately contaminated area with shelter and lower risk of predation, instead of selecting clean areas with predation risk. Finally, we observed the attraction exerted by fluoxetine on *D. magna* (organisms moved to 800 µg/L) even at lethal concentrations (LC50 was 365 µg/L), disturbing the cost-benefits balance. This approach represents an effort to broaden the ecology component within ecotoxicology, where contaminants are integrated as an ecological element (Stress Ecology), providing a tool that could be used complementarily with the traditional forced exposure approach. Finally, the nonforced exposure approach allows to include ecological concepts as habitat selection and colonization (conceptual advance) to Ecotoxicology.

2.01.P-Th105 Application of a Feeding Inhibition Test with the Mayfly *Cloeon dipterum*

***Silke Claßen**[1], Eric Bruns[2], Andre Gergs[3], Katrin Gergs[4] and Jutta Hager[3], (1)Research Institute gaiac, Germany, (2)Environmental Safety, Bayer AG - Crop Science Division, Germany, (3)Bayer AG - Crop Science Division, Germany, (4)gaiac - Research Institute for Ecosystem Analysis and Assessment, Aachen, Germany*

In recent years, the interest of testing nonstandard species for environmental risk assessment of pesticides has increased. Particularly, interest in mayflies increased due to their relevance in aquatic ecosystems and sensitive response to exposure to certain pesticides.

In this context, we developed a semistatic test system to investigate the food uptake and thus the potential feeding inhibition on the mayfly *Cloeon dipterum*, exposed to different concentrations and exposure scenarios of two insecticides. The exposure scenarios differed in the duration of the preexposure to the test substance (48 h, 24 h, 8 h) which allows the quantification of onset of effects. During the feeding period, the larvae were provided with laboratory grown periphyton. For the periphyton culture, a natural inoculum collected in field was used and the periphyton was grown on unglazed tiles under controlled conditions. The quantity of the periphyton was measured fluorometrically as chlorophyll-*a* concentration at the start and the end of the 96 h feeding period. The experiments consisted of 20 replicates for each of the six concentrations and the control. Each replicate contained one single medium-sized larvae of *C. dipterum* grazing on one tile covered with a predefined periphyton layer. Additionally, five replicates were prepared for each concentration and the control to determine the growth of the periphyton in the absence of larval feeding. The food uptake was calculated as amount of periphyton consumed by a larva over the feeding period corrected by the growth of periphyton without grazing. Despite considerable variability, the results revealed a concentration- and time-dependent decrease in food uptake: effects in lower concentrations tend to increase with the exposure duration also in the absence of signs of immobilization. Nevertheless, further development regarding the standardization and culture of food is needed to particularly reduce variability as observed for the measured endpoints.

2.01.P-Th106 All the Way up? – Does Contaminated Biofilm Affect its Grazer *Cloeon dipterum*?

***Sophie Oster**, Mugilvannan Sivagnanam and Mirco Bundschuh, iES Landau, University of Kaiserslautern-Landau (RPTU), Germany*

Ecosystems are multibranched and multilevelled networks. Aquatic ecosystems are based on multiple connections within and among trophic levels supporting ecosystem integrity. Chemical stress can disrupt these interactions and lead to shifts in structure and function. Direct effects of chemicals have been widely studied, but studies of potential indirect effects are scarcer. Against this background, aquatic biofilms acting both as primary producers and food source for primary consumers were offered as food to the mayfly larvae *Cloeon dipterum* after exposure to chemical stress. To do so, we collected biofilm from a small river in a natural reserve in Rhineland-Palatinate (Germany) serving as inoculum colonising ceramic tiles in the Landau Laboratory Stream Microcosms. After a four-week period of precolonisation, biofilms were chronically (14 days) exposed to 1) 10 µg/L of the herbicide propyzamide, 2) 10 µg/L of the antibiotic ciprofloxacin and 3) to the mixture of both. Subsequently, we fed the biofilm to field collected *Cloeon dipterum* larvae (larval stage 1-3) under controlled conditions for 21 days. Grazers were analysed regarding growth, physiological condition (fatty acid composition), and feeding activity, while the biofilm was analysed in terms of biomass using ash free dry weight data, chlorophyll content, and fatty acid composition. The data are currently being analysed supporting a coherent interpretation of potential bottom-up effects among trophic levels.

2.01.P-Th107 The Use of *Potamopyrgus antipodarum* Feeding Rates as a Sensitive Ecotoxicological Endpoint: Effect of Salinity and Niclosamide

*João L.T. Pestana[1], Inês Paulino[2], Marcos Dias[2] and **Ana Luísa Machado**[1], (1)University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Aveiro, Portugal, (2)Biology, University of Aveiro, Aveiro, Portugal*

Potamopyrgus antipodarum is a detritivore freshwater snail species native to New Zealand that has become a successful invader in a variety of freshwater environment. Characteristics such as its worldwide distribution and a wide tolerance to a range of environmental factors led this species to be proposed as a potential model species in ecotoxicology. Additionally, its exclusively parthenogenic reproduction outside its native distribution allows for the easy isolation of clonal lineages. A standard protocol has already been developed for the use of *P. antipodarum* reproductive output (OECD guideline no. 242) as an endpoint to assess potential effects of contaminants exposure.

In this work, we explored the potential use of feeding rate as an additional endpoint in ecotoxicological assays using *P. antipodarum*. We carried out 8 to 10 day feeding tests, in which we measured the leaf consumption (alder leaves discs) of *P. antipodarum* exposed to sublethal levels of salinity and the molluscicide Niclosamide. Results demonstrated the high sensitivity of *P. antipodarum* feeding rates, since significant feeding inhibition was observed in snails exposed to both stressors. These results were also comparable to those obtained with previously performed standard 28-day reproduction tests, in which the number of embryos present inside the oviduct of each female were counted, in response to the same stressors.

The developed bioassay was proven to be as sensitive as reproduction (number of embryos produced per female) presents several advantages in relation to the 28-day reproduction test (since it does not involve the dissection of all test organisms, less time consuming) and offers possibilities to be applied in *in situ* exposures.

2.01.P-Th108 Standard Laboratory and Field Experiments to Assess the Toxicity of Three Pesticide Formulations to Collembola

*Liyan Xie[1], **Saúl Fernandes**[2], Camilla Drocco[3,4], Martin Holmstrup[5], Stine Slotsbo[1], Bernhard Förster[3], Anja Coors[3] and Cornelis A.M. van Gestel[6], (1)Aarhus University, Denmark, (2)Amsterdam Institute for Life and Environment (A-LIFE), Section Ecology & Evolution, Vrije University Amsterdam, Netherlands, (3)ECT Oekotoxikologie GmbH, Floersheim am Main, Germany, (4)AgroSup Dijon, INRAE Agroécologie, Univ. Bourgogne, Univ. Bourgogne Franche-Comté, France, (5)Department of Ecoscience, Aarhus University, Denmark, (6)Amsterdam Institute for Life and Environment (A-LIFE), Vrije University Amsterdam, Netherlands*

Field studies may help to clarify how pesticides change population dynamics and community structures in realistic scenarios. However, ecotoxicity data for most pesticides are only available from single-species tests. The aim of this work is to assess the effects of three commercial pesticide formulations on the diversity of Collembola in an agricultural field in parallel with standard laboratory toxicity tests.

The commercial formulations tested were fungicidal product (200 g/L pyraclostrobin), insecticidal product (100 g/L zeta-cypermethrin), and herbicidal product (300 g/L clopyralid). The toxicity tests were performed following OECD guideline 232 for assessing effects on the reproduction and survival of *Folsomia candida*. The tests used a range of seven concentrations covering the predicted environmental concentrations of the active substances in Lufa 2.2 soil.
Dose-response curves were fit to the data to estimate effect concentrations.
In the field experiment, the formulations were applied at 1× and 10× the recommended dose. Each treatment was replicated in three different plots, randomly placed on the field, and each replicate was sampled three times at each time point. Samples were collected 1 day before pesticide application and 7 and 28 days after application. The number of Collembola was counted, and the diversity of families and species was estimated using Shannon's diversity index. The effects of the pesticides, dose and time were tested using linear mixed-effect models.
The toxicity tests showed that the herbicide and the insecticide had small to no effects on survival, while the fungicide resulted in a LC_{50} of 19.6 (95% CI: 17.5 - 21.8) mg a.s. kg^{-1} soil. The reproduction of *F. candida* was likewise more sensitive to the fungicide, with an EC_{50} of 10.7 (9.4 -11.9) mg a.s. kg^{-1} soil, followed by the insecticide and the herbicide. These values are 10 times higher than the PEC for this active substance after application of 10x the recommended dose. The preliminary results from the field sampling show no significant ($p<0.05$) effects of chemical dose or time on the abundance and diversity of Collembola. Despite that, the average diversity index of the plots treated with the fungicide was consistently lower than the control on days 7 and 28 after pesticide application. These data will be further analyzed using a trait-based approach to gain more insight into the impact of these pesticides on microarthropod functional groups and soil processes.

2.01.P-Th109 Indirect Effects of Antibiotics and Fungicides on Aquatic Macroinvertebrate Food Webs via Bottom-up Regulation

***Frederik Meyer**, Ralf Schulz and Mirco Bundschuh, iES Landau, Institute for Environmental Sciences, University of Kaiserslautern-Landau (RPTU), Germany*

Organic matter of terrestrial origin, such as leaves, represents a large proportion of the energy budget in streams with a forested catchment. Nutrients and energy bound in leaf litter are made accessible to the wider aquatic food web by microbial decomposers (bacterial communities and fungi) and shredding macroinvertebrates. Microorganisms can improve the nutritious quality of leaves for shredders by reducing leaf toughness and by concentrating essential elements (=conditioning). Antimicrobial substances, which are released into streams via wastewater or runoff, can modify the conditioning processes leading to bottom-up directed effects on shredding macroinvertebrates. However, consequences for species interactions translating to changes in the aquatic food web are unclear. Therefore, the main objective of this study was to investigate bottom-up directed effects by antimicrobial stressors in aquatic macroinvertebrate food webs. For this purpose, leaves were conditioned two weeks under exposure to 8 concentrations of an antibiotic (ciprofloxacin) and a fungicide (azoxystrobin), respectively, presuming alterations in the leaf-associated microbial community. After conditioning, these leaves were provided to an extended macroinvertebrate food web in model stream ecosystems (16 x 3.6 m long flow through stream microcosm). During this 4-month experiment several samples were taken. Conditioned leaves were sampled bi-weekly to assess the community of bacteria and aquatic hyphomycetes via next generation sequencing (NGS) and qPCR. At the termination of the experiment for each stream 3 locations were sampled with a self-made Surber sampler (25x25cm) to determine potential community-level effects. Qualitative samples were taken between the three sampling sites for stable isotope and fatty acid analysis. The results are expected to provide new insights into the effect sizes of bottom-up directed effects in heterotrophic food webs on community structure, trophic interactions and energy reserves. Thereby fundamental knowledge is generated for a field which received little to no attention in the past.

2.01.P-Th110 Sensitivity Differences to Imidacloprid Among Aquatic Invertebrates Can be Explained by Toxicokinetic and Toxicodynamic Models

***Anna Huang*[1]*, Ivo Roessink*[1]*, Nico van den Brink*[2] *and Paul van den Brink*[3]*, (1)Wageningen Environmental Research (WUR), Netherlands, (2)Division of Toxicology, Wageningen University & Research, Netherlands, (3)Wageningen University & Research, Netherlands*

In ecological risk assessment, both standard and nonstandard aquatic invertebrate species are used to increase environmental realism. *Daphnia* is one of the most commonly used standard species and is easily cultured in the lab. *Daphnia* has been used for various chemical effect assessments; however, it could not capture the effect of neonicotinoids, frequently used pesticides. Therefore, a previous study proposes to replace or add additional nonstandard test species, such as insects and crustaceans. In addition, such nonstandard aquatic species are often not lab-cultured but collected from the field before actual testing, which introduces potential uncertainties. For example, researchers often pragmatically select test organisms of specific sex and/or size, which may not represent the sensitivity of the whole population.

To understand the mechanism of these sensitivity differences, effect models like toxicokinetics−toxicodynamics models can be used. Also, lately, these models have been recommended to use in risk assessment for the risk assessment of pesticides for aquatic organisms.
To understand the high tolerance of *Daphnia*, we compared the toxicokinetics and toxicodynamic difference between *Daphnia magna* and several aquatic invertebrates, like Mayflies, Amphipods and Isopods. We found that the high tolerance of *Daphnia* could be explained by its fast elimination rate and lack of the biotransformation of the imidacloprid to a toxic metabolite.

In addition, to compare the intra-sensitivity difference, such as size and sex, we performed acute toxicity and simple toxicokinetic experiments with different size and sex groups (neonates of unknown sex, juveniles of unknown sex, adult females and adult males) for both crustacean species (*Gammarus pulex* and *Asellus aquaticus*). For both species, we found that neonates were the most sensitive group. For *G. pulex*, the sensitivity decreased linearly with size, which can be explained by the size-related uptake rate constant in the toxicokinetic process and size-related threshold value in the toxicodynamic process. For *A. aquaticus*, female adults were least sensitive to imidacloprid, which could be explained by the low internal biotransformation of imidacloprid to a toxic metabolite, imidacloprid-olefin.

2.01.P-Th111 *In vitro* Bioaccumulation Assessment of Nanoplastics to Freshwater Mussels Hemocytes - Can These Circulating Cells Serve as Proxy of Plastic Pollution in Environmental Biomonitoring Programs?

***Vanessa Modesto*[1]*, Nicoletta Riccardi*[2] *and Marisa Sarria Pereira de Passos*[3]*, (1)IRSA CNR Verbania: Instituto di Ricerca sulle Acque, Consiglio Nazionale delle Ricerche, Sede di Verbania, Italy, (2)Water Research Institute - Italian National Research Council IRSA-CNR, Italy, (3)EU Commission JRC, Ispra, Italy*

Bioaccumulation is a key process (or factor) in/for the assessment of nanoplastics risk to the environment. Within aquatic ecosystems, freshwater mussels are particularly relevant to serve as bioindicators of plastic pollution due to their high filtration rate and their ability to bioaccumulate and bioconcentrate toxicants. However, methodologies supporting nanoplastics bioaccumulation assessment, facilitating the understanding and data integration into comprehensive biomonitoring programs using these organisms are lacking. Moreover, their suitability for inter-species comparisons, *in vitro-in vivo* extrapolation and the lack of accurate predictive procedures remain major challenges.

Owing to an open circulatory system, freshwater mussels hemocytes may constitute one appropriate noninvasive *in vitro* alternative for a mechanistic understanding of the nanoplastics associated effects. This approach could then be applied on environmental biomonitoring campaigns that will permit to prioritize and survey nanoplastic contaminated areas, prevent harmful exposures to the public and evaluating policy interventions related to environment plastic exposure risk mitigation and management.

In this work, freshwater mussels were used to investigate hemocytes aptness to act as swiftly and early sentinel of nanoplastic exposure. Hemolymph of mussels was (noninvasively) extracted from the posterior adductor muscle and hemocytes were isolated from plasma, counted and cultured to conduct functional *in vitro* assays relevant for nanoplastics bioaccumulation assessment.

2.01.P-Th112 Performance and Robustness of the *ex situ* Continuous Biomonitoring System for Coastal Waters Based on a Heart Rate of Mediterranean Mussel (*Mytilus Galloprovincialis* Lamarck, 1819)

Marko Nikolic[1]*, Sergey Kholodkevich*[2]*, Tatiana Kuznetsova*[2]*, Anton Kurakin*[2]*, Sladjana Nikolic*[3]*, Tanja Tomic*[4] *and* ***Ivana Teodorovic*[5]*, (1)NGO Environment Program, Montenegro, (2)Saint-Petersburg Scientific Research Center for Ecological Safety Russian Academy of Sciences, Russian Federation, (3)University of Montenegro, Institute of Marine Biology, Montenegro, (4)University of Novi Sad, Faculty of Sciences, Serbia, (5)Faculty of Sciences, University of Novi Sad, Serbia*

The focus of this research was the assessment of the robustness of *ex situ* biomonitoring system based on physiological biomarker, namely heart rate of Mediterranean mussel. Experimental set-up provided not only insight into reliability of the early warning system and variability of heart rate over a year-long continuous operation but enabled defining the optimal shelf life of bioindicator organism in the continuous biomonitoring. Basal heart rate dynamics in control conditions, with no significant stress, demonstrated considerable time-dependent individual and group variability. Still, the responses of all tested specimens, regardless of their individual variability, followed a similar behavioral trend, which implies that the test individuals can be clearly regarded as a group. The responses of selected physiological biomarker did not follow circadian or seasonal pattern. The sensitivity of automated *ex situ* system and selected species to natural variation of a number of environmental variables has also been investigated. The results indicate that the mussels' heart rate is not affected by the key environmental factors provided they remain within the usual variation range typical for the selected site. The overall physiological condition of test individuals and performances of monitoring system have been tested on monthly basis by group response to short-term exposure to extreme stress conditions (a sharp salinity decrease). Selected biomarkers, coefficient of variation, and recovery time of heart rate after the exposure to stress proved to be good indicators of condition of individuals in monitoring system. Successive increase of the heart rate recovery time was recorded already from the second month of monitoring onwards, while the complete absence of an expected response to stress – change of the heart rhythm – was apparent during the last four months of monitoring. These results indicate that the individuals in the monitoring system have limited optimal shelf life and that after three to four months of continuous monitoring, the system is subject to "fatigue". To maintain the optimal performance of the system, individuals need to be gradually replaced after three to four months.

2.01.P-Th113 The Effects of Plastic Additives on Male Fertility and Reproductive Behaviour in Marine Amphipod
Bidemi Green-Ojo[1]*, Marina Tenório Botelho*[2]*, Matthew Parker*[3]*, Gisela Umbuzeiro*[2]*, Vicente Gomes*[4]*, Lena Grinsted*[1] *and Alex Ford*[1]*, (1)University of Portsmouth, United Kingdom, (2)School of Technology – State University of Campinas, Brazil, (3)University of Surrey, United Kingdom, (4)University of São Paulo (USP), Brazil*
In a plastic-dominated world, there are predicted to be over 10 000 chemical additives, of which over a quarter are reported to be neurotoxic, immunotoxic, and endocrine disruptors. Most are not chemically bound and are commonly known to leach out into the environment. The ban on legacy pollutants like di-ethylhexyl phthalate (DEHP) and dibutyl phthalate (DBP) does not preclude their potential toxic effects on already exposed biota. At the same time, other groups of plastic additives, including n-butylbenzenesulfonamide (NBBS) and triphenyl phosphate (TPhP), have now been placed on the international watchlist for evaluation. This study aims to assess the effects of these plastic additives on male fertility and reproductive behaviour in the marine amphipod, *Echinogammarus marinus*. We assessed male infertility by exposing male amphipods to environmental and laboratory concentrations of DEHP, DBP, TPhP and NBBS for 14 days, after which sperms were counted. For reproductive behaviour, 20 precopulatory pairs of *E. marinus* were exposed to varying concentrations of the test compounds. High throughput optimization of the precopulatory pairing behaviour was developed and repairing success was recorded at 15mins and daily for 96 h. Sperm count declined after 14 days of exposure. Animals exposed to DBP and TPhP showed a dose-response relationship with significant differences in the highest concentration. Repairing success was impacted by the presence of the test compounds even at low concentrations. Animals in the exposed group took a long time to reform pairs. The percentage of repairing success ranged from 80 – 100 % in the control group and 0 – 40% in the highest concentration for DEHP, DBP, NBBS and TPhP. Overall, this study provides evidence that reproductive mechanisms and sperm parameters of amphipods can be impacted by plastic additives even at environmentally relevant concentrations. Thus, demonstrating the potential of this endpoint in toxicity testing and its implications on population-level effects.

2.01.P-Th114 Assessment of the Toxic Effects of 10 Types of Detergents on the Microcrustacean *Hyalella azteca*
Alma Sobrino-Figueroa[1]*, Alberto Perez-Rojas*[2] *and Sergio Alvarez-Hernandez*[3]*, (1)Hydrobiology, Universidad Autonoma Metropolitana Iztapalapa, Mexico, (2)Universidad Autonoma Metropolitana Iztapalapa, Mexico, (3)Hidrobiology, Universidad Autónoma Metropolitana-Iztapalapa, Mexico, Mexico*
The detergents are synthetic compounds, containing surfactants and additives. They alter the water quality and are toxic to aquatic organisms. Due to the fact that in our country the studies of these products are scarce, in this work the toxicity of 10 commercial brands of detergents, which are used for washing dishes, washing clothes, washing hands, and general use, in the microcrustacean *Hyalella azteca*, was evaluated. Bioassays lasting 96 h were performed. Twenty organisms were exposed to 7 detergent concentrations (1, 5, 10, 20, 40, 60, and 80 mg/L) in triplicate, plus a nontoxic control. With the mortality data, the LC_{50} was determined. Subsequently, a bioassay was carried out exposing the microcrustaceans to 3 sublethal concentrations. After 4 days of exposure, the level of lipid peroxidation (TBARs) and the activity of the AchE enzyme were determined. In the data obtained, significant differences were observed between the response of the control group and the organisms exposed to the detergents ($p < 0.05$). The most toxic detergent was a product used for washing dishes and the least toxic was a product for general use. The highest TBARs levels were recorded in organisms exposed to detergents used for dishwashing and laundry (from 76.5 to 52.4 nM TBARs/mg) and the lowest in microcrustaceans exposed to a general use product (10.6 nM TBARs/mg) (the value obtained in the control was 3.1 nM TBARs/mg). A decrease in AchE activity of between 8 and 46% was observed in organisms exposed to dishwashing, handwashing, and laundry detergents. Since wastewater treatment is limited and detergents are discharged directly into the environment, it is important to know the potentially adverse effects of these compounds in order to propose mitigation measures.

2.01.P-Th115 Effects of Exposure to Cadmium on Juveniles of Pearl Oyster *Pteria sterna* (Gould, 1851)
Alma Sobrino-Figueroa[1]*, Carlos Cáceres Martínez*[2]*, Alberto Perez-Rojas*[3] *and Sergio Alvarez-Hernandez*[4]*, (1)Hydrobiology, Universidad Autonoma Metropolitana Iztapalapa, Mexico, (2)Efecto Arena AC, (3)Universidad Autonoma Metropolitana Iztapalapa, Mexico, (4)Hidrobiology, Universidad Autónoma Metropolitana-Iztapalapa, Mexico, Mexico*
Pteria sterna is an economically important bivalve because it produces high-quality pearls. Currently the natural populations of these organisms have disappeared; the cause is attributed only to overexploitation, since there are no environmental studies to

detect other possible variables that cause the disappearance of the banks. Due to the lack of studies on the effect of metals on *Pteria sterna*, the objective of this work is to evaluate the toxic effect of cadmium on pearl oyster juveniles. Bioassays lasting 48 h were performed where 5 metal concentrations were tested (5, 1, 0.5, 0.1, 0.05 mg L^{-1}). With the mortality data, the LC_{50} was calculated. The bioassays evaluated: respiration rate, excretion rate, O:N ratio, lipid peroxidation degree (Tbars) (in gills) and acetylcholinesterase (AchE) enzyme activity (in foot tissue). The LC_{50} obtained was 1.52 mg L^{-1} (48 hours). Significant differences were observed between control and exposed organisms ($p < 0.05$). The respiration rate of oysters exposed to cadmium was 40% to 80% lower compared to the control. The excretion rate increased between 20% to 60%. Cadmium had an inhibitory effect between 18 and 72% on the activity of the acetylcholinesterase enzyme. The degree of lipid peroxidation in oyster tissues increased up to 200%. The O:N index had values below 10, indicating a high degree of stress. According to our results, it was evident that cadmium in sublethal concentrations has a deleterious effect on oysters, increases the degree of stress, and has an oxidative and neurotoxic effect.

2.01.P-Th116 Comparison of the Acute Toxicity for Two Pyrethroid Pesticides to *Chironomus riparius* and *Glytotendipes tokunagai*

Chang-young Yoon[1], *Kyongmi Chon*[2], *Jun-Hyoung Bang*[1], *Jin-A Oh*[2], *Bo-Seon Kim*[2], *Juyeong Kim*[2] *and Young-Eun Na*[1], *(1)Toxicity and Risk Assessment Division, Rural Development Administration, Korea, Republic of (South), (2)Toxicity and Risk Assessment Division, National Institute of Agricultural Sciences, Korea, Republic of (South)*

The chironomid is a benthic organism and affected by pesticides adsorbed to sediments or remained in sediments through elution into water systems and river flooding. Pyrethroids are synthetic insecticides with chemical structures similar to those of natural insecticides, pyrethrins, and are used worldwide. Etofenprox and fenpropathrin are pyrethroid pesticides, known to have the log P value higher than 3. It means there is a high possibility of soil adsorption. Currently, environmental risk assessment is conducted for aquatic (fish, water fleas, and green algae) and terrestrial organisms (honey bees, earthworms, and birds) for pesticide registration in Korea. However, since benthic organisms are not included in the evaluation target, it is necessary to expand the evaluation species reflecting various habitats. Therefore, we compared the toxicity of *Chironomus riparius* and *Glyptotendipes tokunagai* (the Korean native species) to etofenprox and fenpropathrin to set up the acute toxicity test and risk assessment criteria for benthic organisms. The result of the acute chironomid toxicity tests showed that the 48h EC_{50} values of *Chironomus riparius* and *Glyptotendipes tokunagai* for etofenprox were 0.00112 and 0.00691 mg/L, respectively. In addition, the 48h EC_{50} values of fenpropathrin for *Chironomus riparius* and *Glyptotendipes tokunagai* were 0.0000472 and 0.00600 mg/L, respectively. *Chironomus riparius* showed a higher toxicity sensitivity to etofenprox and fenpropathrin than *Glyptotendipes tokunagai*.

2.02 Aquatic and Terrestrial Plant Ecology, Ecotoxicology and Risk Assessment

2.02.T-01 Novel Genomic Markers of Susceptibility to Paraquat, Diuron, and Atrazine in *Chlamydomonas reinhardtii*

Anze Zupanic[1], *Tim Godec*[2], *Ziva Ramsak*[2], *Carissa R Bleker*[2], *Maja Zagorscak*[2], *Marusa Kerencic*[2], *Marina Klemencic*[3], *Tina Elersek*[2] *and Katarina P van Midden*[3], *(1)Department of biotechnology and systems biology, National Institute of Biology (NIB), Slovenia, (2)National Institute of Biology (NIB), Slovenia, (3)University of Ljubljana, Faculty of Chemistry and Chemical Technology, Slovenia*

Compared to other environmentally relevant chemicals, herbicides are among the best researched. For most herbicides, there is information not only on the direct molecular targets, but also on the downstream events that eventually lead to weed death, and sometimes on the molecular mechanisms of herbicide tolerance in different plant and algal species.

In this study, we wanted to see whether functional genomics performed with a genome-wide mutant library could provide new information on the susceptibility of the unicellular green alga *Chlamydomonas reinhardtii* to three of the most commonly studied herbicides: diuron, atrazine, and paraquat. Diuron and atrazine are herbicides/algicides that bind to the D1 protein of the PSII reaction center (but at different sites), blocking ATP synthesis, while paraquat disrupts the electron flow in PSI and destroys plant tissue by generating free radicals that attack plant lipid membranes. Our hypothesis was that the mutant screening would provide supporting evidence for the known mechanisms of action of the herbicides, but would also shed new light on their exact mechanisms of action.

For diuron and atrazine, there was some overlap between the genetic markers discovered, with most markers related to photosynthesis: Mutants of Cgl54 (PSII D1 precursor processing protein) were more sensitive to both herbicides, while the homolog of Lpa2 (PSII accumulation protein) was more sensitive to diuron alone and Cre11.467652 (component of psaA trans-splicing sub complex I) was more sensitive to atrazine. For paraquat, several mutants were more tolerant to the herbicide, including a putative paraquat transporter and several genes involved in the synthesis of very long fatty acids and ceramides. Several PSI associated mutant we more sensitive (e.g., the recently PSI associated kinase Cpl3). The length-specific modification of ceramides has been linked to the neurotoxic effects of paraquat in small mammals but not in plants/algae, thus representing a potentially novel mechanism of action for paraquat in green algae.

Based on functional genomics as well as previous knowledge, we have developed a new putative adverse outcome pathway for green algae that begins with chloroplast production of ROS and leads to cell death.

2.02.T-02 Exposure of *Lemna Minor* (Common Duckweed) to Uranium and Perfluorooctanoic Acid (PFOA) and Associated Biological Effects

Annelise Gonzales, *Sarah Donaher, Bryanna D. Wattier and Nicole E. Martinez, Environmental Engineering and Earth Sciences,*

Clemson University, Clemson, South Carolina
A variety of processes, both natural and anthropogenic, can have a negative impact on surface waters, which in turn can be detrimental to human and environmental health. Few studies have considered the ecotoxicological impacts of concurrently occurring contaminants, and that is particularly true for mixtures that include contaminants of emerging concern (CEC). In response to this knowledge gap, our study considers potential biological effects in *Lemna minor* (common duckweed) induced by a ubiquitous radionuclide (uranium, U) and a fluorinated organic compound (perfluorooctanoic acid, PFOA, considered a CEC) alone and in combination under controlled laboratory conditions. *L. minor* was grown for 5 days in small, aerated containers. Treatments were: 0, 0.3, and 3 ppb PFOA; 0, 0.5, and 5 ppb U; and combinations of these. Each treatment consisted of four replicates with 7 plants each. Plants were observed daily for frond number and signs of chlorosis and necrosis. Other biological endpoints examined at the conclusion of the experiment were average specific growth rate, chlorophyll content, and antioxidant capacity. Analysis of variance and Tukey's pairwise comparisons were used to determine the significance of the effects of relevant factors on biological endpoints of interest. In single exposure experiments, both PFOA and U concentration significantly impacted frond number ($p = 0.0005$ and $p < 0.0001$ respectively), with the suggestion of a stimulatory effect at 0.3 ppb PFOA and inhibitory effect at 0.5 and 5 ppb U. In the dual exposure experiment, inhibitory effects on frond number were also observed in the contaminant mixtures with high U concentration. PFOA treatment did not significantly influence the average specific growth rate ($p = 0.1206$), but the U treatment did ($p = 0.0015$). Treatment was also a significant contributor to variation in specific growth rate in the dual exposure experiment ($p <0.0001$). Taken together, these results suggest that uranium has a more dominant effect on effects observed in *L. minor* than PFOA.

2.02.T-03 Can we Predict Regime Shifts in Shallow Aquatic Systems Exposed to Multiple Stressors? – Conclusions from Micro- and Mesocosm Experiments

Elisabeth Maria Gross[1], *Joey Allen*[2], *Vinita Vijayaraj*[3], *Martin Laviale*[1], *Nora Kipferler*[4], *Bastian H. Polst*[5], *Grégorio López Moreira Mazacotte*[6], *Franz Hölker*[6], *Joséphine Leflaive*[7], *Mechthild Schmitt-Jansen*[8], *Sabine Hilt*[6] *and Herwig Stibor*[4], *(1)University of Lorraine, France, (2)CNRS - LIEC UMR7360, France, (3)Universite de Lorraine, France, (4)Ludwig-Maximilians University of Munich, Germany, (5)Helmholtz Centre for Environmental Research (UFZ), Germany, (6)Leibniz Institute of Freshwater Ecology and Inland Fisheries (IGB), Berlin, Germany, (7)University of Toulouse, France, (8)Department of Bioanalytical Ecotoxicology, Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany*
Shallow aquatic systems are abundant in agricultural landscapes but highly susceptible to suffer from climate warming and agricultural run-off (ARO). Regime shifts between the dominance of microalgae or macrophytes may occur depending on the level and interaction of multiple stressors acting on the system. The main objectives of our French-German project CLIMSHIFT were (I) to understand the response of shallow aquatic ecosystems to warming and ARO based on a mechanistic understanding of stressor interactions and community responses; (II) to evaluate if the stressors act in an additive, synergistic or antagonistic way on organism physiology, community and ecosystem processes; and (III) to determine potential thresholds for shifts in ecosystem functions for single and combined stressors. CLIMSHIFT included a series of indoor microcosm experiments testing different exposure scenarios to ARO combined with warming on a benthic-pelagic community typical for shallow aquatic systems. Those were upscaled to larger outdoor mesocosms using natural plankton and periphyton communities. In all micro- or mesocosm experiments, we observed regime shifts from the good ecological status with a dominance by macrophytes to a degraded status with a dominance by either phytoplankton, periphyton or blanketing algae. Our CLIMSHIFT project proved that a well-planned experimental design based on a combination of micro- and mesocosm experiments allows to study complex multiple stressor effects on shallow aquatic systems, and to disentangle direct and indirect effects as well as stressor-interaction patterns. Combined nutrient (nitrate) and pesticide effects led to a range of direct and indirect effects on primary producers and consumers, with the most visible being the shift from macrophyte dominance to the dominance either phytoplankton, periphyton or blanketing filamentous algae. Nitrate and warming acted synergistically with pesticides, leading to stronger macrophyte decline. Further, warming can lower the threshold for such shifts. Effects of agricultural run-off on these systems are especially severe in spring, when average rainfall is high and submerged macrophytes start to grow. Lowering local stressors can help maintain shallow aquatic systems in a good ecological status even when global stressors such as climate warming prevail.

2.02.T-04 Use of Visual Phytotoxicity for ER50 Derivation in Nontarget Terrestrial Plant Studies

Giovanna Meregalli[1], *Seshadri Sajjala*[2], *Valentin Mingo*[3], *Eileen Paterson*[2] *and Patricia Lopez-Mancisidor*[2], *(1)Corteva Agriscience, Cremona, Italy, (2)Corteva Agriscience, (3)Corteva Agriscience, Munich, Bavaria, Germany*
Despite the OECD 208 and 227 guidelines indicate that visual phytotoxicity effects should be reported, they do not clearly state the need to derive ER50 based on phytotoxicity. However, in its recurring issues in ecotoxicology document (2019), EFSA stated that "the EC_X based on phytotoxicity should be reported" and "it should be considered for the Tier 1 risk assessment" in case it is the lowest endpoint. As visual estimates may have several sources of imprecision and bias, the reproducibility of visual phytotoxicity assessments for possible derivation of ER50 values and their use in the European risk assessment of nontarget terrestrial plants (NTTP) has been evaluated in this vegetative vigour study.

Five plant species (onion, oilseed rape, soybean, sugar beet, tomato), typically used in NTTP studies, were sprayed with two herbicides with different modes of action. An untreated control and five treatments (from 0.0625x to 1× of their field use rate) were assessed for each herbicide. Phytotoxicity was recorded 21 DAT and evaluated based on photographs. A total of 1227 photos were made available to 23 assessors, who are familiar with and regularly assess visual phytotoxicity in their job. By comparing to the untreated plants, assessors assigned phytotoxicity scores in a blind fashion to the treatments (except for the control plants) using a 0 to 100% scale.

The agreement in scores recorded by the assessors was determined using the Intraclass Correlation Coefficient (ICC), preliminarily for three of the plant species considered in the study, i.e., tomato, sugar beet, and onion.

The ICC derived for tomato and onion were mainly in the poor range with large confidence intervals, indicating a high variability in the scores assigned by the assessors. A better alignment in the assigned scores could be observed for the high treatment rates of one of the herbicides. In the case of sugar beet, despite some large differences between assessors, ICC were mainly in the range of moderate to good, indicating a better concordance of the scores assigned by the 23 assessors, compared to onion and tomato.

The results from this study shed doubts on the use of ER50 values based on visual phytotoxicity scoring in the European ecotoxicological risk assessment for NTTP because inconsistent risk management decisions may be reached.

2.02.T-05 Biochar and Other Amendments for Douglas Fir Survival and Growth on Acidic Mine Tailings
David Olszyk[1]*, Michael Bollman*[1]*, Maliha Nash*[1]*, Kristin Trippe*[2]*, Viola Manning*[2]*, Donald Watts*[2]*, Jeffrey Novak*[2] *and Mark G. Johnson*[3]*, (1)US Environmental Protection Agency, (2)US Department of Agriculture, (3)Center for Public Health and Environmental Assessment, US Environmental Protection Agency*
In the western US and in other nations, there are many abandoned mine sites with heavy metal contaminated tailings that prevent the reestablishment of vegetation and contaminate local ground and surface waters. Successful growth of plants on these sites is often limited by low tailings pH and high tailings heavy metal concentrations, poor structure, compaction, diminished water holding capacity, and limited fertility, carbon, and microbial activity. In a field study at an abandoned mine, we evaluated the effects of a mixture of amendments (lime, biosolids, biochar, microbial inoculum) on tailings pH and metal concentrations; and subsequent impacts on injury, growth and needle elemental concentrations for Douglas fir [*Pseudotsuga menziesii* (Mirb.) Franco] over multiple years. Two years post-tree planting, some trees had died, which was associated with lower tailing pH's. However, for the many live trees the tailings had increased pH, lowered metal availability, and increased moisture retention resulting in seedling survival, growth, and adequate needle nutrient contents for growth; while having reduced needle heavy metal concentrations, such as Cu, vs. dead trees. By four years postplanting, tree growth slowed and trees exhibited nutrient deficiency which may be alleviated by additional fertilization. This study highlights the potential for amendments that include biochar, to enhance plant growth by improving soil chemistry and physical conditions. Our amendment recipe includes approximately 2.5% biochar (by weight), along with lime (1%) and biosolids (0.25%), to promote tree survival and growth on mine tailings. This study also points out the necessity for long-term monitoring of plant responses so that, if needed, additional amendments such as biosolids or lime can be added to sustain tree growth.

2.02.P Aquatic and Terrestrial Plant Ecology, Ecotoxicology and Risk Assessment

2.02.P-We039 Identifying an Alternative Organic Matter Source for Artificial Sediment Used in Aquatic Plant Exposures
Ashlee Kirkwood[1]*, Trevor Nabb*[2] *and Lily Nolan*[2]*, (1)Ecotoxicology, Smithers, (2)Smithers*
Artificial sediment is required for most OECD guideline studies used to evaluate the effects of chemicals on benthic communities, including OECD TG 239, the Water-Sediment *Myriophyllum spicatum* Toxicity Test. It is preferred over natural sediment as it is standardized, which removes the substrate as a variable in the experiments. Peat moss is a component of the guideline artificial sediment mixture, but there has been discussion in recent years that an alternative to the product needs to be considered. Peat moss can only be harvested from delicate wetlands where it provides hydrological services such as water filtration and flooding prevention. Peatlands are also critical carbon sinks, which means that peat extraction has a high carbon footprint. As peat takes hundreds of years to form and the current harvest rate is generally greater than the replacement rate, the impacts from its extraction are difficult to mitigate directly. Another concern is the inconsistency of peat harvested from different regions, as variability in both biological performance and sediment-chemical interactions have been observed; an organic product that can vary widely based on its source is in conflict with the objective of standardization.

A number of scientists have evaluated alternatives to peat moss including coconut coir, wood products, compost, rice hulls, and α-cellulose that provide a source of organic matter similar to peat. For this project, coconut coir was identified as the most desirable replacement since it is easily accessible and cost-effective and has a similar texture to finely ground peat moss. Coconut coir is a by-product of the coconut industry, and while processing it also has negative environmental implications, it is considered a more responsible option and more consistent in composition when compared to peat. Our first trial compared growth of *M. spicatum* plants grown in two artificial sediments: one made with peat moss and one with coconut coir, and resulted in nearly equal growth between the two test groups. A reference test was then conducted with 3,5-DCP to compare potential differences in toxicity to the reference toxicant between the two sediment groups, and resulted in EC_{50} values within historical ranges for both. Additional work will include reference tests with other compounds (e.g., 2,4-D, trifluralin, isoproturon), and similar trials completed with alternative plant species such as *Vallisneria americana* and *Elodea canadensis*.

2.02.P-We040 Protectivity Check of the Tier-1 Pesticide Risk Assessment for Aquatic Primary Producers Based on EFSA Endpoints
Gertie Arts[1]*, Eric Bruns*[2]*, Steven Droge*[3]*, Sarah Hartmann*[2]*, Ivo Roessink*[4] *and Andreas Solga*[5]*, (1)Environmental Risk Assessment, Wageningen University & Research, Netherlands, (2)Environmental Safety, Bayer AG - Crop Science Division, Germany, (3)Environmental Risk Assessment, Wageningen Environmental Research (WUR), Netherlands, (4)Wageningen Environmental Research (WUR), Netherlands, (5)Ecotoxicology, Bayer AG - Crop Science Division, Germany*

Within the context of Regulation (EC) No 1107/2009 effect assessment procedures may be based on a tiered approach. In Europe, it is usually algae and/or vascular plants that determine the environmental risks in the aquatic Tier-1 effect assessment for plant protection products with an herbicidal mode of action (MoA). This tier includes tests with at least two algae and one macrophyte (*Lemna* sp.). If algae and/or vascular plants are the most sensitive group in Tier-1, higher tiers (e.g., micro/mesocosm studies) should focus on this most sensitive group. In recent years several authors compared the Regulatory Acceptable Concentrations (RACs) from Tier-1 with Tier-3 RACs from micro/mesocosm studies with algae and macrophytes to check the protectivity of Tier-1 risk assessment. These efforts resulted in different conclusions about the protectivity of Tier-1. Therefore, research was undertaken to answer the question "Is the pesticide risk assessment for plant protection products still protective after moving from the $E_{b/y/r}C_{50}$ to E_rC_{50}?" by using the data from the Lists of Endpoints published in EFSA conclusions. For 13 herbicides and 3 fungicides with herbicidal MoA (16 in total) the check on protectiveness could be performed based on Tier-1 and Tier-3 data published by EFSA. When moving from $E_{b/y/r}C_{50}$ to E_rC_{50} our results show that in 68 % of the cases (11 substances) protectivity was maintained, as all these values are situated above the line 1:1. This means that in these cases EU Tier-1 is protective for Tier-3. For two substances (12.5 %) a change in protectivity was observed when E_rC_{50} was used instead of an $E_{b/y/r}C_{50}$, as the values drop below the line 1:1. For two substances (12.5 %) both $E_{b/y/r}C_{50}$ and E_rC_{50} are below the line 1:1 and Tier-1 is not protective for Tier-3. For one substance (Linuron; 6.25%), no relevant EFSA risk assessment is available thus a conclusion on the protectivity cannot be drawn. When moving from $E_{b/y/r}C_{50}$ to E_rC_{50} in conjunction with the standard Assessment Factor of 10, protectivity changes from 81% to 68% of the cases.

2.02.P-We041 Effects of the Fungicide Tebuconazole with Herbicidal Mode of Action on Monocot and Dicot Macrophyte Species with Different Growth forms

Gertie Arts[1], *Mishal Antony*[2], *Ulrike Scholz*[3], *Ronny Schmiediche*[3] *and Silvia Mohr*[3], *(1)Environmental Risk Assessment, Wageningen University & Research, Netherlands, (2)Department of Biology, Campus Groenenborger, GU531, University of Antwerp, Belgium, (3)IV 2.5, German Environment Agency (UBA), Dessau-Rosslau, Germany*

Since 2010, it is known that dicot macrophytes, such as *Myriophyllum* sp., can be significantly more sensitive to herbicides with specific mode of actions (MoA) such as auxins than the standard monocot test species *Lemna* sp.. For fungicides such as tebuconazole (TBZ) with a not well-known herbicidal MoA, it is questionable if dicot macrophytes are also more sensitive than the monocot duckweed *Lemna gibba* which was the most sensitive species in acute laboratory tests with TBZ in the first tier of the risk assessment. Therefore, we performed 14 d in-situ macrophyte tests within a comprehensive mesocosm study (project AquaFungi at Risk) at the artificial stream and pond facility (FSA) of the German Environment Agency. The goal of this research was to improve the risk assessment of fungicides with herbicidal MoA for higher aquatic ecosystem/macrophyte protection. To study this, 8 naturally established freshwater mesocosms were dosed once with 6 different concentrations of TBZ (5-5000 µg/L) in the beginning of September 2022. We exposed *Myriophyllum spicatum* shoots in bioassays consisting of 10 plant pots in each mesocosm. Exposure was 14 days with starting dates on day 1 and day 21 after TBZ application, and 35 days, covering the full exposure period for the macrophyte bioassays. Colonies of *Lemnna trisulca* and *Spirodela polyrhiza* were exposed in floating devices for 14 days starting at day 1 and at day 21. Endpoints including main shoot length, total shoot length, number of whorls, total length of side shoots and dry weight were measured for *Myriophyllum spicatum* while dry weight and number of leaves were measured for *L. trisulca* and *S. polyrhiza*. In addition, floating leaf development of free-growing populations of the dicot species *Nymphoides peltat*a and of the monocot species *Potamogeton natan*s were measured in the mesocosms. The results indicate that dicot macrophyte species are more sensitive to TBZ than the monocot species. The Risk Assessment of fungicides should therefore include additional macrophyte testing if the fungicide shows herbicidal MoA.

2.02.P-We042 Transcriptomic and Proteomic Analysis of Ecotoxic Modes of Action in *Myriophyllum spicatum*

Jost Hanfland[1,2], *Steve Uwa Ayobahan*[1], *Joëlle Lousberg*[3,4], *Alexandra Loll*[1], *Lena Kosak*[5], *Karsten Schlich*[3] *and Sebastian Eilebrecht*[6], *(1)Attract Eco'n'OMICs, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany, (2)Faculty of Biology, University of Münster, Germany, (3)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany, (4)Department of Biology, RWTH Aachen University, Germany, (5)Ecotoxicology, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany, (6)Fraunhofer Attract Eco'n'OMICs, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany*

The increasing use of chemicals such as pharmaceuticals, herbicides and pesticides, as well as their subsequent influx into the environment, pose a constant threat to aquatic ecosystems. The effect on aquatic primary producers is tested and the ecotoxicity of pesticides is, among other species and tests, evaluated using *Myriophyllum spicatum* in the OECD guideline test 239. While these standard ecotoxicological tests enable the regulatory assessment of substances, they are limited to measuring the physiological impact, i.e., growth rate reduction. Despite the importance of mechanistic insights, the mode of action resulting in ecotoxicological effects remains unknown. This study aims at the establishment of a suitable workflow and first application to study molecular effects of toxicity in *M. spicatum*.

Transcriptomic and proteomic profiling are applied to a shortened OECD guideline test 239. That way, molecular effects of two well-studied chemicals – the herbicide bentazon and the pharmaceutical atorvastatin – will be studied using RNA sequencing (transcriptomics) and LC-MS/MS based proteomics. Bentazon is a photosynthesis inhibitor targeting the photosystem II and is commonly used as a postemergence herbicide. The cholesterol lowering atorvastatin targets a key enzyme of the isoprenoid pathway, the 3-hydroxy-3-methylglutaryl-CoA reductase, which is ubiquitous in eukaryotes. Both substances have been recently tested in a similar analysis with the duckweed *Lemna minor*, also commonly used for the evaluation of toxic effects on freshwater plants.

As of now, the plants have been exposed to low effect concentrations, corresponding to the EC_5 and EC_{20} values, which were determined in range finding tests. The total RNA and protein of the shoot tips have been extracted and are being analysed. RNA-seq is currently being performed to identify potential molecular effects and suitable biomarkers using a *de novo* assembly. The data will be compared and supported with the proteome derived from a nano-flow LC-MS/MS analysis. It is anticipated that distinct molecular effects can be observed and linked to the known modes of action of bentazon and atorvastatin. As the antipicitated molecular changes may possibly be observed before physiological effects occur, the assessment of biomarkers derived from this may potentially be consulted in future studies for early predictions of toxic effects on organisms and aid the development and toxicological assessment of new substances.

2.02.P-We043 A Review of Laboratory Cultivation of *Laminaria hyperborea*, *Laminaria digitata,* and *Saccharina latissima* as a Basis for Ecotoxicology Studies

Marianne Elizabeth Glascott*, Life Sciences, University of Sussex, United Kingdom*

Laminaria hyperborea, *Laminaria digitata,* and *Saccharina latissima* are dominant kelp species in the South Coast waters of the UK. The two Laminaria species provide a foundation for highly biodiverse UK kelp forests. *S. latissima* is an early colonizer of barren habitats that also forms the basis for commercial kelp cultivation. Kelp forest recovery is a critical element in large-scale seascape restoration along the UK South Coast to buffer climate change impacts and address biodiversity loss. Globally, kelp cultivation is also under development as a key component in global climate change mitigation and adaptation strategies. In the UK, there are increasing concerns regarding the impact of suspended sediments and associated contaminants on kelp survival and growth. These concerns from the public, nongovernmental organisations and government authorities are driving demands for kelp ecotoxicology studies to establish the physical, chemical and biological effects of these sediments. Published protocols, and techniques developed in the field, aim to establish viable macroalgal cultures. Yet, diverse protocols, including inducing osmotic stress to stimulate spore release, applying germanium dioxide to kill diatoms, and abrasion to reduce contamination, are recommended even when the biological impact of their use is often unclear and could illicit resultant stress in the studied species. These stressors may increase susceptibility to environmental toxins leading to experimental results not reflecting the organism's natural response. This review examines both the academic literature and 'custom and practice' within kelp restoration projects and commercial ventures to identify undefined stress effects within existing approaches that, unless defined and quantified, will undermine the validity of ecotoxicology studies. Establishing the impact and magnitude of stress effects is essential in developing a kelp ecotoxicology test and associated protocols.

2.02.P-We044 Establishment of a Flow-Through System for the Macrophyte Growth Inhibition Test (OECD 239) Including New Endpoints on Photosynthetic Activity

Joëlle Lousberg[1,2], Jost Hanfland[1,3], Sebastian Eilebrecht[1], ***Lena Kosak****[4] and Karsten Schlich[1], (1)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany, (2)Department of Biology, RWTH Aachen University, Germany, (3)Faculty of Biology, University of Münster, Germany, (4)Ecotoxicology, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany*

Maintaining constant exposure concentrations during ecotoxicological studies while testing rapidly degradable substances is a challenge. Stable concentrations during exposure are often achieved using flow-through systems. The water-sediment toxicity test with *Myriophyllum spicatum* (OECD TG 239) currently only includes a static and semi-static test design. The aim of our study was to establish a flow-through system for *M. spicatum* toxicity testing.

The standard test design was miniaturised from 2 L to 500 mL and a flow-through system was developed to achieve stable exposure concentration of rapidly degrading substances. The main test design and parameters such as light, temperature and pH were kept as described in the OECD TG 239. The observed endpoints were total shoot length (TSL), fresh (FW) and dry weight (DW). As an additional endpoint, measurement of photosynthetic yield (Y(II)) was established to detect early effects on photosynthesis.

The miniaturised system was compared with the standard test setup using 3,5-dichlorophenol. No significant differences could be detected after 14 days exposure. To prevent excessive growth ¼ Smart & Barko medium was tested as a flow-through medium and achieved similar growth to the standard test setup.

Two model substances were chosen to compare their toxicity in the flow-through and in the static/semistatic system. At first, using the PSII inhibitor bentazone (BT), the growth rate of FW and TSL showed 5-8 times higher EC_{50} values in the flow-through system but with overlapping confidence intervals and no difference for the EC_{50} values of TSL, FW and DW for yield. Using the PAM method with BT, the Y(II) decreased concentration-dependent from day 3. This reduction in Y(II) could be shown to be correlating with the growth rate of the plants. It suggests that the PAM method can detect effects on photosynthesis even before physiological effects can be measured.

Atorvastatin, a pharmaceutical, degraded by 30% after 7 days in a semistatic test design, but remained stable in the flow-through system. Stronger visual effects (e.g., necrosis) were observed, as well as lower EC_{20} values for all endpoints, e.g., 1.8 vs. 4.4 m/L for FW, indicating that the flow-through system is suitable for testing of rapidly degradable substances.

Summed up, the miniaturised and standard tests did not differ, degradable substances can be tested more accurately using a flow-through setup, and photosynthetic yield can be an additional endpoint.

2.02.P-We045 Testing Strategy for Species Sensitivity Distribution (SSD) Tests with Aquatic Plants

Guido Gonsior[1] *and Maren Dill*[2]*, (1)Aquaculture, Ecotox, Marine Science, GG BioTech Design GmbH, Homberg, Germany, (2)GG BioTech Design, Germany*

The guidelines OECD 238 and 239 with the aquatic plant *Myriophyllum spicatum* were set up to cover toxicity on rooted macrophytes in addition to the OECD guideline 221 which covers free floating species. By now it became obvious that the focus on one submerged rooted and one free floating species might under or overestimate effects based on the mode of action of test items. Therefore, further tests and ring-tests with additional species were set up to refine risk assessment.

In most cases the species sensitivity distribution (SSD) approach with at least eight species is used. This leads to the general questions which species show good growth under lab condition, are relevant for the ecosystem, represent different growth forms, and finally can close missing data links. Also, it is essential to follow the standard test protocols as far as possible to compare data of nonstandard species with standard species. We present data of nonstandard macrophyte test species which fulfilled validity criteria according to OECD 239 and recommend a test strategy based on handling, growth form, and sensitivity of test plants.

2.02.P-We046 Assessment of the Harmful Effects of Caffeine on Macrophytes *Lemna gibba* and *Egeria densa*

Alma Sobrino-Figueroa[1]*, Raziel Melo Najera*[2] *and Alberto Perez-Rojas*[3]*, (1)Hydrobiology, Universidad Autonoma Metropolitana Iztapalapa, Mexico, (2)Hydrobiology, Universidad Autónoma Metropolitana-Iztapalapa, Mexico, Mexico, (3)Universidad Autonoma Metropolitana Iztapalapa, Mexico*

Caffeine is one of the most widely consumed stimulant substances worldwide present in food, beverages, and medicines. It is currently considered an emerging pollutant due to its continuous contribution to aquatic systems, where concentrations of 0.007 mg/L to 3.594 mg/L have been detected. Studies on the effects of caffeine on aquatic organisms are scarce. In this work, an evaluation of the harmful effects of caffeine on 2 aquatic plants, the macrophytes: *Egeria densa* and *Lemna gibba*, was carried out on their growth, pigment concentration and their macromolecule content. The macrophytes were exposed for 14 days to five concentrations of caffeine: 0, 0.01, 0.1, 1.0, 10, and 100 mg/L in duplicate. At the end of the exposure period, growth (length and weight) was evaluated to determine the EC_{50} (concentration that inhibits the growth of macrophytes by 50%). In addition, the levels of chlorophylls, carotenes, and macromolecules (lipids, carbohydrates, and proteins) were determined. The data obtained showed that there were significant differences in the response of the macrophytes exposed to caffeine and the control group. Caffeine had deleterious effects on macrophytes. The EC_{50} obtained in the tests with *Lemna gibba* was 7.4 mg/L and 0.07 mg/L for *Egeria densa*. A decrease in the concentration of chlorophylls that varied from 2 to 68% was observed. In the evaluation of macromolecules, a decrease in carbohydrate concentrations from 20 to 46% and lipids from 15 to 60% was detected. The chlorophyll *a*/chlorophyll *b* ratio indicated that the macrophytes exposed to caffeine were under stress conditions. In sublethal concentrations, caffeine had deleterious effects on the macrophytes *Lemna gibba* and *Egeria densa*.

2.02.P-We047 Allometric Relationship of Shoot and Plant Weight in *Myriophyllum spicatum*

Valentin Mingo[1]*, Sabine Eser*[2]*, Patricia Lopez-Mancisidor*[3] *and Giovanna Meregalli*[4]*, (1)Corteva Agriscience, Munich, Bavaria, Germany, (2)Aquatics, Eurofins Agroscience Services Ecotox GmbH, Niefern-Öschelbronn, Germany, (3)Corteva Agriscience, (4)Corteva Agriscience, Cremona, Italy*

The term allometry originally referred to the scaling relationship between the size of a body part and the size of the body as a whole, as both grow during development. More recently allometry has been expanded to refer to biological scaling relationships in general, be it for morphological, physiological, or ecological traits. It is hence plausible to assume that, for plants, the relationship between total plant weight and shoot weight is an allometric one.

Control values for shoot and whole plant weight were available for 43 *Myriophyllum* studies (conducted to OECD TG 239). Studies included 10 replicates with one plant each per control. Five studies additionally contained solvent controls, which were included in the database, resulting in a total of 474 individual datapoints being evaluated.

Based on the standard allometric equation $Y = aX^b$ (i.e., a: proportionality coefficient and b: slope of the regression line), shoot weights (Y) were predicted from whole plant weights (X) for every datapoint. To this end, the two parameters were log-transformed and then plotted on a log-log plot, from which the allometric function was derived. The R^2 of the resulting regression was 0.914.

To test the goodness of the function, predicted shoot weight was compared to the actual shoot weight for any given plant, resulting in a correlation coefficient of 0.956. Additionally, a regression model was run to evaluate the goodness of fit of the model, resulting in an R^2 of 0.914. Finally, the average, standard deviation and coefficient of variance (CV) were calculated for both predicted and actual shoot weights based on the whole dataset. Both the average and standard deviations of predicted shoot weights corresponded to those of actual shoot weights, resulting in highly comparable CV (31.9 vs. 31.6%).

The same approaches were then used to calculate the predicted yield based on the predicted shoot weight data, resulting in a correlation coefficient of 0.955 with the actual yield data. The regression model used to evaluate the goodness of fit had an R^2 of 0.911, confirming a high concordance between actual and predicted yield values.

In conclusion, a reliable allometric relationship between shoot weight and whole plant weight was derived. This equation allows extrapolation of shoot weight values based on whole plant weight experimental data in cases where no experimental data is available for control/solvent control shoot weight.

2.02.P-We048 A Comprehensive Laboratory Comparison of Two Methods for Generating Data for Green Algae Response to Time-Variable Exposures

Eric Bruns[1]*, Johannes Witt*[2]*, Cecilie Rendal*[3]*, Thomas G. Preuss*[2]*, Ian Sims*[3]*, Roger Baetscher*[4]*, Sibylle Eck*[2]*, Jack Rumkee*[3]*, Monika Ratte*[5]*, Emily Scorgie*[6] *and Roman Ashauer*[4]*, (1)Environmental Safety, Bayer AG - Crop Science Division, Germany, (2)Bayer AG - Crop Science Division, Germany, (3)Syngenta, United Kingdom, (4)Syngenta Crop Protection, Basel, Switzerland, (5)ToxRat Solutions GmbH & Co. KG, Germany, (6)Syngenta, Netherlands*

The use of Toxicokinetic-Toxicodynamic (TKTD) modelling in European risk assessments for plant protection products is rapidly gaining momentum – especially following the 2018 publication of the EFSA opinion on TKTD modelling which states that several models are now ready for use in risk assessment. This report reviewed a number of TKTD models for primary producers, including the SAM-X model for green micro-algae. This model was considered not ready for use in risk assessment due to the lack of a robust and ring tested methodology for generating calibration and validation studies. In response, the present work funded by CropLife Europe (CLE) aims to establish robust and standardized guidelines for generating data for algae responses to time-variable exposures. The CLE project tackles two distinct methodologies – a flow-through system and a semistatic system. Each of these methods are evaluated by conducting a laboratory comparison on comprehensive parameters across six and eight independent laboratories respectively. We here provide a detailed overview of the project results to date and discuss the learnings for each of the two methodologies. Analysing the data across the laboratories allows us to refine the protocols, avoiding stumbling blocks experienced by the laboratories. We here present and discuss complications and difficulties experienced by the laboratories, and we provide guidelines for systematic and robust generation of this data in future based on the lessons learned from the laboratory comparison. The two methodologies are fundamentally very different, and we do not offer a direct comparison. Rather, we specify how each method may best be used in a risk assessment context following the guidelines laid down by EFSA. The data generation has been partly funded by CropLife Europe. The participating laboratories were provided some limited support in the form of materials, but the full cost of the labour was carried by each individual laboratory.

2.02.P-We049 Antifouling Coatings: Assessment of the Effects on Phytoplanktonic Nontarget Species

Mar Santos-Simón[1]*, Esther Blanco-Rayón*[1]*, Sergio Seoane*[1]*, Nestor Etxebarria*[2]*, Agnese Marchini*[3] *and* ***Maren Ortiz-Zarragoitia***[4]*, (1)Research Center for Marine Biology and Biotechnology (PiE-UPV/EHU), University of the Basque Country, Spain, (2)University of the Basque Country (UPV/EHU), Spain, (3)Dep. Earth and Environmental Sciences, University of Pavia, Italy, (4)CBET+ Group, Research Centre for Experimental Marine Biology and Biotechnology Plentzia Marine Station PIE, Spain*

Biofouling is the settlement and growth of microorganisms, algae, plants, and/or animals on wetted artificial surfaces. To prevent the settlement and growth of these communities, antifouling coatings are commonly applied. Despite being biocide-based coatings (BC) the most widespread coatings, there is some uncertainty regarding their actual effectiveness or their potential indirect environmental impact. Thus, new commercially available alternatives, such as foul-release (FR) coatings, are being developed. This study aimed to test the effects of the two antifouling typologies in nontarget species, exposing selected phytoplankton species to different concentrations of paint lixiviates in lab conditions. PVC panels with a standardized surface were coated with BC and FR coatings, submerged in 1 L filtered and sterilized sea water and placed on a shaker for 24 h. The solutions were used to expose cultures of three different phytoplankton species (*Isochrysis galbana*, *Tetraselmis chuii,* and *Cylindrotheca* sp.) to different lixiviate concentrations, each of which had 3 replicates, following OECD guidelines with small modifications. Exposure was carried out for 72 h and growth was measured every 24 h. After 72 h, samples from each culture were taken to measure 1) photosynthesis efficiency, 2) pigment content, and 3) oxidative stress through biochemical biomarkers (CAT, GST, and lipid peroxidation). Extra samples were taken for potential further analysis on transcription levels of HSP and metallothioneins. Exposure to BC lixiviates significantly affects the growth of the three species, being *T. chuii* the only species that recovered and grew after 48 h of exposure to the highest (25%) BC lixiviate concentration. As regards the photosynthesis efficiency, the fluorescence yield (Fv/Fm) particularly dropped for BC-exposed Cylindrotheca cultures, but not for the other two tested species. In all studied species, FR-exposed cultures performed without differences to the controls. Further biochemical analysis will provide insights of physiological mechanisms that could also contribute to a greater resistance to these components.

2.02.P-We050 Method and Performance Evaluation in a Ring Test: Algal Growth Inhibition Test with Time-Variable Exposures

Marina Wyss[1]*,* ***Patricia Marini***[2]*, Helene Eckenstein*[1] *and Stefan Hoger*[1]*, (1)Innovative Environmental Services (IES) Ltd., Switzerland, (2)Ecotoxicology, Innovative Environmental Services (IES) Ltd., Switzerland*

The Algal Growth Inhibition Test according to OECD Guideline 201 is an essential part of the ecotoxicological risk assessment of plant protection products. However, the test system is limited in different exposure scenarios and does not reliably reflect real environmental conditions due to the static single exposure. To better include important factors such as multiexposures, dissipation, or recovery times, we performed algae growth inhibition tests in flow-through bioreactors using time-varying exposure regimes and combined the experiments with a SAM-X *in silico* toxicokinetic/toxicodynamic (TK/TD) model for green microalgae. This innovative test setup combined with a modelling approach provides a deeper insight into population effects and thus might refine future Tier 2C risk assessments for primary producers. We will present the feasibility and some exposure scenarios of the flow-through system for model validation and calibration based on our participation in the CropLife Europe ring test using *Raphidocelis subcapitata* and an herbicide.

2.02.P-We051 The Effect of Sodium Bicarbonate on Key Algal Species in the Static, Closed System Test Design

***Christopher Luke Boagni**, Eurofins Agroscience Services, Easton, Maryland*

In algal toxicity studies (OECD 201), one avenue for testing volatile test substances is utilizing the static, closed system, in which headspace is kept to a minimum or eliminated during preparation and exposure of the test organism. By doing so, this retains the test substance in the aqueous phase and prevents the test substance from entering the vapor phase and escaping the test system. Due to the removal of gas exchange, growth of algal test organisms in this test system can be limited by carbon dioxide depletion. The test guidance (OECD 23) suggests overcoming this issue by decreasing inoculation volume and supplementing the test solution with sodium bicarbonate. The test guidance is not specific as to what inoculation volume should be used or how much sodium bicarbonate should be added to the test medium. Most algal mediums outlined in the test guidance inherently have 15 mg/L sodium bicarbonate, with the exception of saltwater algal medium, which does not contain sodium bicarbonate. The purpose of this work is to elucidate the effect of varying concentrations of sodium bicarbonate on algal growth in a closed, static system. To explore the varying response, key algal genera such as *Raphidocelis*, *Navicula*, *Anabaena*, and *Skeletonema* will be investigated. These genes are commonly used in species sensitivity distribution tests and are recommended species in the OECD 201 guideline. This study design utilizes replicates that will be sacrificed daily to take samples for cell counts without introducing headspace into the test vessel. Mean cell density, growth rate, and yield will be measured to quantify the effect on the changing concentrations of sodium bicarbonate on cell growth. Growth will be evaluated based on significant difference ($p<0.05$) of the test groups. Preliminary results from studies conducted by our lab have indicated that algal species respond differently to trends in sodium bicarbonate concentrations within the test medium. Algal toxicity studies with volatile test substance are technically very difficult and may produce inconsistent results. Results presented will assess whether modifications to the carbonate system will improve reliability and reproducibility of algal toxicity tests conducted within a closed system.

2.02.P-We052 Evaluation of the Reproducibility, Reliability, and Regulatory Relevance of Plant Visual Injury Assessments

***Joshua R. Arnie**[1], Patricia Lopez-Mancisidor[2], Gunther Ulric du Hoffmann[3], Henry O Krueger[1], Eileen Paterson[2], Gwendolin Kraetzig[4], Jeffrey C. Wolf[5], Timothy Springer[6], John W. Green[7], Ashlee Kirkwood[8], Andreas Duffner[9], Rena Jutta Irene Isemer[10] and Sebastian Fellmann[11], (1)Eurofins Agroscience Services, Easton, Maryland, (2)Corteva Agriscience, (3)Eurofins Agroscience Services, (4)ADAMA Deutschland GmbH, Germany, (5)EPL, Inc., Sterling, Virginia, (6)Springer Ecotox Consulting, Canada, (7)Ecostatistical Consulting, JohnWGreen-ecostats.com, (8)Ecotoxicology, Smithers, (9)Eurofins Agroscience Services Ecotox GmbH, Niefern-Öschelbronn, Germany, (10)Crop Science, Bayer AG - Crop Science Division, Germany, (11)Bayer AG - Crop Science Division, Germany*

In nontarget terrestrial plant (NTTP) studies (OECD 208 2006a and OECD 227 2006b) quantal data (e.g., survival) and continuous data (e.g., biomass) are assessed to estimate an ER_{50} with linear and nonlinear regression models, respectively. In the EU the ER_{50} is used to assess the risk of plant protection products (PPP) on NTTP and define potential restrictions of the products uses. The EFSA Technical Report (2019) proposes to consider also an ER_{50} based on visually assessed plant injuries, such as chlorosis, necrosis, wilting, etc., for the risk assessment if this is lower compared to others. The visual injury assessments are qualitative scores which are assigned to treated plants by comparison with untreated control plants. The NTTP guidelines do not provide adequate guidance as to which scoring system is to be used and how this should be applied to assess plant visual injuries in NTTP studies, e.g., it is not specified which and how many symptoms should be considered in one score and whether scores should be assigned per plant or per replicate. Also, there is no advice provided on how a statistically sound ER_{50} can be derived from this data. The assigned scores are ordinal data which do not allow for a statistical estimation of an ER_{50} as it is done for continuous or quantal data. Nevertheless, some countries in the EU request an ER_{50} for visual injury data to assess the risk of PPP. The SETAC Visual Injury Working Group (WG) was established to overcome these discrepancies between the limits of the methodology for the visual injury assessments and what authorities expect it to deliver. To evaluate and improve the reproducibility, reliability, and regulatory relevance of plant visual injury endpoints the WG will provide a detailed problem formulation. This will highlight the challenges of the methodology of visual assessments in the lab, the statistical evaluation of the data, and discuss the meaning of the data in the regulatory context. Based on these findings a definition of relevant criteria for a suitable scoring system will be possible to provide data that can be used for an ER_{50} estimation. This will serve as a base for a harmonization and standardization of the visual injury assessments for regulatory purposes. Further research on the implementation of reliable scoring systems and potential statistical evaluation with, e.g., Rao-Scott Cochran-Armitage by Slices needs to be evaluated in future.

2.02.P-We053 Biocide, Antioxidant, and Anti-Inflammatory Activities of Essential Oils Distilled from Aromatic Plants Grown on Trace Elements Polluted Doils

***Anthony Verdin**[1], Julien Langrand[2], Robin Raveau[2], Lloris Mistrulli[2], Joel Fontaine[2], Dominique Courcot[3], Sophie Fourmentin[2] and Anissa Lounès-Hadj Sahraoui[2], (1)UCEIV, University of the Littoral Opal Coast, France, (2)Uceiv, Université du Littoral Côte d'Opale, France, (3)Unité de Chimie Environnementale et Interactions sur le Vivant, UCEIV UR4492, FR CNRS 3417, University of Littoral Côte d'Opale (ULCO), France*

Essentials oils (EO) from coriander (*Coriandrum sativum*), sage (*Salvia sclarea*), and angelica (*Angelica archangelica*) were investigated for their biocide properties (antifungal and herbicidal) and their antioxidant and anti-inflammatory activities.

The novelty of this work lies in the integration of the principles of the circular economy (self-financing of the system) for the rehabilitation of polluted soils. Indeed, the essential oils producing plants under study were grown at Metaleurop Nord, a site highly contaminated by heavy metals, in the presence or absence of mycorrhizal inoculum. After the recovery of the different plants, essentials oils were extracted and tested for their biological properties.

Antifungal properties were assessed through *in vitro* direct contact and volatility assays, demonstrating that all EOs present a fungistatic activity. Similarly, direct contact herbicidal assays have highlighted an herbicidal activity of all EOs, which may be used as biopesticides.
Antioxidant activities of essentials oils were assessed by the scavenging of the diphenylpicrylhydrazyl (DPPH) radical method and anti-inflammatory potency was investigated through their ability to reduce inflammatory response induced by atmospheric fine particles ($PM_{2.5}$) in human bronchial epithelial cell lines (BEAS-2B). Antioxidant effect was found for all EO but angelica and coriander leaves showed stronger antioxidant activity than coriander seeds and the sage. For the anti-inflammatory investigation, the same conclusion on the EOs from angelica and coriander leaves was highlighted as these two oils were able to counteract the induction of inflammation.

2.02.P-We055 Impacts of Petroleum-Based and Plant-Based Plastic Particles on Dry Acidic Grassland Plant Species
*Ines Maria Alonso Crespo[1] and **Alicia Mateos Cardenas**[2], (1)Leuphana University Lüneburg, Germany, (2)University College Cork, Ireland*
Microplastics are ubiquitous in all environments and plastic pollution has now become a new major environmental issue. Recent studies have pointed to agricultural fields as major terrestrial sink of microplastics. Grasslands are reservoirs of biodiversity, especially plants species. Great part of European grasslands originate from previously arable land, which raises concerns over the future of restoration and the improvement of grasslands, biodiversity and ecosystem functioning. The effects of land-use change, invasive species and climate change on grasslands is relatively well understood, however the study of the impacts of micro- and nanoplastic accumulation is still in its infancy. This novel, topical, and multidisciplinary study aims at understanding the effects of a range of petroleum-based and plant-based micro- and nanoplastics on plant physiology and growth from a grassland perspective. For this, plastic particles will be spiked into soil where standard grassland plant species will be sown and grown for 8 weeks. Nanoplastics will be administered through their watering cycles. The results from this novel study will be presented especially focusing on the impacts on key parameters in plant development, such as shoot and root growth. Also, microplastic adsorption to roots and nanoplastic intake in plant tissue will be examined. Overall, this study will inform about the different ecotoxicological effects of a range of plastic particles on terrestrial plants.

2.02.P-We056 Temperature Effects on the Toxicity of Triclosan to Oilseed Rape (*Brassica napus* L.)
***Diana Miškelytė**[1] and Jurate Zaltauskaite[2], (1)Vytautas Magnus University, Lithuania, (2)Lithuanian Energy Institute, Lithuania*
There is growing concern about the environmental effects of antimicrobial chemicals because of their increasing levels in the environment and lack of information about their ecotoxicity. Triclosan (TCS) is one of the most widely used antimicrobial agents in both pharmaceuticals and personal care products, and it is a frequently detected emerging organic contaminant in the environment. Reported studies of TCS toxicity to terrestrial plants mostly rely on whole-organism morphological or physiological endpoints. There is a need for more profound studies about TCS-induced effect at biochemical plant level to discover underlying toxicity mechanisms. Moreover, climate change is an increasingly urgent problem with potentially far-reaching consequences for life on earth. Little is known about the effect of climate parameters on the ecotoxicity of the antimicrobials, including TCS. The main objective of this study was to evaluate temperature effect on triclosan toxicity to oilseed rape (*Brassica napus* L.). *Brassica napus* was grown in TCS contaminated soil (10-400 mg kg^{-1}) under different temperatures (21℃ and 25 ℃). *B. napus* morphological (dry weight, length of the roots, and shoots), biochemical indicators (the activity of enzymes), and the damage of oxidative stress (lipid peroxidation) were detected.

2.02.P-We057 Development of a Standard Protocol for the Assessment of Reproductive Endpoints in Nontarget Terrestrial Plants under Greenhouse Conditions
***Andreas Duffner**[1], David Olszyk[2], Bianca Flickinger[3], Eugenia Soler[4], Fernando Huerta[4], Holger Teresiak[5], Gwendolin Kraetzig[6], Joanna Davies[7], Lucia Privitera[8] and Christine Mihan[9], (1)Eurofins Agroscience Services Ecotox GmbH, Niefern-Öschelbronn, Germany, (2)US Environmental Protection Agency, (3)BASF SE, Germany, (4)EUROFINS TRIALCAMP, SLU, Alcacer, Spain, (5)Agro-Check, Germany, (6)ADAMA Deutschland GmbH, Germany, (7)Syngenta, United Kingdom, (8)Greenhouse Team, AgroChemex Environmental Ltd, United Kingdom, (9)Bayer AG - Crop Science Division, Germany*
Ecotoxicological testing to assess the effects of plant protection products on nontarget terrestrial plants (NTTPs) under greenhouse conditions is conducted according to standard guidelines (e.g., OECD 208 and OECD 227). EFSA's Scientific Opinion of 2014 on the risk assessment of plant protection products (PPP) for nontarget terrestrial plants raised awareness of a potential need to assess effects on plant reproduction, e.g., seed production.

Literature reviews and experimental studies evaluated the feasibility and relevance of plant reproductive endpoints (e.g., Christl et al. 2020, Duffner et al. 2020). In summary, they concluded that (a) assessment of reproductive endpoints in selected plant species is in principle feasible, (b) there is no clear trend that reproductive endpoints are more sensitive than vegetative ones, and (c) specific cases may exist where reproductive endpoints appear to be more sensitive depending on e.g., mode of action of a plant protection product and/or test species.

For cases where effects on reproductive endpoints need to be assessed for regulatory purposes, a standard test protocol is required. Thus, a working group within the SETAC Plant Interest Group was launched in November 2021 to collect and analyze relevant and available data and experiences in order to provide guidance for a plant reproduction protocol. The working group meets regularly in three subgroups covering (a) Plant species selection, (b) Challenges & Restrictions, and (c) Protocol elements to develop the protocol.

The objective of this poster is to create awareness of the topic, to provide an overview and status of this working group, and, in particular to present some of the challenges and foster a discussion on possible solutions in order to obtain a broadly acceptable standard test protocol.

2.02.P-We058 Changes in Antibiotics Levels After Treating Poultry Litter and Their Effects on the Early Stages of Chicory Seedling Development

*Camila T. Velez[1], Lucas Leonel Alonso[1], Paula Otero[1], **Daniel Alberto Wunderlin**[1], Natalia S. Almada[2], Juan M. Gange[2], Irma I. Bernigaud[2], Natalia A. Mortola[2] and Natalia S. Podio[1], (1)Instituto de Ciencia y Tecnología de Alimentos Córdoba (ICYTAC), CONICET and Department of Organic Chemistry, FCQ, UNC, Argentina, (2)Instituto Nacional de Tecnología Agropecuaria (INTA), Argentina*

Poultry litter (PL) is used as fertilizer because it contains essential nutrients for crops. However, it has proven to be an important reservoir of pollutants, especially antibiotics (ATBs). ATBs can be accumulated in soils, being taken up by edible plants, entering the food chain with unknown environmental and human health risks. Thus, this work seeks: (1) to characterize the ATBs present in raw and treated PL to verify their drop upon self-heating processes; (2) to study the effect of treatment + ATBs on the germination of chicory seeds, verifying the phytotoxicity of treated PL containing ATBs on the early stages of seedling development. Thus, we used five methods of treatment: T1-Pile without cover and without turning; T2-Pile with cover and without turning; T3-Pile with cover and with turning; T4-Mini pile with cover and with turning; and T5-Pile without cover and with turning. ATBs in PL were extracted by salt-assisted solvent extraction and quantified by UPLC-MS/MS. Phytotoxicity assays were carried out by diluting samples (raw PL and T1-T5) with ultrapure water at three proportions (10, 50 and 100 g/L). Seeds were added to Petri dishes containing filtration paper and control and PL solutions (raw and T1-T5), and further incubated in the dark for 6 days (in triplicate). After 6 days of incubation, seedlings were harvested and dissected. Germination rate and lengths were recorded. Cotyledons, shoots, and roots from each Petri dish were pooled and dried to measure dry biomass, moisture, and specific lengths. Nine antibiotics were found in PL samples, being higher in raw PL but decreasing upon treatment in the following order: T4>T3>T2>T1>T5. Phytotoxic assays showed that all the samples at 50 and 100 g/L decreased the biomass of root, and both length and specific length of root and shoot with respect to control. T3 and T4 seem to be the least effective treatments to eliminate ATBs, showing the highest phytotoxicity with respect to other treatments, being the root and shoot parameters the most affected by the presence of ATBs in PL (average correlation -0.67, $p<0.05$). Thus, this study confirms that ATBs have negative effects on the early stages of chicory seedling development. Our current results also demonstrate that different PL treatments have diverse efficacy to eliminate them from polluted PL. Therefore, finding a good treatment to remove ATBs and other pollutants from PL looks needed to avoid negative effects on plants growing in amended soils.

2.02.P-We059 Intralaboratory Variability of Visual Phytotoxicity Assessments in Nontarget Terrestrial Plant Studies

*Patricia Lopez-Mancisidor[1], Seshadri Sajjala[1], Valentin Mingo[2], Eileen Paterson[1] and **Giovanna Meregalli**[3], (1)Corteva Agriscience, (2)Corteva Agriscience, Munich, Bavaria, Germany, (3)Corteva Agriscience, Cremona, Italy*

The EFSA recurring issues in ecotoxicology guidance from 2019 indicates that “the EC_X based on phytotoxicity should be reported” and “it should be considered for the Tier 1 risk assessment” in case it is the lowest endpoint. As visual estimates may have several sources of imprecision and bias, aspects of the reproducibility of the visual phytotoxicity assessments for possible derivation of ER50 values and their use in the European risk assessment of non-target terrestrial plants (NTTP) have been evaluated in this vegetative vigour study.

Five plant species (onion, oilseed rape, soybean, sugar beet, tomato), typically used in NTTP studies, were sprayed with two herbicides with different modes of action. An untreated control and five treatments (from 0.0625× to 1× of their field use rate) were assessed for each herbicide. Phytotoxicity was recorded 21 DAT and evaluated based on a total of 1227 photos of the plants. Twenty three experienced assessors from 10 labs assigned phytotoxicity scores to the plants based on the photos blinded to the treatment. For seven labs, 2-4 assessors participated and assigned scores independently from their colleagues. The data from these seven labs was used in this analysis. As staff working at the same company can be assumed to have received similar training and/or is operating to the same internal guidance, the intralaboratory variability of the scores assigned to the plants was evaluated.

The alignment in scores recorded by assessors from the same company was determined using the Intraclass Correlation Coefficient (ICC), preliminarily for three of the plant species considered in the study: tomato, sugar beet, and onion.

For the scoring of tomato and onion, the analysis showed a high intralaboratory variability between assessors, except for one laboratory where consistent scoring was provided by the observers. A much higher intralaboratory consistency was found in the visual phytotoxicity scores assigned to sugar beet plants.

Overall, inconsistent assessments among staff were observed at six of the seven laboratories that participated in the study, especially for some species commonly used in NTTP tests (e.g., onion and tomato). The use of ER50 values based on visual phytotoxicity scoring in the European ecotoxicological risk assessment for NTTP needs to be carefully considered.

2.02.P-We060 Determine Endpoints on Visual Effects for Terrestrial Plant (NTTP) Risk Assessment

Carmen Schweikert[1] *and Thomas Gräff*[2]*, (1)IV 1.3-1, German Environment Agency (UBA), Dessau-Rosslau, Germany, (2)German Environment Agency (UBA), Dessau-Rosslau, Germany*

Besides emergence, biomass, and shoot length, authorities ask to determine ER_{50} values for visual effects to conduct terrestrial plant (NTTP) risk assessment for plant protection products (PPP). Guidelines for terrestrial plant testing (OECD 208 and 227) provide some general guidance to assess visual effects (also referred to as “visible detrimental effects” or “visual injury,” such as chlorosis, necrosis, wilting, leaf and stem deformation). However, the assessment of the data on visual effects presented in the studies for authorisation process is not always documented in a way to readily conclude on the ER_{50} needed for NTTP risk assessment. Although presentation of the effects on visual injury as percent compared to the untreated control is recommended for the assessment of visual phytotoxicity in the above-mentioned guidelines, a number of studies provide an alternative scoring system. We present a scheme on how to derive effect endpoints (ER_{50}) for different data set types and give advice for appropriate statistical methods. To shed light on the uncertainties of the different procedures, statistical analyses were conducted using the examples of ER_X and Cochran-Armitage approach.
We want to share this proposal to facilitate the determination of the endpoint “visual injury” from the studies used to evaluate the risk of PPP to NTTPs and to thereby support the evaluation of such data for PPP risk assessment.

2.02.P-We061 Terrestrial Plant Species Sensitivity Distribution Approaches for Veterinary Medicinal Products

Chris Sinclair*, Roy Macarthur and Nick Jarratt, Fera Science Ltd., York, United Kingdom*

Veterinary medicines may enter the terrestrial environment through the application of livestock manure and slurries to land as a soil improver, or through direct defecation by treated animals. As part of the environmental risk assessment for these compounds the risk posed to terrestrial taxa including higher plants needs to be considered. Specific guidance on assessing the risks to terrestrial plants is available and follows a tiered process where initially acute data is used to generate the predicted no-effect concentration (PNEC). Usually the lowest EC_{50} from an OECD208 seedling and emergence study is used which considers six plant species (from six families, including two monocotyledonous and four dicotyledonous species including a Brassica). Should the risk be unacceptable then chronic data (NOEC or EC_{10}) usually from the same study can be used to refine the PNEC and thus refine the risk. Should the risk still be unacceptable then there are higher tier options available, one of which is the use of a species sensitivity distribution (SSD) to refine the PNEC.

The establishment of the SSD requires a minimum of eight species and using data for ‘the same, most sensitive endpoint’ an SSD can be established and the PNEC set as the lower confidence level concentration at which 95% of the species are theoretically protected (i.e., HC_5 LL). Two approaches are recommended within the EMA guidance for the establishment of the SSD (RIVM ETX and EPA CADDIS). We have explored the use of these approaches and we have identified that they do not generate the same HC_5 LL and hence PNEC and can vary significantly. In the presentation we will demonstrate the difference in PNEC values generated for a range of veterinary medicines using the two approaches based on real plant ecotoxicological data, we will describe the main statistical differences underlying the approaches and, through simulation modelling demonstrate how the approaches differ. Finally, we will make a recommendation on the use of an SSD modelling approach for higher tier plant environmental risk assessment for veterinary medicines.

2.03.P Aquatic Model Ecosystems and Aquatic Ecosystem Models: How Can They Be Used to Support Ecological Risk Assessment of Chemicals?

2.03.P-We062 Mesocosm Studies: Representativeness and Reliability

Marie Brown[1]*, Ellie Welch*[2]*, Nadine S. Taylor*[1] *and Seamus Taylor*[3]*, (1)Cambridge Environmental Assessments (CEA), United Kingdom, (2)Aquatic Ecotoxicology, Cambridge Environmental Assessments (CEA), United Kingdom, (3)ADAMA Deutschland GmbH, Germany*

In recent years the representativity and reliability of mesocosm data for regulatory risk assessment has been challenged, with some research suggesting that the organism diversity and abundance found in mesocosms do not represent the same levels typically found in natural waterbodies. In addition, some mesocosm studies have been criticised for their low statistical power to detect treatment related effects.

Despite these criticisms, mesocosms remain a valuable option in the risk assessment toolkit and recent improvements in study design and ecological representativity provide evidence that fresh concerns may be unwarranted.

In this poster we will provide evidence from recent mesocosm studies to demonstrate that when compared to natural edge-of-field waterbodies, mesocosms can provide a conservative, and protective, tool to evaluate the effects of pesticides to freshwater communities in different water body types (streams, ponds and ditches). Furthermore, we will show how mesocosm study designs can be informed by lower tier data to comprise sensitive and vulnerable organism groups, at abundances that allow robust statistical endpoints to be determined.

Through this analysis, we aim to demonstrate that data from mesocosm studies can be representative of the natural waterbodies they are attempting to emulate. These data will be supported by statistical (MDD) analysis to highlight the reliability and relevance of higher tier mesocosm studies in environmental risk assessment.

2.03.P-We063 Towards a Virtual Mesocosm for Pesticide Risk Assessment: A Comparison of Four Models Applied to Mesocosm Data

*Chiara Accolla[1], **Amelie Schmolke**[1], Nika Galic[2], Steven M. Bartell[3], Daniel Dawson[4], Klaus Peter Ebke[5], Jana Gerhard[6], Ann-Kathrin Loerracher[5], Isabel O'Connor[7], Laura Mudge[4], Robert Pastorok[4], Damian V Preziosi[4], Brandon Sackmann[8], Juergen Schmidt[5], Nele Schuwirth[9], Tido Strauss[6] and Roman Ashauer[2,10], (1)Waterborne Environmental, Inc., (2)Syngenta Crop Protection, Basel, Switzerland, (3)Stantec, Canada, (4)Integral Consulting, Inc., (5)MESOCOSM GmbH, Institut für Gewässerschutz, Germany, (6)gaiac - Research Institute for Ecosystem Analysis and Assessment, Aachen, Germany, (7)EBP Schweiz AG, Zürich, Switzerland, (8)GSI Environmental, Inc., (9)Systems Analysis and Modelling, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Dübendorf, Switzerland, (10)Department of Environment and Geography, University of York, York, United Kingdom*

Aquatic mesocosm studies are used in higher-tier aquatic risk assessments of pesticides. Aquatic systems models (ASMs) could be used to interpret and extend mesocosm experiments, e.g., by modeling ambient environmental and pesticide exposure conditions untested in the empirical systems. Mesocosm studies can provide data for aquatic systems models (ASMs), which are rarely available for natural systems. Thus, ASMs could become valuable tools to complement higher-tier aquatic risk assessments.

We present the results of a comparative modeling ("ring") study with four previously published ASMs (Streambugs, AQUATOX, CASM, and StoLaM+StreamCom). In the project, the four models were calibrated and validated to mesocosm control and toxic effect data conducted by Mesocosm GmbH at FNU Research Centre Neu-Ulrichstein, Germany. In the treatment studies, a fungicide was applied.

We reviewed the data for patterns and consistencies across studies and derived control and effect calibration and validation criteria for the ASMs applicable across studies. The ring study revealed uncertainty and data gaps related to the characterization of the mesocosm systems necessary for ASM parameterizations and evaluation of model performance. The calibrated ASMs met the predefined control calibration and validation criteria to varying extents. Each model performed differently in describing the abundances and dynamics of the organism groups and taxa in the food web. Organism groups best represented in simulations varied among the four models. In the effects simulations, the ASMs captured the most pronounced treatment-related effects across the study period. Some models successfully represented indirect effects resulting in increased taxon abundances in the mesocosm studies.

This study is a crucial first step toward the use of ASMs as 'virtual mesocosms' that can inform higher-tier aquatic risk assessments. The application of ASMs in the context of higher-tier aquatic risk assessments in the European Union can potentially extend the use of data from these studies by applying primarily different exposure profiles, but ultimately also environmental conditions and species compositions.

2.03.P-We064 Use of Hybrid Ecosystem/IBM Models to Mimic Outdoor Aquatic Mesocosms for Pesticide Risk Assessment

***Tido Strauss**[1], Natalie Carmen Dallmann[1], Josef Koch[1], Juergen Schmidt[2], Chiara Accolla[3], Amelie Schmolke[3], Nika Galic[4] and Roman Ashauer[4], (1)gaiac - Research Institute for Ecosystem Analysis and Assessment, Aachen, Germany, (2)MESOCOSM GmbH, Institut für Gewässerschutz, Germany, (3)Waterborne Environmental, Inc., (4)Syngenta Crop Protection, Basel, Switzerland*

Aquatic mesocosms are artificial ecosystems regularly used as proven test systems for higher-tier risk assessments of pesticides. At the same time, mechanistic effect models are also considered useful tools for ecological risk assessment of chemical stressors. In recent years, individual-based population models (IBMs) have been increasingly used in ecological risk assessment, often coupled with TKTD effect models. Integrated within ecosystem models, they can be powerful tools for predicting species population dynamics for different environmental scenarios.

This study is part of a larger ring study comparing four aquatic system models (ASMs) with different model structures to evaluate whether such modelling approaches can be used to simulate aquatic mesocosms. The ring study is a step toward the use of ASMs in the regulatory context of pesticide risk assessment in the future. Here we present one of the four ASMs, which is the hybrid ecosystem model framework StoLaM+. StoLaM+ links the lake model StoLaM, a hydrodynamic-ecological compartment model including several zooplankton and phytoplankton species, and IBMs for pelagic taxa such as daphnids, copepods and the dipteran *Chaoborus crystallinus*. Model dynamics are driven by year-specific meteorological weather data. The IBMs incorporate TKTD effect models for dynamic simulation of pesticide effects. Data from several outdoor aquatic mesocosm studies with and without pesticide treatment were available for several calibration and validation steps of the models.

This presentation focuses on the pelagic food web, where the most pronounced direct effects of the applied fungicide were found on planktonic crustaceans. The degree of adaptation of the model parameters to the respective case study is essential for the simulation quality as well as the transferability of the model to deviating ecological scenarios. In this application example, most of the parameters of the StoLaM+ model were kept unchanged and only study-specific parameters and pesticide- and organism-specific parameters of the effect models were calibrated. We derived validity criteria for the simulation quality from the minimum detectable differences (MDD values) in the mesocosm study and the deviation between treatments and controls over the experimental time. Simulated direct and indirect effects of the fungicide on the pelagic organisms are presented and discussed in comparison with the effect data of the experimental mesocosm studies.

2.03.P-We065 Process-Based modelling of Shallow Aquatic Microcosms Reveals Adaptation of Phototrophic Communities to Agricultural Run-off and Warming

Bastian H. Polst[1]*, Grégorio López Moreira Mazacotte*[2]*, Elisabeth Maria Gross*[3]*, Mechthild Schmitt-Jansen*[1]*, Franz Hölker*[2] *and Sabine Hilt*[2]*, (1)Department of Bioanalytical Ecotoxicology, Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany, (2)Leibniz Institute of Freshwater Ecology and Inland Fisheries (IGB), Berlin, Germany, (3)Liec Cnrs Umr 7360, University of Lorraine, France*

Surface run-off transports nutrients and pesticides from agricultural sites into nearby shallow aquatic ecosystems that are dominated by different primary producer groups: submerged macrophytes, periphyton or phytoplankton. Agricultural run-off (ARO) can induce shifts from a macrophyte-dominated to a phytoplankton-dominated state, which may alter or impair their ecological functioning and services. Global warming may further increase the risk of these ARO-induced shifts. A microcosm experiment mimicking ARO effects on shallow aquatic systems with different primary producer groups was combined with process-based modelling to test three hypotheses: 1) Differences in the vulnerability of different primary producers to ARO increase the risk of shifts to a phytoplankton-dominate state; 2) warming further increases this risk; 3) process-based modelling supports mechanistic understanding of ARO effects on primary producers through comparison of different scenarios.

A simplified shallow aquatic system containing different primary producer groups (phytoplankton, periphyton, submerged macrophytes) was exposed to a gradient of ARO (five different concentrations of a mixtures of nitrate, an herbicide, an insecticide, a fungicide, copper) at two different temperatures, 22°C and 26°C, for three weeks. A tailor-made process-based model was used to test eight different scenarios, targeting different temperature-dependent growth rates, herbicide sensitivities and community adaptation to pesticides.

In the experiment ARO had negative effects on macrophytes while phytoplankton was positively affected. Warming further enhanced phytoplankton growth. Comparing model scenarios with the observed results revealed that the best quantitative and qualitative fit was achieved when community adaptation of phytoplankton was considered with lower herbicide sensitivity at higher temperature.

Our study highlights the benefits of combining process-based modelling with experiments to disentangle and mechanistically understand effects of multiple stressors in shallow aquatic systems. Warming and ARO were shown to potentially lead to a shift from macrophyte dominance to phytoplankton dominance, and fast phytoplankton community adaptation to pesticides contributed to this effect.

2.03.P-We066 The Interplay Between Pollutants and the Adaptative Behavior in Ecological Communities

Constanza Vega Olivares[1] *and Andreu Rico*[2]*, (1)IMDEA Agua, Spain, (2)IMDEA Water Institute, Spain*

The relationship between the adaptive responses of predators and the stability of communities has been previously analyzed only considering pristine environments, even though many ecological systems are exposed to pollutants, among other disturbances. Many pollutants tend to accumulate in the tissues of organisms, resulting in species present in trophic webs not only transmitting their effects among themselves, but also transmitting the pollutants through their trophic interactions. In this context, adaptive behaviour, considered in this study as changes in prey preference, can inhibit pollutant transport through trophic networks without completely limiting biomass flow. In this study, the effectiveness of adaptive responses of predators in promoting the persistence and diversity of species in trophic networks subjected to stress from a bioaccumulative pollutant was evaluated. A community model based on the bioenergetic model was used, where the effects of the network topology (species richness and connectivity), the pollutant concentration and the adaptive behaviour over the species persistence and Shannon-Wiener diversity index were distinguished. In this work it was shown that adaptive behavior promotes species diversity in communities subject to stress from a bioaccumulative pollutant but does not promote species persistence. Therefore, the adaptive responses of predators have a beneficial role on the diversity of species in trophic webs affected by bioaccumulative pollutants.

2.03.P-We067 Towards a Virtual Mesocosm: Using the CASM-cosm to Assess Pesticide Risks

Steven M. Bartell[1]*, Chiara Accolla*[2]*,* ***Amelie Schmolke***[2]*, Cindy Woodard*[1]*, Peter Ebke*[3]*, Nika Galic*[4] *and Roman Ashauer*[4]*, (1)Cardno, Inc., (2)Waterborne Environmental, Inc., (3)MESOCOSM GmbH, Institut für Gewässerschutz, Germany, (4)Syngenta Crop Protection, Basel, Switzerland*

The comprehensive aquatic systems model (CASM) is a bioenergetics-based food web/ecosystem model used previously to assess pesticide risks in experimental ponds, lower-order streams, off-channel habitats, and wetlands. The CASM was adapted to simulate the FNU Research Centre outdoor pond mesocosms located near Neu-Ulrichstein, Germany. The resulting CASM-cosm included multiple populations of periphyton, phytoplankton, zooplankton, and benthic macroinvertebrates designated as important based on available control mesocosm data. The growth of the modeled populations was determined by parameters derived from the technical literature and previous CASM applications and physical-chemical data specific to each mesocosm study. The CASM-cosm was calibrated to four FNU mesocosm study control data sets. Calibration was performed by manually adjusting key growth parameter values (e.g., rates of photosynthesis, consumption, respiration) and comparing modeled to observed abundance and associated ASM ring study calibration criteria for the modeled populations. The calibrated model was within the range of the calibration criteria for 88 percent of the possible comparisons for the modeled macroinvertebrates and 71 percent for modeled zooplankton. The calibration matched 10 percent of the comparisons for modeled phytoplankton and 13 percent for periphyton. The control calibration was subsequently calibrated to population abundance data for mesocosms treated with the pesticide azoxystrobin (AZT). The calibration to measured effects of AZT was performed by deriving toxicity benchmark values (e.g., EC50 values) for each modeled population. Values of the model inputs used in the calibration to the control data were not changed during calibration to the AZT mesocosm data. Repeated simulations with systematically adjusted EC50 values were performed to match the magnitudes and temporal patterns of population abundances reported for the treated mesocosms. Daily values of control and treatment population biomass were plotted for the 365-day simulations. Percentage impacts (+/-) on abundance were plotted in relation to minimum detectable differences defined by the variability of population responses among replicate (N = 3) treatment mesocosms. Average differences between calibrated model and measured percentage impacts ranged from 10 for nauplii to 83 for small Cladocera. The CASM-cosm provides a virtual representation of the FNU mesocosms for higher-tier pesticide risk assessments.

2.03.P-We069 Seasonal Variability Physicochemical Parameters in the Mesocosm System Located in Southern Poland

Katarzyna Winiarska[1], *Inga Mrzyk*[2], *Agnieszka Godziek-Botor*[2], *Katarzyna Brzozowska-Wojoczek*[2], *Anna Wróbel*[2], *Agnieszka Żmijowska*[2] *and Marcin Wójcik*[2], *(1)Institute of Industrial Organic Chemistry, Poland, (2)Łukasiewicz Research Network-Institute of Industrial Organic Chemistry Branch Pszczyna, Poland*

In 2020, nearly 25 thousand tons of plant protection products (in terms of active substance) were sold in Poland. Most of them, i.e., 56%, are herbicides, weed destructors and moss killers, 32% are fungicides, 5% are insecticides, 4% are plant growth regulators, and 3% are others. Plant protection products have been known for decades and there is no doubt that they play an essential role in maintaining high level food production, but on the other hand, they affect the aquatic ecosystem and many biological processes involved.

In view of this fact, performing an outdoor mesocosm study for environmental risk assessment appears to be of ever-greater importance. Studies in the mesocosm system are designed to simulate the natural aquatic ecosystem, which can be created in the form of independent tanks or separate parts in existing ponds. During the study, physicochemical analyses of water are performed in regular periods of time. An extremely important element is the proper preparation of the mesocosm system before starting the experiment. Based on this, the above described study was performed, the aim of which was to conduct the research determining the physicochemical structure of the ecosystem over two growing seasons. In 2020 and 2021, the individual tanks with aquatic ecosystem established in 2019 were subjected to a number of physicochemical tests. Physical and chemical parameters of water such as pH, temperature, hardness, turbidity, conductivity, NO_2^-, NO_3^-, NH_4^+, PO_4^-, TOC were determined. The obtained results are a set of historical data for the mesocosm studies.

2.03.P-We070 Aquatic Risk Assessment for Nonstandard Chemicals with Physical Mode of Action (Forming a Film at the Water Surface) and Mesocosm Data - 2D and 3D

Heino Christl *and Nicole Santos, Tier3 Solutions GmbH, Germany*

Standard aquatic RA assumes solubility of substances in water, and compares predicted concentration in the field with effect concentrations. There are however substances not miscible with water, and despite of some emulsifier in the formulation the spray mist of a drift event settles on the water surface, where it may form a film if the amount per area is high enough. This film can cut off the atmospheric air supply for aquatic insects, if it is thick enough and continuous. In the case presented here, these aquatic insects were assessed in mesocosm studies with realistic spray applications, mimicking spray drift. Also predicted environmental exposure focusses on spray drift – as agreed with regulatory authorities. Hence both exposure levels and effect levels can be expressed as rates, and be compared directly - two-dimensional approach (2D), applying the usual assessment factor. The standard procedures in aquatic risk assessment are three-dimensional (3D), comparing exposure and effect concentrations, which is appropriate for most organisms. For the surface dwellers discussed here, concentrations are purely theoretical (virtual – nominal concentrations), as in reality the substances act as a surface film. Due to different depths considered in e-fate and ecotoxicology (30 cm depth assumed in e-fate, 75 and 100 cm tested in the ecotoxicological experiments), the virtual concentrations that would be used in a standard risk assessment are not representative of these not-miscible substances and surface-dwelling organisms. Here a direct RA based on rates (mg/m²) would address the issue. If based on virtual concentrations (mg/L), a correction factor for water depths would have to be introduced. As an example, the case of Paraffin oils (CAS n°8042-47-5) will be presented in detail. This presentation may be relevant also for other substances under assessment, with very high Log Koc, and the specific organisms affected by films forming on the water surface.

2.03.P-We071 Are Mesocosms Really Not suitable for the Risk Assessment of Plant Protection Products?

Udo Hommen[1], *Eric Bruns*[2], *Klaus Peter Ebke*[3], *Ivo Roessink*[4], *Tido Strauss*[5] *and Nadine S. Taylor*[6], *(1)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany, (2)Environmental Safety, Bayer AG - Crop Science Division, Germany, (3)MESOCOSM GmbH, Institut für Gewässerschutz, Germany, (4)Wageningen Environmental Research (WUR), Netherlands, (5)Research Institute gaiac, Germany, (6)Cambridge Environmental Assessments (CEA), United Kingdom*

A recently published article on the representativity of macroinvertebrate communities in micro- or mesocosm studies used as a higher tier tool in the environmental risk assessment of plant protection products (PPPs) in the EU concluded that micro-/mesocosm studies do not represent natural macroinvertebrate communities. We believe that this conclusion is unfounded for multiple reasons.

Fundamentally, the article based its conclusion on the analysis of studies in lentic micro- and mesocosms submitted to the UBA in a comparison to data from streams used as reference sites in a recent monitoring project in Germany for testing effects on typical stream taxa. Additionally, streams are not the only type of water bodies in agricultural landscapes and stream taxa are not, per se, more sensitive or vulnerable to pesticides than species living in ponds or ditches. Having initially identified 47 studies, the data used in the final analyses by Reiber et al. was constrained to eventually comprise of only 7 micro- or mesocosm studies, where mean numbers of taxa were considered by the Reiber et al. as sufficiently abundant for statistical evaluation. These were then compared against mean number of taxa present in at least five, of 22, streams. This appears to be a biased comparison.

Here we intend to revisit the data provided by the 7 selected studies from this publication, with the objective of determining how many, and which, taxa were considered as potentially sensitive or vulnerable and allowed a meaningful statistical analysis of effects with no other constraints. In our view, carefully designed and well conducted micro- and mesocosm studies do provide reliable and useful data for the prospective environmental risk assessment of PPPs, and other chemicals, since they are the only aquatic experimental option to cover long-term as well as indirect effects under semi-natural conditions. Whilst artificial streams offer an alternative to lentic systems if there is a special concern on typical stream taxa, it should be considered that lentic test systems provide additional safety for extrapolation to streams since the exposure events to tested in lentic systems are usually prolonged compared to the ones expected for pesticides in streams and the sensitivity of typical stream taxa can be checked in laboratory tests if needed.

2.03.PC Aquatic Model Ecosystems and Aquatic Ecosystem Models: How Can They Be Used to Support Ecological Risk Assessment of Chemicals?

2.03.P-We068 Effects of Herbicide Application on Early LIFE Stages of Fish: Connecting Laboratory and Field Work

Gavin Dehnert[1] *and William Karasov*[2]*, (1)VCGRE, University of Wisconsin, Madison, (2)Forest and Wildlife Ecology, University of Wisconsin, Madison*

Invasive, non-native aquatic species like Eurasian watermilfoil (Myriophyllum spicatum) are rapidly spreading across the United States. Both established and new aquatic herbicides, such as 2,4-Dicholorphenoxyacetic acid (2,4-D) and florpyrauxifen-benzyl (FPB), are popular choices to combat and control invasive species due to their efficacy and ease. Aquatic herbicides are typically applied in the spring for maximum efficacy on their target species, however this timing corresponds with many early life stages of non-target organisms. Many aquatic herbicides active ingredients and degradants are stable in the water column leading to prolonged exposure throughout development. Recent laboratory research has shown that ecologically relevant concentrations of 2,4-D can negatively impact multiple species of freshwater fish species at different points during ontogeny; however, it is poorly understood whether these laboratory results accurately predict impacts in the natural lake environment undergoing standard practices of aquatic herbicide application. Therefore, first we investigated the effects of 2,4-D whole-lake treatments on the development and survival of fathead minnows in lakes undergoing treatment using mobile, in situ, and laboratory exposure systems. Fathead minnow larvae were exposed to either control lakes or lakes undergoing 2,4-D whole-lake treatment and effects on morphology, survival, and growth were evaluated. We found that exposure of fathead minnow larvae to EPA-permitted 2,4-D whole-lake treatments reduced survival as compared to controls matching previous laboratory results. Second, we conducted a pilot study to investigate the effects of a new aquatic herbicide, FPB, whole-lake treatment on the development and survival of fathead minnows in lakes undergoing treatment using in situ and laboratory exposure systems. We found that exposure of fathead minnow larvae to EPA-permitted FPB whole-lake treatments reduced survival as compared to controls in some lakes and had no effect in other lakes. Further laboratory research is needed to elucidate the field study results.   together, our results shed light on the broader environmental costs of aquatic herbicide application on non-target organisms, which can help inform data driven management decisions and improve risk assessment for non-target organisms.

2.04 Are the Sub-Individual Responses Translated into Effects to the Higher Level of Biological Organization?

2.04.T-01 Pollution-Induced Community Tolerance in Freshwater Biofilms – From Molecular Mechanisms to Loss of Community Functions

Stefan Lips[1]*, Floriane Larras*[2]*, Elise Billoir*[3]*, Marie-Laure Delignette-Muller*[4] *and Mechthild Schmitt-Jansen*[5]*, (1)Department of Bioanalytical Ecotoxicology, Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany, (2)KREATiS, France, (3)University of Lorraine, France, (4)Université de Lyon 1, CNRS, VetAgro Sup, UMR 5558, France, (5)Department of Bioanalytical Ecotoxicology, Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany*

Aquatic biofilms include a variety of phyla, such as unicellular microalgae, bacteria, archaea, fungi, and protozoa, whose diversity and ubiquitous occurrence turns biofilms into a hotspot of ecological functions. Exposure to herbicides poses a threat to aquatic biofilms by affecting their community structure, physiology and function. These changes render biofilms to become more tolerant during exposure, but on the downside community tolerance has ecologic costs. We quantified microbial tolerance development against the herbicide diuron using the approach of pollution-induced community tolerance (PICT), analysed the molecular mechanisms of tolerance at the transcriptional and metabolic levels, and assessed its impact on ecological function.
We cultivated two different freshwater biofilm communities for a period of five weeks, with one set of the communities being contaminated with 4 µg L-1 diuron. Subsequently, the communities were characterized for structural and functional differences, especially focusing on their crucial role of primary production. Further, the molecular fingerprints of the communities were assessed using meta-transcriptomics (RNA-Seq) and GC-based community metabolomics approaches and analyzed with respect to changes in their molecular functions.

Chronic exposure to diuron impaired freshwater biofilms in their biomass accrual, with particular reduction of autotrophic biomass. This loss was associated with a change in the molecular fingerprint of the communities and substantial structural and physiological changes. An increase in diuron tolerance has been detected in the contaminated communities and molecular mechanisms facilitating tolerance have been found. It was shown that genes of the photosystem, reductive-pentose phosphate cycle and arginine metabolism were differentially expressed among the communities and that an increased amount of potential antioxidants was found in the contaminated communities. This led to the hypothesis that contaminated communities may have adapted to oxidative stress, making them less sensitive to diuron. Moreover, the photosynthetic light harvesting complex was altered and the photoprotective xanthophyll cycle was increased in the contaminated communities. Despite these adaptation strategies, the loss of autotrophic biomass has been shown to impair primary production. This impairment persisted even under repeated short-term exposure, so that the tolerance mechanisms cannot safeguard primary production.

2.04.T-02 Reduced Interspecific Competition Compensates the Costs of Pesticide Adaptation in a Dominant Aquatic Species

Ayesha Siddique[1]*, Naeem Shahid*[2] *and Matthias Liess*[3]*, (1)Ecotox, Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany, (2)System-Ecotoxicology, Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany, (3)Department of System Ecotoxicology, Helmholtz Centre for Environmental Research (UFZ), Germany*

Pesticide exposure alters invertebrate species composition in streams even below regulatory concentrations. Tolerant species are characterized by ecological traits enabling fast recovery of impaired populations. Additionally, pesticide tolerance enables their survival in contaminated streams. Tolerance can be increased through genetic adaptation; however, it involves fitness trade-offs. Here we show that pesticide exposure increased the pesticide tolerance, reduced the genetic diversity, resulted in an adopted genetic composition and reduced individual fitness. For 38 small streams we reveal that agricultural pesticide exposure resulted in loss of vulnerable species. For the less-vulnerable and dominant crustacean *Gammarus pulex,* an AFLP–assay comprised of 451 loci in 1035 individuals revealed an increased frequency of "high contamination alleles" and a decrease of "low contamination alleles" with increasing contamination. Furthermore, short geographical distance to nearby refuge sections reduced the tolerance development, but increased the genetic diversity and frequency of "low contamination alleles" presumably through individual migration. Finally, the individual per capita growth decreased with increasing trade-offs of acclimation and/or genetic adaptation. Nevertheless, *G. pulex* contributed an average of 44% of macroinvertebrate abundance and benefited from reduced interspecific competition with vulnerable species in contaminated streams. We conclude that pesticide contamination at already very low toxic pressure select for tolerant genotypes with less performant individuals and hypothesize that dominant species with high adaptive potential may nevertheless persist due to reduced interspecific competition with vulnerable species.

2.04.T-03 Linking Individual Responses to Collective Outcomes: Does Exposure to Fluoxetine Disrupt the Collective Behaviour of Fish?

Marcus Michelangeli[1,2]*, Jake Martin*[1,2]*, Tomas Brodin*[1]*, Jolle Jolles*[3]*, Jack Brand*[2]*, Rhiannon Eastment*[2]*, Hung Tan*[2]*, Kate Fergusson*[2] *and Bob B.M. Wong*[2]*, (1)Wildlife, Fish and Environmental Studies, Swedish University of Agricultural Sciences (SLU), Sweden, (2)School of Biological Sciences, Monash University, Australia, (3)Center for Ecological Research and Forestry Applications*

Collective behaviours in wildlife, such as schooling in fish, are key traits shaping ecological communities and demographic processes. The performance and outcomes of such collective actions rely heavily on the interactions among group members. Yet, whilst exposure to pharmaceutical pollutants has been shown to elicit a range of behavioural effects on individual organisms, research on how these individual effects manifest at the group-level is severely lacking. This is a critical knowledge gap because many animal species rely on the ability to form cohesive groups that are essential to their feeding and mating biology, as well as for their capacity to avoid predators.

In this study, we examined how a multigenerational exposure to a pervasive antidepressant pollutant, fluoxetine, affects the structure, movement and foraging behaviour of guppy (*Poecilia reticulata*) schools. We tested mixed-sex schools of fish across two ecological contexts (in an open arena and in the presence of food) five times, both before and after exposure to one of three ecologically relevant exposure treatments (0 ng/L, 30ng/L, and 300 ng/L). We quantified repeatable group-level behaviours and outcomes, including group cohesion, alignment, leadership, and foraging efficiency using high-throughput animal tracking software. Since fluoxetine has previously been shown to increase activity and decrease sociality in fish, we predicted that fluoxetine exposed fish would exhibit weaker collective movement (e.g., reduced cohesion and alignment), resulting in a breakdown in group performance and consistency across contexts. I will present preliminary findings from this work, and show how behavioural tests in social isolation are insufficient for predicting the environmental risk of chemical pollutants in social species. I will also discuss robust methodological approaches for testing ecologically relevant behaviours across multiple levels of biological organization – from individuals to animal social groups.

2.04.T-04 Linking Subtle Individual Responses to Population Level Effects of Pharmaceutical Exposure in an Outdoor Mesocosm

Elien Versteegen[1]*, Ivo Roessink*[2]*, Edwin Peeters*[1] *and Paul van den Brink*[3]*, (1)Aquatic Ecology and Water Quality Management, Wageningen University & Research, Netherlands, (2)Wageningen Environmental Research (WUR), Netherlands, (3)Wageningen University & Research, Netherlands*

Current environmental risk assessment of psychotropic drugs fails to reflect on the subtle effects that low drug concentrations may have in aquatic environments. Due to the biologically active nature of psychotropics, their interaction with the nervous system, and their resemblance to infochemicals, they might affect behavior of organisms even at low environmental concentrations. At these low concentrations, effects on the individual survival might seem absent, but small changes in behavior can possibly result in changes at population and/or ecosystem level. To account for these subtle effects in the current environmental risk assessment, there is a need for new measurement endpoints to access effects across different levels of ecological organization (i.e., individual, population, community, and ecosystem). The main aim of this study is to find correlations between subtle behavioral effects and changes in the structure and functioning of an aquatic ecosystem as a result of exposure to low environmentally relevant concentrations of the antiepileptic drug carbamazepine.

The effects of chronic exposure to carbamazepine (14 weeks exposure to 0.001 – 100 µg/L) were studied in an outdoor mesocosm setup and combined with the behavioral analyses of two species. The locomotion patterns of *Gammarus pulex* and *Lymnaea staganalsis* individuals, taken from the mesocosms, were analyzed with a camera setup. Combined with population data of all species present in the mesocosms (macroinvertebrates and zooplankton), abiotic variables, and phytoplankton chlorophyll-*a*, this experiment obtained data that spanned three levels of biological organization: individual, population, and ecosystem level.

On community level we did not discover effects; the macroinvertebrate and zooplankton community composition were not affected by carbamazepine treatment. On individual level we recorded that locomotion of *G. pulex* had a strong photokinetic response to sudden darkness. The average swimming speeds dropped when organisms in the mesocosm were exposed to 1 µg/L carbamazepine.

Determining whether these individual behavioral endpoints are relevant at higher levels of ecological organization could emphasize the relevance of using behavioral endpoints for regulatory purposes. This experiment showed that the observed changes in average swimming speed of *G. pulex* do not propagate to community level effects.

2.04.T-05 Networks in Aquatic Communities Collapse upon Neonicotinoid-Induced Stress

Henrik Barmentlo[1]*, Maarten Schrama*[2]*, Ellen Cieraad*[1]*, Geert R de SNoo*[1]*, Martina G. Vijver*[1]*, Cjm Musters*[1] *and Peter M van Bodegom*[1]*, (1)Leiden University, Leiden, Netherlands, (2)CML, Leiden University, Leiden, Netherlands*

Neonicotinoids are the type of insecticides that are used most in the world are exceeding environmental norms in surface waters across the world. The actual risk to freshwater ecosystems remains unclear since translation from single species bioassays to actual community or ecosystem responses has proven notoriously difficult.

To this end, we investigated how the neonicotinoid insecticide thiacloprid potentially induces changes in invertebrate species composition and we linked individual species via the use of co-occurrence network analyses show how this degraded community coherence. By obtaining information on individual species feeding guilds and biomass, we were able to draw relations between species and their effects on ecosystem functioning.

We investigated the effects of the neonicotinoid thiacloprid on invertebrate species alpha, beta-diversity, co-occurrence, and ecosystem functioning using an outdoor mesocosm facility consisting of 36 individual ditches. These ditches are fully naturally colonized by biota. Here, we exposed the naturally formed freshwater ecosystem to an environmentally relevant concentrations of thiacloprid: 0, 0.1, 1 and 10 µg/L (n=9). We measured the aforementioned parameters following a before-after control design. By using feeding trait data and several measured ecosystem processes, we related individual species to their relative roles in the ecosystem.

We observed no effects on alpha diversity, while invertebrate thiacloprid concentrations induced a significant transition in invertebrate biodiversity. This coincided with a severe impairment of the co-occurrence network to such an extent that all thiacloprid impacted communities could not be statistically deviated from 1000 randomly generated communities (i.e., a null model) while the control significantly outperformed the null model, implying biological organization.

This degradation of community coherence coincided with significant reduction in the shredder feeding guild. In turn, this led to a stunted organic matter consumption and strong dominance of floating algal beds which suppressed phytoplankton growth (as modeled using piecewise structural equation modeling).

We found notable and strong effects below nearly all recognized toxicity levels for thiacloprid using a co-occurrence and feeding guild approach, showcasing the potential for these methods to couple species data to higher levels of biological organization.

2.04.P Are the Sub-Individual Responses Translated Into Effects to the Higher Level of Biological Organization?

2.04.P-Tu048 Evaluation of Individual and Mixed Toxicity of Preservatives in Household Chemical Products using Zebrafish Embryo/Larvae

Chaeun Park*, Sujin Lee and Kyunghee Ji, Yongin University, Korea, Republic of (South)*

Isothiazolinones and parabens have been widely used as preservatives in a variety of household chemical products. Increasing evidence has demonstrated that these chemicals disrupt endocrine system in animals; however, limited information is available on the developmental toxicity and their underlying mechanisms in a combined exposure. In the present study, the effects of mixed exposure to benzisothiazolinone (BIT), methylisothiazolinone (MIT), methylparaben (MP), and propylparaben (PP) on development and thyroid endocrine system were investigated using zebrafish embryo/larvae. Hatchability and larvae survival were significantly reduced in PP 0.3 µg/L, PP 30 µg/L, BIT+PP 0.3 µg/L, and BIT+PP 30 µg/L treatment groups. Malformation rates were significantly increased following exposure to PP, and the combined exposure of PP and BIT exhibited a greater effect on the abnormal development. The transcription of genes related to thyrotropin-releasing hormone (TRH) and thyroid-stimulating hormone (TSH) was significantly upregulated in fish exposed to BIT, MIT, and BIT+PP exposure groups. Our observation indicates that isothiazolinones and parabens have the potential to affect thyroid hormone feedback circuit, and co-exposure to these two compounds could augment endocrine disruption. Further studies are needed to understand interaction of compounds found in consumer products.

2.04.P-Tu049 A Holistic Approach to Determine Freshwater Mussel Response to Pharmaceuticals in Virginia, USA
***Kathleen Mayer**, Tyler Allen and Austin D. Gray, Department of Biological Sciences, Virginia Tech*
It is documented that various classes of pharmaceuticals, such as antidepressants and nonsteroidal anti-inflammatory drugs, are entering aquatic environments as co-occurring contaminants or mixtures. As a contaminant of emerging concern, there is a need to investigate the role of pharmaceutical pollution in biodiversity loss. Stream networks commonly receive pharmaceutical contaminants, and these habitats within North America house the most biodiverse mussel populations. Due to mussel populations residing in areas commonly polluted with pharmaceuticals, there is a research need to understand how these ecologically important organisms respond to different classes of pharmaceuticals. Transcriptomic studies that have been conducted for different bivalve species have suggested that variation exists in expressed genes that regulate innate immune response. While these studies provide a molecular approach to address bivalve response to environmental stimuli, the focus is typically on marine bivalve species rather than freshwater species. This leaves a gap for this project to explore pharmaceutical effects on freshwater mussels that are declining within the southeast region of the United States in Virginia. This dissertation proposal project will consist of laboratory and field-based assessments that will utilize molecular and ecological approaches, such as real-time PCR (i.e. polymerase chain reaction) of key immune response genes, luminescent-based assays of key antioxidants (e.g., glutathione), "omic" approaches such as proteomics utilizing LC/MS instrumentation, and macroinvertebrate assessments to address how mussels and their communities respond to pharmaceuticals. As pharmaceutical pollution gains more attention, a more holistic approach to how organisms respond to these agents of global change is crucial to better evaluate the ecosystem and community responses.

2.04.P-Tu050 PFAS in the Marine Environments: Does Perfluorotetradecanoic Acid (PFTeDA) Affect Marine Benthic Invertebrates?
***Katarzyna Smolarz**[1], Jakub Obszarski[2], Justyna Świeżak[3] and Anna Hallmann[4], (1)Division of Marine Ecosystems Functioning, University of Gdansk, Poland, (2)Institute of Oceanography, University of Gdansk, Poland, (3)Marine Ecosystems Functioning, University of Gdansk, Poland, (4)Department of Pharmaceutical Biochemistry, Medical University of Gdansk, Poland*
Per- and polyfluoroalkyl substances (PFAS) include a variety of synthetic chemicals that are present in most of the everyday products and industries. Due to their widespread occurrence, growing numbers, persistence in the natural environments, bioaccumulation potential and toxicity they are now one of the major threats in the aquatic environments. Due to the fact that purification treatment plants are not able to remove these substances, PFAS have been detected in various abiotic (water, sediments) and biotic (fauna, flora) matrices in both freshwater and marine environments, specifically in areas under stronger anthropogenic pressure. Moreover, little is known about the levels and composition of PFAS in the marine environments and their effects on nontarget marine fauna. Perfluorotetradecanoic acid (PFTeDA), belonging to PFAS family, has been found to affect male reproductive system in terrestrial vertebrates, but the knowledge on PFTeDA toxicity to marine organisms, and specifically benthic key species, is lacking. Therefore, the main purpose of this study was to assess the toxicity of this emerging and understudied PFAS using an experimental approach in which the blue mussels *Mytilus trossulus* collected in the Gulf of Gdańsk (Poland) were exposed to 30 and 300 ng/L of PFTeDA over a period of 10 days. To understand PFTeDA effects, an integrated multibiomarker approach based on markers characterising the activity of xenobiotic detoxification systems, oxidative stress response, general health status, and physiological and morphological abnormalities was used.
No mortality during the experiment was observed. On the tissue level, various progressive and regressive changes were found. In the respiratory system, significant increase in the presence of the tissue oedema and necrosis, infiltration of hemocytes, as well as deformities were observed in the exposed mussels when compared to those from the control. In the digestive system, atrophied digestive tubules of hepatopancreas were seen in over 57% and 87% of exposed mussels (30 and 300 ng/L, respectively). Also, the presence of cellular markers of the oxidative stress (superoxidase dismutase activity) in the tissues of PFTeDA-exposed mussels were found. Thus, the PFTeDA appears to mainly affect respiratory and digestive systems which may lead to energetic misbalance and weakening of exposed individuals.

2.04.P-Tu051 Microplastic Ingestion in Juvenile Meagre – A Wide-Spectrum Biomarker Approach
***Carolina Pinheiro Rocha**[1], Vanessa Madeira Lopes[2], Tiago Repolho[3], Rui Rosa[3], João Carlos Marques[1] and Ana Marta Goncalves[4], (1)University of Coimbra, MARE - Marine and Environmental Sciences Centre, Portugal, (2)Faculdade de Ciências, University of Lisbon, MARE – Marine and Environmental Sciences Centre / ARNET – Aquatic Research Network, University of Lisbon, Portugal, (3)MARE – Marine and Environmental Sciences Centre / ARNET – Aquatic Research Network, University of Lisbon, Portugal, (4)University of Coimbra, MARE - Marine and Environmental Sciences Centre / Department of Biology and CESAM, University of Aveiro, Portugal*
The impact of microplastics (MP) in aquatic biota is vast. However, many experimental studies are based upon the use of MP

concentrations which do not reproduce naturally occurring ones, especially regarding micron-sized fractions. While such studies contribute to better understand the worst-case scenarios of MP impacts in organisms, the sublethal effects elicited at environmentally relevant concentrations are often overlooked. Therefore, understanding if field-measured MP concentrations could trigger early-warning signs of toxicity in fish is of vital importance. The aim of the present study was to assess the impact of polyethylene (PE) powder ingestion in juvenile meagre (*Argyrosomus regius*). Microplastics' polymers, their size, shape, and concentration were chosen according to data retrieved from water and fish samples, originated from semi-intensive aquacultures on the Portuguese coast. The present study consisted of exposing 35 *A. regius* juveniles to a concentration of 36 PE particles L^{-1} for 21 days. Fish tissue (n = 18) was sampled for the biomarker analysis, namely: cortisol, digestive enzymes, antioxidant enzymes, respiratory enzymes, ubiquitin, heat-shock protein content, fatty acids, and carbohydrates content. The remaining 17 specimens were transferred to clean water and kept to depurate (7 days), to account for possible plastic excretion. After depuration, fish tissue was sampled for analysis of the above-mentioned biomarkers. Understanding the potential sublethal effects (i.e., inflammatory response) of PE ingestion is of utmost importance, once the detrimental effects to marine biota are still poorly understood and expected to increase as a result of ongoing accumulation of produced pollution and climate change, that rapidly alter environmental paradigms. Biomarker analysis is ongoing, as well as the determination of eventual particle degradation during exposure. Nonetheless, early results allow to expect inflammatory responses caused by accumulation or tissue damage by MP. As meagre is intended for human consumption, both environmental and human health matters can be at stake, which usually gains higher interest from decision-makers concerning pollution policy and regulation, to which this study intends to contribute to with further information.

2.04.P-Tu052 Sublethal Effects of Thallium in the Freshwater Flatworm *Girardia tigrina*

Patricia Caballero Carretero[1]*, Diana Campos*[2]*, João L.T. Pestana*[2] *and Jose-Luis Martinez-Guitarte*[3]*, (1)National Distance Education University (UNED), Spain, (2)University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Aveiro, Portugal, (3)UNED, Spain*

Thallium is a highly toxic metal present in the environment at low concentrations. Nowadays, it is considered an emergent pollutant because of its use in industries, metal mining, and smelting. Moreover, it is one of the main wastes from electronic trash. Due to these anthropogenic activities, it has been shown that thallium reaches freshwater ecosystems. However, only a few studies are assessing the toxicity of thallium in freshwater organisms at environmental concentrations, and the majority are focusing on *Daphnia magna*. This study assesses the effect of the exposure to thallium (I) nitrate in the freshwater flatworm *Girardia tigrina* at environmentally relevant concentrations. The aim of this study is to broaden the information of the thallium's effect in other freshwater organisms.

Planarians with a length of 1 cm were exposed to a range of sublethal concentrations of thallium nitrate (25 µg/L, 75 µg/L, 225 µg/L, 675 µg/L) for 8 days. In this study behavioral endpoints as locomotion and feeding rate but also head regeneration after decapitation were analyzed. The biochemical responses have also been analyzed measuring lipids, carbohydrates, and proteins contents and the oxygen consumption rate. Enzymatic activities like glutathione S-transferase (GST), catalase (CAT) and acetylcholinesterase (AChE), as well as lipid peroxidation (LPO) and total glutathione (tGSH) have been also analyzed to address effects on the antioxidant system of planarians.

Preliminary results show that planarians cannot regenerate after an exposure to concentration of 675 µg thallium /L and higher. However, sublethal concentrations do not elicit significant effects on locomotion or feeding rate. Regarding the biochemical response, planarians tend to decrease their consumption of energy reserves at the highest concentration studied. Finally, a decrease of GST and AchE activity is shown after an exposure of 75 µg/L as well as evidence of increased lipid peroxidation exposed to thallium. These data suggest that low concentrations of thallium disrupt detoxification and neurotransmission pathways in planarians. Results highlight the importance of molecular level effects of low concentrations of thallium with additional research at transcriptional level needed to have a global scenario of its ecotoxicity to planarians.

2.04.P-Tu053 Fish Parasites as Bioindicators of Element Exposure in the Marine Environment: An Environmental Parasitology Approach

Anja Erasmus*, Angela Minnie, Johannes Hendrik Erasmus, Victor Wepener and Nicholas J. Smit, Water Research Group, Unit for Environmental Sciences and Management, North-West University, South Africa*

Anthropogenic activities, resulting in elemental exposure, in proximity to the marine environment reportedly have major impacts on ecosystem health and functioning. It is therefore important to consider all aspects of these ecosystems to better understand how ecosystems function. Parasites (endoparasitic worms) have been reported as promising sentinels for element accumulation; however, studies like these are lacking in South Africa. Linking cryptofauna to ecosystem health through environmental parasitology can possibly explain various accumulation patterns. Thus, the present study aimed to determine the elemental concentrations in the South African endemic fish, *Diplodus hottentotus* (Zebra) and its intestinal acanthocephalan parasites (also known as spiny- or thorny-headed worms). Fish were collected in the infratidal zone at the coastal town of Chintsa, along the east coast of South Africa. All five Zebras collected were infected with an acanthocephalan from the family Pomphorhynchidae with low (<30) to high (>30) intensity of infection. Fish were weighed, measured, and dissected, and collected muscle, liver, and parasite tissues were frozen for element analysis. A subsample of acanthocephalans was fixed for morphological and molecular identification. Inductively coupled plasma-mass spectrometry (ICP-MS) was used to measure the element concentrations in host muscle and liver tissue, as well as the acanthocephalan parasite tissue. Statistical significance was determined using one-way ANOVA and Kruskal-Wallis tests. Essential elements and arsenic accumulated in significantly higher concentrations in the host tissue compared to the parasites. In contrast nonessential elements (e.g., chromium, cadmium, lead) were significantly higher in the parasites than the host tissues. Although Al, Fe, and Zn were the highest elements measured, these do not reflect metal pollution but rather natural geogenic input into the nearshore marine environment. The high arsenic levels are derived from natural upwelling events in the region. The higher nonessential elements in the parasites reflect the inability to regulate the elements to the same degree as their hosts. These results underline the role that parasites play in ecosystem functioning such as reducing possibly toxic elements from accumulating in their host tissue.

2.04.P-Tu054 Changes in the Ultrastructure of a Community of Microalgae and a Toxigenic Cyanobacterium Exposed to a Commercial Formulation of Glyphosate

*Claudia Hernández-García and **Fernando Martínez-Jerónimo**, Instituto Politécnico Nacional Escuela Nacional de Ciencias Biológicas, Mexico*

Human activities influence the health of aquatic ecosystems, as many harmful chemical wastes are dumped into freshwater bodies. Intensive agriculture contributes to deterioration by discharging fertilizers and pesticides that affect the aquatic biota. Glyphosate is the most widely used herbicide in the world, and microalgae are particularly sensitive to its formulations.

Exposure to glyphosate can cause some green microalgae to be displaced from the phytoplankton community, altering the floristic composition that could favor the dominance of cyanobacteria. The combination of chemical stressors, such as glyphosate, and biological stressors, such as cyanotoxins and other secondary metabolites of cyanobacteria, could produce a combined and potentially more harmful effect on microalgae; these could affect the algal growth, physiology, and morphology. This study evaluated the combined effect of glyphosate (Faena®) and one toxigenic cyanobacterium on the morphology and ultrastructure of microalgae in an experimental community. For this, a strain of *Microcystis aeruginosa* (a cosmopolitan cyanobacterium that forms harmful blooms), and the microalgae *Ankistrodesmus falcatus*, *Chlorella vulgaris*, *Pseudokirchneriella subcapitata,* and *Scenedesmus incrassatulus*, were cultivated individually and together, exposing them to sub-inhibitory concentrations of glyphosate (IC_{10}, IC_{20}, and IC_{40}). Effects were evaluated by scanning electron microscopy (SEM) and transmission electron microscopy (TEM). Exposure to Faena® (glyphosate) affected microalgae's external morphology and ultrastructure, both individually and in combined cultures. SEM showed a loss of the typical shape and integrity of the cell wall and an increase in biovolume. In TEM, reduction and disorganization of the chloroplast, variation in starch and polyphosphate granules, formation of vesicles and vacuoles, degradation of the cytoplasm, and loss of continuity of the cell wall were observed. The combined exposure of microalgae to glyphosate and cyanobacteria produced more severe alterations than those described above. The presence of *M. aeruginosa* was an additional stress factor for the microalgae that added to the chemical stress produced by Faena® and increased the damage to the algal morphology and ultrastructure. These results warn about the effects of glyphosate and toxigenic cyanobacteria on algal phytoplankton in polluted and anthropically eutrophicated freshwater ecosystems.

2.04.P-Tu055 Ultrastructure Changes in the Midgut of Stingless Bees *Melipona scutellaris* Exposed to Fungicide Pyraclostrobin

***Caio Eduardo da Costa Domingues**[1], Lais Vieira Bello Inoue[2], Aleš Gregorc[1], Elaine Cristina Mathias Silva-Zacarin[3] and Osmar Malaspina[2], (1)University of Maribor, Slovenia, (2)Centro de Estudos de Insetos Sociais (CEIS) Instituto de Biociências (IB), Universidade Estadual Paulista (UNESP) - "Júlio de Mesquita Filho", Brazil, (3)Biology, Federal University of Sao Carlos (UFSCar), Sao Carlos, Brazil*

Stingless bees of the Meliponini tribe, *Melipona scutellaris* (Latreille, 1811), are native to the northeast region of Brazil. These native bee species hold economic importance and relevance related to the pollination of native plants. Fungicides have been widely used in agriculture, and forager bees can be exposed to them by a collection of floral resources (nectar and pollen) containing residues. Residual pesticide molecules in ingested food can be absorbed in the midgut of bees. In this context, the goal of the present study was to evaluate the effects of sublethal concentrations of pyraclostrobin on the midgut of *M. scutellaris* forager workers using an ultrastructural approach. Bees were collected from three nonparental healthy managed colonies (Rio Claro city, São Paulo State, Southeastern Brazil) and kept at laboratory conditions (28 ± 1°C, 70 ± 5% humidity) in cages. The caged bees were orally exposed for five days to two concentrations of pyraclostrobin in syrup (50% sucrose solution): 0.125 ng a.i./µL (P1) and 0.005 ng a.i./µL (P2). Control bees were fed a no-fungicide sucrose solution, and the acetone solvent control received a sucrose solution containing acetone (1% of the final volume). Each experimental group contained 80 bees (n = 20 per cage in four replicates). At the end of the toxicological bioassay, midguts from cooling-anesthetized bees (n = 3 per experimental group) were dissected and immersed in a formaldehyde-glutaraldehyde fixative (Karnovsky) for 2 hours at room temperature and routinely processed for Transmission Electron Microscopy. The ultrastructural analysis demonstrated that both fungicide concentrations induced alteration in the midgut, such as cytoplasmic vacuolization (more intense in P1), presence of atypical nuclei morphology, or pyknotic nuclei indicative of cell death (both were more intense in P1). Additionally, there was an alteration in the ultrastructure of spherocrystals (P1), which could be a reflex of cellular metabolism impairment and excretion of toxic products in this metabolism in the digestive cells as a response to fungicide exposure. The results of the present study reinforced the hypothesis that orally ingested pyraclostrobin induced cytotoxic effects in the midgut of native stingless bees. These cell responses of the midgut at the sub-individual level be a prelude to a reduced survival rate at an individual level, as observed in our previous study performed by our research group.

2.04.P-Tu056 Cell Biomarkers and Behavioral Evaluation on the Neotropical Solitary Bee *Tetrapedia diversipes* Topically Exposed to Imidacloprid Insecticide and Pyraclostrobin Fungicide

***Elaine Cristina Mathias Silva-Zacarin**[1], Josimere Conceição de Assis[2], Rafaela Tadei[3], Hellen M. Soares Lima[2], Pamela Decio[4],*

Kyl Assaf[2], Vanessa Menezes-Oliveira[5], Caio Eduardo da Costa Domingues[6] and Cláudia Inês da Silva[2], (1)Biology, Federal University of Sao Carlos (UFSCar), Sao Carlos, Brazil, (2)Biology, UFSCar - Federal University of São Carlos, Sorocaba, Brazil, (3)Biology, São Paulo State University (UNESP), Brazil, (4)Biologia, UFSCar - Federal University of São Carlos, Sorocaba, Brazil, (5)Federal University of Tocantins (UFT), Brazil, (6)University of Maribor, Slovenia
Solitary bees present great species diversity, but ecotoxicological studies about them are still scarce. This study aimed to evaluate the effect of residual doses of imidacloprid and pyraclostrobin, alone and in combination, on the behavioral pattern (individual response) and the fat body (sub-individual response) of the neotropical solitary bee *Tetrapedia diversipes* (Klug, 1810). Males and females of newly emerged adults were submitted to bioassays of acute topical exposure. Experimental groups were essayed: control, solvent control, imidacloprid (0.0028 ng/µL), pyraclostrobin (2.7 ng/µL), and imidacloprid + pyraclostrobin (at the same concentration as pesticide isolated). Video tracking evaluation was performed with the treated adults along postexposure time (1 h, 24 h, 48 h, 72 h, 96 h) in a flat laboratory arena. The videos were analyzed using the EthoVision software to measure: velocity, moved distance, percentage of resting time, and percentage of mobile time. After 96 hours of acute contact exposure, each experimental group's fat body from females and males was dissected and processed for histological analysis. Histological slides were stained with hematoxylin and eosin (HE) for morphological analysis, and histochemical techniques: xylidine ponceau (total protein detection) to determine the granulation stages of trophocytes; periodic Acid-Schiff (PAS) for cell polysaccharides detection. The data demonstrated that the residual doses applied in *T. diversipes* are sublethal. During the first 24 hours, the fungicide subtly reduced the distance and velocity of bees into the arena; the imidacloprid tended to increase the bee activity. Thus, at the individual level, both pesticides influenced the movement of bees, but the effects were minimized over time postexposure. Both oenocytes and trophocyte cells showed morphological and histochemical changes at the sub-individual level after topical pesticide exposure. Imidacloprid modified the protein granulation stage in trophocytes and pyraclostrobin increased the polysaccharides in these cells, which can lead to changes in the physiological processes dependent on protein and glycogen mobilization from fat body. This work is the first ecotoxicological study with a neotropical solitary bee species at a sub-individual scale and cellular level. The data obtained will broaden the knowledge concerning the effects of residual doses of imidacloprid and pyraclostrobin on native bees.

2.04.V Are the Sub-Individual Responses Translated Into Effects to the Higher Level of Biological Organization?

2.04.V-01 Comparison of Species Responses to Mixed Metal Exposure

***Yared Hailaye Bezabhe**[1], Berkay Paylar[2], Jagadish Chandra Kumar Mangu[3], Viresh Thamke[4], Aboi Igwaran[1], Carina Modig[1], Daniel Ragnvaldsson[5], Jana Jass[6] and Per-Erik Olsson[6], (1)Orebro University, Örebro, Sweden, (2)Varbergagatan 226, Sweden, (3)Department of Science and Technology, Orebro University, Örebro, Sweden, (4)The Life Science Center-Biology, School of Science and Technology, Orebro University, Örebro, Sweden, (5)Envix nord AB, Sweden, (6)School of Science and Technology, Orebro University, Örebro, Sweden*
Humans and other animals are exposed to mixed chemicals present in water, air, or food. Mixed metal exposures are common in the aquatic environment, affecting both invertebrates and vertebrates. In the present study we determined the effects of metal mixtures in a time dependent concentration gradient from a lake receiving runoff water from a decommissioned mine. Acute toxicity was determined for four invertebrate models, *Caenorhabditis elegans*, *Daphnia magna*, *Ceriodaphnia dubia*, and *Heterocypris incongruens*, and one vertebrate model, Zebrafish (*Danio rerio*) and two cell lines, Zebrafish liver cell line (ZFL) and Human hepatocellular carcinoma cell line (HepG2). The metal mixes elicited the highest mortality in *D. magna* (100%), followed by *C. dubia* (100%), *H. incongruens* (95%), ZFL cells (65%), *D. rerio* (37%), human HepG2 cells (20.5%) and with the lowest response observed for *C. elegans* (7%). Analysis of gene expression showed that the metal response genes, mt-1 and mt-2 correlated well to the exposure conditions in all tested models. The results show that *D. magna* is the most sensitive model organism for effect identification of mixed metal exposures. In such exposures, significant upregulation of metallothionein genes was protective to *C. elegans*, *D. magna*, and HepG2 cells.

2.05 Arthropods at Risk? Current and Future Perspective on Insect Ecotoxicology

2.05.T-01 Effects of Clothianidin and Flupyradifurone on Bumblebee Colony Development at Fluctuating Ambient Temperature

*Nora Kildebo[1], Julie Sørlie Paus-Knudsen[2], Jan Heuschele[3], Michael Garratt[4], Tom Andersen[2], Alison O'Reilly[5], Dara Anne Stanley[5], Henrik Andersen Sveinsson[2], Anders Nielsen[6] and **Katrine Borga**[2], (1)Biosciences, University of Oslo, Norway, (2)University of Oslo, Norway, (3)Department of Biosciences, University of Oslo, Norway, (4)University of Reading, United Kingdom, (5)University College Dublin, Ireland, (6)Norwegian Institute of Bioeconomy Research (NIBIO), Norway*
Although neonicotinoids and the replacement flupyradifurone share the same mode of action, the latter is marketed as pollinator-friendly. Knowledge of their effects on pollinators other than the Western honeybee is limited, and most focus has been on individual adult bees. Furthermore, few studies consider how environmental conditions such as temperature affect the toxicity of chemicals, especially under chronic exposure. Lastly, risk assessment is performed on one chemical at a time, while mixture toxicity is a more relevant scenario for bees.

We study how the neonicotinoid clothianidin and flupyradifurone, alone and in combination, affect colony development of the buff-tailed bumblebee (*Bombus terrestris audax*) under fluctuating ambient temperature. We expected colder temperatures and higher concentrations or mixture treatments to elicit stronger adverse effects. Bumblebee colonies were exposed to one of six treatments: a low (4 mg/L) or a high (4 x low) concentration of clothianidin, a low (1 mg/L) or high (4 x low) concentration of flupyradifurone, a mixture of the two at low concentration or a control treatment. Exposure was through artificial nectar over 21 days, followed by 21 days postexposure. The experiment ran sequentially from May until August to allow a natural ambient temperature gradient.

The effects of temperature on bumblebee colony development depended on the focal endpoint, insecticide, and concentration, and no general temperature-dependent toxicity was identified. Only exposure to the high concentration of flupyradifurone followed the expectation of more adverse effects at colder temperatures when looking at weight gain and the number of bees in the colony at the end of the experiment. Low exposure concentrations of flupyradifurone were more toxic at warmer than colder temperatures for both endpoints. The low concentration of clothianidin showed a complex interaction with temperature, while the high concentration of clothianidin was more toxic at warmer temperatures. The mixture treatment had comparable effects to flupyradifurone for the number of bees and gave a stronger negative effect on weight gain than when the insecticides were administered alone.

This study shows the importance of testing field-realistic doses over a realistic exposure period in combination with natural variables. Climatic conditions and multiple stressors should be considered when performing risk assessment of chemicals.

2.05.T-02 Comprehensive Lipid Profiling to Study the Effect of the Growth Inhibitor Insecticide Teflubenzuron on the Nontarget species *Folsomia candida* over time

***Diana Ilyaskina*[1]**, *Saúl Fernandes[2], Cornelis A.M. van Gestel[3], Marja Lamoree[4] and Pim Leonards[5], (1)Amsterdam Institute for Life and Environment (A-LIFE), Section Environment & Health, Vrije University Amsterdam, Netherlands, (2)Amsterdam Institute for Life and Environment (A-LIFE), Section Ecology & Evolution, Vrije University Amsterdam, Netherlands, (3)Amsterdam Institute for Life and Environment (A-LIFE), Vrije University Amsterdam, Netherlands, (4)A-Life, Vrije University Amsterdam, Netherlands, (5)Vrije University Amsterdam, Netherlands*

The application of pesticides affecting the growth of invertebrates raised concerns about their impact on nontarget species, as most of these chemicals end up in the environment. Although classical risk assessment methods can provide valuable information about the toxicity of chemicals, they cannot uncover the affected molecular pathways. Omics-based approaches in combination with phenotypic assessment can provide insights into potential biomarkers and most affected pathways in animals exposed to chemicals. This study aimed to investigate the lipidome of springtails *Folsomia candida* exposed to environmentally relevant concentrations of the insecticide teflubenzuron (0.000, 0.006, 0.014, and 0.035 mg/kg of soil) over time. To characterize the lipidome of *F. candida*, the time points as 1, 2, 7, 14, and 21 days were selected. The results showed clear separation in the lipidome of *F. candida* on different days, as the lipidome was affected by the reproduction cycle of springtails and the presence of offspring. Considering that all time points were significantly different, the response to teflubenzuron can be expected to be different through the exposure duration. The focus was on days 7 (only adults present in the soil) and 14 (adults inhabit together with the first generation of offspring). In both groups, the decrease in N-acyl ethanolamines and phosphatidylcholines is an indicator of membrane disbalance and oxidative stress. On day 7, upregulation of Omega-3 fatty acids, carnitines and ceramides was observed. This group of lipids plays an essential role in fatty acid β-oxidation in mitochondria. Down-regulation of triacylglycerols (TG) and diacylglycerols (DG) indicates effects on lipid storage, cell signaling, and energy metabolism alterations. Exposed groups from day 14 showed also the regulation of phosphatidylglycerol. This class is exclusively present in the inner membranes of mitochondria and plays a key role in the defense mechanism and cell apoptosis. The results of this study indicated the importance of following molecular disruption during different life stages to determine the possible pathways affected by chemicals. Additionally, analysis of springtails exposed to teflubenzuron showed a significant effect on lipid homeostasis and storage, membrane synthesis, and energy metabolism. Moreover, the current results suggest that insecticide causes inflammation and oxidative stress.

2.05.T-03 Exploring Plasticisers Mix Physiological Impacts on the Moth Larvae *Spodoptera littoralis* (Noctuidae)

***Johanna Rivas*[1]**, *Annick Maria[2], Annabelle Fuentes[2], David Renault[3] and David Siaussat Pr[2], (1)Sorbonne University, France, (2)Institute of Ecology and Environmental Sciences, France, (3)University of Rennes 1, France*

The production of plastics and plasticisers has greatly increased in the recent decades, along with uncontrolled plastic discharges. Accumulation of plastic debris in the environment, and the progressive release of their main constituents, in particular the plasticisers Bisphenol A (BPA) and Di(2-ethylhexyl)phthalate (DEHP) have increased pollution intensity in many terrestrial and aquatic habitats. As plasticisers can act as Endocrine Disrupting Chemicals (EDCs), it is crucial to increase our understanding of their potential effects on wildlife, including terrestrial invertebrates that have been less examined than their aquatic counterparts.

So far, we previously demonstrated the deleterious impacts of these two plasticisers on a terrestrial insect, the pest *Spodoptera littoralis* (Boisduval) (Lepidoptera: Noctuidae) fed on artificial diet containing DEHP or BPA. To mimic environmentally realistic exposures of these two compounds, we developed a new contamination approach by growing plants which were sprayed with DEHP, BPA and mixture of the two compounds. Larvae of *S. littoralis* were further fed with leaves from these plants, thus allowing to observe if realistic contamination also alter postembryonic development. We then completed previous metabolic analysis showing energetic disruption by the development of a glycolytic enzyme activities that would help us to better understand the DEHP metabolic disruption, when larvae are fed by laboratory food.
Experiments showed that postembryonic development disruption could be observed in *S. littoralis* when exposed to contaminated tomato leaves at larval stage. Our results emphasized the need to study co-occurrent EDCs on terrestrial invertebrates into trophic chain. We also found that individuals could be affected differently according to their sex. This parameter should be considered in

future studies working on EDCs effects. Some mechanisms underlying the disruption in larval stage were explored by the determination of glycolytic enzyme activities. More mechanisms have to be explored to explain postembryonic development disruption. Next studies should focus on hormonal potential disruptions for the co-occurrence of EDCs in larval stage. BPA, DEHP, and its metabolites could be quantified in the future in tomato leaves and larvae of *S. littoralis*. Finally, it would be also interesting to get more information on other levels of the organism, such as gene expression and metabolomic profiles.

2.05.T-04 Practical Implementation of the Assessment of Invertebrate Behavior and Its Use in Behavioral Ecotoxicology
Laura Johanna Soose[1], *Jörg Oehlmann*[1], *Andreas Schiwy*[2], *Henner Hollert*[3] *and Jonas Jourdan*[1], *(1)Aquatic Ecotoxicology, Goethe University Frankfurt, Frankfurt am Main, Germany, (2)Evolutionary Ecology and Environmental Toxicology, Goethe University Frankfurt, Frankfurt am Main, Germany, (3)Evolutionary Ecology and Environmental Toxicology, Goethe University Frankfurt, Frankfurt am Main, Germany*
Sublethal behavioral endpoints as a tool for modern ecotoxicology become a promising element at the interface among basic sciences and regulatory practices. So far, the lack of standardization of behavioral test methods makes them rarely considered in a regulatory context, even though they show enhanced sensitivity compared to standard endpoints and can serve as early warnings. Our approach aims to achieve standardization by using high-throughput behavioral observations allowing us to quantify behavioral changes with an optical behavior monitoring tool. Behavioral abnormalities can have severe consequences on the individual and population levels. For example, disturbed locomotion activity can impact drift, mate-finding, predation risk, and thus the overall population dynamics. Chemicals never act alone in the environment, but rather in a framework of diverse other stressors, including natural ones, such as parasites and invasive species – which makes behavioral studies even more multifaceted. To quantify and compare behavioral responses we chose four local amphipod species (*Gammarus fossarum, G. pulex*, *G. roeselii,* and *Dikerogammarus villosus*) with different historical (e.g., native, invasive), but also ecological (e.g., healthy and parasitized) backgrounds. Common parasites are Acantocephala which are known to manipulate their hosts' behavior. They accumulate pollutants and are suspected to influence the pollutant metabolism of the hosts. We exposed the amphipods to various anthropogenic chemicals, like active pharmaceutical ingredients (API) and insecticides. We then extended this to include the natural behavior-influencing stressor of parasitization. Our results revealed behavioral abnormalities within short time exposure (90-120 min) at sublethal and environmentally relevant concentrations of anthropogenic chemicals. Furthermore, our results show that behavioral responses seem to be species specific, with sensitive headwater species showing the strongest behavioral responses. Irrespective of chemical contamination, parasitization with acanthocephalans has resulted in generally higher activity of amphipods. Our approach shows the enormous potential of behavioral ecotoxicology and the realistic possibility of achieving standardization. With the right tools, it is feasible to create a comprehensive, interdisciplinary, multiscale approach to systematically identify behavioral endpoints and implement them in risk assessment of substances.

2.05.T-05 In-Field Deposition of a Sprayed Reference Chemical on Flying Insects: Normalization of Overspray by Surface Area or Habitat?
Steven Droge[1], *Nina Jansen*[1], *Dick Belgers*[2], *Marie-Claire Boerwinkel*[3], *Henk Jan Holterman*[4] *and* ***Ivo Roessink***[5], *(1)Environmental Risk Assessment, Wageningen Environmental Research (WUR), Netherlands, (2)Team Environmental Risk Assessment, Wageningen Environmental Research (WUR), Netherlands, (3)Team of Environmental Risk Assessment, Wageningen Environmental Research (WUR), Netherlands, (4)Agrosystems Research, Wageningen University & Research, Netherlands, (5)Wageningen Environmental Research (WUR), Netherlands*
There is growing concern in society about insect biodiversity decline, and the potential impact of agrochemicals. The risk assessment procedures of agrochemicals for nontarget arthropods (NTA), pollinators, and other terrestrial invertebrates is aimed to be a conservative evaluation of exposure calculations and effect studies, both in the field and the near off-field area. The data requirements for NTA risk assessment in the EU consist of effect studies with at least two standard NTA organisms exposed only to dried residues, using glass plates in tier 1 or on leaf material and quartz sand in extended lab studies. The spray dose applied in these relates to recommended product use (in g a.s./ha), allowing for a risk analysis based on applied field rate and lethal/effect rate in the experiment. In a field where chemicals are sprayed on crops, the NTA present above the soil are exposed via direct overspray, via contact with (fresh and) dried residues on plant material and soil surface material, and via intake from residues accumulated in food (plant material, prey, soil surface material). The risk assessment for bees and other pollinators already includes data requirements on effects by overspray (droplet contact test), and intake via food (via spiked feeding solution). In the current study, we focus on the in-field risk to NTA and pollinators due to direct overspray. The current study aimed to better characterize the actual deposit on NTA and non-managed pollinators (e.g., 90-percentiles per species), compared to the applied dose rate. A first field study established the vertical range of spray deposits of a fluorescent reference chemical using filters fixed at five different heights in a field of densely planted (nonflowering) White mustard (*Sinapis alba*). A second field study determined the spray deposit of the fluorescent tracer on NTA and pollinators present in the top layer of in a flowering field of oilseed rape (OSR). The deposit per surface area of individual organisms (or pooled samples of one species) was measured and compared to the deposit on filter discs placed horizontally in the OSR top layer. Collection of organisms was done by collecting bumble bees and solitary bees at nesting boxes, net sampling, hand-catching of individuals within two hours after spraying. Various flying insects have a 90-pct deposit per surface area that is 37-86% of the disc filters, deposits on bugs range between 4-30% of the applied rate.

2.05.P Arthropods at Risk? Current and Future Perspective on Insect Ecotoxicology

2.05.P-Tu057 A Laboratory Test for Assessing Effects of Plant Protection Products on the Herbivorous Nontarget Arthropod *Locusta migratoria* (Caelifera, Acrididae)

Jörg Leopold[1]*, Charlotte Elston*[2]*, Susanne Oberdörster*[3] *and Stefan Kroder*[4]*, (1)ibacon GmbH, Germany, (2)Syngenta, United Kingdom, (3)Bayer AG - Crop Science Division, Germany, (4)ADAMA Deutschland GmbH, Germany*

A newly developed laboratory test with nymphs of the herbivorous locust *Locusta migratoria* as surrogate species for oral toxicity to nontarget arthropods is presented. Grasshoppers are abundant in agricultural landscapes, and therefore may represent a relevant group of arthropods for testing oral toxicity, which was considered a relevant exposure route in the 2015 EFSA Scientific Opinion on non-target arthropods. The objective of the test is to assess the oral toxicity of pesticides to locust nymphs including sublethal effects on the reproductive capacity of the developed adults. Seven days old nymphs are exposed to treated maize leaf discs for 48 hours in the first phase with mortality assessments after 24 and 48 hours. At the end of the exposure period, the amount of consumed leaf area is quantified by video analysis to confirm sufficient exposure. In the second phase, the surviving locusts of each treatment group are kept in one rearing cage for approx. seven weeks until adult stage and sexual maturity is reached. During this time, mortality of different developmental stages is recorded at regular intervals. Adult male and female locusts are allowed to mate in the same rearing cages. For egg laying, one oviposition cylinder per cage filled with wet coconut humus is offered through an opening in the bottom of the cage. Oviposition cylinders are renewed after 48 hours to count eggs in two consecutive samplings. The egg pods are sieved out and incubated in a climate cabinet for three to four weeks. Bellaplast bowls equipped with mesh cover and filled with wet coconut humus are used as egg pod containers. After day 10, the bowls are daily checked for hatched nymphs until no further hatching occurs for seven days, and egg pods are dissected for counting unhatched eggs. The total test duration is 10 to 12 weeks.

The endpoints of the test are the nymphal mortality after 48 hours, the cumulative mortality recorded for different developmental stages until adult maturity, the mean number of eggs per surviving female per day and the proportion of fertile eggs:
The test is carried out in a dose-response or limit design. Water and toxic reference (e.g., dimethoate) test groups are used as negative and positive controls. First results of a dose-response design study with dimethoate are presented.

Future work shall focus on the determination of reliable validity criteria and optimisation of the test design.

2.05.P-Tu058 Development of an Ecotoxicological Testing Method to Assess Side-Effects of Plant Protection Products on Herbivorous Lepidopteran Larvae (*Spodoptera exigua*) under Laboratory Conditions

Lena Böhrs[1]*, Andreas Duffner*[1]*, Charlotte Elston*[2]*, Stefan Kroder*[3] *and Susanne Oberdörster*[4]*, (1)Eurofins Agroscience Services Ecotox GmbH, Niefern-Öschelbronn, Germany, (2)Syngenta, United Kingdom, (3)ADAMA Deutschland GmbH, Germany, (4)Bayer AG - Crop Science Division, Germany*

In the current environmental risk assessment of Plant Protection Products (PPP) to nontarget arthropods (ESCORT 2), oral exposure via food ingestion by herbivorous species is not considered and therefore, no standard laboratory test protocols for oral exposure of arthropods other than bees are available. In the 2015 EFSA Scientific Opinion on nontarget arthropods, Lepidoptera is one of the suggested taxa to cover this herbivorous oral route of exposure. The plant-feeding caterpillars can easily consume contaminated plant material while the adults are often nectar feeder and pollinators, and the taxon therefore plays an important role in many ecosystems of Europe.

Studies performed over the previous years showed that this approach is feasible in general. However, more work is needed to see if it is possible to develop a robust and seasonally independent testing method. For this purpose, in May 2022 CropLife Europe NTA expert subgroup initiated the development of an ecotoxicological testing method to assess effects of plant protection products on herbivorous lepidopteran larvae of *Spodoptera exigua* under laboratory conditions.

Suitability and challenges of using *Spodoptera exigua* as herbivorous species for ecotoxicological testing and the relevance for the risk assessment have been investigated.
The objective of this poster is to create awareness and to give an overview of this ongoing project. In particular the main challenges and possible solutions will be presented and discussed in order to obtain a broadly accepted testing method.

The research was divided into two parts (a) finding the best handling and food for *Spodoptera exigua* prior and after to the exposure phase and (b) the assessment of mortality, food consumption and sublethal endpoints of this herbivorous lepidopteran species after exposure to a reference item.

2.05.P-Tu059 DEHP and BPA Act as Endocrine Disrupting Chemicals in the Pest Moth *Spodoptera littoralis*

David Siaussat[1]*, Amandine Aviles*[2]*, Isabelle Boulogne*[3]*, Annick Maria*[1]*, Francoise Bozzolan*[4]*, Martine Maibeche*[4]*, Matthieu Dacher*[4]*, Aurelie Goutte*[5]*, Manuel Massot*[6] *and Fabrice Alliot*[4]*, (1)Institute of Ecology and Environmental Sciences, France, (2)University of Southern Denmark, Denmark, (3)University of Rouen, (4)Sorbonne University, France, (5)EPHE, PSL Research University, (6)University of Sorbonne, France*

Bis(2-ethylhexyl) phthalate (DEHP) and Bisphenol A (BPA) are a widely produced plasticiser found in many everyday life products like medical tools and floor covering. DEHP and BPA are found everywhere in the environment, in particular in sediments, soils, and plants. They are recognised as an endocrine disrupting chemical (EDC) in vertebrates. While invertebrates represent most of animal biodiversity and play critical roles in the aquatic and terrestrial ecosystems, few studies have focussed on the effects of these plasticisers on those species and particularly in terrestrial insects whereas the two lipidic hormone families, ecdysteroids and juvenile hormones, are involved in the control of the postembryonic development and adult physiology in insects.

In this context, we used the Egyptian Cotton leafworm *Spodoptera littoralis* as a model to study the effects of larval exposure to DEHP and BPA on postembryonic development, male sexual behaviour, and development of the offspring of treated males or females. We showed that, as in vertebrates, these two compounds act as EDC in this species by affecting the ecdysteroid pathway, and alters postembryonic development, male sexual behaviour, and life-stage duration in the offsprings.

2.05.P-Tu060 Collembola in Depth: Temporal Variability of Vertical Stratification in the Soil Profile

***Melanie Hagen-Kissling*[1]**, *Livia De Felici[2], Rik Delhem[2], Charlotte Elston[3], André Grove[2] and Bogdan Dehelean[2], (1)Eurofins MITOX B.V., Amsterdam, Netherlands, (2)Eurofins-MITOX B.V., Amsterdam, Netherlands, (3)Syngenta, United Kingdom*

Springtails (Collembola) are among the most abundant groups of soil decomposers, inhabiting various organic substrates and using a wide range of food sources. They show a clear vertical stratification, with some taxa occurring in the soil only (euedaphic species) to taxa living partly within the soil and partly on the surface (hemiedpahic) to species living mainly on or above the ground (epedaphic). Depending on substrate quality and abiotic conditions, springtails move between these layers and resulting differences or changes in vertical stratification in the springtail community composition can be substantial. While the spatial aspect of this phenomenon is well known, the temporal variation in this vertical stratification is not documented so far.

Using aspirator and stratified activity-based in-soil sampling (“mine traps”) in an agricultural field, we investigate the occurrence and abundance of springtail species on the ground (aspirator sampling) and in different soil depths (-10 cm, -20 cm, mine traps). Data were collected over more than two years, covering two cropping systems (sugar beet, winter wheat). We investigated the effect of habitat quality (crop identity, BBCH) and abiotic conditions (rain, temperature, season) on the vertical stratification of springtails and examined the temporal variation in these ecological profiles.

Here we ask: (1) Can we observe species specific vertical shifts over time (upward or downward), and can we link these shifts to environmental conditions (crop, abiotic conditions)? (2) Do (differences in) species-specific vertical shifts lead to altered soil layer-specific springtail communities?

Changes in soil microclimate might lead to new soil invertebrate community structures, where both overall abundances and layer-specific species composition could change. Such a shift in vertical distribution or vertical stratification of soil springtails in response to environmental conditions can have large effects on the soil food web and other soil processes.

2.05.P-Tu061 Effects of Insecticides at Different Levels of Biological Organization: Using Changes in Lipidomics to Explain Effects on Growth and Reproduction of *Folsomia Candida* Exposed to Teflubenzuron

***Saúl Fernandes*[1]**, *Diana Ilyaskina[2], Cornelis A.M. van Gestel[3], Matty P. Berg[1], Marja Lamoree[4] and Pim Leonards[5], (1)Amsterdam Institute for Life and Environment (A-LIFE), Section Ecology & Evolution, Vrije University Amsterdam, Netherlands, (2)Amsterdam Institute for Life and Environment (A-LIFE), Section Environment & Health, Vrije University Amsterdam, Netherlands, (3)Amsterdam Institute for Life and Environment (A-LIFE), Vrije University Amsterdam, Netherlands, (4)A-Life, Vrije University Amsterdam, Netherlands, (5)Vrije University Amsterdam, Netherlands*

Standard methodologies to assess the effect of pesticides on Collembola lack a mechanistic understanding of the changes in reproduction, growth and survival, hence fitness. The use of untargeted metabolomics in risk assessment can uncover the molecular pathways leading to adverse outcomes. Untargeted screening of molecular changes over time (such as changes in lipidome) provides a more detailed picture of the sublethal effects of pollutants present in the environment. In this study, we determined the effect of the insecticide teflubenzuron on the lipidome, growth (biomass) and reproduction of *Folsomia candida* (22 days old) exposed to 0.000, 0.006, 0.014, and 0.035 mg a.s kg^{-1} LUFA 2.2 soil. The endpoints were measured after 1, 2, 7, 14, and 21 days of exposure.

The results showed a trade-off between growth and reproduction of *F. candida* at the highest concentration tested. The number of offspring produced on day 21 differed significantly from the control, but the growth of the adults was not affected. Significant changes in reproduction on day 21 suggested the inhibition of egg laying between days 5 to 10 of exposure. Therefore, the lipidome of the adults on day 7 was assessed in order to link lipid alteration with growth and reproduction. The main affected lipid classes were N-acylethanolamines (NAE), fatty acids (FA), diacylglycerols (DG), and triglycerols (TG). The increase of NAE and FA clearly indicates inflammatory reaction, lipid peroxidation, and energy metabolism disbalance, which can explain the decrease in reproduction. Overall, TG and DG play a vital role in egg production, therefore, their decrease can be early indicators of reproduction deprivation caused by teflubenzuron. Additionally, phospholipids (PC) did not change in exposed animals which corresponds to the lack of changes in growth, since PC are the main contributors to the cellular membrane.

The results of this study for the first time use changes observed in the lipidome of *F. candida* to explain effects on individual fitness. The trade-off between a decreasing number of offspring and continuous growth was supported by the outcomes of the lipidome assessment. Dysregulation of the lipid classes as TG, DG, FA, and NAE suggests deprivation in reproduction, possible starvation, and inflammatory reaction to exposure. Further, combined studies including different species can contribute to a better understanding of the toxicity of teflubenzuron from the molecular to the population level.

2.05.P-Tu062 Uncovering Potential Chemical Stressors for Insects: *In vitro* Toxicity of Soil and Water Samples from Private Gardens

Johanna Bock *and Jörg Oehlmann, Aquatic Ecotoxicology, Goethe University Frankfurt, Frankfurt am Main, Germany*

Insects as a large taxonomic group are experiencing a drastic biodiversity decline, while covering many niches in ecosystems and providing important functions. Therefore, it is of great concern to further uncover causes, with the goal of identifying mechanisms to dampen species loss. The interdisciplinary project "SLInBio" (insektenvielfalt-frankfurt.org/) is investigating how the perception and valorization of insects can be increased in Frankfurt am Main and what contribution cities can make to the conservation of insect diversity. Hence, social-ecological interactions between lifestyles and everyday practices of city dwellers and urban insect diversity are being analyzed. This includes a strong communication with garden owners, since they hold the potential to influence small-scale habitat quality: in urban areas, private gardens display a relevant amount of the total green area distributed among the city; hence gardens pose important habitats for organisms. But individual practices and preferences in aesthetics and the usage of pesticides or fertilizers, chemical run-off from building materials, water management or animal keeping can strongly influence habitat quality and thus insect biodiversity. As an ecotoxicological approach, soil and water samples were collected from 17 gardens and their ponds, distributed among the city of Frankfurt am Main. Samples were extracted and tested with toxicological in vitro assays to determine potential toxic effects. Baseline toxicity was assessed with the Microtox® assay, mutagenicity with an Ames test and dioxin-like activity with a yeast reporter gene assay. The results revealed significant differences between the sampled gardens regarding chemical pollution by biologically interfering substances. Gardens are classified depending on the practices that gardeners apply in their area, which were identified by a survey performed by the Institute for Social-Ecological Research Frankfurt am Main. The survey results will then be connected to the ecotoxicological data. This will identify the impact that individuals have on toxicological parameters relevant to aquatic and terrestrial organisms, hopefully uncovering feasible changes that can be performed by gardeners on their private property to support local insect diversity.

2.05.P-Tu063 Critical Review and Recommendations to Improve the Quality and Reproducibility of the US EPA Chronic Mysid Testing Guideline: Update on a CropLife America and CropLife Europe Project

Alan Samel[1]*, Jane Staveley*[2]*, Margaret Fleming*[2]*, Alan J. Jones*[3]*, Eric Bruns*[4]*, Adric D. Olson*[5,6]*, Clifford Habig*[7]*, Bridget O'Neill*[8]*, Audrey Bone*[9]*, Kevin Henry*[10]*, Gwendolin Kraetzig*[11]*, Twyla Michelle Blickley*[8]*, Joseph Marini*[12]*, Lee Sayers*[12]*, Amanda Milligan*[13]*, John Aufderheide*[13]*, Sean Gallagher*[13] *and Suzanne Z Schneider*[13]*, (1)Global Regulatory Sciences, FMC Corporation, Newark, (2)Exponent Inc., (3)ADAMA Ltd., (4)Environmental Safety, Bayer AG - Crop Science Division, Germany, (5)BASF Corporation, (6)BASF Agriculture Solutions, (7)Compliance Services International (CSI), (8)Corteva Agriscience, (9)Bayer AG - Crop Science Division, Germany, (10)Tessenderlo Kerley, Inc., (11)ADAMA Deutschland GmbH, Germany, (12)Smithers, (13)Eurofins Agroscience Services*

The US Environmental Protection Agency (EPA) OPPTS 850.1350 Mysid Chronic Toxicity Test (draft, 1996) is conditionally required (40 CFR Part 158.630) for the registration of pesticide products in the U.S. though this study is not required by regulatory agencies outside of North America (EU, for example), results have an impact on product registrations across the globe if the endpoint drives the risk assessment.

The primary challenges with successful completion of this study are due to a lack of detailed information within the EPA test guideline (TG) on the study design and conduct. Issues with test organism performance often result in studies that do not meet acceptability criteria, necessitating a study repeat.

Crop Life America (CLA) has previously identified issues concerning the language in the existing TG, including: 1) lack of clarity about study endpoints; 2) limited guidance for handling the second generation (G2) populations; 3) difficult to achieve data quality objectives for growth and reproduction; and 4) a need to update procedures to reflect methodological improvements following 20+ years of laboratory experience in performing this study. A joint CLA-CLE (Crop Life Europe) project was undertaken to review issues with study design and subsequently develop recommendations for the modernization of the TG. In addition, the relevance of using endpoints from marine organisms for an edge of field aquatic risk assessment is questioned and discussed.

2.05.P-Tu064 Bti-Induced Changes in Aquatic Subsidy Dynamics Transfer to Linked Terrestrial Food Web

Sara Kolbenschlag[1]*, Eric Bollinger*[1]*, Verena Gerstle*[2]*, Ralf Schulz*[3] *and Mirco Bundschuh*[3]*, (1)University of Kaiserslautern-Landau (RPTU), Germany, (2)DFG-Grk. SystemLink iES Landau, Institute for Environmental Sciences University of Koblenz-Landau, Germany, (3)iES Landau, Institute for Environmental Sciences, University of Kaiserslautern-Landau (RPTU), Germany*

Emerging aquatic insects link aquatic and adjacent terrestrial food webs and serve as high-quality prey in both habitats. The availability of this aquatic subsidy is of high importance for terrestrial predators such as riparian spiders, bats, or birds. In a previous study on aquatic subsidy conducted in twelve floodplain pond mesocosms (FPMs), a change in the emergence dynamics of the main constituent, (i.e., nonbiting midges (Chironomidae), was detected and attributed to the application of the mosquito control agent *Bacillus thuringiensis* var. *israelensis* (Bti). The resulting temporal reduction in prey density might induce the predators to switch to alternative, potentially less nutritious food sources. To investigate this, we collected female spiders (*Tetragnatha extensa*) from the riparian vegetation of the FPMs in parallel to the first study as well as their potential aquatic and terrestrial prey. We used stable isotope ratios to analyse the spiders' diet in terms of aquatic proportion, niche size, and trophic position. Additionally, the energetic budget (i.e., protein, lipid, glycogen, and carbohydrate content) of the Chironomidae was measured to track Bti-induced changes in their quality. While the content of the energetic components and thus the prey quality did not significantly change, effects of Bti on the spiders' diet were observed. The trophic position was lower in treated FPMs while the aquatic proportion was slightly reduced. We assume that spiders did not only feed more on terrestrial prey but also on other aquatic organisms, such as mayflies, whose emergence was unaffected by Bti. These results show that the previously observed change in the emergence dynamics of Chironomidae can transfer adverse effects of an anthropogenic stressor from aquatic to terrestrial systems. It highlights that not only changes in the total abundance of aquatic subsidy but also temporal changes are of high importance. Terrestrial predators may suffer from a less nutritious diet during periods of increased energy demand (e.g., during reproduction or before hibernation) leading to reduced reproductive success or lower general fitness. Thus, we suggest on the one hand to include a temporal perspective in studies on aquatic-terrestrial linkages and on the other hand to intensify the investigation of cross-boundary effects of anthropogenic stressors.

2.05.P-Tu065 Assessing Risk to Pest Control and Pollination: Which are the Representative Bulnerable NTA Taxa?
***Grzegorz Sylwester Sowa**[1], Steven Droge[2] and Lorraine Maltby[3], (1)University of Sheffield, United Kingdom, (2)Environmental Risk Assessment, Wageningen Environmental Research (WUR), Netherlands, (3)School of Biosciences, School of Biosciences, SHEFFIELD, United Kingdom*
Nontarget arthropods (NTAs), defined as arthropods living on the surface of soil or plants, are taxonomically diverse, exhibit a diverse range of traits and undertake many important ecological functions that support wider biodiversity and deliver ecosystem services (ES), in particular pest control and pollination. Identifying representative and vulnerable taxa that drive ES delivery will enable risk assessment to be more focussed and ecologically relevant. Here we present an approach for identifying representative vulnerable NTA in European agricultural landscapes. We focus on the ES of pest control by predators and parasitoids, and pollination (excluding managed bees), and six major arable crops: wheat, maize, barley, oilseed rape, potato, and beet. Using the arthropod database compiled by Riedel et al. (2016) and information in the EFSA scientific opinion on NTAs (EFSA 2015) we have identified representative NTA families for each ES by crop and by EU zone based on their abundance, dominance, diversity, distribution prior prioritisation. Vulnerability of representative NTA families was assessed following the method of de Lange et al. (2012). Key NTAs for pest control include: Linyphiidae sheet weavers spiders), Lycosidae (wolf spiders) Carabidae (ground beetles), Staphylinidae (rove beetles), Coccinellidae (ladybirds), Syrphidae (hoverflies), Tachinidae (tachinid lies), Braconidae, Aphelinidae (parasitoid wasps) and Ichneumonidae (icheumonid wasp). Key NTAs for pollination include: Andrenidae (mining bees), Apidae and Halictidae (bees), Noctuidae (owlet moths), and Syrphidae (hoverflies). This information will help to develop a methodology for linking direct toxic effects and impact on ES and support the dialogue between risk assessors and risk managers by providing the scientific evidence necessary for the definition of specific protection goals for key ES provided by NTAs.

2.05.P-Tu066 Effects of the Experimental Exposure to Triazole Fungicides on Two Groups of Insects
***Paula Bolívar Muñoz**[1], Claudia Santamaria[2], Manuel Ortiz Santaliestra[3] and Rafael Mateo Soria[4], (1)Institute for Game and Wildlife Research, IREC (CSIC-UCLM), Spain, (2)Institute for Research in Hunting Resources (IREC), Spain, (3)Instituto de Investigación en Recursos Cinegéticos (IREC) CSIC-UCLM-JCCM, Spain, (4)Wildlife Toxicology, Instituto de Investigación en Recursos Cinegéticos (IREC) CSIC-UCLM-JCCM, Spain*
The use of pesticides in agriculture is one of the main causes of biodiversity loss in agro-ecosystems. Triazoles fungicides are among the most widely used pesticide groups nowadays. The mechanism of action of these substances consists of impeding the formation of the fungal wall by inhibiting the formation of ergosterol, one of the wall's main components. Studies in vertebrates have reported that triazole fungicides may act in a similar way as in target fungi, affecting sterol synthesis and altering the levels of some sterols like the sexual hormones, which ultimately reduces the reproductive output. In arthropods, the alteration of the sterol biosynthesis pathway by triazoles may be interfering with the production of ecdysteroids, a type of hormones involved in moulting and reproduction processes. Invertebrates are key elements in ecosystem functioning because they maintain plant biodiversity as pollinators and serve as food base for other animals, hence it is necessary to understand how the use of triazoles in crops may be affecting them. We present two experimental studies to evaluate the effect of triazoles on two model species with different metamorphic cycles: an orthopteran, the Jamaican field cricket (*Gryllus assimilis*), with a direct development cycle, and a coleopteran, the yellow mealworm beetle (*Tenebrio mollitor*), with a more complex metamorphosis. These two species are exposed to prothioconazole and tebuconazole formulations simulating field exposure scenarios either through food (simulating an exposure to seed coating products) or by overspray (simulating an exposure to foliar treatment). We monitor fertility, fecundity, alterations in the developmental rate, and malformations associated with the exposure to triazoles. Furthermore, we use HPLC-MS/MS to quantify ecdysteroid levels and analyse triazole residues at different life stages of the individuals. With this work we aim to disentangle how triazoles might be affecting arthropods as well as to characterise biomarkers of triazole effects on these animals in the field.

2.05.P-Tu067 The Mealworm Dietary Exposure Lifecycle Test: A Potential Model System in Environmental Risk Assessments
***Michael-Thomas Ramsey**, Ecotoxicology, Labcorp Early Development, United Kingdom*
This study was undertaken to explore the necessary procedures required for conducting a higher-tiered Good Laboratory Practice (GLP) Laboratory test to evaluate the effects of a test substance in a diet on the survival and reproduction of the mealworm, *Tenebrio molitor*.

Tenebrio molitor is a holometabolic insect that lives in flour, bran, and similar products. They are being recognised more as a beneficial insect as, economically, they are among the most important species used for the large-scale conversion of plant biomass into protein. They also possess the ability to break down plastic with no ill effects or accumulation of toxic substances. They are a robust species that can thrive under laboratory conditions, which make them an ideal candidate system for EIA testing.

In this work, we showcase the four experimental trials from which we successfully determined the final protocol for this test design. Each trial was conducted to determine: (1) the time taken to complete study, (2) the viability of larva are in diet (test substrate), (3) the most appropriate assessment techniques, (4) time duration of each life cycle stage, (5) a procedure for egg collection and assessment, (6) the acceptable control performance criteria across each life cycle stage, (7) the rate and reference item to be used for a toxic reference, and (8) the sample size required at each rate to accurately determine the lethal concentration for mortality and Effected Concentration for the reproductive output following exposure to a test item in the substrate.
We conclude this work with the results of a full test-run of the final protocol (water control and toxic reference only) that incorporated the optimised parameters determined from the four experimental trials. The exciting results obtained from this final experiment allow us to demonstrate the effectiveness of this test design and the potential of *Tenebrio molitor* as a test system.

2.05.P-Tu068 Refined Parameters for Bumblebee Microcolony Dietary Exposure Tests

***Michael-Thomas Ramsey**, Ecotoxicology, Labcorp Early Development, United Kingdom*

Honeybees have long been a surrogate for other non-Apis bees in laboratory testing owing to the vast understanding of their biology and their compliance with a laboratory setting. Recognising the importance of bumblebees to managed and natural landscapes, there is a pronounced need for bumble bee-specific methodologies to develop a better understanding of their biology and how these bees respond to various stressors. Current testing formats reduce experimental complexity, as they limit investigations to acute exposures in adult bees, and ignore important effects related to colony health and production of new progeny. As a result, microcolony studies have grown in popularity.

In this preliminary study, we explore the necessary procedures and parameters required to optimise a GLP laboratory microcolony feeding test to determine whether sugar syrup and pollen contaminated with doses of a test item could affect the food consumption, worker survival and the size of the brood, as well as cause any delay of adult emergence in the bumblebee *Bombus terrestris*.

In this work we showcase the results of the 5 individual trials that led us to the optimised parameters and processes for the final study design. These trials consisted of an 85-day study concept trial, a 35-day feeding syrup trial, a 42-day toxic reference trial, a 21-day revised enclosure feasibility trial and a 42-day dietary improvement trial.

Over these individual trials, conducted with the aim of minimising untreated control mortality, we successfully established the following: (1) the number of mother colonies required to produce the required amount of queenless microcolonies, (2) the most appropriate dietary sugar solution composition, (3) the frequency at which the micro-colonies require feeding, (4) the average time duration for worker-dominance and drone laying, (5) the natural mortality of individuals kept in this setting, (6) the most effective method for diet administration, (7) the optimal nest box design and the level of intervention required to maintain hygiene levels, (8) the sample size required at each rate to accurately determine the lethal concentration for mortality and Effected Concentration for the reproductive output following exposure to a test item in each diet.

2.05.P-Tu069 Longevity of *Apis mellifera carnica* and *Bombus terrestris* Exposed to Pesticides (Alone and in Combination) in Laboratory Conditions

*Caio Eduardo da Costa Domingues, **Leticia Salvioni Ansaloni** and Aleš Gregorc, University of Maribor, Slovenia*

The disappearance of honeybees and colony mortality have beset beekeepers worldwide in recent years. In that same sense, bumblebees have been shown to reduce occurrence and richness globally. Currently, pesticides and other environmental stressors have been linked to this issue. The pesticides are widely used in crops where bees forage and collect resources with residues that can harm their colonies. From this point of view, the present purpose was to evaluate and compare the effects of the fungicide Folicur EW 250 and insecticide Daskor 440, alone and in combination, on Carniolan honeybee (*Apis mellifera carnica*) workers and bumblebees (*Bombus terrestris*) longevity. The Carniolan honeybees were collected from three different colonies by the apiary installed at the University of Maribor, Hoče - Slovenia. The bumblebees were collected in lavender crops around the same place mentioned above. Both bee species were caged in plastic cups and transferred to an incubator at 28ºC, with 70% relative humidity. Toxicological bioassays of oral exposure were performed. The foragers of both species were divided ($n = 20$ bees in five replicates for Carniolan honeybee; $n = 10$ bees per treatment for bumblebee) into three experimental treatment groups and control: fungicide Folicur EW 250 (0.250 ng/µL) - FGD, insecticide Daskor 440 (0.250 ng/µL) - ISD, pesticides in combination (0.125 ng/µL) – FGD+ISD and untreated control (CTL). For the control bees, syrup (water + sugar, 1:1) was offered without adding pesticide. Mortality was recorded daily until the last bee died, and statistical analysis was performed using the Kaplan-Meier Survival Analysis: Log-Rank method with the Holm-Sidak multiple comparison test. After 47 days for *A. mellifera carnica*, the results showed decreased longevity (<0.0001) of bees exposed to pesticides being FGD (8 days), ISD (7 days), and FGD+ISD (10 days) when compared to CTL (17 days). Regarding *B. terrestris*, the exposure time was 26 days, and we also observed longevity decreasing (<0.05), FGD (8 days), ISD (7 days), and FGD+ISD (7.5 days) in comparison to CTL (12.5 days). The outcomes suggest that the tested pesticides impacted the survival rate of both studied species. Considering the biological characteristics and the degree of sociability, *B. terrestris* may be more endangered since it can affect colony homeostasis, which is smaller. These data will be used for further new experiments with other approaches.

2.05.P-Tu070 Behavioral Evaluation of Imidacloprid's Repellency Capability in the Stingless Bee *Melipona quadrifasciata* (Apidae: Meliponini)

Rebeca E. S. Castor[1], Rafaela Tadei Ms[2], Pamela Decio[3], Bárbara Silva Barbosa[1], ***Elaine Cristina Mathias Silva-Zacarin[4]*** *and Rogério Hartung Toppa[5], (1)Biology, UFSCar - Federal University of São Carlos, Sorocaba, Brazil, (2)Biology, São Paulo State University (UNESP), Brazil, (3)Biologia, UFSCar - Federal University of São Carlos, Sorocaba, Brazil, (4)Biology, Federal University of Sao Carlos (UFSCar), Sao Carlos, Brazil, (5)Dca, UFSCar - Federal University of São Carlos, Sorocaba, Brazil*

Stingless bees such as *Melipona quadrifasciata* are exposed to pesticides found in fragmented habitats where they usually forage. Pesticides are recognized as an important driver of pollinator declines. Aiming to evaluate the immediate repellency capability of the stingless bee *M. quadrifasciata* to imidacloprid-treated food, bioassays were performed through a behavioral approach. Individuals of *M. quadrifasciata* were collected at the entrance from three non-parental healthy managed colonies (Sorocaba city, SP State, Southeastern of Brazil) and kept in laboratory conditions (28±2°C, 70±5% humidity) in cages. We analyzed behavioral parameters of locomotion (average speed, distance traveled, time in motion, rotation frequencies) and choice of food resource of *M. quadrifasciata* between feeders with and without the neonicotinoid insecticide imidacloprid in an arena. Arena contained two feeders (300 µL capacity) positioned on opposite sides with a distance of 10.5 cm between them. The feeders were filled with: food containing 0.01 ng/µL of imidacloprid (10 ppb), food containing 10 ng/µL of imidacloprid (10 ppm), pure food (only sucrose solution 50% m/v), and/or sucrose solution + acetone solvent. Each bee (15min fasting) was individually transferred to the arena (N = 12 bees per colony) and filmed for 10 minutes in 12 different scenarios of food choice. The videos analyzed by EthoVision software and the obtained data were submitted to generalized linear models (GLM) to analyze the influence of insecticide presence in the behavior responses of bees. The distributions used in the GLMs were gaussian, quasipoisson, and binomial negative. Analysis of data showed absence of repellency to imidacloprid. Food contaminated with both concentrations of imidacloprid showed no difference in the frequency of bee revisits compared to food without insecticide. Bees remained longer on food contaminated with 0.01 ng/µL of imidaclopride than on food without this insecticide (control). Imidaclopride interfered exclusively with the movement time of the exposed-bees inside the arena, which significantly was increased probably because of the initial superstimulation induced by the neonicotinoid after its immediate ingestion. These data demonstrated that stingless bees cannot control their exposure to neonicotinoids in food, thus the treating flowering crops with neonicotineoids could present a hazard to this native bee species.

2.05.P-Tu071 Comparison Between Ywo Neotropical Solitary Bees as Potential Model Species for Ecotoxicological Assays

Elaine Cristina Mathias Silva-Zacarin[1]*, Rafaela Tadei Ms[2], Pamela Decio[3], Cláudia Inês da Silva[4], Stephany Azzola Oliveiro[4], Iara Alexandre Silveira[4] and Osmar Malaspina[5], (1)Biology, Federal University of Sao Carlos (UFSCar), Sao Carlos, Brazil, (2)Biology, São Paulo State University (UNESP), Brazil, (3)Biologia, UFSCar - Federal University of São Carlos, Sorocaba, Brazil, (4)Biology, UFSCar - Federal University of São Carlos, Sorocaba, Brazil, (5)Centro de Estudos de Insetos Sociais (CEIS) Instituto de Biociências (IB), Universidade Estadual Paulista (UNESP) - "Júlio de Mesquita Filho", Brazil*

Toxicological data about the social honeybee are used in pesticide regulatory processes in Brazil, which does not cover the great diversity of Neotropical solitary native species. In order to indicate surrogate species of *Apis mellifera* for pesticide risk assessments, we compared two solitary bees, *Centris analis* and *Tetrapedia diversipes*, to verify their application for ecotoxicological bioassays in South America. Wooden trap-nests for both species were installed in southeastern Brazil. Each trap-nest contained 48 holes containing a paper straw in each one. Once a month, half of the closed nests by founding females were collected and transferred into laboratory conditions (28 ± 2ºC; 65 ± 10% humidity). In both species, the nest contained an average of two to three brood cells built, and a sexual ratio with the number of males almost twice that of females. Individuals of *C. analis* emerged at a shorter time after the nest collection than *T. diversipes*. Furthermore, the distance of time between the first to the last individual of the same nest of *C. analis* (1.42 ± 0.24 days) is lower than *T. diversipes* (3.51 ± 1.05 days). According to this parameter, *C. analis* showed more advantages than *T. diversipes* because the use of individuals of the same age is recommended for ecotoxicological assays. Another disadvantage of *T. diversipes* is the higher parasitism ratio (13.65 ± 3.93%) and lower emergence ratio (54.5 ± 5.67%) by nest than *C. analis* (6.41% ± 2.66% and 78.4 ± 6.06 %, respectively). These factors may influence the total number of individuals obtained from the nest collection, which reached an average per year of 368.33 ± 87.35 bees of *C. analis* and 182.33 ± 59.4 of *T. diversipes*. Besides, the nest viability rate of *C. analis* was 89.88 ± 6.16% and of *T. diversipes* was 66.11 ± 14.5%. Although, under laboratory conditions, adults of *T. diversipes* showed easier maintenance than *C. analis*, with a higher survival rate and longevity. *T. diversipes* is a small bee and exhibits slower behavior than *C. analis*, a fast and of medium size bee, which had a higher food consumption. The higher consumption rate per bee may increase its exposure to pesticide residues. Concluding, both species showed advantage and/or disadvantage in laboratory conditions. Adjustments are necessary in order to choose the best model species for Neotropical solitary bees in ecotoxicological assays for pesticide risk assessment.

2.05.P-Tu072 Evaluation of Oral Toxicity of Abamectin Pesticide for Bees Native to *Scaptotrigona postica* Species and its Subeffects

Gabriela Reani Rodrigues Garcia[1]*, Joyce Oliveira Costa[1], Janete Brigante[1], Waleria Ferreira Rabêlo[1], Michiel Daam[2], Fernanda Canduri[1], Eny Maria Vieira[3] and Diandra Alencar[1], (1)University of São Paulo (USP), Brazil, (2)NOVA School of Science and Technology, Portugal, (3)DQFM, University of São Paulo (USP), Brazil*

Bees are insects of great importance for biodiversity and agricultural production, since they are one of the responsible for promoting pollination, fruit generation and even providing honey, wax, propolis and pollen. In Brazil there is a wide variety of native bees known to have no stinger and poison, they are responsible for pollinating a wide variety of plants of the Brazilian ecosystem. Focusing on bees popularly called Mandaguari (*Scaptotrigona postica*), its role as pollinating agent is quite efficient, since the amount of individuals per hive can reach more than 20 000 bees, thus positively impacting the pollination process of Brazilian forests. However, with the growing global demand for food, combined with economic interests to increase agricultural production, there is a growing use of pesticides, such as abamectin, which is considered highly toxic to bees and classified as dangerous to the environment. This substance is often used via foliar spraying in cotton, peanut, potato, among others. This fact can contribute to the decrease in the bee population and cause contamination of bee products. Considering that there are few studies related to the effects of pesticides on native bees, the present study aimed to determine the lethal concentration of abamectin (CL50;0.0023 g L^{-1}) as well as its lethal dose (DL50; 0.0093 µg a.i./bee) for the species *Scaptotrigona postica*, as well as the high rate of mortality and absence of flight ability of organisms against the high doses of the contaminant. Mandaguari's protein profile and the interference of the same contaminant in insect metabolism were also analyzed through the biochemical electrophoresis test in polyacrylamide gel, verifying the intensification of some enzymes such as catalase and peroxidase in individuals exposed to the contaminant, a strategy used by bees for detoxifying and tolerance.

2.05.P-Tu073 Poisoning or Starvation? – Investigation of Deaths in *Apis mellifera* in a Chronic Laboratory Study

Timm Knautz, *Annika Barme and Tatsuya Sekine, ibacon GmbH, Germany*

Repellent effects and food refusal are commonly known challenges in the conduction of oral biotests. The poor palatability of some pesticides leads to avoidance behaviour in bees. Reduced ingestion of the test item by test organisms not only causes difficulties in the calculation of effect doses due to nonlinearity in the dose-response relationship but also complicates the interpretation of data, whether mortality is caused by a direct test item effect or due to starvation.

To get more clarity on this topic the aim of this study was in a first experiment to define a threshold value which honeybees are suffering from starvation and are likely to die without influence of a toxicant. The first experiment was based on the chronic honeybee laboratory study (OECD Guideline 245) replacing different toxicant doses by different food quantities of 50 % w/v sucrose solution (5.0, 10.0, 15.0, and 20.0 mg feeding solution/bee/day). The amount of the daily administered feeding solution was adjusted to the number of living bees per test unit. In one additional treatment bees were starved for 6 hours (maximum oral application time for the acute honeybee test) and fed *ad libitum* afterwards. Mortality was assessed in a 24 hours interval. Absence of food for up to 6 hours had no adverse effect in this experiment, lethal starvation effects in acute honeybee studies can thus be excluded. A threshold of 10 mg feeding solution/bee/day was the minimum amount of food needed without long-term starvation effects on honeybees. In a second experiment a test item was administered to the bees with and without the option of an additional untreated feeding solution inside the test units (based on an OECD 245 study design). High mortality and reduced food uptake (< 10 mg feeding solution/bee/day) were observed in the upper concentrations when only test item treated feeding solution was administered to the bees. In contrast, mortality was significantly lower when an additional untreated feeding solution was present in the test unit. This indicates a strong repellent effect of the test item. Considering the previously determined starvation threshold the high mortality is likely to be a result of starvation or a combination of both factors rather than a pure test item effect. This result can facilitate the interpretation of chronic toxicity data and help to distinguish between toxicant related effects and starvation effects.

2.05.P-Tu074 Defining Habitat Scenarios at Zonal Level for the Environmental Risk Assessment of Plant Protection Products to NTAs

*Daniel Paredes[1,2], **Grzegorz Sylwester Sowa**[3], Steven Droge[4], Lorraine Maltby[3] and José Paulo Sousa[1], (1)University of Coimbra, Centre for Functional Ecology, Portugal, (2)Environmental Resources Analysis Research Group, Department of Plant Biology, Ecology and Earth Sciences, Universidad de Extremadura, Spain, (3)University of Sheffield, United Kingdom, (4)Environmental Risk Assessment, Wageningen Environmental Research (WUR), Netherlands*

The impact of PPPs on NTAs in agricultural landscapes depends on the particular landscape characteristics (i.e., composition and configuration) and complex spatial and temporal population dynamics, including ‘action at a distance’ or ‘source sink’ phenomenon. Some NTAs have high mobility and can disperse across the landscape, while others have low mobility and limited dispersal. Therefore, NTAs differ in their range distribution, with some taxa only being found in one type of habitat in the landscape whereas others may range across multiple habitat types including in-crop and off-crop. In addition to individual range differences, NTAs will be adapted to specific climatic ranges and habitat types, which combined with variations in phenology and life-histories, will result in spatial and temporal variation in the species composition of NTAs in agricultural landscapes.

We present the methodology adopted to develop habitat scenarios at zonal level for NTAs (pest control agents and wild pollinators) in targeted crops and present two exemplary cases for two crops in the northern (potatoes) and southern (olive groves) zones.

Habitat scenarios for each focal crop at each zone were derived based on high spatial resolution open source ALMaSS landscapes by applying a developed algorithm that randomly selects 1000 points of the focal crop, and extracts information on the habitat configuration surrounding each point. Two radius buffers were selected according to the typical activity range for pest control agents (predators and parasitoids) and wild pollinators. Based on the information retrieved, four types of habitat scenarios were defined: “simplified” (habitat with a high proportion of the focal crop); “agricultural dominated” (habitat with a high proportion of other crops); “natural habitat dominated” (habitat with high proportions of natural habitats, e.g., forest, hedgerows, beetle banks, etc); “diversified” (made up of similar proportions of the former categories). The habitat composition on each type of habitat scenario is represented by the 95th percentile composition based on all information collected.

On the two exemplary crop cases (potatoes and olive groves), the information on each habitat scenario was crossed with available information on NTA species assemblages common on those habitats, helping to define representative vulnerable NTA species to be used in risk assessment of the use of PPPs on those crops on those zones.

2.06 Ecosystems Responses Under a Multiple Stressors Scenario in a Rapidly Changing Climate (Part I: Effects, Adaptations, *in vitro*, Population-Level)

2.06.T-01 Effects of Climate Change and Emerging Contaminants on Caddisflies: Insights from a Multiple Stress Experiment

Ana Previsic[1]*, Iva Kokotović*[2]*, Marina Veseli*[1]*, Filip Ložek*[2]*, Zrinka Karacic*[3] *and Marko Rozman*[3]*, (1)University of Zagreb, Faculty of Science, Department of Biology, Croatia, (2)Department of Biology, University of Zagreb, Croatia, (3)Ruder Boskovic Institute, Croatia*

Freshwater biodiversity, ecosystem functions, and services are changing at an unprecedented rate due to the impacts of vast number of stressors overlapping in time and space (e.g., habitat alterations, pollution, climate change). Ecological impacts of emerging contaminants (ECs) such as pharmaceuticals (PhACs) and endocrine disruptors (EDCs) on freshwater ecosystems are not fully understood due to a large number of compounds present in the environment, as well as complexity of these ecosystems. Warming related to climate change can increase the toxicity of some chemicals in water making them more dangerous. Thus, such a combination of stressors may have ecological impacts on aquatic organisms like freshwater insects, which perform important ecological functions linking the freshwater and terrestrial ecosystems. Our study aimed at characterizing effects of individual and combined stressors such as pollution with PhACs and EDCs and increased water temperature on first level consumers (shredding aquatic insects) in freshwaters. We conducted the microcosm experiment with a simplified freshwater food web containing moss (Bryophyta) and a shredding caddisfly larvae of *Micropterna nycterobia* (Trichoptera). The experiment was conducted in the randomized factorial design, with four treatments: control (C), increased water temperature +4 °C (T2), ECs mix (EC), and multiple stressor treatment (MS = EC + T2). The ECs mix was composed of 15 PhACs and 5 EDCs belonging to different classes, and concentration of each compound was kept at 500 ng/L. Negative effect of increased water temperature on development of *M. nycterobia* was observed as decrease in body weight of larvae and earlier emergence of adults. The lipidome of *M. nycterobia* adults was also mainly affected by the temperature increase in both males and females. However, the presence of PhACs and EDCs in water had higher impact on metabolism of aquatic life stages of *M. nycterobia* than water temperature increase. Multiple stressor effect was recorded in *M. nycterobia* adults, both in metabolic response, and as a decrease in total lipid content. Thus, combined effects of increased water temperature and presence of PhACs and EDCs in water negatively impact population dynamics of aquatic insects, but they also indicate a reduction in biomass and resource quality for both, aquatic and terrestrial food webs.

2.06.T-02 Using a 30-Year Macroinvertebrate and Chemical Record to Discover What Drives Biodiversity in English Rivers

Andrew C Johnson[1]*, Dinara Sadykova*[1]*, Yueming Qu*[1]*, Francois Edwards*[2]*, Monika D. Juergens*[1]*, Virginie Keller*[1]*, Michael Eastman*[1]*, Pete Scarlett*[1] *and Nuria Bachiller Jareno*[3]*, (1)UK Centre for Ecology & Hydrology (UKCEH), United Kingdom, (2)APEM, United Kingdom, (3)University of Portsmouth, United Kingdom*

National macroinvertebrate diversity has steadily improved in England over the past 30 years, but why? In this study we matched macroinvertebrate records over 30 years with location, chemical, and physical records. The measurement locations and sample timings were different, so this required considerable effort to reconcile 62 000 biological records with about 500 000 chemical (and physical) records. We selected 1519 macroinvertebrates sites across England from the Freshwater river macroinvertebrate surveys (Biosys) dataset, on the basis of their long and consistent records. The kick sampling methodology used by the EA has not changed over 30 years. The analysis focused on family richness which is an indicator of the overall taxonomic community status and also Ephemeroptera, Plecoptera, Trichoptera (EPT) family richness which is the total number of family within three major orders of stream insects that are sensitive to water pollution. In this exercise, we matched macroinvertebrate sites with the nearest chemical measurement sites from the WIMS dataset. Of these, 28 variables offered data where >50% records were above an LOD. We used GLMM statistical analysis to identify which stressor or stressors can best explain the variability in macroinvertebrate family richness over 30 years in rivers with greater than, or less than, 5% wastewater content. All possible combinations were compared by GLMM which required up to 26 000 different model runs. It was found for both rural and urban rivers that zinc played the strongest role in controlling variance. What was extraordinary was that the zinc influence extended below EQS levels. All the models with all possible combinations of the chemical variables could explain deviance up to 40% for urban areas and up to 33% for rural EPT family richness and 27% for macroinvertebrate family richness (worms, mollusks, insect larvae etc.) in the higher wastewater (urban) sites and up to 21% in the low wastewater (rural) sites. Thus, these variables do not exclusively explain the variance. If another chemical played a role, that was not measured, it must be one that has declined in concentration. This study represents an attempt to ‘listen to nature’. Rather than presume or infer what factors or chemicals suppress biodiversity, we have used a vast record of biological and chemical monitoring to tell us what matters to wildlife. Potentially this approach turns the way we regulate water quality to improve biodiversity on its head.

2.06.T-03 Pesticide Adaptation Increases Synergism Between Multiple Stressors in *Gammarus pulex*

Naeem Shahid[1]*, Ayesha Siddique*[2] *and Matthias Liess*[3]*, (1)System-Ecotoxicology, Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany, (2)Ecotox, Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany, (3)Department of System Ecotoxicology, Helmholtz Centre for Environmental Research (UFZ), Germany*

Aquatic organisms are confronted with multistress conditions that often cause nonadditive effects. Although scientific evidence for synergistic effects is mounting, we lack information on how pesticide adaptation or ecological memory shapes the multiple stress–response relationships. Here we collected *Gammarus pulex* from small streams with a wide range of pesticide contamination and exposed them to a mixture of neonicotinoid insecticide clothianidin and an azole fungicide prochloraz under different temperature regimes. Under optimal temperature (16°C), *G. pulex* with prior pesticide exposure in the field showed up to 3-fold higher tolerance to clothianidin alone and in mixture with prochloraz, as compared to the non-contaminated reference populations. The difference between pesticide tolerance of both groups decreased with increasing temperature stress. Although there was no synergistic interaction between clothianidin and prochloraz, effect was significantly stronger in reference populations. Further, the combination of both toxicants and temperature stress caused synergism shown by a model deviation ratio (MDR) = 4.0 even at 1 μg/L of prochloraz that is frequently detected in the environment. Under multiple stress conditions, interaction was stronger and more frequent in pesticide-tolerant populations. These synergistic interactions were quite well predicted by the stress addition model (SAM). Our findings demonstrate that heat stress interacts with mixture toxicity and causes even stronger effects on pesticide adapted organisms. Therefore, the impacts of pesticide cocktails on the ecosystems under global warming cannot be overlooked.

2.06.T-04 Springtail Mortality in Response to Sequential Exposure to Chemical and Climate Change-Related Stressors
***Heidi Sjursen Konestabo**[1], Hans Petter Leinaas[2], Cornelis A.M. van Gestel[3], Tone Birkemoe[4] and Katrine Borga[2], (1)Department of Biosciences, University of Oslo, Norway, (2)University of Oslo, Norway, (3)Amsterdam Institute for Life and Environment (A-LIFE), Vrije University Amsterdam, Netherlands, (4)Norwegian University of Life Sciences (NMBU), Norway*
In their environment, organisms are exposed to a combination of anthropogenic and naturally occurring environmental stressors. Temperature changes may affect the tolerance to toxicants of several terrestrial arthropod members of the soil community, making climate change relevant in understanding toxicity. Besides imposing physiological effects due to variations in temperature, climate change may also affect soil hydrology in a complex way, with effect varying regionally, from predicted increased precipitation in some regions to decreases in other. Thus, both waterlogging and drought may occur and affect soil community composition and performance. Species living on or near the soil surface are generally more drought tolerant than species inhabiting lower layers, and local conditions may further influence their tolerance. To understand how toxicant exposure followed by drought and temperature increase affects the soil invertebrate community, varying between climatic regions, species, and populations, we compared two springtail species from Arctic and temperate regions with contrasting drought tolerance, *Folsomia quadrioculata* being more sensitive to drought than *Hypogastrura viatica*. Two Arctic and two temperate populations from each species were first exposed to four sublethal concentrations of the neonicotinoid imidacloprid (0 – 0.1 mg/kg) in soil mesocosms at 15°C for 14 days, followed by different levels of drought stress (85 - 100 % relative humidity) at 15°C and 20 °C for 3 h (*F. quadrioculata*) or 7 days (*H. viatica*), assessing survival. Drought tolerance decreased with increasing imidacloprid concentrations in all populations from both species, and this effect was stronger in the temperate compared to the Arctic populations. Drought stress at a higher temperature further decreased survival in the most drought tolerant springtail species *H. viatica*, while this effect was not as strong in the less drought tolerant species *F. quadrioculata*. In conclusion, macroclimatic adaptations affected imidacloprid toxicity in Arctic vs. temperate springtail populations, but with increasing drought and temperature stress, these adaptations were not reflected in the mortality across populations and species. Thus, local adaptations to microclimate should be taken into account to better understand the responses to chemical stressors with concurrent exposure to other stressors.

2.06.T-05 Synergic Effect of Nitrate Exposure and Heatwaves on the Growth and Metabolic Activity of Microalgae
***Sabiha Akter**[1], Hamada Abd Elgawad[2], Gudrun De Boeck[1], Gerrit T.S. Beemster[3] and Jonas Schoelynck[1], (1)Biology, ECOSPHERE, University of Antwerpen, Antwerpen, Belgium, (2)Biology, University of Antwerp, Belgium, (3)Biology, University of Antwerp, Integrated Molecular Plant Physiology Research Group, Belgium*
Aquatic ecosystems are threatened by climate warming as well as other anthropogenic stressors such as eutrophication by, e.g., nitrate. However, it remains unclear how nitrate exposure can alter the resilience of microalgae to climate warming in general, and heat waves in particular. Any change in community structure or abundance of microalgae can affect the overall energy flow of a freshwater ecosystem. To get a better understanding of these processes, the effect of elevated temperature and nitrate pollution on growth, metabolites (sugar, and protein), oxidative damage (lipid peroxidation), and antioxidant (polyphenols, proline) accumulation within the cells of *Chlamydomonas reinhardtii* and *Pseudokirchneriella subcapitata* were investigated. A 3 × 3 factorial design was used, where microalgae were exposed to one of three ecologically relevant levels of nitrate (5, 50, or 200 mgL^{-1} NO_3^{-1}) at temperatures of 20 °C for 2 weeks. Subsequently, two heatwave scenarios were imposed: a short heatwave at 24°C for 2 weeks, and a long heatwave with an additional 2 weeks at 26°C. A positive synergic effect of heatwaves and nitrate on the growth and metabolic activity was observed in both algae. In the short heatwave scenario, this oxidative damage was controlled by increases in antioxidant (polyphenols, proline) levels but in the continuing long heatwave, the antioxidant (proline) response decreased. The high growth rates, high metabolic activity, low oxidative stress, and high antioxidants during short heatwaves in moderate nitrate (50 mgL^{-1}) seem to increase the food availability to zooplanktonic grazers in a sustainable way. On the other hand, long heatwaves in high nitrate conditions seem unsustainable due to the increased oxidative stress and relatively low antioxidants (proline), increasing the risk for massive algal die-offs. Heatwaves and nitrate can also affect the community structure of the microalgae as both microalgae show similar changes but to a different magnitude.

2.06.P Ecosystems Responses Under a Multiple Stressors Scenario in a Rapidly Changing Climate (Part I: Effects, Adaptations, *in vitro*, Population-Level)

2.06.P-Mo108 Impact of Warming on the Sensitiveness of Artemia franciscana **to the Pesticides Oxyfluorfen and Copper**
Andreia Filipa Mesquita[1], Fernando J.M. Gonçalves[2] and ***Ana Marta Goncalves[3]****, (1)Department of Biology & CESAM - University of Aveiro, Aveiro, Portugal, (2)University of Aveiro, Aveiro, Portugal, (3)University of Coimbra, MARE - Marine and Environmental Sciences Centre / Department of Biology and CESAM, University of Aveiro, Portugal*
Nowadays, environmental concerns are not only a worry of the scientific community but also an increasing worry of the politician and social communities. Climatic changes assume a terrific position in politician programme, since the effects undervalue until now are showing to be real and it is increasing the frequency and severity of extreme events as floods, wildfires, storms, hurricanes, likewise the temperature increase, well significant in some world regions. The increase of the human population is also a main concern, and it is critical search for solutions to produce enough food to feed everyone. Pesticides have been used as an easy solution to achieve large amounts of food, since they may prevent pests and consequently increase the natural production. However, their overuse has been reported as dangerous to the ecosystems and its communities, with noxious impacts not only on the soil but also in aquatic surrounding systems. By this, this work proposes to: a) determine the lethal concentration of oxyfluorfen and copper to the zooplankton *Artemia franciscana*, at different temperatures (15ºC, 20ºC and 25ºC); b)understand the biochemical impacts, namely on the sugars composition, of the tested chemicals at the different temperatures scenarios, on *A. franciscana;* and c) evaluate the impact of the climatic changes, particularly the temperature increase, on the brine shrimp sensitiveness to the tested pesticides. To achieve the aims, the organisms were exposed to a concentration range of oxyfluorfen and copper, individually, at the three temperatures per 48 hours to determine the lethal concentration of each chemical at the different temperatures. Moreover, sublethal bioassays were conducted for 7 days to understand the effects of the compounds at the different temperatures on the biochemical profiles of *A. franciscana*. Acute tests showed that the chemicals toxicity increase with the temperature increase, and oxyfluorfen reveals to be more noxious to *A. franciscana* than copper. Considering the biochemical impacts, glucose and mannose were the dominant sugars in *A. franciscana* profiles, regardless of the temperature and treatment. Furthermore, significant differences were observed among temperatures, being the highest differences between the organisms exposed to 15ºC and the ones exposed to 25ºC.This study highlights the dangerous impacts of warming at lethal level, but also at the nutritive value, exhibiting significant changes on sugars profiles and thus on energetic sources.

2.06.P-Mo109 Physiological Effects of Microplastic During Simulated Marine Heatwaves in the Mediterranean Coral *Astroides calycularis*
Marco Munari[1], Verdiana Vellani[2], Matteo Nannini[3], Laura Tamburello[3], ***Silvia Giorgia Signorini[4]****, Camilla Della Torre[5], Saba Diletta Bacchini[5] and Luigi Musco[6], (1)Integrated Marine Ecology, Università di Padova, Italy, (2)Dipartimento di Scienze della Vita, Università di Trieste; CoNISMa-Consorzio Interuniversitario per le Scienze del Mare, Trieste, Italy, (3)Integrated Marine Ecology, Stazione Zoologica Anton Dohrn (SZN), Italy, (4)Department of Biosciences, Università degli Studi di Milano, Italy, (5)Dipartimento di Bioscienze, Università degli Studi di Milano, Italy, (6)Dipartimento di Scienze e Tecnologie Biologiche ed Ambientali, Università del Salento, Italy*
Climate change and pollution are impacting marine habitats, both directly and indirectly. Among them marine heatwaves and microplastic are recognized as global threats, especially in the Mediterranean basin where environmental changes are happening at faster rates. In this study, we studied the effects microplastics during simulated heatwaves on respiration and excretion rates were studied in the Mediterranean coral *Astroides calycularis*. Coral colonies were exposed to four different conditions (presence/absence of microplastics and ambient/increased temperature) for four weeks under laboratory conditions, increasing the temperature by 1 °C/week (from 26 °C to 29 °C), and maintaining the 29 °C peak for 1 week. During the exposure, oxygen consumption was measured for each colony using respiration chambers. An aliquot of seawater was collected from each chamber for the ammonia excretion analysis, and mortality rate was also measured. ANCOVA (polyps/colony as covariate) was applied to highlight significant interactions between microplastics and heatwaves on physiological rates during a 4 weeks' exposure, while ANOVA was used for testing differences in the mortality rate. Mortality was not significantly different among conditions and physiological rates increased with temperature. Respiration and excretion rates showed a bell-shape trend, with higher values after 3 weeks, at 29 °C, probably due to the proximity to the warm sublethal thresholds, being around 24-29 °C according to the literature. The decrease detected for both rates after four weeks could be due to acclimatisation to laboratory conditions or to adaptation: if the latter case, reducing metabolic rates is a strategy for energy conservation to better survive in a stressful scenario. Increased temperature was the main factor affecting metabolic rates, while the presence of microplastics only reduced respiration rate after 3 weeks of exposure. Our data suggest that temperature between 27 °C and 29 °C is probably within a zone of metabolic thermal compensation for the species.

2.06.P-Mo110 Impacts of the Cumulative Effect of Copper Exposure and Ocean Acidification on Cold-Water Octocoral *Viminella flagellum* – A Transcriptional Approach
Beatriz Lopes da Silva Dias Mano[1]*, António Godinho[2], Joana Goulart[2], Marina Carreiro-Silva[2] and Ines Martins[2], (1)Department of Oceanography and Fisheries at Horta, University of Azores, IMAR - Instituto do Mar, Portugal, (2)University of the Azores, Institute of Marine Sciences - Okeanos, Portugal*
Deep-sea mining is one of the potentially most threatening activities for the marine environment. The mechanical and toxic effects originated by the sediment plumes is described as highly deleterious for the deep-sea organisms. In parallel, the excessive amounts of CO_2 that have been absorbed by the oceans is leading to a decrease in the pH of seawater, named ocean acidification (OA). This phenomenon is expected to severely affect seawater chemistry (e.g., trace metal speciation) restricting calcification of marine organisms and favouring erosion of habitats created by marine calcifiers, such as Cold-Water Coral (CWC) species. The characteristics of long living and slow growing make CWC particularly vulnerable to anthropogenic impacts. The octocoral

Viminella flagellum is one of the most important structuring species in the Azores. The polymetallic sulfide (PMS) particles originated from mining activities plumes have adverse consequences for *V. flagellum* communities, such as the polyps smothering and clogging and the toxic effect of copper (Cu) that is one of the most released metals from the PMS particles. How can vulnerable CWC overcome the cumulative effect of Cu exposure, under a mining activities scenario, and OA? To address this question, four OA/Cu-contamination scenarios were used: (1) ambient pCO_2/pH level as measured in the in-situ conditions (385 µatm/pH 8.09); (2) high pCO_2/reduced pH (1000 µatm/7.73); (3) ambient pCO_2/pH level and additional Cu concentration (60 µg/L); (4) high pCO_2/reduced pH and additional Cu concentration (60 µg/L). The pH/pCO_2 modification was achieved by bubbling seawater with either pure CO_2 (to increase pCO_2) or CO_2-free air (to decrease pCO_2). The results show a Differential Gene Expression (DGE) between treatments. Our experimental results indicate that it is Cu exposure that modulates *V. flagellum* gene expression rather than seawater acidic conditions. Also, the cumulative effect of both seems to suppress most of the genes expressed under noncumulative treatments. In this work we discuss the molecular effects of the interactive effects of anthropogenic activities on CWC and the importance of identifying genetic biomarkers of physiological stress for future studies of environmental risk assessment.

2.06.P-Mo111 The Influence of Salinity on the Toxicity of Chemical UV-Filter 4-MBC to Sperms and Adults of the Free-Spawning Mussel *Mytilus galloprovincialis* (Lamark, 1819)

Alessia Cuccaro[1]*, Lucia De Marchi*[2]*, Matteo Oliva*[2]*, Giorgia Fumagalli*[2]*, Gianfranca Monni*[3]*, Valentina Meucci*[3]*, Amadeu M.V.M. Soares*[4]*, Rosa Freitas*[5] *and Carlo Pretti*[3]*, (1)University of Aveiro, Aveiro, Portugal, (2)Interuniversity Consortium of Marine Biology and Applied Ecology "G. Bacci", Italy, (3)University of Pisa, Italy, (4)University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Aveiro, Portugal, (5)Department of Biology & CESAM, University of Aveiro, Aveiro, Portugal*

In marine-coastal systems, organisms are exposed to a growing number of stressors, with associated ecotoxicological risks at different life stages and ecological levels. Considering the nature and different mechanisms of actions of stressors, their co-occurrence can result in possible interactive effects. Among stressors, changes in environmental abiotic factors related to Climate Change (i.e., salinity shifts) or new pollutants (i.e., personal care and cosmetic ingredients) have been identified as key emerging concerns. Particularly, 4-methylbenzylidenecamphor (4-MBC), as one of the most used UV-filters in several products, tends to be continuously discharged into aquatic environments, posing a high risk for inhabiting organisms. However, the toxicity exerted in nontarget species at different biological levels is almost unknown, especially under predicted Climate Change (CC) scenarios. Thus, the present study aimed to clarify if and how salinity variations (S 20, 30, and 40) potentially modulate impacts of 4-MBC environmentally relevant and slightly high contaminations (1, 10, and 100 µg/L) on different biological levels (male gametes and adults) of *Mytilus galloprovincialis.* By adopting *in vivo* and *in vitro* approaches, physiological and biochemical endpoints were assessed in short- and long-term assays, providing ecologically more relevant information on organism responses. Results showed that salinity acting alone posed the greatest impairments on both biological levels at the lowest (20) and highest (40) tested levels. When salinity acts as a co-varying stressor (salinity-dominant interaction), enhanced effects resulted evident, inducing a greater redox *status* imbalance and oxidative stress in both stages. The major toxic UV-filter impacts were detected in the worst salinity conditions (20 and 40), with main effects in terms of: I) sperm structural impairments, motility and kinetic alterations, DNA damage, and shorted longevity; II) physiological dysfunctions, metabolic capacity and energy reserves impairments, oxidative DNA damage as well as oxidative and biotransformation enzyme activity variations at adult stage. Additionally, a salinity-dependent uptake of waterborne 4-MBC was detected after 28 days exposure. Overall, it stands out that salinity influences biological pathways and, thereby, reinforces the high potential ecological risk of UV-filter environmental contaminations on *M. galloprovincialis*, especially in an expected salinity stress scenario.

2.06.P-Mo112 Integrative Approaches Highlight the Adaptive Potential and Plasticity of the Invasive *Hemigrapsus sanguineus* and *H. takanoi* While Outperforming *Carcinus maenas* in Europe

Lénia D. Rato[1]*, Sara Novais*[2]*, Tiago Filipe da Silva Simoes*[1]*, Jadilson M. Damasceno*[1]*, David W. Thieltges*[3]*, Jaap van der Meer*[4]*, João Carlos Marques*[5] *and Marco F.L. Lemos*[1]*, (1)Polytechnic of Leiria & MARE, Portugal, (2)Instituto Politécnico de Leiria, Portugal, (3)Department of Coastal Systems, NIOZ - Royal Netherlands Institute for Sea Research, Texel, Netherlands, (4)Wageningen Marine Research Institute, Wageningen University & Research, Netherlands, (5)University of Coimbra, MARE - Marine and Environmental Sciences Centre, Portugal*

Ecosystem services are increasingly relevant in policymaking and threatened due to overexploitation, climate change, pollution, and invasive species. Besides human-mediated introduction, the success of coastal bioinvasions is influenced by ecosystem disturbances. The plastic capacity of invaders then became an increasing matter of concern under such rapidly changing environments.

Predatory crabs are among the most conspicuous marine invaders: Asian shore crabs (*Hemigrapsus takanoi* and *H. sanguineus*), native along northwestern Pacific rocky shores, established viable and dense populations throughout northern European waters. Detrimental effects were reported on native crab species (*Carcinus maenas*), food webs, and bivalve spat - posing a threat to natural stocks and aquaculture. *Hemigrapsus* spp remain unreported in southern Europe, where suitable habitats reach higher temperatures: their ecophysiology is fairly unknown, namely under warming or pollution scenarios.

This project investigated the adaptative potential and plasticity of native and invasive crabs by addressing exposure responses to 1) warming (chronic), 2) a new generation pesticide (acute and chronic), and 3) a heatwave (acute thermal stress) and pesticide LOEC (bifactorial) at the organism level – bioassays concerning lethality, behaviour, growth, feed intake, or respiration – and sub-individual level – enzymatic and biochemical assays related with detoxification, oxidative stress and related damage, energy metabolism, and neurotransmission.

The results pinpoint that warmer regimes may not deter *Hemigrapsus* spread to Southern European coastal areas. In addition, the native *C. maenas* was more impacted by the exposure to a new generation pesticide. These findings suggest that, in the *C. maenas* native range, *Hemigrapsus* seem to have higher plasticity under global change scenarios, prompting the native displacement, and expected dominance in the invaded range.

Addressing the impacts of global change drivers is relevant to unravel the underlying mechanisms for bioinvasions success and facilitate informed management measures in some of the most worrying topics to environmental sciences and society.

2.06.P-Mo113 Light Pollution Increases Sensitivity of an Aquatic Insect to Thermal Stress and Pesticide Exposure
*Diana Campos[1], Joana Carmo[2], Ana Luísa Machado[1] and **João L.T. Pestana**[1], (1)University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Aveiro, Portugal, (2)University of Aveiro, Department of Biology, Aveiro, Portugal*
Urbanization is steadily increasing worldwide imposing novel challenges on urban/suburban aquatic ecosystems. As an example, light pollution has become an emergent issue of environmental concern since many health and ecological detrimental effects artificial light at night (ALAN) have been identified.

Besides light pollution, urban aquatic ecosystems are usually recipients of runoff from municipal and industrial discharges resulting in increased concentrations of chemical contaminants (including pesticides). Moreover, considerably warmer temperatures are observed in urbanized aquatic ecosystems ("urban heat islands") due to urban air and ground temperatures, paved surfaces, and decreased riparian vegetation. Although ALAN, warming, and chemical contamination are common stressors present in urban areas, their interaction and combined effects are not studied. Here we present preliminary data testing for the hypothesis that exposure to low and environmentally relevant levels of ALAN can change the upper thermal tolerance and sensitivity to pesticide exposure of *Chironomus riparius* larvae.

To assess thermal tolerance, we determined the critical thermal maximum (CTMax) in *C. riparius* larvae after exposure to three ALAN conditions (0, 1, and 10 lux during nighttime). The results show that ALAN decreases the upper thermal tolerance of *C. riparius* larvae (CTMax). Pesticide tolerance was evaluated through survival curves (time-to-event analyses) where *C. riparius* larvae reared in the same ALAN treatments (0 and 10 lux during nighttime) were exposed to a lethal Glyphosate (Roundup) concentration. Mortality was evaluated every 30 min over 8 hours. Significantly different survival curves indicate a higher sensitivity of *C. riparius* larvae previously exposed to ALAN. Ongoing experimental work is investigating the physiological basis of decreased thermal tolerance (heat shock proteins and oxidative stress/ damage) and also validating results concerning increased sensitivity to pesticides with other compounds (neonicotinoids, pyrethroids). Our results suggest that for a better assessment of ecological effects of climate change and of chemical contamination in urban aquatic ecosystems, it is crucial to consider anthropogenic-induced changes to light conditions.

2.06.P-Mo114 Using a Dynamic Energy Budget (DEB) Model to Analyze the Sublethal and Lethal Effects of Insecticides at Different Temperatures
***Anna Huang**[1], Paul van den Brink[1], Nico van den Brink[2] and Jan Baas[3], (1)Wageningen Environmental Research (WUR), Netherlands, (2)Division of Toxicology, Wageningen University & Research, Netherlands, (3)Wageningen University & Research, Netherlands*
Temperature is an important factor for biological processes, i.e., by affecting growth, feeding, and reproduction, especially for aquatic ectothermic species. Furthermore, temperature changes the behaviour of chemicals, such as their fate and bioavailability in the environment. The importance of gaining a better understanding of how temperature affects chemical toxicity is emphasized by the observation that many previous studies have found that the acute lethal toxicity of chemicals increases with temperature. Although a better understanding of the impacts of temperature on lethal and sublethal endpoints is important, few studies have been conducted, and the underlying mechanisms of temperature effects are largely unknown.

Temperature can affect the toxicity of chemical substances by effects on the kinetics: temperature affects the uptake of chemicals, and therefore (apparent) toxicity could be changed. Also, the intrinsic sensitivity of organisms can be influenced by altering certain gene expressions or enzyme activities. To understand these processes and allow to separate the drivers, toxicokinetic-toxicodynamic (TKTD) models like the Dynamic Energy Budgets (DEB) models are needed for lethal and especially sub-lethal endpoints.

In this study, we have applied DEB models to data on the lethal and sublethal effects of imidacloprid and flupyradifurone on *Gammarus pulex* at different temperatures. Our results showed that for both insecticides, the dominant rate constant and threshold value tend to decrease with increasing temperature for both lethal and sublethal effects, while the effect strength and background mortality tend to increase with increasing temperature. The results showed that temperature influences both the kinetic of chemicals and the intrinsic sensitivity of organisms. In addition, a 180-day experiment is currently being performed to capture the effect of temperature on mortality and growth. The preliminary results suggest that the DEB model fits well and that damage from imidacloprid is diluted by growth.

Overall, the current results indicate that the relationship between each parameter and temperature might vary with species and chemicals; therefore, more studies need to be conducted to get a general and clearer picture. Also, this present study deepens the understanding of the mechanism of temperature on pesticide toxicity, which can be used for future risk assessment when the temperature is integrated.

2.06.P-Mo115 DOM Quality and Origin Does Not Greatly Affect Uptake and Accumulation of Lipid Soluble Contaminants in Two Coastal Filter Feeders

Sabrina Schultze[1]*, Hilde Langva*[1]*, Nina Knudtzon*[1]*, Thomas Rundberget*[2]*, Marios Chatzigeorgiou*[3]*, Steven Brooks*[2]*, Amanda Poste*[2]*, Dag Hessen*[1]*, Anders Ruus*[1,2]*, Tom Andersen*[1] *and Katrine Borga*[1]*, (1)University of Oslo, Norway, (2)Norwegian Institute for Water Research (NIVA), Norway, (3)University of Bergen, Norway*

Coastal darkening, the increased input of darker terrestrial derived dissolved organic matter in coastal system, has been a growing environmental concern in recent years.

Terrestrial dissolved organic matter (terrDOM) is overall comprised of larger humic molecules with stronger amphipathic properties compared to marine DOM (marDOM) and thus has a more favourable adsorption profile for lipophilic contaminants. Previous studies show that the presence of terrDOM leads to reduced concentration of contaminants in the open water column and less uptake directly from the water (bioconcentration), thus indicating that some contaminants adsorb well to terrDOM. However, the very same properties may lead to an increased contaminant uptake via feeding processes, especially in filter feeding organisms. Thus, we expected higher bioaccumulation rates in filter feeders exposed to terrDOM than marDOM.
To test our hypothesis with two mechanistically different filtration types (cirri-trapping vs. mucus feeding), we exposed blue mussels (*Mytilus edulis*) and subsequently ascidians (*Ciona intestinalis*) to teflubenzuron - a lipophilic (log K_{OW}: 5.39) veterinary drug commonly used in aquaculture against sea lice infestations - under four different DOM conditions. We employed a factorial design that was comprised of 24 aquaria in each of the two experiments. The different DOM types used include DOM derived from phytoplankton (marDOM), DOM derived from forest leaves (terrDOM), a mix of the two (mixDOM), and seawater with low natural background DOM. All seawater was filtered to 0.2 µm before potential DOM addition.

Contrary to expectation, our results showed that terrDOM exposure did not lead to the highest bioaccumulation in any of the two taxa, but rather a trend toward higher bioaccumulation with marDOM or mixDOM exposure. However, terrDOM exposure also did not lead to lower bioaccumulation than the seawater only treatment either. Bioaccumulation of teflubenzuron was overall higher in blue mussels than ascidians.

2.06.P-Mo116 Analytical and Risk Assessment Monitoring of Drinking Water Treatment Plants in Biscay (Basque Country)

Belen Gonzalez-Gaya[1]*, Iker Alvarez*[2]*, Naroa Lopez*[3]*, Vanesa Benito*[4]*, Leire Mijangos*[5]*, Mireia Irazola-Duñabeitia*[6]*, Maitane Olivares*[5]*, Ailette Prieto*[5]*, Jose Maria Suescun*[7]*, Olatz Zuloaga*[5]*, Santos Paunero*[8] *and Nestor Etxebarria*[6]*, (1)ESTACION MARINA DE PLENTZIA. UPV/EHU, Spain, (2)UPV/EHU, Leioa, Spain, (3)Analytical Chemistry, EHU/UPV, Leioa, Spain, (4)Biotechnology, GAIKER Technology Centre, Basque Research and Technology Alliance (BRTA), Zamudio, Spain, (5)Analytical Chemistry, University of the Basque Country (UPV/EHU), Spain, (6)University of the Basque Country (UPV/EHU), Spain, (7)Department of Research and Development, CADAGUA, (8)Bilbao-Bizkaia Water Consortium (CABB)*

The quality of drinking water shows increasing safety requirements and the highest standards to ensure human health. In the EU the legal framework is governed by the Drinking Water Directive (DRW,2020/2184), including the first watch list (2022). However, we can only find a list of parametric values for less than 20 organic micropollutants. Therefore, there is a clear need for more comprehensive knowledge about the presence of emerging pollutants and the potential toxicological hazard to human health in raw and treated waters.

In this scenario, the Water Council of Bilbao-Bizkaia (CABB), together with researchers of the UPV/EHU, Gaiker and Cadagua, led the project *EmerGen* to screen some of the most sensitive drinking water treatment plants (DWTPs) in Bizkaia (Basque Country, Spain). For that, we monitored the quality of 5 raw and treated waters over 2 years, including an experimental pilot plant designed to reuse the water from the Nervión-Ibaizabal River in Bilbao in the event of a serious lack of the typical supplies in summer. The aim of this work was to monitor sensitive and demanding DWTPs in Bizkaia to assess the quality of the raw and treated waters in terms of the presence of contaminants of emerging concern, and the toxicological effects such as mutagenicity. In addition to this, the efficiency of the implemented water treatments was also considered, especially when the eventual supplies cannot ensure the expected requirements.
Ten monitoring campaigns were carried out from July 2020 till May 2022, one per season and two in summer. An automatic large-volume solid-phase extraction system (LV-SPE, MAXX Mess-u Germany) holding a triphasic cartridge (WAX, WCX, HR-X) was used to sample 20-40 L from each DWTP. Water extracts were injected in a Thermo Scientific Dionex UltiMate 3000 coupled to a UHPLC-q-Orbitrap (Focus) (Thermo Scientific) operating in full scan−data dependent MS2 acquisition mode. Two independent data handling strategies were implemented: multitarget screening of CECs and nontarget screening. With these quantitative data, we estimated the risk quotient (RQ) values based on PNEC values available in the NORMAN database

The experimental treatment plant in Etxebarri exhibited the highest concentrations due to the contamination load of the river, and the RQ values for Telmisartan and Cortisone were >1, considered of concern. In the other 4 DWTPs, the ranges of the concentrations are within <0.1 -30 ng/l and the RQs were significantly lower.

2.06.P-Mo117 Water Stress from Future Climate Changes and Modeling Impacts to the Environment from Consumer Product Chemical Exposure in the United States and Europe *Raghu Vamshi[1], **Brenna Kent**[1], Scott Dyer[1] and Andrea Carrao[2], (1)Waterborne Environmental, Inc., (2)Kao USA*
Growing human population in combination with expansive evidence of climate change has added stress on freshwater availability at a global scale. Water stress is impacting communities to focus on water conservation, reuse, and recycling technologies for freshwater use. However, they may require innovations in consumer products that depend on water for their function and disposal. Water stress across the two regions, United States (US) and Europe (EU), were examined by evaluating datasets considering historic, current, and future water availability and use scenarios. Inclusion of anticipated climate change events required datasets that incorporated scenarios of estimated future population and water use with high spatial resolution. These datasets captured predicted temporal trends for the years 2020-2050 and were integrated with wastewater treatment plant infrastructure data across the US using EPA's Clean Water Needs Survey and Europe using EEA's Waterbase. The consolidated information was used to develop current and future water use scenarios. The influence of future water use scenarios on down-the-drain chemical exposures were predicted by evaluating four consumer product chemicals with various phys/chem properties and use patterns. Results from the modeling provided a quantitative forecast of the potential impacts of water stress on down-the-drain chemical exposure and potential risk. Incorporating spatial and temporal variation in water stress and understanding its impact on the environment from chemical risk, through the lens of future scenarios, provides a new dimension in the development of consumer products. Incorporating these issues into product development, now, will ensure that both consumers and the environment will be appropriately stewarded, especially considering future environmental challenges in the US and EU.

2.06.V Ecosystems Responses Under a Multiple Stressors Scenario in a Rapidly Changing Climate (Part I: Effects, Adaptations, *in vitro*, Population-Level)

2.06.V-01 Global Climate Change Increases the Impact of Pollutant Mixtures in the Model Species *Paracentrotus Lividus* ***Juan Ignacio Bertucci**[1], Carmen Veloso-Cerredelo[1] and Juan Bellas[2], (1)Contaminación Marina, Centro Oceanográfico de Vigo - IEO- CSIC, Spain, (2)Centro Oceanográfico de Vigo - IEO- CSIC, Spain*
The ingestion of microplastics (MP) at environmentally relevant concentrations has been shown to cause stress, false feeling of satiation, reproductive complications, and reduced growth rate in several aquatic organisms. Due to their inherent hydrophobicity, organophosphorus pesticides such as chlorpyrifos (CPF) are strong candidates to be adsorbed by MP in the environment. Oceans are also impacted by several aspects of global climate change such as the increase in seawater temperature -ocean warming (OW)- and their acidification -ocean acidification (OA)-. The goal of the present work is to study whether global climate change factors could increase the toxicity of pollutants on *P. lividus*. To achieve this, a fertilization assay was carried out following the United States Environmental Protection Agency guidelines, and a sea urchin embryo test (SET) was carried out to determine growth and alteration level of larvae, and the index of contaminant impact. For both assays, treatments consisted of a control with Filtered Sea Water (FSW, "Control"), MP 3000 particles / mL ("MP"), acidified FSW ("OA"), CPF at 250 µg/L, a combination of both MP (3000 particles / mL) and CPF (250 µg/L) (MP+CPF), and a treatment of MP+CPF under OA conditions (OA+MP+CPF). Each treatment was tested at two temperatures: 20ºC and 24ºC (OW conditions). The fertilization assay showed that the negative effect of CPF on the fertilization rate is higher when MP are present in the media, which may act as carriers. Also, the global climate change conditions predicted by FAO increase the sensitivity of embryos to MP and CPF. The highest growth inhibition of *P. lividus* larvae was observed in the treatment MP+CPF. At morphological level, our study shows that an increase in temperature increased the ratio POL/BL, which means that under the predicted OW conditions, the arms of larvae would be proportionally longer in relation to the rest of the body. The presence of CPF reduced the relative length of the arms, while the relative width of larvae was increased, that is, larvae exposed to CPF tend to adopt a rounded shape which is obviously detrimental to their normal buoyancy and could affect their ability to feed in the water column. The combination of CPF with other stressors seems to aggravate this situation. Our findings support the idea that global change conditions could have a severe impact on marine life, increasing the negative effect of toxic agents commonly present in the sea.

2.07 Ecosystems Responses Under a Multiple Stressors Scenario in a Rapidly Changing Climate (Part II: Microcosms, Mesocosms, Factorial Design, Community-Level)

2.07.T-01 Leaf Species-Dependent Fungicide Effects on the Structure and Function of Leaf-Associated Microbial Communities
***Sara Isabel Bastos Goncalves**[1], Ruben Post[2], Marco Konschak[3], Jochen Zubrod[4], Alexander Feckler[1] and Mirco Bundschuh[5], (1)iES Landau, Germany, (2)iES Landau, University of Kaiserslautern-Landau (RPTU), Germany, (3)University of Kaiserslautern-Landau (RPTU), Germany, (4)Zubrod Environmental Data Science, Germany, (5)iES Landau, Institute for Environmental Sciences, University of Kaiserslautern-Landau (RPTU), Germany*
Microbially mediated leaf litter decomposition is a vital ecosystem function in streams within forested areas, which can be affected by fungicides. However, fungicide effects on leaf litter decomposition have been investigated almost entirely with black alder leaves, a leaf species with traits beneficial to consumers (i.e., low recalcitrance and high nutrient content). At the same time, little is known about fungicide effects on microbial colonisation and decomposition of other leaf species with less beneficial traits. In this 21-day lasting study, we explore the effects of increasing fungicide sum concentrations (0 to 3000 µg/L) on microbial colonisation and decomposition of three leaf species (black alder, Norway maple, and European beech) varying in terms of recalcitrance and nutrient content. The rate of leaf litter decomposition, leaf-associated fungal biomass, and bacterial density were

quantified to evaluate potential effects at the functional and structural levels. In absence of fungicides, beech, as the species with the least beneficial leaf traits, showed a 50% lower decomposition rate than alder and maple. On the contrary, fungal biomass did not follow this pattern of leaf litter decomposition observed for the three leaf species, suggesting a decoupling of biomass and functional trait composition in fungal communities. In the presence of high fungicide concentrations (300-3000 µg/L), beech showed a concentration-related decrease not only for microbial leaf litter decomposition but also for fungal biomass. This suggests that beneficial traits of leaf litter (as for alder and maple) enable leaf-associated microorganisms to acquire leaf-bound energy more easily to endure potential effects induced by fungicide exposure. Our results point to the need to deepen our understanding on how leaf species' traits relate with the impact of chemical stressors on the leaf decomposition activity of microbial communities. This step seems relevant for a more complete understanding of anthropogenic effects on carbon and nutrient cycling in streams.

2.07.T-02 Chemical Stress Increases Methane Production in Freshwater Sediments: Role of Temperature Feedbacks, Adaptation, and Resistance

Eric Bollinger[1]*, Sabine Filker*[2]*, Jochen Zubrod*[3]*, Paul Schwilden*[1]*, Alina Mees*[1]*, Foon Yin Lai*[4]*, Timo Fuchs*[1]*, Lutz Ahrens*[4]*, Ralf Schulz*[5]*, Andreas Lorke*[1] *and Mirco Bundschuh*[5]*, (1)University of Kaiserslautern-Landau (RPTU), Germany, (2)University of Technology Kaiserslautern, Germany, (3)Zubrod Environmental Data Science, Germany, (4)Department of Aquatic Sciences and Assessment, Swedish University of Agricultural Sciences (SLU), Sweden, (5)iES Landau, Institute for Environmental Sciences, University of Kaiserslautern-Landau (RPTU), Germany*

The increasing emissions of atmospheric greenhouse gases are the main driver of climate change and a serious concern for human health and the environment. Microbial methane (CH_4) production in anaerobic freshwater sediments is the largest and most unresolved source of atmospheric CH_4. Given the rising CH_4 emissions, researchers have been investigating environmental controls and climate change feedbacks for decades. Despite their omnipresence, the impact of anthropogenic chemical stressors (e.g., antibiotics) on methanogenesis in freshwater systems is still largely unknown. Against this background, we first incubated natural pond sediment at four levels of a five-component antibiotic mixture. Second, three temperatures (i.e., 10, 15, and 20 °C) were employed as additional factor to assess interactions on the toxicokinetics and -dynamics of antibiotics. Third, the adaptability of a pristine and a preexposed microbial community was investigated. Both communities were treated with antibiotics for three weeks and consecutively incubated at three concentrations of the same antibiotic mixture. In every experiment, the effect of antibiotics was decisive with the CH_4 production rates almost doubling at the highest treatment concentration (i.e., 5000 µg L^{-1}). Furthermore, higher temperatures resulted in increasing effects of antibiotics indicating a potential feedback-loop. Both the pristine and the exposed community showed effects of antibiotics on methanogenesis with effects increasing in the former and decreasing in the latter after the first treatment phase. Compound-specific isotope signatures indicated that the same synthesis pathways (i.e., mainly acetate and H_2/CO_2 as substrates) were utilized and metabarcoding of the 16S rRNA gene suggests changes in the community composition of microorganisms relevant to methanogenesis.

2.07.T-03 Seasonal Fluctuation of Metabolomic and Photosynthetic Yield Response of *in situ* Freshwater Biofilms Exposed to a Model Herbicide

Arthur Medina[1]*, Melissa Eon*[2,3]*, Débora Millan-Navarro*[3]*, Nicolas Mazzella*[3] *and Nicolas Creusot*[3]*, (1)Gironde, National Research Institute for Agriculture, Food and Environment (INRAE), France, (2)AQUA, INRAE, France, (3)INRAE BORDEAUX, France*

With increasing aquatic chemical pollution, the study of microbial communities (e.i periphytic biofilms) improves the ecological dimension of biomonitoring. Despite a growing knowledge, there is a paucity of information about the seasonal fluctuation of their sensitivity to chemical stress. If classical endpoints often lack sensitivity and focus only on one component of the biofilm, untargeted metabolomics can provide a comprehensive and sensitive picture of the molecular response prior physiological. The present study aims to characterize the changes of sensitivity of freshwater periphyton to the model herbicide terbuthylazine over months through the combined measurement of the photosynthetic yield (ΦPSII) and the metabolomics response based on high-resolution mass spectrometry. To do so, periphytic biofilms were sampled on a pilot site and exposed during 4 h in controlled conditions to a range of six concentrations of herbicide. The sensitivity of periphyton to chemical was assessed through the determination of Benchmark Doses with a standard deviation of 1% compared to the control (BMD) and their cumulative distribution for metabolomics data. The results indicate a change in the sensitivity over the months for both endpoints. Indeed, BMD of ΦPSII vary from 5.5 to 13.8 µg/L. Multivariate analyses on metabolomics data showed a response at 0.3 µg/L of terbuthylazine; our results highlighted that the metabolomics response is more sensitive than the photosynthesis since almost 50% of the metabolome have reacted at the BMD *ΦPSII*. Metabolite identification found significant pathway modification under exposure. This study shows that sensitivity of periphyton to chemical stress fluctuates along the year, highlighting the need to consider it for field studies. In addition, this work confirms the higher sensitivity of metabolomics against photosynthetic response in the form of their BMD responses. The metabolite annotation highlighted similar pathway response effect but different regulation. The continuation of these investigations along the year will provide additional insight on the influence of environmental parameters on the sensitivity of periphyton to chemical stress. Especially, metabarcoding analyses should highlight the natural taxonomic shift according to environmental conditions and hone the identification of which metabolites and pathways are sensitive to environmental conditions against those specifically impaired by the chemical stress.

2.07.T-04 Contamination on Ecosystems and Habitat Selection – The Role of Ecological Interactions on the Behavioural Responses

*David Salvatierra[1], **Andrea Cordero**[1], María del Pilar Gonzalez Muñoz[1], Mohammed Islam[1,2], Julián Blasco Moreno[3] and Cristiano Araújo[1], (1)Institute of Marine Sciences of Andalusia (CSIC), Spain, (2)Faculty of Fisheries, Sylhet Agricultural University, Bangladesh, (3)Spanish National Research Council (CSIC), Spain*
The reason by which ecotoxicity tests are reductionist regarding to ecosystems complexity is due to the fact that the environmental variables can be more easily controlled by the experimenter. In this sense, two important scenarios have not been usually integrated to ecotoxicology: i) the chemicals are not always homogeneously distributed in the ecosystems and ii) the effect of the ecological interactions (such as predation, competition, etc.) can exert on how organisms respond to toxicity. The aim of the present study was to assess how contamination can affect the spatial distribution of organisms in a chemically heterogeneous landscape and how the habitat selection in a contaminated environment is influenced by the interactions that organisms have with other ecological factors. To that end, three study cases were analyzed where contamination was evaluated along to stressors/attractors simultaneously in two nonforced free-choice multicompartmented assay systems: the linear and the Heterogeneous Multi-Habitat Assay System (HeMHAS). For the tilapia fry case, the organism avoided the contaminant, but when confronted to food the fish intermittently moved to the most contaminated compartment. For the freshwater shrimp case, the organisms avoided the contamination but this response was density-dependent inversely-proportional, so the higher density the lower avoidance, and conversely. For the estuarine shrimp case, it avoided the contaminant as well, but when confronted to predation risk, the response shifted. In addition, when organisms were faced to the attraction of food along to both stressors, the foraging behavior was impaired in the presence of contamination. As conclusion, the nonforced exposure systems (e.g., HeMHAS) showed to be suitabile to simulate chemically heterogeneous environments to assess how contaminants disturb the habitat selection by organisms. In addition, it was evidenced how the contamination affects the organism's response to other ecological variables performing a cost-benefits analysis to reduce exposure to contamination and obtain more benefits. This novel methodology (nonforced exposure) and the integration of ecological interactions provide, respectively, new practical and conceptual approaches to assess the contamination effects from a landscape perspective. This could provide a little more of ecology to ecotoxicology studies.

2.07.T-05 Single and Combined Effects of Pesticides and Metabolites in Microbial Litter Decomposition in Streams
*Camille Amélie Sand[1], Yoann Menard[1] and **Joan Artigas**[2], (1)Université Clermont Auvergne, France, (2)Agence Comptable Service Facturier, University of Clermont Auvergne, Clermont-Ferrand, Cedex 1, France*
The combined effects of pesticide parent compounds and their corresponding transformation products (metabolites) are often omitted in aquatic ecotoxicology studies. This gap of information is surprising given the large amount of pesticide molecules with relatively low half- life times and a plethora of metabolites found in aquatic environments. In the present study, we aim to compare the effect of tebuconazole and its metabolite hydroxy-tebuconazole on microbial litter decomposition, and to determine whether the presence of other pesticides and metabolites frequently found in surface waters (i.e., glyphosate and AMPA) increase the toxicity of the hydroxy-tebuconazole toward microbial litter decomposition. We conducted a microcosm experiment to address the research questions described above. A total of 15 glass aquariums of 15 L were filled with dechlorinated tap water supplemented with N and P and spiked with the different contaminants (i) tebuconazole (10 µg/L), ii) hydroxy-tebuconazole (10 µg/L), iii) glyphosate (0.1 µg/L) + aminomethylphosphonic acid (AMPA) (0.3 µg/L), and iv) the combination of hydroxy-tebuconazole (10 µg/L) + glyphosate (0.1 µg/L) + AMPA (0.3 µg/L)) or without (v) control. Each aquarium contained precolonized black alder leaves enclosed in fine-mesh bags (0.5 mm mesh size) to assess microbial decomposition. The results show that tebuconazole and its metabolite hydroxy-tebuconazole had similar effects in reducing microbial decomposition of leaf litter and the diversity of aquatic hyphomycete communities, even if tebuconazole effects tended to be stronger than those of hydroxy-tebuconazole. Glyphosate and AMPA did not enhance the toxicity of hydroxy-tebuconazole on leaf-associated microbial communities, except when combining hydroxy-tebuconazole, glyphosate, and AMPA which consistently impaired the diversity of the aquatic hyphomycete communities.

2.07.P Ecosystems Responses Under a Multiple Stressors Scenario in a Rapidly Changing Climate (Part II: Microcosms, Mesocosms, Factorial Design, Community-Level)

2.07.P-Mo119 Aquatic Macroinvertebrates Under Multiple Stress: Insights from a Mesocosm Experiment
***Iva Kokotović**[1], Marina Veseli[2], Vojtěch Kolář[3,4], Simon Vitecek[5], Marko Rozman[6] and Ana Previsic[2], (1)Department of Biology, University of Zagreb, Croatia, (2)University of Zagreb, Faculty of Science, Department of Biology, Croatia, (3)University of South Bohemia in České Budějovice, Czech Republic, (4)Biology Centre CAS, Institute of Entomology, Czech Republic, (5)WasserCluster Lunz, Austria, (6)Ruder Boskovic Institute, Croatia*
Freshwaters are frequently subject to a complex mixture of stressors like pollution and climate change. Moreover, wastewater effluents are one of the main sources of chemical pollutants in freshwater ecosystems. Multiple stressor impact on these ecosystems directly acts at the level of biodiversity-ecosystem functioning relationships. Studies on multiplicative effect of climate change, e.g., changing water temperature and chemical pollutants on freshwater biodiversity and implications thereof are limited. Accordingly, the aim of the current study was to investigate single and combined effects of wastewater effluent and elevated water temperature on aquatic macroinvertebrates. A mesocosm experiment was conducted with a simplified freshwater food web containing nonvascular macrophytes (moss) and Ephemeroptera, Plecoptera, Trichoptera, and Amphipoda, feeding as shredders and grazers. Samples were collected at the beginning and end of the experiment, whereas emerging animals were collected daily. Analyses enabling assessment of the response of nonmodel aquatic macroinvertebrates to selected stressors are ongoing, such as total protein and lipid content, and metabolome and lipidome profiling. Preliminary results show species-specific

response to stress. An increase in body weight of caddisfly larvae was observed at the end of experiment, except in multiple stressor treatment. Similarly, a drop in total lipid content in caddisfly larvae was related to increased water temperature or multiple stressor treatment. Furthermore, reduced lipid content related to multiple stressor treatment was also observed in adult mayflies. The current study will give novel insights into the molecular response of aquatic macroinvertebrates subjected to anthropogenic stressors.

2.07.P-Mo120 The Impacts of Increased Temperature and Pollution on the Biological Functions of Two Caddisflies Species *Drusus croaticus* and *Allogamus uncatus*

Filip Ložek[1], *Iva Kokotović*[1], *Marko Rozman*[2], *Ivana Grgić*[2], *Antonia Smolić*[3] *and Ana Previsic*[3], *(1)Department of Biology, University of Zagreb, Croatia, (2)Ruder Boskovic Institute, Croatia, (3)University of Zagreb, Faculty of Science, Department of Biology, Croatia*

Aquatic ecosystems worldwide are increasingly exposed to both natural and anthropogenic stressors. Climate change-related alterations, like changes in temperature patterns of surface waters, are often linked with chemical pollution from different sources (e.g., surface runoff, discharge of both raw and treated wastewater, industrial waste disposal, etc.). Such a combination of stressors may have ecological and biological impacts on aquatic organisms such as freshwater insects which perform various important ecological functions in freshwater and terrestrial ecosystems. The main goals of the study were to: i) identify the potential impacts of multiple stressors (increased temperature and chemical contamination) on metabolomic and lipidomic profiles of two ecologically different species of caddisfly larvae, ii) analyze their behaviour expressed as locomotor activity (i.e., distance moved), and iii) evaluate the potential biological and ecological risk of climate change together with emerging contaminants. To simulate the environmental complexity of multiple stressors in laboratory conditions, we exposed caddisflies larvae *Drusus croaticus* and *Allogamus uncatus* separately to a cocktail of emerging contaminants in environmentally relevant concentrations of 500 ng, at optimal (8 °C) increased (12°C) temperature for 21 days. The cocktail included: i) psychoactive pharmaceuticals - fluoxetine, sertraline; ii) beta-blocker - sotalolol; iii) alkaloid - caffeine; iv) anticonvulsant - carbamazepine; v) antibiotic/macrolide - azithromycin; vi) industrial antioxidant - diphenylamine (DPA); vii) plasticizer - tributoxy ethyl phosphate (TBEP), and viii) nonsteroidal anti-inflammatory drug ketoprofen. Preliminary results suggest both species of caddisflies showed decreased locomotor activity when exposed to a higher temperature (12 °C), before exposure to the cocktail of emerging contaminants. After exposure to the cocktail of emerging contaminants, both species exhibited differences in locomotor activity, most apparent on day 21*: D. croaticus* showed increased locomotor activity at 8 °C and decreased locomotor activity at 12 °C, while *A. uncatus* showed decreased locomotor activity at both temperatures compared to controls. Based on preliminary results of locomotor activity analyses, we concluded that multiple stressors may contribute to a disruption of natural behaviour, which could potentially lead to higher susceptibility of caddisflies to predation.

2.07.P-Mo121 Combined Effects of Warming and Pesticides on Freshwater Invertebrates: A Mesocosm Study

Claire Duchet[1], *Helena Švecová*[2], *Vojtěch Kolář*[1], *András Csercsa*[1], *Barbora Zdvihalova*[3], *Tomáš Randák*[2] *and David Boukal*[1], *(1)University of South Bohemia in České Budějovice, Czech Republic, (2)University of South Bohemia in České Budějovice, Faculty of Fisheries and Protection of Waters, Czech Republic, (3)Entomology, Institute of Entomology / Biology Center CAS, Czech Republic*

Warming climate and chemical pollution are two widespread stressors of freshwater biota. Warming, predicted to be up to +8°C by 2100, can impact freshwater biota through a range of mechanisms such as increased individual growth rates and altered nutrient cycling. Pesticides are usually not intended for direct use in water bodies; however, they enter the aquatic compartment via spray drift, runoff, and leaching, are widespread in freshwater habitats, and usually reach surface waters as mixtures. Many freshwater organisms, unable to readily migrate between habitats when facing adverse conditions, are particularly threatened by these stressors.

We assessed the combined effects of warming and a mixture of pesticides on a freshwater community in a 2*2 factorial design (i.e., with/without pesticides and with/without warming) in heated outdoor mesocosms. We combined a single-pulse cocktail of 6 pesticides (herbicides and fungicides), at concentrations commonly measured in surface waters in the Czech Republic, with warming at +4°C above ambient. The experimental community was assembled from common macroinvertebrate and plankton taxa from different trophic levels (e.g., predators, filter feeders and grazers, detritivores, and primary producers). The experiment ran during summer (June/August). We repeatedly measured pesticide concentrations, environmental parameters (dissolved oxygen, conductivity, pH, turbidity, and temperature), chlorophyll-*a* concentration, zooplankton density and aquatic insect emergence.

Both warming and pesticide mixture altered the invertebrate community composition and insect emergence patterns in the experiment. Pesticide mixture negatively affected the zooplankton dynamics and strongly inhibited the emergence of mayflies (*Cloeon* sp., Ephemeroptera), whereas both pesticides and warming had a strong negative effect on the emergence of the damselflies (Zygoptera). Our results suggest that environmentally relevant pesticide concentrations combined with climate warming can affect freshwater biota through individual-level responses leading to trophic cascades.

2.07.P-Mo122 Disentangling the Effects of Multiple Stressors and Chemical Mixtures: Stressor Prioritization Using Monitoring Data Across Germany

Nele Markert[1,2], *Barbara Guhl*[1] *and Christian K. Feld*[2], *(1)North Rhine-Westphalia Office of Nature, Environment and Consumer Protection (LANUV NRW), Germany, (2)University Duisburg-Essen, Germany*

River fauna and flora are exposed to a large number of micropollutants, which are released into the environment every day.

Combined effects of the complex chemical mixtures of these substances on community composition and diversity have been addressed in previous research studies. However, a variety of anthropogenic stressors including eutrophication, salinization, hydrological alteration and habitat degradation further influences aquatic biodiversity and related ecosystem functions of rivers. So far, effects of micropollutants have often been analyzed separately from those of other stressors and have only rarely been included in multiple-stressor studies. For a better guidance to river ecosystem management, comparative analyses of the relevance of individual stressors and combinations thereof are required.

We present the findings of a current study that aims at identifying and quantifying the effects of different stressors belonging to physicochemical, hydrological, and morphological stressors as well as risk variables representing the mixture toxicity for 51 selected micropollutants. The effects are evaluated for benthic invertebrates, benthic diatoms, and fishes, using a variety of ecological metrics and including biodiversity and ecosystem functions. A comprehensive dataset of rivers in Germany was compiled using available monitoring data taken in accordance with the EU Water Framework Directive. Random forests and subsequent variance partitioning were applied to put the different stressors' effects into a hierarchical context and to compare individual and combined effects on the three organism groups. At the same time, this study also highlights the challenging requirements for environmental data sets which are intended to be used for the analysis of multistressor effects and ultimately for the planning of appropriate management measures.

2.07.P-Mo123 Mediterranean Freshwater Ecosystems Under Pesticide and Climatic Stress: Effects of Imidacloprid, Elevated Temperatures, and Heatwaves

Markus Hermann[1], *Francesco Polazzo*[2,3], *Melina Crettaz*[2], *Ariadna García-Astillero Honrado*[2], *Edwin Peeters*[1], *Andreu Rico*[2] *and Paul van den Brink*[4], *(1)Aquatic Ecology and Water Quality Management, Wageningen University & Research, Netherlands, (2)IMDEA Water Institute, Spain, (3)Evolutionary Biology and Environmental Studies, University of Zurich, Switzerland, (4)Wageningen University & Research, Netherlands*

An increase in mean temperatures and higher severity and frequency of weather extremes, like heatwaves (HWs), are anticipated environmental changes in Europe under future global climate change (GCC), particularly in the Mediterranean. These climate alterations in daily temperature ranges and heat extremes will affect freshwater ecosystems and ectotherms that live within them. Because temperature per se may not only act as isolated perturbation, complex stressor interactions, like with pesticides, may lead to still unknown effects. Few multiple stressor studies investigated GCC-related temperature scenarios and chemical effects on population-, community-, or ecosystem-level. Among these studies, environmental realism regarding daily temperature fluctuations and thus natural variability are barely considered in experimental designs. Thus, our study goal was to investigate the multiple stressor effects of changing, elevated temperatures, HWs, and the neonicotinoid insecticide imidacloprid on Mediterranean freshwater ecosystems. We studied various ecosystem endpoints on different trophic levels. Multiple stressor effects on ecosystem processes and functioning were assessed by investigating stressor-induced alterations in community dynamics and structure, population dynamics, biomass dry-weight, and physicochemical water parameters. Finally, we built a structural equation model (SEM) to reveal direct and indirect food web effects and ecological effect chains.

Temperature was successfully controlled with the "Transportable temperature and heatwave control device" (TENTACLE) with an observed increase of the ambient temperature from April to July, ranging +15 to 30°C. Imidacloprid showed a temperature-dependent fate in water with the highest DT50-values under ambient temperatures whereas the lowest were noted under HWs. Zooplankton community analyses presented significantly 35% of the variation in species composition (p=0.02) due to imidacloprid and temperature treatments. While imidacloprid as isolated stressor showed no significant community effects, significantly adverse effects of HWs in the presence and absence of imidacloprid were noted during the first two HWs followed by recovery dynamics. Individual population dynamics, such as of the rotifer Polyartha and Cyclopoids, presented significantly adverse effects. Besides direct effects, our SEM showed ecological effect chains through significantly negative relationships across trophic levels of the food web.

2.07.P-Mo124 Ecosystem Resilience and Recovery of a Natural Saline Lake in Response to a Supra-Seasonal Drought

Lizaan de Necker[1,2], *Luc Brendonck*[3,4], *Ruan Gerber*[4], *Victor Wepener*[4] *and* ***Nicholas J Smit***[5], *(1)North-West University, South Africa, (2)South African Institute for Aquatic Biodiversity, South Africa, (3)University of Leuven, Animal Ecology, Global Change and Sustainable Development, Belgium, (4)Water Research Group, North-West University, South Africa, (5)Water Research Group, Unit for Environmental Sciences and Management, North-West University, South Africa*

Global climate change threatens aquatic ecosystems by altering rainfall patterns, air temperatures, and the severity and frequency of natural disasters such as floods and droughts. Natural saline lakes have great ecological importance but are overlooked in conservation efforts as their economic value is not well-understood. The primary threats to these natural saline lakes are climate- and anthropogenic-induced alterations to their hydrology and salinity, leading to modifications in their biodiversity and ecological functions. Lake Nyamithi is one of South Africa's only natural saline lakes and is threatened by legacy pollutants, climate change, regulation of water flow, and invasive species. Between 2015 and 2016, South Africa experienced one of the most severe droughts ever recorded and this study aimed to investigate the possible effects of the drought on the aquatic invertebrate and fish communities of Lake Nyamithi. Aquatic invertebrates and water samples were collected for biodiversity and water quality analyses respectively during pre-drought, peak drought, and recovery conditions while fishes and potential basal sources were collected during the predrought and recovery conditions. Various univariate and multivariate analytical techniques were used to assess aquatic invertebrate community structure and the $\delta^{13}C$ and $\delta^{15}N$ values of food web elements and fish were analysed using Bayesian mixing models and Bayesian Laymen metrics to investigate the fish community and the contribution of basal sources to the fishes' diets. The salinity of the lake increased three-fold from the predrought (±3 $g.L^{-1}$) to the drought (±10 $g.L^{-1}$) with a consequent reduction in taxon richness of both aquatic invertebrates and fishes, including invasive species, as few taxa were able to tolerate the severely increased salinity. Several aquatic biota were able to (re)colonise the lake, excluding invasive species, once it received water and salinity decreased (<8 $g.L^{-1}$). Although the food webs were similar between the pre-drought and recovery periods, the drought altered the basal food web from a C_3 to C_4-dominated structure. Fish consumers adapted their diet accordingly by shifting their reliance from C_3 to C_4 basal sources. These findings demonstrate not only the environmental resilience of Lake Nyamithi and the biological plasticity of its aquatic biota but the importance of freshwater inflow to the continued functioning of natural saline lakes.

2.08 Ecosystems Responses Under a Multiple Stressors Scenario in a Rapidly Changing Climate (Part III: Environnemental Risk, Modelling, Ecosystem-Level)

2.08.T-01 How a Data-Driven Stochastic Model Helps to Predict Micropollutant Discharges to Surface Saters

Lena Mutzner[1] *and Luca Vezzaro*[2]*, (1)Urban Water Management, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Dübendorf, Switzerland, (2)Department of Environmental and Resource Engineering, Technical University of Denmark (DTU), Lyngby, Denmark*

Urban wet-weather discharges (combined sewer overflows, CSO and stormwater outlets from separate sewers, SWO) contain various micropollutants which can negatively impact surface water quality. Recent work highlights that micropollutant discharges show a high spatiotemporal variability, which challenges the prediction of potentially toxic impacts to surface waters. Stochastic models based on known distributions can help in handling this inherent variability. We analyzed monitoring data from 77 CSO and SWO sites to estimate: i) the variability among sites and ii) predict micropollutant concentrations along a river with a stochastic model. The results show how we can make a first estimate of the impact of wet-weather discharges on receiving waters without site-specific micropollutant information, which is useful for regulators and utilities as a step toward zero pollution.

2.08.T-02 Integration of Climate Model Projections and Pesticide Application Scenarios for Probabilistic Risk Assessment with a Bayesian Network Model

Jannicke Moe[1]*, Sophie Mentzel*[1]*, Rasmus Benestad*[2]*, John Daniel Hader*[3]*, Rory Nathan*[4]*, Rik Oldenkamp*[5] *and Wayne G. Landis*[6]*, (1)Norwegian Institute for Water Research (NIVA), Norway, (2)Norwegian Meteorological Institute, Norway, (3)Stockholm University, Sweden, (4)Engineering and IT, University of Melbourne, Australia, (5)Vrije University Amsterdam, Netherlands, (6)Western Washington University*

We present a Northern European case study from the recent SETAC Pellston workshop on integration of global climate change (GCC) modeling into ecological risk assessment. In Northern Europe, global climate change (GCC) is expected to result in increased temperature and precipitation. The changes in weather patterns are expected to increase the occurrence of crop pests such as weeds, fungal disease, and insect pests. Increased pest pressures can in turn be expected to then alter agricultural practices such as the frequency and combination of pesticide applications. Additionally, climate change may potentially have more direct effects on the environmental exposures in the transport, fate, and degradation of pesticides.

A Bayesian network (BN) has previously been developed as a meta-model for incorporating future climate projections and pesticide application scenarios with information from toxic effects data to support environmental risk assessment for streams in agricultural areas. This BN model was initially parameterized for a Norwegian case study with predicted environmental concentrations from a processed-based pesticide exposure model and species sensitivity distributions derived from toxicity tests data.

Within the Pellston workshop, we aimed to improve the existing BN model by incorporating more recent and realistic climate change scenarios, a higher number of climate models, and better methods for regional downscaling. An exposure prediction model was run with alternative climate model that accounted for specific environmental factors linked to the study area, chemical properties of the pesticides, and more realistic pesticide application scenarios. Our experiences from this case study will aid efforts to better account for uncertainty related to climate change in exposure modeling, effect assessment, and risk characterization. The graphical display of the BN model approach can also aid communication of risk under climate change scenarios to stakeholders such as policy makers and regulators.

2.08.T-03 Chemical Pollution: An Overlooked Elephant in the Room of Ecology – Publication Patterns Reveal a Low Connection Between Chemical Pollution and Biodiversity Research

Since the onset of the Anthropocene, anthropogenic drivers including changes in land use, climate change, invasion of alien species, and chemical pollution have played a central role in the degradation of ecosystems and loss of biodiversity globally.

In the case of chemical pollution, six decades of ecotoxicological research have yielded tens of thousands of scientific papers. In order to analyze general research and publication patterns on chemical pollution, we conducted two Scopus searches. The first search used several synonyms of "chemical pollution" to target papers published since 1992. The second search (ecological search) imposed variants of the terms "ecology" or "ecosystem" to the title, abstract, or keywords to capture studies that were related to ecology or ecosystems. We compared these results with similar searches for other drivers and biodiversity loss, and found that while drivers such as climate change and habitat loss have been readily embraced by general ecological research, chemical pollution remains surprisingly under-assessed and hence remains as an overlooked elephant in the room of ecology. Detailed inspection of the results of the ecological search showed that a large proportion of the studies on chemical pollution lack sufficient experimental, field, or analysis complexity that are necessary to enable derivation of true ecological implications. Instead, many papers seem to have mentioned ecology or ecosystems merely to frame the study within a wider context.

Chemical pollution papers have been published in a narrow selection of specialised journals that rarely publish articles on other topics. Few ecological journals are in this set. This shows that, while research on chemical pollution is very prolific, it has thus far been conducted using a single-discipline approach and predominantly in disconnection from general ecology. The rich extensive scientific literature base, methodological arsenal developed during decades of ecotoxicological research, and increasing political and international commitment on the topic provide a powerful platform to promote a higher degree of interdisciplinarity in chemical pollution research. This is pressingly needed to deliver science that better informs political and regulatory action for the protection of Earth's ecosystems and biodiversity.

2.08.T-04 How Will Climate Change Affect the Distribution of Macroinvertebrates in European Surface Waters and their Sensitivity to Chemical Pollution?

***Andreu Rico**[1], Sami Domisch[2], Martina Flörke[3], Paul van den Brink[4], Sanne Berg[4] and Francesco Polazzo[5], (1)Cavanilles Institute of Biodiversity and Evolutionary Biology, University of Valencia, Spain, (2)Institute of Freshwater Ecology and Inland Fisheries (IGB), Germany, (3)Ruhr University Bochum, Germany, (4)Wageningen University & Research, Netherlands, (5)IMDEA Water Institute, Spain*
Climate change is predicted to have profound impacts on freshwater ecosystems due to rising temperatures and altered hydrological regimes. Particularly, extreme events have been shown to deeply influence freshwater biota, but how they will influence the distribution of freshwater organisms at the European scale remains an open question. Using an ensemble of bioclimatic envelope models (BEMs) considering future climatic and hydrological changes, we modelled the climatic suitability of 286 stream macroinvertebrate genera across Europe for 2050 and 2080 using a spatial resolution of 5 arc minutes. We first studied how macroinvertebrate taxa will shift their distribution and how this is reflected in terms of taxa gains/losses across Europe. Then, we used biological traits to assess whether the changes in taxa distribution are mirrored by shifts in functional richness. Finally, we analyzed how the relative portion of sensitive taxa to different chemical groups (i.e., narcotics, acetylcholinesterase (AChE) inhibitors, ion/osmoregulatory/circulatory (IOC) impairment chemicals, neurotoxicants, reactive substances, and electron transport inhibitors) will shift due to climate change using taxonomy-based and biological trait-sensitivity models. We found that climate change will result in a loss of suitable habitats for a large part of the modelled taxa in the southern and eastern parts of Europe, while a general increase in habitat suitability is expected in the Northern part of the continent. Yet, these large changes in habitat suitability did not result on marked changes in functional richness in our analysis, suggesting that functional redundancy will play a significant role in the delivery of ecosystem functions in the future. Finally, changes in the relative distribution of sensitive taxa will strongly depend on the chemical group considered. For most chemical groups, the changes in relative number of sensitive taxa were only moderate ($<10\%$). However, two chemical groups (i.e., AChE

and IOC impairment) show strong differences between the present and the future scenarios. This study shows that abiotic factors related to global climate change can influence distribution patterns of freshwater macroinvertebrates and the relative sensitivity of macroinvertebrate species assemblages to chemical exposure. This suggests that water quality monitoring tools and risk assessment should consider the variation in species distribution related to global climate change.

2.08.T-05 Climate Change and Pesticides Century-Long Impact on Freshwater Functional Biodiversity
Niamh Eastwood[1]*, Jiarui Zhou*[2]*, William A. Stubbings*[1]*, Mohamed Abou-Elwafa Abdallah*[1]*, Thomas Davidson*[3] *and Luisa Orsini*[1]*, (1)University of Birmingham, United Kingdom, (2)School of Biosciences, University of Birmingham, United Kingdom, (3)Aarhus University, Denmark*
Biodiversity supports diverse ecosystem functions and services, yet is threatened globally by anthropogenic environmental change such as chemical pollution, climate change and land use change.

These abiotic factors occur and interact over decade-to-century long timescales and the effects are therefore difficult to study directly. Furthermore, shorter term studies begin from an already shifted baseline of community assemblage and may miss longer term trends. Here, we have used a sedimentary archive from a lake with a well-known history of chemical pollution and climate change spanning the past 100 years. We have reconstructed the community-wide responses to environmental change using multimarker sedDNA metabarcoding and reconstructed functional ecosystem changes using KEGG pathways reconstructed from the lake bacterial community.
We study 100 years of community-level biodiversity, climate change and chemical pollution trends. We apply explainable network models with multimodal learning to community-level functional biodiversity, to establish correlations with biocides and climate change records. We identify the top individual abiotic factors and combinations of chemical and climate factors with adverse effects on functional biodiversity. The freshwater community assemblage and functionality changed over time without returning to its original state, even if the lake partially recovered in recent times. Insecticides and fungicides, combined with extreme temperature events and precipitations, explained up to 90% of the functional biodiversity changes. Community-level biodiversity reliably explained freshwater ecosystem shifts whereas traditional quality indices and indicator species proved to be poor metrics for these shifts. The ranking of individual chemicals enables the identification of priority targets for regulation of chemicals with adverse effects on biodiversity.

2.08.P Ecosystems Responses Under a Multiple Stressors Scenario in a Rapidly Changing Climate (Part III: Environnemental Risk, Modelling, Ecosystem-Level)

2.08.P-Mo125 Emissions of Organic Micropollutants and Antibiotic-Resistant Bacteria via Different Urban Entry Pathways
Liza-Marie Beckers[1]*, Joscha Stiedl*[2]*, Sandro Castronovo*[3]*, Björn Jacobs*[1]*, Manoj Schulz*[1]*, Georg Reifferscheid*[2] *and Arne Wick*[3]*, (1)Aquatic Chemistry, Federal Institute of Hydrology (BfG), Koblenz, Germany, (2)Biochemistry and Ecotoxicology, Federal Institute of Hydrology (BfG), Koblenz, Germany, (3)G2-Aquatic Chemistry, German Federal Institute of Hydrology, Germany*
Micropollutants as well as pathogens including antibiotic-resistant bacteria (ARB) and antibiotic resistant genes (ARG) can enter surface waters via wastewater treatment plants (WWTP). However, also, combined sewer overflows (CSO) and rain sewers can be relevant entry pathways for these contaminants and might gain increasing importance due to an expected higher frequency of heavy rain events as a result of climate change. Thus, the aim of this study is to assess the relevance of different entry pathways of pollutants, ARB and ARG. A monitoring concept was designed and applied in Koblenz (Germany) allowing for the event-based, simultaneous sampling and analysis of organic micropollutants, metals as well as ARB and ARG. The sampling strategy includes i) flow-proportional 24-hours composite samples over the course of one week at a WWTP effluent and ii) automatic event-based, flow-proportional sampling at a CSO and a rain sewer. About 70 organic micropollutants are analyzed in the dissolved and particle phase using multi-target methods by liquid chromatography coupled to tandem-mass spectrometry (LC-MS/MS). Furthermore, metals and polyaromatic hydrocarbons (PAHs) are analyzed according to ISO guidelines. ARG and ARB are determined i) qualitatively by selective agar plates and antibiograms, and ii) quantitatively by qPCR and modern full length-16S sequencing. Results from first sampling campaigns of a WWTP effluent and a CSO event show clear differences in pollutant concentrations as well as microbial communities and presence of ARB and ARG. In the WWTP effluent, higher concentrations of organic micropollutants associated with domestic wastewater were detected with the exception of compounds with a high degradation potential (e.g., ibuprofen) and compounds associated with outdoor applications (e.g., mecoprop). In the CSO sample, higher concentrations of PAHs and metals as well as a higher bacterial burden were detected. Pollutant loads were generally higher in the WWTP effluent. Still, the CSO represents a considerable and for some pollutants and pathogens an exclusive emission source. The monitoring will be extended to additional monitoring sites, non-target analysis as well as further events and seasons allowing for a comprehensive characterisation and assessment of different entry pathways and evaluation of correlations among the occurrence of pollutants and antibiotic resistance.

2.08.P-Mo126 Measured Peak Concentrations of Organic Micropollutants during Combined Sewer Overflows
Viviane Furrer[1]*, Heinz Singer*[2] *and Christoph Ort*[2]*, (1)SWW, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Dübendorf, Switzerland, (2)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Dübendorf, Switzerland*
Combined sewer overflows (CSOs) are a pathway of wastewater and stormwater into open water bodies, where they can have toxicological effects on the aquatic environment. Combined sewage is a mixture of a large number of organic micropollutants

(MPs) applied either indoors or outdoors with strongly fluctuating concentrations due to variation in use patterns at the source and dilution. Previous studies showed that the toxicity of fluctuating concentrations can be higher than their average and that the toxicity can depend on the sequence in which the substances occur. Furthermore, a mixture can be toxic even though the single substances lie below the toxicity thresholds. Hence, a comprehensive risk assessment requires the consideration of the complete mixture of MPs at high temporal resolution. However, most studies measuring MPs in CSOs analysed event mean concentrations. Therefore, we aim to quantify the concentrations of a large set of organic MPs (300 targets) in CSOs at high temporal resolution as input for a more comprehensive toxicity analysis and to identify discharge mitigation measures.

For this, we sampled and analysed polar organic MPs at two CSO sites in Switzerland. At the first site, we measured three overflow events with a field deployable mass spectrometer delivering 20 minutes resolution data. For seven more events at site 1 and 10 events at site 2 we used automated samplers and LC-HRMS analysis in the lab, to generate 10 minutes composite samples (based on 2 min grab samples). The samples were analysed for 300 target substances representing different sources, out of which 63 were evaluated so far.

The results show that the organic MP concentrations can vary strongly during an overflow event. This is especially true for small catchments and substances coming from sources with high variation, such as pharmaceuticals. Furthermore, we could find 51 out of 63 target substances so far, which indicates that combined sewage consists of many different organic micropollutants with diverse temporal profiles.

This analysis delivers a unique dataset showing the sequence and concentration levels of peaks for a large number of organic MPs at CSOs. The results will serve as a realistic exposure scenario and help to design more realistic toxicity assessments.

2.08.P-Mo127 Pathways of Biocides in an Exemplary Urban Catchment: Impact of Combined Sewer Overflows and Storm Water Outlets on Surface Water Pollution

Korinna Ziegler[1]*, Christiane Meier*[1]*, Stephan Fuchs*[2]*, Lukas Kopp*[2] *and Frank Sacher*[3]*, (1)German Environment Agency (UBA), Dessau-Rosslau, Germany, (2)Karlsruhe Institute of Technology (KIT), Germany, (3)TZW DVGW (German Water Centre), Germany*

Biocides have a widespread use in urban areas (e.g., disinfectants, material preservatives, and pest control products) and can enter the environment through multiple pathways. In urban areas the sewer system is the main entry pathway for a large number of substances from different sources like households, industry, and road runoff. Substances, among them biocides, are often discharged directly into surface waters via storm water outlets and combined sewer overflows without any treatment. Numerous studies show that these substances can frequently be detected and therefore influence surface water quality. However, the discharge of biocides into surface waters via effluents of sewage treatment plants (STP) and combined sewer overflows (CSO) is little investigated. Therefore, the German Environment Agency (UBA) initiated a project to investigate the impact of different urban entry paths on river water contamination with biocides in an exemplary urban catchment in Germany. For this study a number of sampling sites were selected in the city of Karlsruhe to examine the river Alb, the effluent of the municipal wastewater treatment plant, storm water outlets, and combined sewer overflows. Based on criteria like physicochemical properties, ecotoxicity, and relevance for surface water pollution a total of 42 biocidal active substances and transformation products (mainly disinfectants, material preservatives, and pest control products) were prioritized and will be analyzed in about 130 samples over a period of a year. Preliminary results show that about 26 biocides and transformation products were detected in a large number of samples. Mainly biocides used as material preservatives, e.g., carbendazim, diuron, and terbutryn, were found in nearly all samples of the different sampling sites, whereas other substances, for example the pyrethroid permethrin was mostly found in CSO samples. Furthermore, to assess the relevance for surface water contamination the exceedances of the environmental quality standards (EQS) or the predicted no effect concentrations (PNEC) were examined in this project and show exceedances, e.g., for the substances imidacloprid (STP effluent) and permethrin (CSO). The project provided important insights into the occurrence of biocides in urban runoff components and identified combined sewer overflows as a relevant emission pathway in urban areas.

2.08.P-Mo128 Comparative Assessment of the Ecotoxicity of Rainwater Runoff Originating from a Highway and a Low-Traffic Zone

***Gert De De Keersmaeker** and Karel De Schamphelaere, Ghent University - GhEnToxLab, Ghent, Belgium*

Rainwater runoff is receiving increased attention as a potential vector of inorganic and organic pollution toward surface water. In particular, concerns are being raised about the impact of transported heavy metals and transformation products from tire wear particles. Furthermore, climate change could potentially alter this impact, especially in regions where it will manifest as more intense precipitation events combined with longer dry periods. For the purpose of this explorative assessment, runoff samples at a highway junction and a low-traffic residential area were taken in the vicinity of Ghent, Belgium. Each sample consisted of 5 consecutive subsamples, with the purpose to investigate the existence of a so-called first-flush effect. Organics present in the subsamples were extracted via a mildly hydrophobic Chromabond HR-X Solid Phase Extraction (SPE) resin, and metals concentrations were determined via Inductively Coupled Plasma Optical Emission Spectroscopy (ICP-OES) measurements. Additionally, the toxicity of the extracted organic compounds was assessed using a 72-hour algae growth inhibition assay using *Raphidocelis subcapitata*. The generated data were used to compare the two sample locations as well as to assess the existence of a first-flush effect. Finally, further research pathways and assessment refinement options are discussed.

2.08.P-Mo129 Molecular Tool Shows Effects of Extreme Weather Events in Aquatic Quality Monitoring

Marlea H.A.B. Wagelmans[1]*, Jari Claassen*[2] *and Marc van Bemmel*[3]*, (1)Rijkswaterstaat, Netherlands, (2)RWS-WMCN, Lelystad, Netherlands, (3)Orvion*

The Netherlands is a delta of a total of four international rivers. Rijkswaterstaat is responsible for the aquatic quality in the large rivers, lakes, and the coastal areas.

Rijkswaterstaat has started a pilot to assess the applicability of Next Generation Sequencing (NGS) to monitor the effects of chemicals and weather on the aquatic ecosystem as well as the resilience of the aquatic system in case of incidents and extreme weather conditions. The pilot is being performed at the border laboratory in the Meuse. Each month a water sample is taken and analyzed by means of NGS. This characterizes all known bacteria and archaea and gives a clear overview of the biodiversity in the river. The biodiversity is compared with the results of the chemical analyses and the flow-through bioassays that are regularly performed at the border laboratory as well as climatic conditions. During the pilot we will gain insight into the annual fluctuations of the biodiversity. The pilot has been running for over 1.5 years now. During this period we have had some extreme weather events: summer flooding in July 2021 and extreme drought in July and August 2022. This resulted in changed conditions in the river. The microbial populations have been changed as a result of this, showing that the microbial population is not only influenced by chemical conditions but also by (extreme) weather conditions.

2.08.P-Mo130 A Bayesian Network Approach to Assess the Impacts of Climate Change and the ´Farm-to-Fork´ Strategy on the Ecological Risks of Pesticides in a Protected Mediterranean Wetland

Andreu Rico[1]*, Sophie Mentzel*[2]*, Yasser Fuentes-Edfuf*[3]*, Jannicke Moe*[2] *and Claudia Martínez*[4]*, (1)Cavanilles Institute of Biodiversity and Evolutionary Biology, University of Valencia, Spain, (2)Norwegian Institute for Water Research (NIVA), Norway, (3)IE Business School, Spain, (4)IMDEA Water Institute, Spain*

Pollution by agricultural pesticides is one of the most important pressures affecting Mediterranean coastal wetlands. Pesticide risks are expected to be influenced by climate change, which will result in an increase of temperatures and a decrease in annual precipitation in these areas. These future climate prospects could also increase the prevalence of agricultural pests, which may result in an increase of pesticide dosages by farmers. On the other hand, the European ´Farm-to-Fork´ strategy promotes the 50% reduction of pesticide usage by 2030. The influence of climate change and pesticide management measures on pesticide risks need to be evaluated making use of realistic environmental scenarios. This study aimed to assess how different climate change and pesticide use scenarios affect the ecological risks of pesticides in the Albufera Natural Park, a protected Mediterranean coastal wetland. We performed a probabilistic risk assessment for nine pesticides applied in rice production using scenarios comprised of three climatic regimes (the 2008 record and projections for 2050 and 2100), three pesticide application regimes (the recommended dose, and 50% increase and 50% decrease), and their combinations. The scenarios were used to simulate pesticide exposure concentrations in the water column of the rice paddies using the RICEWQ model. The pesticide effects were assessed using acute and chronic Species Sensitivity Distributions (SSDs) built with laboratory toxicity data for aquatic organisms. Risk Quotients were calculated as probability distributions using a Bayesian network approach, using best fitting distributions for the calculated exposure data and SSDs. Our results show that future climate projections will influence exposure concentrations for some of the studied pesticides, yielding higher dissipation and lower exposure and risks in scenarios dominated by an increase of temperatures. Management measures such as those dictated by the European ´Farm-to-Fork´ strategy are crucial to reduce risks in Mediterranean coastal wetlands but will need additional protection measures. Our case study shows that pesticides such as azoxystrobin, difenoconazole and MCPA are posing high ecological risks and should be further monitored in Mediterranean coastal wetlands surrounded by intensive rice farming.

2.08.P-Mo131 Climate Change Impacts in EstaRRejA Region – The TERRA Project

Ana Rita R. Silva[1]*, M. Nazaret Gonzalez-Alcaraz*[2]*, Marija Prodana*[3]*, Patricia V. Silva*[4]*, José Nereu Pinto*[3] *and* ***Susana Loureiro***[3]*, (1)University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Aveiro, Portugal, (2)Agronomic Engineering, Technical University of Cartagena, Spain, (3)CESAM & Department of Biology, University of Aveiro, Aveiro, Portugal, (4)Department of Materials and Ceramic Engineering & CICECO - Aveiro Institute of Materials, University of Aveiro, Aveiro, Portugal*

Over the last years, great efforts have been made to tackle the climate crisis; however, climate change continues to impact our planet. According to the Intergovernmental Panel on Climate Change (IPCC) predictions, atmospheric CO_2 levels and mean temperature are expected to rise continuously, inducing an increase in the frequency, intensity, and duration of extreme weather events (e.g., droughts and floods). The impact of climate change may be exacerbated in contaminated areas, like those in proximity to industrial chemical complexes, where the ecosystems might be under long-term multiple pressures. The Industrial Chemical Complex in Estarreja, in northern Portugal, has been operating for more than half-century and is one example of a historically contaminated area. Considering the reported increase of worldwide extreme climate event frequency in the last years, the project TERRA aims at understanding the effects of climate change alterations on terrestrial and aquatic ecosystems using as a case study the contaminated soils area in Estarreja. For that, extreme climate events, considering climate change scenarios predicted by IPCC (including changes in combined climate factors), will be simulated to evaluate their effects on the ecotoxicity in terrestrial and aquatic organisms. Moreover, soil/water properties (e.g., pH, chemical content, soil organic carbon) will be evaluated to establish the link between soil/water characteristics and potential ecotoxicological effects under changing climate factors. Additionally, TERRA intends to understand the dynamics behind the contamination in the Estarreja region by evaluating contamination levels in this area and comparing with previous studies conducted more than five years ago. TERRA will provide crucial data for Portugal and the world regarding the consequences of climate change in contaminated areas. The present project will also promote easy and active communication with society, with the final aim of increasing awareness about climate change and its environmental impacts.

2.08.P-Mo132 Integrating Expertise on Climate Modeling and Environmental Risk Assessment: A SETAC Pellston Workshop in the Oslo Fjord

Jannicke Moe[1]*, Alistair B.A. Boxall*[2]*, Kevin Brix*[3]*, Wayne G. Landis*[4]*, Jennifer Stauber*[5]*, Samuel Welch*[1] *and Ralph G. Stahl Jr.*[6]*, (1)Norwegian Institute for Water Research (NIVA), Norway, (2)University of York, United Kingdom, (3)EcoTox LLC, (4)Western Washington University, (5)CSIRO, Australia, (6)DuPont (retired)*

A SETAC Pellston workshop was organized 20-24 June 2022 near Oslo, Norway, with the topic "Incorporating climate change model predictions into ecological risk assessments to help inform risk management, adaptation, and mitigation strategies". SETAC Pellston workshops in general aim to bring together environmental professionals from academia, government, industry/business, and NGOs to advance the state of knowledge and identify solutions for pressing environmental challenges. The goals of this workshop were:

1. To bring leading practitioners in global climate change (GCC) science and ecological risk assessment together to catalyze and solidify future workings across the two communities.
2. Develop methods for incorporating GCC science into ecological risk assessment frameworks to ensure that they address current and potential future risks, whether for chemicals or other stressors.
3. Communicate the conclusions to key stakeholders including the IPCC, national and international governmental organizations, and researchers to establish SETAC as a key partner in GCC science.

An important purpose of this workshop was thus to involve expertise on climate modeling as well as expertise on chemistry, toxicology, and environmental risk assessment. Approximately 20 scientists were invited to the workshop to provide a balance of expertise as well as sectors, geographical locations, genders, and career stages. The workshop location Oscarsborg is a historical fortress located on a small island in the Oslo fjord, selected in line with the principle of holding SETAC Pellston workshops in secluded locations to encourage focused attention from participants. Nevertheless, real-time online participation was offered as an alternative to in-person attendance when necessary. This poster will focus on the workshop organisation and expertise, while the scientific outcome of the workshop will be reported in other presentations in this session.

2.08.V Ecosystems Responses Under a Multiple Stressors Scenario in a Rapidly Changing Climate (Part III: Environnemental Risk, Modelling, Ecosystem-Level)

2.08.V-01 Climate Change and Atmospheric Deposition as Drivers of Forest Ecosystem Integrity and Services: A Modelling Approach Crossing Different Spatial Scales

Stefan Nickel[1]*, **Winfried Schröder**[1,2] and Martin Jenssen*[3]*, (1)Planwerk, Germany, (2)Faculty II, University of Vechta, Chair of Landscape Ecology, Germany, (3)Evangelische Johanniter-Schulen Wriezen, Wriezen, Germany*

Action 5 of the EU Biodiversity Strategy calls Member States to map and assess the condition of ecosystems and their services. Therefore, we developed a spatial explicit methodology for assessing and classifying forest ecosystem integrity under conditions of climate change and nitrogen deposition. The methodology presented covers three spatial levels: the nation-wide level (Germany), the regional (exemplified by the Kellerwald National Parc) and the site level in terms of forest stands representing forest types. These were derived from vegetation and soil data covering about 22 000 forest stands. Based on this, the methodology enables to determine whether the conditions of forest ecosystem types differ between that in a reference period (1960-1990) from current (1991-2010) and potential future ecosystems conditions (2011-2070). The deviances of ecosystem integrity indicators from the reference states were quantified on an ordinal scale from very low to very high enabling to estimate at three spatial levels whether an ecosystem type will get extinct and replaced by another one or not. The first step investigated at the national level whether the spatial pattern of these forest types is expected to be stable over time compared to the reference period or whether spatial shifts and extinction of forest types are likely to occur. This analysis indicated,that up to 2070 the areal coverage of forest ecosystem types at montane and altimontane levels will decrease while that of ecosystem types in Atlantic and sub-Atlantic ecoregions will increase. Respective statistics were computed for the EUNIS and FFH ecosystem classification as well as for threatened plant species and their biotopes. Using 14 indicators for 6 ecosystem functions, historical reference conditions were quantified for 60 forest ecosystem types. The comparison with current and potential future ecosystem conditions enabled the ordinally scaled classification of ecosystem integrity at the level of indicators, functions, and ecosystem types. Projections of expected ecosystem changes were based on: 1. Dynamic modelling of soil indicators considering climate change and anthropogenic nitrogen deposition at the site level; 2. Fuzzy modelling and mapping soil moisture; and 3. Rule-based classification and GIS-Mapping of ecosystem services.

2.09 Ecotoxicology of Biota Inhabiting Wetland Ecosystems

2.09.P-We072 Microplastic Contamination of Water and Tadpoles in Amphibian Breeding Pools in Scotland (UK)

Chloe Houseman[1]*, Jeanette Rotchell*[2] *and **Frances Orton**[3]*, (1)School of Health and Life Sciences, University of the West of Scotland, United Kingdom, (2)University of Hull, United Kingdom, (3)UK Centre for Ecology & Hydrology (UKCEH), United Kingdom*

Microplastic (MP) contamination has been widely reported across a range of aquatic environments and their compartments including in water, sediments, and biota. There are indications that small freshwaters (SFWs) such as ponds may be highly contaminated with MPs due to their low volumes combined with close proximity to MP sources, such as domestic wastewater inflows, urban run-off, and agricultural land. Amphibians are one of the most common vertebrates to inhabit SFWs. In this study, we first investigated MP contamination of amphibian breeding pools *via* water, sediment, and internal levels (common toad [*Bufo bufo*] tadpoles). We then analysed for relationships between MP abundance and surrounding land use characteristics (Geographic Information systems approach) to identify possible sources of contamination. To characterise land use, we used QGIS (3.28) using a buffer zone of 0.5 miles around the shoreline of each pond, and associations between land types and MP contamination levels were analysed (Generalised Linear Mixed Modelling). Finally, we analysed for correlations (Spearman Rank correlation) between internal MP levels and tadpole development (body mass, length). Water and sediment samples were collected from nine ponds across the central belt of Scotland at four-time points in Spring 2021. Where found (n = 4 ponds), 20 tadpoles were collected *per* pond on the third and fourth visits. The levels of MPs found across all site characterisations ranged between 0–30 items/L in water and 12–1484 items/kg in sediments. Tadpoles also contained MPs ranging between 0 – 163 items/g tissue (0 – 19 items/individual). MP abundance in sediments was positively correlated with the proportion of land cover characterised as industrial (R^2 = 0.037; p = 0.002) or as pasture (R^2 = 0.024; p = 0.011). In tadpoles, the vast majority of MPs were found in the gut (81.26 %, n = 464) compared to the liver (8.06 %, n = 46), and carcass (10.68 %, n = 61), suggesting dietary uptake. Across all sites, a significant negative correlation (p < 0.01) was found between tadpole MP abundance and body mass (R^2 = -0.1135), total length (R^2 = -0.1587) and snout-vent length (R^2 = -0.1805), suggesting that MPs may be negatively impacting wild tadpole health. These results provide important insights into the extent of MP pollution in SFWs, which currently do not form part of routine water quality monitoring, as well as potential links between MP ingestion and health endpoints in wild amphibians.

2.09.P-We073 Impact of Pesticide Overspray on Amphibians and the use of Earthworms as Surrogates for Evaluating its Effects

Samuel González López[1]*, Daniele Marini*[2]*, Sara Costa*[3]*, Cecilia Dall'Aglio*[2]*, Isabel Lopes*[4]*, João Pimenta*[5] *and Manuel Ortiz Santaliestra*[6]*, (1)Instituto de Investigación en Recursos Cinegéticos (UCLM-CSIC-JCCM), Spain, (2)Department of Veterinary Medicine, University of Perugia, Italy, (3)University of Aveiro, Aveiro, Portugal, (4)University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Aveiro, Portugal, (5)School of Science and Technology, University of Évora, Évora, Portugal, (6)Instituto de Investigación en Recursos Cinegéticos (IREC) CSIC-UCLM-JCCM, Spain*

Amphibians are the most threatened group of vertebrates, and the impact of pesticides has been pointed as one of their main threats. However, amphibians are not generally included in the environmental risk assessment of pesticides, assuming that the evaluation conducted on other vertebrate taxa grants them protection. This assumption raises concern, considering the differences in structure and function of amphibian skin with respect to the integument of other groups. Here, we studied the effects of overspray with the current-use fungicide oxathiapiprolin on juvenile frogs (*Pelophylax perezi*) and in adult earthworms (*Eisenia andrei*), with the aim of evaluating their suitability as a surrogate invertebrate species for amphibians and therefore promote the reduction and replacement of vertebrate use in ecotoxicity experimentation. To do so, froglets and earthworms were grown in the laboratory and exposed by overspray using a pump calibrated to simulate realistic pesticide application regimes. Amphibian assays included two individuals per replicate that were processed on days 7 and 21 postexposure for histological examination, whereas earthworm assays were run for 72 hours. We also recorded survivorship and changes in body condition. In amphibians, mortality was higher in the oxathiapiprolin-treated groups than in the negative control group, but the differences were not significant. Besides, a reduction in the body condition of frogs exposed to oxathiapiprolin was noted relative to negative control frogs on day 7. On the other hand, exposure to oxathiapiprolin caused no mortality in adult earthworms and no effects on their weight. Regarding effects on the tissues, the analysis of H&E-stained histological sections from frogs on day 7 postexposure showed subdermal interstitial tissues of an intense black resembling melanin accumulation and enlarged pigmented macrophage centres. This marked pigmentation could be a physiological response to damage directly or indirectly produced by oxathiapiprolin. Furthermore, exposure to oxathiapiprolin caused macroscopic lesions in the skin of earthworms. The fact that there is an effect in the tissues after pesticide overspray in both organisms suggests that earthworms could be fitting as surrogates for amphibians regarding dermal toxicity. The results add valuable data on the toxicity of current-use pesticides on amphibians.

2.09.P-We077 Water Quality and Land-Use Impacts on Development of Larval Amphibians in the UK

Frances Orton[1]*, Chloe Houseman*[2]*, John Howieson*[3]*, Catherine Helen Whatley*[4] *and Charles Tyler*[5]*, (1)UK Centre for Ecology & Hydrology (UKCEH), United Kingdom, (2)School of Health and Life Sciences, University of the West of Scotland, United Kingdom, (3)School of Life Sciences, University of the West of Scotland, United Kingdom, (4)School of Science and Sport, University of the West of Scotland, United Kingdom, (5)University of Exeter, United Kingdom*

When last assessed in 2004, 32% of amphibian species were threatened with extinction, and at least 43% were in decline, which is faster than any other vertebrate group. As the vast majority of amphibians incorporate an aquatic larval phase during their lifecycle in mainly small freshwater bodies (i.e., ponds, pools, ditches, streams), water quality and the surrounding land use of the water body have importance for their development. As early life stages are known to be particularly sensitive to various stressors compared to their adult counterparts, conditions during aquatic stages are fundamental to both their immediate health and subsequent adult fitness. The small size, high spatial density, and tendency to complete development within a small water body also make larval amphibians excellent models for assessing environmental stressor impacts on animal health. In this study, we collected body length and/or body mass and developmental stage data for wild tadpoles from two anuran species (common toad: *Bufo bufo*; common frog: *Rana temporaria*) and a newt species (palmate or smooth newt: *Lissotriton sp.*) over several years (2015, 2019, 2021, 2022) across Devon and the central belt of Scotland (UK) along with pond water quality parameters (temperature, pH, total dissolved solids, conductivity, salinity) and made assessments of the surrounding land using a Geographic Imaging Systems (GIS) approach. As expected, over the pre-metamorphic development period, there was a positive correlation between snout-vent length (SVL)/body mass and developmental stage in all species/sampling years; however, the strength of this association differed between years and species (R^2 range: 0.42-0.91). Data were further analysed using a series of generalised linear mixed models with SVL/body mass data were normalised by developmental stage prior to statistical analysis. For common frogs (2015, 2021), higher pH (range: 5.7-8.2) was associated with larger body mass. A similar effect was observed for common toads (2019, 2022), whereby higher pH (range: 5.2-7.8) was associated with larger SVL. However, for common frogs/newts (2022), no relationship was found between pH (range: 5.6-8.1) and SVL. Further analyses of water quality and surrounding land are being undertaken to understand the relative influence of these parameters on amphibian larval development. The resulting data will also provide an important baseline for studies using morphology for wild UK larval amphibian populations.

2.09.T-01 Effects of the Fungicide Azoxystrobin in Two Ecotypes Representative of Mediterranean Coastal Wetlands: A Mesocosm Experiment

Pablo Amador[1]*, Constanza Vega Olivares*[2]*, Natividad Isabel Navarro*[1]*, Jesús Moratalla*[1]*, Melina Crettaz*[2]*, Daniel Franco*[2] *and Andreu Rico*[1]*, (1)Cavanilles Institute of Biodiversity and Evolutionary Biology, University of Valencia, Spain, (2)IMDEA Water Institute, Spain*

Coastal wetlands are under intense anthropogenic pressure, which affects the structure and functioning of their communities. In Spain, the emission of nutrients and pesticides from intensive agriculture have been considered as the main drivers of biodiversity loss. Using a mesocosm experiment, this study aims to study the sensitivity of two different communities representative of the Albufera Natural Park (the Albufera Lake and the surrounding springs, called *Ullals*) to the fungicide Azoxystrobin (applied as Ortiva, YF9246). Effects were evaluated over a period of 56 days on different structural parameters (phytoplankton, zooplankton, macroinvertebrates, insect emergence, macrophyte growth) and functional parameters (organic matter decomposition, biofilm growth). Fungicide effects on the structure of the distinct communities were assessed using the Principal Response Curve method, while effects on single populations and other functional and water quality parameters were estimated using the Williams test and calculating No-Observed-Effect Concentrations (NOEC) for each model ecosystem. Results show that both communities respond in a different manner to the fungicide application. Macrophyte growth (*Ceratophyllum*) was affected from the 2 µg/L concentration on in the Albufera treatment but no significany differences were found for Ullals. Effect's timespan also varied between treatments, with periphyton colonization rate being affected from day 0 in Albufera and from day 28 in the Ullal treatment. Invertebrates also showed a different response depending on the treatment. Even though zooplankton biomass was significantly higher in the *Albufera* treatments than in the *Ullal* treatments, both systems shared a large drop in the abundance of the *Ceriodaphnia*. A very clear trend was found in macroinvertebrates within the *Ullal* treatment, where the crustaceans *Echinogammarus*, *Palaemonetes,* and *Dugastella* disappeared completely in the 200 µg/L concentration. In general, we conclude that current exposure levels may affect the structure and functioning of Mediterranean coastal wetland ecosystems. However, the Ullal communities seem to be more sensitive to azoxystrobin contamination, potentially due to differences in chemical bioavailability and species composition. This study highlights the need to prioritise these habitats for conservation and the need to set specific water quality standards for particular ecotypes within the Mediterranean region.

2.09.T-02 Using Nonlethal Measures of Fish and Invertebrate Health to Assess the Impacts of Fertilizing Wild Rice with Aquaculture Waste

Vince Palace[1]*, Nicholas Blandford*[2]*, Leah Dickenson*[2]*, Krista Robertson*[2]*, Mark L. Hanson*[2]*, Kenneth Jeffries*[2]*, Margaret Docker*[2]*, Lisa Peters*[1]*, Markus Hecker*[3]*, Denina B.D. Simmons*[4]*, Daniel Heath*[5] *and Bruce Hardy*[6]*, (1)Experimental Lakes Area (IISD-ELA), Canada, (2)University of Manitoba, Canada, (3)Toxicology Centre, University of Saskatchewan, Canada, (4)Ontario Tech University, Canada, (5)Integrative Biology, University of Windsor, Windsor, ON, Canada, (6)Myera Group, Canada*

The growth of freshwater finfish aquaculture is impaired by inefficiencies associated with the transportation of feed from coastal areas to production sites. Large volumes of wastewater, enriched with nitrogen and phosphorus, can also contribute to eutrophication, threatening the health of downstream aquatic ecosystems. Wetland plants and algae can remove nutrients and can then be harvested and incorporated into functional fish feeds, reducing requirements to transport feed. The ability of wild rice (*Zizania palustris* L.) to assimilate nutrients was evaluated in mesocosms (2 m diameter; ~1500 L) amended with a gradient of aquaculture waste applied over 12 weeks. Reference enclosures, not receiving waste, were also included in the study. Aqueous concentrations of total phosphorus, total dissolved phosphorus, and soluble reactive phosphorus increased with volumes of aquaculture waste applied and throughout the growing season. Ecosystem health was evaluated in each mesocosm by examining zooplankton taxon abundance and diversity metrics, using traditional enumeration techniques and eDNA, and compared to reference enclosures that did not receive waste applications. Fathead minnows were also stocked into each mesocosm. No differences were observed in their body condition, liver, or gonad size at the end of the study. Mucus was sampled from these fish twice over the growing season to examine transcriptomic and proteomic responses to elevated nutrient concentrations in water. Measures of ecosystem health and water quality will be used to establish the capacity of cultured wild rice to remove nutrients from aquaculture waste streams in a co-cultured scenario. Future field-based studies will also explore the diversion of excess nutrients, not removed by wild rice, to produce algae and floating vegetation that can be incorporated into functional fish feeds.

2.09.T-03 Synergistic Effects of Larval Exposure to an Aquatic Pollutant and Food Stress Get Stronger After Metamorphosis in an Amphibious Insect of Temporary Wetlands

Sarah Jorissen[1]*, Lizanne Janssens*[1]*, Julie Verheyen*[2] *and Robby Stoks*[1]*, (1)KU Leuven, Belgium, (2)Biology, KU Leuven, Belgium*

Many animals living in temporary wetlands have a complex life cycle with aquatic larvae and terrestrial adults, as seen for example in amphibians and amphibious (semiaquatic) insects such as damselflies. To improve the ecological risk assessment of aquatic pollutants it is needed to study their effects not only in the aquatic larval stage, but also in the terrestrial adult stage of the many animals with a complex life cycle. This remains understudied, especially with regard to interactive effects between aquatic pollutants and natural abiotic stressors. We studied effects of exposure to the pesticide DNP (2,4-Dinitrophenol) and how these were modulated by limited food availability in the aquatic larvae, and the possible delayed effects in the terrestrial adults of an amphibious insect specialized in temporary wetlands: the damselfly *Lestes viridis*. Our results revealed that DNP and low food each had negative effects on the life history, behaviour, and to a lesser extent on the physiology of not only the larvae, but also the adults. The negative effect on larval development time resulted in delayed metamorphosis which may have strong fitness consequences by increasing mortality from pond drying in temporary wetlands. Food limitation magnified the toxic effects of DNP as seen by a strong decline in larval survival, metamorphosis success, and adult lifespan. Notably, the synergism between the aquatic pollutant and food limitation for survival-related traits was stronger in the nonexposed adults than in the exposed larvae, likely because metamorphosis is stressful itself. Our results highlight that identifying effects of aquatic pollutants in temporary wetlands and synergisms with natural abiotic stressors, not only in the aquatic larval but also in the terrestrial adult stage, is crucial to fully assess the ecological impact of aquatic pollutants and to reveal the impact on the receiving terrestrial ecosystem through a changed aquatic-terrestrial subsidy.

2.09.T-04 Predicting Amphibian Body Burdens After Dermal Uptake of Pesticides from Soil
***Valentin Mingo*[1]**, *James Robert Wheeler[2], Vincent Kramer[3] and Manousos Foudoulakis[4], (1)Corteva Agriscience, Munich, Bavaria, Germany, (2)Corteva Agriscience, Netherlands, (3)Corteva Agriscience, United States, (4)Corteva Agriscience, Chalandri, Greece*
Although currently considered covered by surrogate bird and mammal Environmental Risk Assessment (ERA) schemes, concerns for amphibian risk assessment have arisen regarding dermal exposure to pesticides in the terrestrial phase, primarily due to the high permeability of their skin and the lack of a protective layer such as fur or feathers. It is therefore hypothesized that dermal uptake could significantly surpass oral/dietary exposure. It thus becomes necessary to determine the relative importance of different exposure routes for the integrated toxicity outcome, including dermal uptake of contaminants for terrestrial amphibians.

To this end, a modelling approach with the aim of providing realistic estimates of amphibian body burdens after dermal exposure to contaminated soil was developed and is here presented.
A one-compartment Toxicokinetic (TK) model was derived and tested using a publicly available dataset containing relevant exposure and uptake information for juvenile frogs exposed to 12 different pesticides. Parameters used in the model included tested species, body weight, soil concentration, body burdens, skin surface area, skin thickness, K_{oc}, permeability coefficient of the pesticide, and water uptake rate of the animals. Additionally, Poly-parameter Linear Free Energy Relationships modelling was used to describe the distribution of the corresponding pesticide between water and frog tissue and integrated into the equation.

Modelled body burdens were compared to actual, measured body burdens for a total of 407 individuals exposed to the 12 different pesticides. In order to compare the overall predictability of the model for a given pesticide, predictions and measured concentrations were averaged over all individuals for a given pesticide.

Overall, a good concordance between modelled and measured body burdens was observed, with the predicted and measured body burdens differing by a factor of 3 on average. Results were subsequently plotted on a log-log plot and a regression analysis performed, resulting in an R^2 of 0.78 and a correlation coefficient of 0.88, suggesting good predictivity of the model.
Based on these results, we suggest this or similar models could be used to characterize dermal exposure in amphibians, to screen for pesticides of concern and prioritize ERA efforts, while at the same time reducing the need for animal testing.

2.09.P Ecotoxicology of Biota Inhabiting Wetland Ecosystems

2.09.P-We072 Microplastic Contamination of Water and Tadpoles in Amphibian Breeding Pools in Scotland (UK)
Chloe Houseman[1], Jeanette Rotchell[2] and ***Frances Orton*[3]**, *(1)School of Health and Life Sciences, University of the West of Scotland, United Kingdom, (2)University of Hull, United Kingdom, (3)UK Centre for Ecology & Hydrology (UKCEH), United Kingdom*
Microplastic (MP) contamination has been widely reported across a range of aquatic environments and their compartments including in water, sediments, and biota. There are indications that small freshwaters (SFWs) such as ponds may be highly contaminated with MPs due to their low volumes combined with close proximity to MP sources, such as domestic wastewater inflows, urban run-off, and agricultural land. Amphibians are one of the most common vertebrates to inhabit SFWs. In this study, we first investigated MP contamination of amphibian breeding pools *via* water, sediment, and internal levels (common toad [*Bufo bufo*] tadpoles). We then analysed for relationships between MP abundance and surrounding land use characteristics (Geographic Information systems approach) to identify possible sources of contamination. To characterise land use, we used QGIS (3.28) using a buffer zone of 0.5 miles around the shoreline of each pond, and associations between land types and MP contamination levels were analysed (Generalised Linear Mixed Modelling). Finally, we analysed for correlations (Spearman Rank correlation) between internal MP levels and tadpole development (body mass, length). Water and sediment samples were collected from nine ponds across the central belt of Scotland at four-time points in Spring 2021. Where found (n = 4 ponds), 20 tadpoles were collected *per* pond on the third and fourth visits. The levels of MPs found across all site characterisations ranged between 0–30 items/L in water and 12–1484 items/kg in sediments. Tadpoles also contained MPs ranging between 0 – 163 items/g tissue (0 – 19 items/individual). MP abundance in sediments was positively correlated with the proportion of land cover characterised as industrial (R^2 = 0.037; p = 0.002) or as pasture (R^2 = 0.024; p = 0.011). In tadpoles, the vast majority of MPs were found in the

gut (81.26 %, n = 464) compared to the liver (8.06 %, n = 46), and carcass (10.68 %, n = 61), suggesting dietary uptake. Across all sites, a significant negative correlation ($p < 0.01$) was found between tadpole MP abundance and body mass (R^2 = -0.1135), total length (R^2 = -0.1587) and snout-vent length (R^2 = -0.1805), suggesting that MPs may be negatively impacting wild tadpole health. These results provide important insights into the extent of MP pollution in SFWs, which currently do not form part of routine water quality monitoring, as well as potential links between MP ingestion and health endpoints in wild amphibians.

2.09.P-We075 Third Update of the Ecotoxicology of Amphibians and Reptiles Textbook - Recent Advancements in Amphibian and Reptile Ecotoxicology

***Elena Adams*[1]*, Catherine Aubee[2], Julie Brodeur[3], Paula F.P. Henry[4], John Marton[5], Manuel Ortiz Santaliestra[6] and Scott M. Weir[7], (1)Environmental Safety, Bayer AG - Crop Science Division, Germany, (2)U.S. Environmental Protection Agency, (3)CONICET - INTA, Argentina, (4)U.S. Geological Survey, (5)Corteva Agriscience, (6)Instituto de Investigación en Recursos Cinegéticos (IREC) CSIC-UCLM-JCCM, Spain, (7)DAWSON*

Prior to the year 2000, ecotoxicological research focused on amphibians or reptiles was scarce compared to that for other vertebrate groups, often consisting of basic experimental approaches with limited ecological relevance. The First World Congress of Herpetology held in 1989 brought about by reports of global amphibian population declines, dramatically highlighted the importance and potential fate of this class of organisms. The 21st century has seen an increased understanding of ecotoxicology of amphibians and reptiles. More research has yielded greater numbers and diversity of publications, plus two editions of a textbook, *Ecotoxicology of Amphibians and Reptiles* by Sparling et al., which SETAC's Interest Group members are now seeking to update. For the second edition, Sparling et al. performed a literature review covering the years 1996-2008 showing that 10 years after publication of the first edition, amphibians and reptiles remained underrepresented in the ecotoxicology literature relative to other vertebrates. Since the second edition, there has been a dramatic increase in the number of research studies and papers focusing on amphibians and reptiles and the effects and burdens of contaminants on these two classes of vertebrates. Therefore, we conducted a title-based literature review for the years 2006-2022. Although the number of citations increased since the second edition, preliminary results show that amphibians and reptiles still remain underrepresented in ecotoxicology literature. Of the 22 056 citations examined (1.3-fold increase in comparison to 1996-2008), 71% were for fish, 11% for mammals, and 10% for birds. Since the second edition, the number of citations related to amphibians increased from 3.8% to 5.3%. For reptiles, the number of citations increased from 0.8% to 3.1%. Moreover, there was a 2- and 5-fold increase of contaminant-related publications for amphibians and reptiles, respectively. Further evaluations on topics such as main contaminant classes, annual publication numbers, most studied taxa and emerging stressors such as climate change and diseases, are ongoing and detailed results will be presented at the conference.

2.09.P-We076 Occurrence of Common Frog and Common Toad in Agricultural Fields in Germany: Potential for Exposure to Plant Protection Products

***Arnd Weyers*[1]*, Nadine S. Taylor[2], Hanna Samantha Schuster[2] and Lennart Weltje.[3], (1)Environmental Safety, Bayer AG - Crop Science Division, Germany, (2)Cambridge Environmental Assessments (CEA), United Kingdom, (3)Agricultural Solutions - Ecotoxicology, BASF SE, Germany*

The appropriate and effective assessment of the ecological risk of chemicals to amphibians is a current topic of debate. Amphibians are a highly endangered class of vertebrates and while the major causes for population declines are habitat loss and diseases, other factors like introduced predatory species and exposure to chemicals, including plant protection products (PPPs), are also implied. For risk assessment of PPPs, a consideration of exposure and toxicity is required. Here, we present results of a project that studied occurrence and habitat use of adult and metamorph common frogs (*Rana temporaria*) and common toads (*Bufo bufo*) in an agricultural landscape, and the implications for potential exposure to PPPs.

The 4 sites (ponds) selected for the study had >85% agricultural land (mainly cereal fields) surrounding the ponds and were suitable to study amphibian occurrence in agricultural land. Adults were monitored with radio tracking devices for 2 years and juveniles were caught in pitfall traps using drift fences and then released.

Adult frogs and toads were rarely observed in arable fields, i.e., only 0.5% and 4% of the sightings, respectively. Abundance of metamorphs in arable land around two sites was 0% and 16% of the catches. For a third site, completely surrounded by arable fields, the number was higher at 39% (frogs) and 26% (toads) of sightings. The fourth site had no interpretable metamorph data, because of an accidental manure contamination of the water body killing most tadpoles. Metamorphs of both species tended to remain close to their natal ponds and their in-field occurrence decreased with distance from the water body.
Thus, the presence of amphibians in arable fields was limited and primarily occurred later in the summer, when metamorphs had left the breeding pond and when crops were denser and hence crop interception of sprayed PPPs is higher. This, together with the hiding behaviour during the day would limit the risk of dermal exposure.
The use of buffer zones around water bodies in agricultural areas would thus be highly effective as a risk mitigation strategy in protecting the metamorph life stages and will also reduce spray drift entry into water bodies following PPP applications. We hope that the results will contribute to data-driven environmental decision-making and to the discussion on effective risk assessment and mitigation options for this taxonomic group.

2.09.P-We078 Characterizing the Effects of Chronic Conventional Heavy Crude Oil Exposure on the Behaviour of Larval Wood Frog (*Lithobates sylvaticus*) in Outdoor Mesocosms

Adam Scott[1], Aidan Guttormson[1], Vince Palace[2], Lisa Peters[2], Gregg Tomy[1], Bradley Park[1], Caleb Hasler[3], Mark L. Hanson[1] and

Jose Luis Rodriguez Gil[2]*, (1)University of Manitoba, Canada, (2)Experimental Lakes Area (IISD-ELA), Canada, (3)University of Winnipeg, Canada*
Amphibians are amongst the most globally endangered groups of organisms, in part due to the sensitivity of their habitats. A large portion of North American crude oil reserves are landlocked and their exploitation requires extensive networks of pipelines, rails, and roads which in many cases cross sensitive amphibian habitats, such as wetlands. As part of a larger program of research aimed to understand the fate, impacts, and remediation approaches to oil spills in boreal freshwater ecosystems, the Floating Wetland Treatments to Enhance Remediation (FloWTER) study examined the efficacy of plant-microbe relationships for *in situ* degradation of oil-derived hydrocarbons in outdoor mesocosms. As part of the study, the uptake and effects of *in situ* chronic exposure to a conventional heavy crude oil (CHV) water-accommodated fraction on the growth, development, and behaviour of wood frog (*Lithobates sylvaticus*) tadpoles were characterized in the presence or absence of floating aquatic plants, and a no oil control. Weekly behavioural assays were recorded on a subset of five tadpoles from each mesocosm to examine swim speed, latency time, distance traveled, and nearest neighbour distance over the exposure period. Additional tests assessing changes in the response of the tadpoles to a predator cue were performed at the end of the exposure period. The sensitivity of the behavioural test set-up and the wood frog tadpoles themselves was also assessed by performing complete concentration-response test with anxiolytic and anxiogenic reference chemicals (ethanol and caffeine), a step that to the best of our knowledge, had not been previously reported for this species. No significant treatment effects were observed in the basal behaviour of the tadpoles. The presence of the predator cue induced an increase in activity in the tadpoles; however, we did not observe differences in the ability of the tadpoles to respond to the cue between treatments. Our reference chemical tests did show that our test system was able to detect changes in behaviour in wood frog tadpoles. The observed lack of treatment effects was likely due to the observed rapid dissipation of the oil-derived hydrocarbons from the water column resulting in limited exposure to the tadpoles. This research provides much needed data on the toxicological effects of CHV on amphibians to inform risk assessment related to the over-land transportation of crude oil and potential impacts of freshwater oil spills

2.09.P-We079 Occurrence and Potential Ecotoxicity of Pesticides Transformation Products in Pond Ecosystem
Gaspard François Léopold Conseil[1]*, Sylvain Milla*[2] *and Damien Banas*[2]*, (1)UR AFPA, University of Lorraine, France, (2)University of Lorraine, France*
In Europe, numerous small water bodies (SWB) punctuate the hydrographic network without being integrated in the Water Framework Directive (WFD), making these areas understudied. Ponds are an integral part of SWB and highly valuable wetlands, providing ecosystem and economic services. Due to their proximity to agricultural lands, their contamination statuses are subjected to change, especially regarding the occurrence of Plant Protection Products (PPPs).
The newly frequent detection of PPPs and some of their transformation products (TPs) in aquatic ecosystems, such as ponds, led to the inclusion of these substances in the monitoring of contaminants in French surface water bodies. Indeed, the potential ecotoxicity of these TPs has newly raised questions and aroused widespread interest concerning the risk that they can pose to wildlife inhabiting these areas.

Our project first aims to generate data on TPs occurrence in different ponds and then attempts to identify some associated potential ecotoxicological effects. To do so, *in vivo* assays were realized by characterizing different biological responses of freshwater crustaceans exposed to previously identified TPs. Identification of TPs by chemical analysis in 12 sampling sites (i.e., ponds) is shown. The main work presented here tries to establish a link between data concerning ecotoxicological values of TPs, generated from *in silico* analyses (QSAR prediction), and those obtained by employing *in vivo* models.

Here, a focus is placed on the species *Daphnia magna* by applying the OECD 202 standard test as a first approach. After the exposure, the TPs studied such as 2-chloronicotinic acid or metolachlor CGA 357704 show different toxicities among them and compared to their parent compounds (e.g., boscalid and S-metolachlor). This provides new data on the acute toxicity of TPs for primary consumers such as water fleas. Our results suggest that these substances should be considered when assessing the ecotoxicity of ponds water.
Considering different combinations of substances quantified *in situ* (in ponds) and most frequently detected ones, cocktails of PPPs and TPs will also be tested on daphnia. The freshwater algae *Raphidocelis subcapitata* will be also employed to be more relevant with the type of TPs found, mainly deriving from herbicides (e.g., chloroacetanilides).

2.09.P-We081 Morphological Temporal Effect of Metallic Nanoparticle Contamination from Environmental Atmospheric Particulate Matter in Gills of the Mangrove Crab *Ucides cordatus*
Kainã Rocha Cabrera Fagundes[1]*, Luan Oliveira*[2]*, Felipe Santana*[3]*, Julia Valente*[2] *and Renata Mari*[1]*, (1)UNESP- Campus do Litoral Paulista, Brazil, (2)UNESP - Câmpus do Litoral Paulista, Brazil, (3)Biological and Environmental Sciences, UNESP- Campus do Litoral Paulista, Brazil*
The atmospheric particulate matters (PM) are usually related to mining and metallurgical industry. Since the Industrial Revolution, the contamination by metals is still a problem and tracking the contaminant in the environment and the biota can be hard work. In water, metallic PM contaminants appear to dissociate into nanoparticles, so the presence in circulatory system may facilitate their internalization into cells. The effect of metallic PM with non- and emerging metals in estuarine biota is still up for characterization. Therefore, this study aimed to describe the histopathological effects in mangrove crab gills under atmospheric PM. The animals were acclimatized for a period of 10 days at DCM/UNIFESP (Santos, SP). Then, there were 30 days of exposure in 40 L aquariums in quintuplicates, consisting of the following groups: control (CTL); concentration 0.01 $g.L^{-1}$ (1); 0.1$g.L^{-1}$ (2); and 1.0 $g.L^{-1}$ (3). Each aquarium contained 10 individuals under constant aeration and photoperiod of

12Hlight:12Hdark. Tissue collections were defined by the times: 7 days after exposure (T7); 15 days (T15) and 30 days (T30). The atmospheric MP were from Complex Tubarão, Espírito Santo, Brazil. The tissues were fixed in formaline 10% and proceeded under histological routine. Cuts of 5 µm were stained with Hematoxilin-Eosin (HE). In T7, the gills were, in general, well-structured and intact. Only in concentration 3, the pillar cells presented nucleus with the dysmorphic chromatin. In T15, both the pillar cells and the coticule capsule were unstructured, with major presence of hemocytes and immune cells in the lumen of the lamellae and hemal channel, in all concentrations. These characteristics can be a hemorrhagic process leading to an inflammatory and necrosis. So, in T30, the gills were completed unstructured, they had unidentifiable cells given the damage caused. In conclusion, after an exposure of 30 days, the gill structures were damaged by time exposition, whatever the concentration. The atmospheric PM can morphological responses that after a long exposure time can lead to chronic diseases and death, resulting in populational impact and affecting lots of niches.

2.09.P-We082 Heavy Metal Body Burdens and their Interaction with Metabolites in the Pacific Black Duck (*Anas Superciliosa*) in Victoria, Australia

Damien Nzabanita[1], Jordan Hampton[2], Jasmin Hufschmid[2] and ***Dayanthi Nugegoda****[3], (1)RMIT University, School of Science, Australia, (2)Veterinary Science, University of Melbourne, Australia, (3)School of Science, RMIT University, Australia*

Heavy metals are cumulative toxicants with important implications for wildlife in freshwater systems as their accumulation has the potential to cause negative health and ecological effects. Over the past decade, the study of metabolomics has expanded in multiple scientific fields such as environmental science, and toxicology and its application have recently increased in the humanities and medical sciences where mounting evidence has shown that metabolites are related to exposure to heavy metals. However, comparable studies on animal species especially ducks are currently lacking. This study aimed to examine the body burden of heavy metals and metabolites in Pacific black ducks from three Victorian freshwater biomes in Australia: one peri-urban site in south-west Victoria [designated Lake Connewarre (LC)] and two sites in rural coastal eastern Victoria [designated Macleod Morass (MM) and Dowd Morass (DM)] and assess whether the change of metabolites was correlated with high levels of heavy metal exposure. Feathers were used to analyse chromium, copper, iron, mercury, manganese, lead, and zinc while muscles were analysed for metabolites. Inductively coupled plasma mass spectrometry and gas chromatography-mass spectrometry were used to analyse the metals and metabolites, respectively. Principal Component Analysis was conducted to determine whether the change of these metabolites was linked to heavy metals. The overall results within each location showed that the mean concentration of all metals was lower in MM than in the other locations LC and MM. Lead and mercury were both significantly different between LC and MM, but showed no difference between DM and MM. Aminoimidazole, α-lactic acid, lysine, taurine, and linoleic acid metabolites were significantly different between LC and MM. However, their change was not linked with lead or mercury indicating that the non-invasive feather analysis was not directly correlated with changes in metabolites. It is possible that the excretion of these toxic metals into feathers is effective as a detoxification mechanism, hence not linked to metabolic function. This study provides toxicology information with ecological and health implications in waterbirds from a relatively poorly studied global region in south-eastern mainland Australia.

2.09.P-We083 Lindane and Endosulfan Exposure in White-Headed Duck and Marbled Teal from a Wetland Dedicated to Agricultural Irrigation: Tracking the Success of Pesticides Ban in El Hondo Natural Reserve (SE Spain)

Pedro María-Mojica[1,2], Isabel Navas,[3], José Peñalver[4], María Belén Nieto[1] and ***Antonio Juan Garcia-Fernandez****[5], (1)Health Sciences, Faculty of Veterinary, University of Murcia, Spain, (2)Servicio de Vida Silvestre, Wildlife Recovery Center "Santa Faz", Generalitat Valenciana, Spain, (3)Health Sciences-Faculty of Veterinary-IMIB, University of Murcia, Spain, (4)Health Sciences, University of Murcia, Spain, (5)Toxicology and Risk Assessment Research Group, Faculty of Veterinary, University of Murcia, Spain*

El Hondo Nature Reserve collects water from the River Vinalopó and the River Segura, and is comprised of two large regulating reservoirs (1100 ha.) and their associated wetlands. The wetland was created in the 1920s to provide water for irrigation to local farms. Other relevant human activities include hunting and fishing. This wetland appears in the Ramsar list, and it is also classified as Protected Area for Birds due to not only the abundance of birds (172 species, 50 of them breeding there) but also the ecological relevance of some bird species, such as marbled teal (*Marmaronetta angustirrostris*) and white-headed duck (*Oxyura lecucocephala*).

Although the agricultural use of lindane and endosulfan was banned in Europe around 2007, there is a particular need for the ongoing monitoring of these banned organochlorine pesticides, and measures should be taken to mitigate the exposure of vulnerable populations. One hundred and fourteen ducks found dead in El Hondo between 1998-2022 were selected and classified in "*before*"/"*after*" 2007 (date of death). Liver and brain of 56 marbled teals (41/15) and 58 white-headed ducks (26/26) were analyzed. After extraction and purification, one microliter of the final extract was analyzed using a GC/MS. The identification and quantification of the compounds was based on an external standard prepared by dissolving in hexane a reference standard: HCH isomers (α-HCH, β-HCH, γ-HCH (lindane) and δ-HCH) and endosulfan (endosulfan I, endosulfan II, endosulfan sulfate).

No differences in pesticide concentrations were observed between species. In general, frequency of detection and concentrations of lindane and endosulfan were significantly lower in ducks dead after pesticide prohibition. Lindane, together β-HCH, was the HCH isomer mainly detected in both species, with concentrations in liver higher than in brain. Endosulfan I was more detected (70-80%) than endosulfan II (36-44%) in both species in the period before pesticide prohibition; however, after 2007, the frequency of detection of both compounds decreased until 20-30%.

In conclusion, these results show that lindane and endosulfan exposure in anatidae inhabiting El Hondo has decreased significantly, which suggests a lower use of these compounds since their prohibition. However, they are still being detected in some animals, which could indicate an illegal market or the existence of commercial product remnants in some farms.

2.10.A Field Studies, Monitoring and Effects Research in Wildlife

2.10.A.T-01 POPs Maternal Transference and Consequences for Egg Development and Reproduction Success in Green Sea Turtles (Chelonia mydas)

Inês Filipa Cigarro Morão[1]*, Tiago Filipe da Silva Simoes*[1]*, Roger B. Casado*[1]*, Sara Vieira*[2]*, Juan Munoz-Arnanz*[3]*, Begona Jimenez*[4]*, Marco F.L. Lemos*[1] *and Sara Novais*[5]*, (1)Polytechnic of Leiria & MARE, Portugal, (2)Associação Programa Tatô & CCMAR, Portugal, (3)Institute of Organic Chemistry - Spanish Research Council (IQOG-CSIC), Spain, (4)Institute of Organic Chemistry - Spanish National Research Council (IQOG-CSIC), Spain, (5)Instituto Politécnico de Leiria, Portugal*

Persistent Organic Pollutants (POPs) have global distribution and are known to be harmful to wildlife. Due to their complex life cycle, their diets and migratory behaviours, marine turtles tend to accumulate these pollutants in their tissues. Just a few studies have been made to understand the load and the POP effects in sea turtles' tissues that may influence their overall health and especially the quality of their eggs to infer about the health of future sea turtles' generations. Five of the seven existing and threatened sea turtle species can be found in São Tomé and Príncipe archipelago. The green sea turtle, *Chelonia mydas,* is the most common species nesting in the archipelago, and there are some indications about possible effects of metals on nesting females in those islands. However, effects of POPs in these females or in their eggs are still lacking. Thus, the aim of this study was to determine the levels of different POPs (PCBs, OCPs and PBDEs), both in the blood of nesting females of green sea turtles and in their eggs, to infer about maternal transference, and to evaluate if such contamination could be associated with differences in the morphology, composition, and quality of their eggs, as well as reproductive success (clutch size, hatching rate, and emergence rate). For sea turtle eggs, most of the egg mass is represented by the yolk, which is highly rich in lipids. As metabolic and signalling mediators, yolk fatty acids (FAs) are essential for embryo development and posthatch activity. The results indicate that the screened contaminants significantly affected the egg compartments and lipid reserves. FA results from the egg yolk showed that the ones linked to the polar fraction (mostly associated to lipoproteins) seemed to be more influenced by the POP levels. A maternal transference phenomenon was also elucidated here for most of the contaminant's congeners analysed. This study provided valuable information about the current POP levels in female green sea turtles and in their eggs from São Tomé Island, indicating their widespread presence. Moreover, this study showed how the contaminants transferred from the female turtles to their eggs may be affecting their reproduction by altering egg properties for proper embryo development, their clutch size and nesting season success. Further studies to monitor marine pollution and damages derived from it in other developing stages and marine turtle species are needed to increase conservation efforts.

2.10.A.T-02 Anticoagulant Rodenticide Toxicity in Terrestrial Raptors: New Tools to Estimate the Potential Impact of Mortality on Populations

Veronica Silverthorn[1]*,* ***John E. Elliott***[1]*, Peter Henrys*[2]*, Sofi Hindmarch*[3]*, Pierre Mineau*[4]*, Tony Redford*[5]*, Victoria Bowes*[5]*, Joseph Okoniewski*[6] *and France Maisonneuve*[1]*, (1)Environment and Climate Change Canada, Canada, (2)Center for Ecology and Hydrology, United Kingdom, (3)Fraser Valley Conservancy, Canada, (4)Pierre Mineau Consulting, Canada, (5)BC Ministry of Agriculture and Lands, Canada, (6)New York State Department of Environmental Conservation*

Anticoagulant rodenticides (ARs) have caused widespread contamination and poisoning of predators and scavengers, particularly terrestrial birds of prey. AR poisoning is diagnosed mainly on evidence of hemorrhage in conjunction with summed hepatic AR residues > 0.1 – 0.2 ug/g liver wet weight. However, simple summation of residues is confounded by variability in the potency and toxicokinetics of individual residues. Other factors also affect sensitivity of nontargets to ARs, including: exposure dose, timing and frequency of exposure, and intra- and interspecific differences in sensitivity related to body condition, nutritional state, and other factors. There is, therefore, a need for compound and species-specific AR toxicity criteria to assess population-level effects on predatory birds. Previously we developed a novel approach based on probabilistic methods. However, with limited datasets and number of species, those assessments were limited in determining uncertainty around the probabilistic curves. Other shortcomings included: assumed additivity, inability to analyze individual species and compounds, uneven sample size in the binary data set of birds classified as 1s (positive) or 0s (negative) for pathophysiological signs of anticoagulant rodenticide poisoning, as well as an assessment of how trauma cases bias results. To improve the approach, we compiled a database of hepatic SGAR residues and postmortem evaluations from 951 terrestrial raptor carcasses collected throughout Canada and the USA, 1989 – 2021, representing 26 species of mainly owls and hawks. We developed species- and residue-specific probability curves to assess the toxicity of bromadiolone, brodifacoum, and difethialone and adjusted total SGARs using toxic equivalency factors from individual residue curves. To address unequal sampling of 0s and 1s in the data, logistic regressions were run on Monte-Carlo simulated binary data.

2.10.A.T-03 Development of Innovative Physiological-Based Kinetic (PBK) Model to Predict Exposure of Small Mammals to Anticoagulant Rodenticides, Posing High Risks to Environmental Health (Urine and/or Faeces)

Yiming Liu*, Toxicology, Wageningen Environmental Research (WUR), Netherlands*

Anticoagulant rodenticides (ARs) are widely used in the world. ARs can inactivate the vitamin K clotting system, potentially leading to bleeding episodes and even the death of the exposed organisms. However, this clotting system is not exclusive for rodents, indicating that ARs may cause high potential risks to nontarget species.

Hence, a specific monitoring system to quantify the exposure of nontarget organisms to ARs and assess associated risks is required. Physiologically based kinetic (PBK) modelling and PBK-based reverse dosimetry are proposed to underpin nondestructive monitoring approaches. In this study we have developed such PBK models for ARs to be used to quantify actual exposure of target species to ARs by measuring the concentration of parent compounds and associated metabolites in, e.g., faeces and urine. Parameters describing the kinetics of ARs in target species were quantified through *in vitro* experiments and available *in vivo* exposure data and literature. Overall, the results reveal that predicted time-dependent changes of ARs matched the data from available in vivo studies quite well. Based on this, further PBK modelling-based reserve dosimetry methods will be refined to predict the *in vivo* levels of ARs in rodents. In the models, the concentration of ARs in both liver and blood increased to highest level within 24 hours and then slowly decreased. Hydroxylated metabolites of ARs were detected in the metabolism assay and will be further used to optimize the model interpretations and perform risk assessments of ARs.

2.10.A.T-04 Environmental Pollution and Nutritional Quality Modulate Immune Response of the Wood Mouse (*Apodemus sylvaticus*) through Hormonal Disturbances

Quentin Devalloir[1]*, Clémentine Fritsch*[2]*, Francis Raoul*[2]*, Yara Alchammas*[2]*, Shinji Ozaki* [3]*, Vincent Driget*[2]*, Nico van den Brink*[4] *and Renaud R Scheifler*[2]*, (1)Laboratoire Chrono Environnement, France, (2)UMR 6249 Chrono-environnement, CNRS / Université Bourgogne Franche-Comté, USC INRA, France, (3)UK Centre for Ecology & Hydrology (UKCEH), United Kingdom, (4)Division of Toxicology, Wageningen University & Research, Netherlands*

Over the last decades, rapid changes in our societies introduced multiple anthropogenic stressors such as pollution or low diet quality/availability related to habitat loss and fragmentation. Diet quality was found to be dampened by these changes reducing the availability of micronutrients in the diet. Among them, selenium (Se) is an essential element, involved in metabolic processes (including immunity) and reactive oxygen species scavenging. In opposition, nonessential elements like cadmium (Cd) and lead (Pb) can enhance physiological disturbances on health in wildlife. Both Cd and Pb enhance immune cell damage and decrease cellular immunity, promoting higher susceptibility to infectious diseases. This study aimed at evaluating the ability of Cd and Pb and low nutritional quality to modulate immune response to a lipopolysaccharide (LPS) challenge in wood mice (*Apodemus sylvaticus*) under potential control of endocrine regulation. Wood mice were trapped in sites exhibiting “High” and “Low” levels of Cd and Pb contamination near a former smelter in Northern France (Metaleurop Nord). Individuals were either challenged immediately after capture or maintained 5 days in captivity, fed standard or Se-deficient diet. Immune response to challenge was measured with leukocyte count and plasma concentration of TNF-α, a pro-inflammatory cytokine involved in the recruitment of immune cells. Faecal and plasma corticosterone (CORT), a stress-hormone involved in murine anti-inflammatory processes, was measured to assess potential endocrine mechanisms. Hepatic Cd, Pb and Se concentrations were also determined. Higher hepatic Se and lower faecal CORT were measured in free-ranging wood mice from “High” site. The immune response of LPS-challenged individuals from “High” site displayed lower levels of white blood cells count and a higher plasma TNF-α concentration than in “Low” site. Animals maintained in captivity for 5 days had lower concentrations of plasma TNF-a. Individuals from “High” site maintained in captivity had lower levels of inflammation and no increase of anti-inflammatory CORT when fed with Se-deficient diet. These results are in favour of a higher inflammatory response to challenge in free-ranging animals exposed to Cd and Pb. Mechanisms by which inflammatory response is modulated may be due to neuroendocrine disturbances mediated by Cd and/or Pb exposure. The role of Se on the immune response to challenge and its environmental sources remain to be determined.

2.10.A.T-05 In Natura Exposure of Soil, Earthworms, and Small Mammals to Pesticides in Agricultural Landscapes: From Fears to Facts

Celine Pelosi[1]*, Colette Bertrand*[2]*, Brice Appenzeller*[3]*, Michael Coeurdassier*[4]*, Gaëlle Daniele*[5]*, Emmanuelle Vulliet*[6]*, Florent Lafay*[5]*, Renaud R Scheifler*[7]*, Francis Raoul*[7]*, Sabrina Gaba*[8]*, Vincent Bretagnolle*[9] *and Clémentine Fritsch*[7]*, (1)INRAE (Institut National de la Recherche Agronomique), France, (2)INRAE, France, (3)Department of Population Health, Luxembourg Institute of Health, Luxembourg, Luxembourg, (4)UMR 6249 Chrono-environnement, CNRS – UBFC, Université de Franche-Comté, France, (5)UMR CNRS ISA 5280, University of Lyon 1, France, (6)Institut des Sciences Analytiques, UMR 5280, France, (7)UMR 6249 Chrono-environnement, CNRS / Université Bourgogne Franche-Comté, USC INRA, France, (8)UMR 7372 CEBC, France, (9)CNRS CEBC, France*

A significant lack of knowledge on the fate of pesticides in the environment and their unintended effects hinders the understanding and mitigation of their impacts on biodiversity. As part of the RESCAPE project (RESistance of agricultural landSCAPEs to pesticide transfers in soils and living organisms) the exposure of soil, earthworms, and small wild mammals (that can represent a trophic chain) to currently used pesticides and "old" pesticides (banned and restricted in use) was studied to shed light on the knowledge on these issues. Multiresidue pesticide analyses revealed that 100% of the soils, 92% of the earthworms and 100% of the small mammals contained at least one pesticide. In small mammals, a total of 112 compounds (fungicides, herbicides, and insecticides) were detected, with 32-65 residues detected per individual (13-26 old pesticides and 18-41 currently used pesticides in each animal). For earthworms, 46% of samples (coming from both treated fields and nontreated habitats) presented a high risk of chronic toxicity. Moreover, among the currently used pesticides, some were systematically found in the three matrices: the insecticide imidacloprid, the herbicide diflufenican, and the fungicide epoxiconazole. This work suggests that exposure of wildlife to mixtures of pesticides is a rule rather than an exception, highlighting the need to consider the concept of the eco-exposome and questioning the relevance of current assessment and evaluation processes.

2.10.B Field Studies, Monitoring and Effects Research in Wildlife

2.10.B.T-01 Factors Modulating Exposure of Red-Legged Partridges to Pesticides: Diet and Spatial Ecology
Elena Fernández Vizcaíno[1]*, Francois Mougeot*[1]*, Xabier Cabodevilla*[2]*, Mario Fernández-Tizón*[1]*, Rafael Mateo Soria*[3] *and Manuel Ortiz Santaliestra*[1]*, (1)Instituto de Investigación en Recursos Cinegéticos (IREC) CSIC-UCLM-JCCM, Spain, (2)Departamento de Zoología y Biología Celular Animal, Facultad de Farmacia, Universidad del País Vasco (UPV), Vitoria-Gasteiz,, Spain, (3)Wildlife Toxicology, Instituto de Investigación en Recursos Cinegéticos (IREC) CSIC-UCLM-JCCM, Spain*
The treatment of seeds with pesticides is an extended practice in current agriculture. Granivorous birds, such as the red-legged partridge (*Alectoris rufa*), have a high exposure risk as they can consume those seeds that remain on the surface during sowing. Experimental studies have evidenced effects on the reproductive capacity of red-legged partridges fed with seeds treated with approved doses of triazole fungicides, the active ingredients most commonly used for treatment of nonirrigated cereal seeds. However, information about the exposure risk for wild birds and the factors that modulate it is still scarce. The aim of this study is to know how the uptake of triazole fungicides by partridges is influenced either by the consumption of cultivated plant species during the sowing season or by the presence of birds on recently sown fields. We also studied if the spatial ecology of red-legged partridges can serve as a proxy to estimate their pesticide risk exposure. From autumn 2017 to summer 2018, we collected feces (n = 144) from 35 different partridge flocks in an agricultural area in central Spain. We analyzed pesticide residues in feces by LC-MS and diet composition by metabarcoding. We tracked another 15 birds using GPS loggers that recorded daily positions in order to monitor the use of different patches. Residues of tebuconazole were detected in 16.6% of birds. During the peak of the sowing season, cultivated plants constituted more than half (56.1%) of the diet ingested by partridges, with barley as the most consumed species (40.7%). Spatial ecology revealed that all flocks where tebuconazole was detected had recently used sown fields, while negative flocks had no contact with these areas. We found that the study of spatial ecology in partridges could be a useful tool for estimating exposure risk after sowing. Our results highlight the importance of considering detailed ecological information for the refinement of the exposure characterization as part of the environmental risk assessment of pesticides.

2.10.B.T-02 Feathers as Temporal Archives of Ecological Stress and Metal Exposure in a Terrestrial Raptor: A Long-Term Study on Breeding Tawny Owls
Elisabeth Hansen[1]*, Jan Ove Bustnes*[2]*, Igor Eulaers,*[3]*, Dorte Herzke*[4]*, Bård-Jørgen Bårdsen*[2]*, Georg Bangjord*[5]*, Sohpie Bourgeon*[6] *and Manuel Ballesteros*[2]*, (1)Arctic Marine Biology, UiT - The Arctic University of Norway, Norway, (2)Norwegian Institute for Nature Research, (3)Norwegian Polar Institute, Norway, (4)Norwegian Institute for Air Research (NILU), Norway, (5)Norwegian Environment Agency, Norway, (6)UiT - The Arctic University of Norway, Norway*
Metal contamination is a global environmental problem. As exposure of wildlife to heavy metals such as mercury has been associated to adverse biological effects, mitigation regulatory efforts have been implemented. Long-term studies are therefore well suited to investigate the adverse effects of toxic metals since they span the large variability of metal environmental contamination while also integrating fluctuating environmental conditions such as climate and food availability. However, long-term studies that investigate multiple ecological and environmental stressors on the stress and fitness of wildlife are challenging and therefore scarce. To assess the impact of metal pollution on wildlife, raptors have often been used as biomonitors due to their high position in food webs and high exposure to contaminants. Here, we studied a resident nest box population of tawny owls (*Strix aluco*) in Central Norway over a 34-year period. The tawny owl is a common terrestrial bird of prey in Europe and a long-lived species that is territorial throughout the year. Between 1986 and 2019, population data and tail feathers from females have been collected annually resulting in approximately 1200 feathers. Their feathers represent an excellent nondestructive matrix to retrospectively analyze metal contamination in their local environment and stable isotopes as dietary proxies. In addition, corticosterone (CORT) levels in feathers were measured. As the primary avian glucocorticoid, feather CORT provides a long-term integrated measurement of physiological stress in relation to ecological variables including reproductive and fitness related traits or climate and food availability. In addition, the stress of being contaminated has been a subject of growing interest, and previous studies have also reported links between feather CORT and metals in wild birds. In the current study, we aimed to examine how annual variations in anthropogenic (metals contamination) and natural environmental stressors (climate variables, and diet), individually or jointly, modulate the individual physiological stress response (CORT) and fitness (reproduction and survival) in a key Norwegian terrestrial sentinel species. Finally, we investigated the ecological drivers of CORT, and examined whether CORT could be a proximal mechanism underlying the effects of stressors on the breeding success and fitness of tawny owls living in a rapidly changing environment and exposed to multiple stressors.

2.10.B.T-03 Monitoring Veterinary Pharmaceuticals in Livestock Carcasses Supplemented for Avian Scavengers
Marta Herrero Villar[1]*, Pablo R. Camarero*[2] *and Rafael Mateo Soria*[3]*, (1)Institute for Game and Wildlife Research, IREC (CSIC-UCLM), Spain, (2)Instituto de Investigación en Recursos Cinegéticos (IREC) CSIC-UCLM-JCCM, Spain, (3)Wildlife Toxicology, Instituto de Investigación en Recursos Cinegéticos (IREC) CSIC-UCLM-JCCM, Spain*
Veterinary pharmaceuticals are considered emerging contaminants in the environment. Some of these compounds reach avian scavengers through trophic chain when consuming contaminated carcasses. This is of increasing concern in EU, especially after the detection of the first case of diclofenac intoxication in one cinereous vulture (*Aegypius monachus*) in Spain. Here we analysed 48 commonly used veterinary pharmaceuticals in tissues from livestock carcasses supplied at feeding stations for avian scavengers consumption in Spain. These included antibiotics, nonsteroidal antiinflammatory drugs (NSAIDs), external antiparasitic drugs, and one antimuscarinic drug. Carcasses were collected in 2022 in 10 feeding sites in Aragon. Samples selected were liver, muscle, and kidney from pig (n = 93), sheep (n = 18), goat (n = 7), cow (n = 1), chicken (n = 30), and rabbit (n = 10). These were analysed using liquid chromatography coupled to a mass spectrometry (LC-MS-TQ). NSAIDs were detected in 7.5% (12/159) and antibiotics in 53.5% (85/159) of the total livestock carcasses supplied. Diclofenac was detected in 1.1%, ketoprofen in 3.2%, flunixin in 1.1%, hydroxyethil salicylate 1.1%, and meloxicam in 6.5% of the analysed pig tissues. Some of these

compounds were also detected in sheep (flunixin, 16.7%), goat (flunixin, 14.3%), and chicken (flunixin, 13.3%; meloxicam: 6.7%). Antibiotics detected in the total of carcasses analysed were: ciprofloxacin and lincomycin, both 17.6%; tilmicosin, 16.4%; marbofloxacin, 10.1%; enrofloxacin, 9.4%; tulathromycin, 5.7%; trimethoprim; 4.4%, sulfadiazine, 3.8%; gamithromycin, 1.9%; doxycycline, sulfadimidine, and oxytetracycline, all 1.3%; tetracycline, chloramphenicol, and florfenicol, all 0.6%. Highly toxic NSAIDs for vultures, including diclofenac, were detected in livestock carcasses. Even if most of the detected NSAIDs were not present at high doses that could potentially cause mortality, the highest flunixin levels detected could already pose a risk to vultures. Pharmaceuticals were mostly detected in pig carcasses, including highly toxic NSAIDs, suggesting a higher risk of exposure through their consumption. For the first time we present data on veterinary pharmaceutical residues in carrion from chicken and rabbit, which show high prevalence of antibiotics. The obtained information will be used to describe the determinants of the exposure to pharmaceuticals in avian scavengers necessary to establish measures of risk mitigation.

2.10.B.T-04 The ATTAC Guiding Principles to Openly and Collaboratively Share Wildlife Ecotoxicology Data
Cynthia C. Munoz[1]*, Sandrine Charles*[2]*, Emily McVey*[3] *and Peter Vermeiren*[1]*, (1)Radboud University, Netherlands, (2)UMR CNRS 5558, University Claude Bernard Lyon 1, Villeurbanne, France, (3)Board for the Authorisation of Plant Protection Products and Biocides (Ctgb), Ede, Netherlands*
The inability to quantitatively integrate scattered data regarding potential threats posed by the increasing total amount and diversity of chemical substances in our environment limits our ability to understand whether existing regulations and management actions sufficiently protect wildlife. Systematic literature reviews and meta-analyses are great scientific tools to build upon the current push for accessibility under the Open Science and FAIR movements. Despite the potential of such integrative analyses, the emergence of innovative findings in wildlife ecology and ecotoxicology is still too rare relative to the potential that is hidden within the entirety of the available scattered data. To promote the reuse of wildlife ecotoxicology data, we propose the ATTAC workflow which comprises five key steps (Access, Transparency, Transferability, Add-ons, and Conservation sensitivity) along the chain of collecting, homogenizing, and integrating data for subsequent meta-analyses. The ATTAC workflow brings together guidelines supporting both the data prime movers and re-users. As such, the ATTAC workflow could promote an open and collaborative wildlife ecotoxicology able to reach a major objective in this applied field, namely, providing strong scientific support for regulations and management actions to protect and preserve wildlife species in the context of chemical risk. This presentation will provide a brief overview of the ATTAC workflow, focusing on the five main steps, the philosophy behind, and its added value to promote an open and collaborative wildlife ecotoxicology in the coming years.

2.10.B.T-05 Frontiers in Quantifying Wildlife Behavioural Responses to Chemical Pollution
Michael Grant Bertram[1]*, Jake Martin*[1]*, Erin McCallum*[1]*, Lesley A. Alton*[2]*, Jack Brand*[2]*, Bryan W. Brooks*[3]*, Daniel Cerveny*[4]*, Jerker Fick*[5]*, Alex Ford*[6]*, Gustav Hellström*[4]*, Marcus Michelangeli*[1]*, Shinichi Nakagawa*[7]*, Giovanni Polverino*[8]*, Minna Saaristo*[9]*, Andy Sih*[10]*, Hung Tan*[2]*, Charles Tyler*[11]*, Bob B.M. Wong*[2] *and Tomas Brodin*[1]*, (1)Wildlife, Fish and Environmental Studies, Swedish University of Agricultural Sciences (SLU), Sweden, (2)School of Biological Sciences, Monash University, Australia, (3)Environmental Science, Baylor University, (4)Swedish University of Agricultural Sciences (SLU), Sweden, (5)University of Umea, Sweden, (6)University of Portsmouth, United Kingdom, (7)University of New South Wales, Australia, (8)Monash University, Australia, (9)EPA Science, Environment Protection Authority Victoria, Australia, (10)University of California, Davis, (11)University of Exeter, United Kingdom*
Animal behaviour is remarkably sensitive to disruption by chemical pollution, with widespread implications for ecological and evolutionary processes in contaminated wildlife populations. However, conventional approaches applied to study the impacts of chemical pollutants on wildlife behaviour seldom address the complexity of natural environments in which contamination occurs. This talk will present a new review by Bertram et al. (2022, Biological Reviews, https://doi.org/10.1111/brv.12844), which aims to guide the rapidly developing field of behavioural ecotoxicology toward increased environmental realism, ecological complexity, and mechanistic understanding. This review identifies research areas in ecology that to date have been largely overlooked within behavioural ecotoxicology but which promise to yield valuable insights, including within- and among-individual variation, social networks and collective behaviour, and multistressor interactions. Further, the review features methodological and technological innovations that enable the collection of data on pollutant-induced behavioural changes at an unprecedented resolution and scale in the laboratory and the field. In an era of rapid environmental change, there is an urgent need to advance our understanding of the real- world impacts of chemical pollution on wildlife behaviour. This review therefore provides a roadmap of the major outstanding questions in behavioural ecotoxicology and highlights the need for increased cross-talk with other disciplines in order to find the answers.

2.10.P Field Studies, Monitoring and Effects Research in Wildlife

2.10.P-We084 Are Metal Levels in Female Sea Turtles Influencing Their Eggs?
Inês Filipa Cigarro Morão[1]*, Tiago Filipe da Silva Simoes*[1]*, Roger B. Casado*[1]*, Sara Vieira*[2]*, Marco F.L. Lemos*[1] *and Sara Novais*[3]*, (1)Polytechnic of Leiria & MARE, Portugal, (2)Associação Programa Tatô & CCMAR, Portugal, (3)Instituto Politécnico de Leiria, Portugal*
Marine turtles are global migrators with a complex life cycle that involves several ecosystems. Due to their long lifespan, as well as their feeding habits, these reptiles tend to accumulate persistent pollutants in their tissues, such as metals and metalloids. These pollutants are widely distributed and are known to have harmful effects in a myriad of organisms. Sea turtles are known to accumulate these pollutants, but few studies have been made to address how the effects of metal pollution in reproductive female individuals may influence their overall health and especially the quality of their eggs to infer on health of future sea turtles'

generations. São Tomé Island hosts important nesting and feeding grounds for four of the seven existing species of sea turtles, including the green (*Chelonia mydas*) and the hawksbill (*Eretmochelys imbricata*) sea turtles. The main goal of this study was to explore if the contamination by different metals and metalloids in the blood of nesting female green and hawksbill sea turtles could be associated with morphological characteristics and composition of their eggs and respective compartments (e.g., total fat, weight from the different compartments, shell thickness, and egg dimensions). In sea turtle eggs, the yolk represents most of the egg mass, and it is highly rich in lipids. Additionally, yolk fatty acids are the major source of energy for embryo development and for the posthatching activity, as both metabolic and signalling mediators. As metals are known to exert a strong negative influence on lipids and fatty acids, this study also aimed to evaluate if the energetic reserves quality for the embryo development (fatty acids in the yolk) in these two species would be affected by the contamination status of their mothers. Results indicate that the screened contaminants significantly affected the egg diameter, shell and membrane weight, shell thickness and lipid reserves. Regarding the fatty acids from the egg yolk, the ones linked to the polar fraction (mostly associated to lipoproteins) seemed to be more influenced by the contaminant levels of the females, where significant correlations were found particularly with fatty acids with higher unsaturation degrees, such as n3 and n6, thus suggesting oxidative events in yolk fat membranes and protein mobilization. Overall, this study showed that how these contaminants present in the blood of female turtles may be affecting their reproductive output by altering egg quality.

2.10.P-We085 Biomonitoring of Metals in Blood andFeathers of Cinereous Vultures (*Aegypius monachus*) Nestlings from do Tejo Internacional Natural Park (Portugal), 2018-2021.

Antonio Juan Garcia-Fernandez[1], *Pedro Jiménez*[2], *Alfonso Godino Ruíz*[3], *Alicia Montano*[2,4] *and Isabel Navas*[5], *(1)Toxicology and Risk Assessment Research Group, Faculty of Veterinary, University of Murcia, Spain, (2)Health Sciences, University of Murcia, Spain, (3)Hawk Mountain Sanctuary, Portugal, (4)Consejería de Agua, Agricultura y Medio Ambiente de la Región de Murcia, Spain, (5)Health Sciences-Faculty of Veterinary-IMIB, University of Murcia, Spain*

The Parque Natural do Tejo International (Tejo N.P.) encompasses a portion of the municipalities of Castelo Branco and Idanha-a-Nova (Portugal), with around 154 breeding bird species, including cinereous vulture (*Aegypius monachus*). To our knowledge, this should be the first study about the presence of several metals in both blood and feather samples, from nestlings of this species. It has been suggested that one the main cause of death in Cinereous vultures could be lead poisoning by consuming of carcasses left by hunters using lead ammunition. Cinereous vulture is considered an endangered species in Portugal, and it is well known that abnormal exposure to some metals can affect species at the population level. The aim of this study is biomonitoring metals in blood and feathers of 34 nestlings of Cinereous vulture from Tejo N.P. (Portugal), to estimate the type of exposure and, if possible, potential effects by Pb and other metals of concern (Cd, Hg, As, Zn, Cu). Samples were collected during 4 breeding seasons: 2018 (n =7), 2019 (6), 2020 (10), and 2021 (11). Analyses were done by ICP-MS after wet digestion in quartz tubes. CRM TORT-2 was used for quality assurance. Median concentrations (ng/g) detected were Zn(115,764) > Cu(5,966) > Pb(785) > Hg(269) > As(255) > Cd(14.4) in feathers, and Zn(5,106) > Cu(404) > Pb(119) > As(6.70) > Hg(2.30) > Cd(0.30) in blood. Zn and Cu are essential trace elements, whilst the rest of elements have not known biological activity. Median concentrations in feathers were significantly higher than in blood, with the following feather/blood rates: Hg(117) > Cd(48) > As(38) > Zn(22) > Cu(15) > Pb(7). Twelve vultures had blood Pb levels below 8.00 µg/dL (background exposure level), 14 were below 20.00 µg/dL (analytical biomonitoring), 7 vultures were below 40 µg/dL (subclinical biomonitoring), and only one vulture had 45.34 µg/dL (preventive intervention). In other words, 24% of the population studied had blood lead concentrations of concern. Concentrations detected in this study will be contrasted with the scarce available published data on this species. In conclusion, although more information about metal exposure in Cinereous vultures is necessary, these results indicate that the exposure to lead should be periodically monitored and studies of biomarkers should be carried out to observe potential effects metal-induced.

2.10.P-We086 Estimation of the Daily Incidence of Lead Ammunition Ingestion in Griffon Vulture with Regurgitated Pellets

Rafael Mateo Soria[1], *Pepa Lavilla*[2] *and Rhys E Green*[3], *(1)Wildlife Toxicology, Instituto de Investigación en Recursos Cinegéticos (IREC) CSIC-UCLM-JCCM, Spain, (2)Instituto de Investigación en Recursos Cinegéticos (IREC) CSIC-UCLM-JCCM, Spain, (3)Department of Zoology, University of Cambridge, United Kingdom*

The birds of prey can be exposed to high lead (Pb) doses by ingesting shotgun pellets or bullet fragments that are embedded in the tissues of the prey they consume. Although birds of prey, including scavengers, can eliminate Pb ammunition by regurgitating it into pellets, the extremely acid gastric fluid of these species favours its partial dissolution and absorption during the digestion process. The objective of this study was to quantify the frequency of Pb ammunition ingestion in griffon vultures (*Gyps fulvus*) to establish whether the prevalence and concentrations observed in vultures in other studies in Spain can be fully explained by the ingestion of Pb ammunition. The study also allowed us to assess the spatiotemporal variations of ammunition ingestion and the relationship with game meat consumption. Fresh pellets (n = 622) were collected throughout all seasons of the year between 2020-2022 at roosting sites in Spain. Pellets were X-rayed and those with the most radiopaque particles were examined and the metal particles retrieved for the identification of element composition by ICP-MS. The main prey present in each pellet was identified by colour and microscopic characteristics of hairs. The X-ray examination revealed the presence of radiopaque particles of Pb (8.5% of pellets), Cu (1.1%), Fe (0.3%), and Bi (0.3%). In summary, 9.6% of pellets contained ammunition fragments, that is, Pb and/or Cu. Prevalence of ammunition ingestion were significantly higher in the periods with large game hunting (11.7%, n = 385) than in the rest of the year (6.3%, n =237, p = 0.011). The studied pellets contained game animals (33.0%), livestock (33.6%), or a mixture of both (33.4%), and the presence of ammunition particles was higher in pellets with game animal remains (17.6%) than in those with livestock remains (3.3%, p = 0.001). Assuming an average pellet regurgitation time of 3 days and a time for elevated (>20 g/dL) blood Pb concentration after ammunition ingestion of 14 days, we may estimate a similar daily incidence (3-4%) from the prevalence obtained from blood Pb analysis in live free-ranging vultures (44.5%) and from noninvasive monitoring of regurgitated pellets (9.6%). The high rate of ammunition ingestion associated with the consumption of game animals may well explain the high prevalence of blood Pb levels >20 µg/dL according to the similar incidence estimated from blood analysis and noninvasive pellet monitoring.

2.10.P-We087 Fecal Calcium Levels of Bird Nestlings as an Indicator of Species-Specific Sensitivity to Metal Pollution
*Silvia Espín†[1], **Lyydia Irmeli Leino**[2], Miia J. Rainio[2], Pablo Sanchez Virosta[1], Jukka Suhonen[3] and Tapio Eeva[2], †deceased 6th April 2022, (1)University of Murcia, Spain, (2)Department of Biology, University of Turku, Finland, (3)University of Turku, Finland*
Sensitivity of bird species to environmental metal pollution varies but there is currently no general framework to predict species-specific sensitivity. Such information would be valuable from the conservation point-of-view. Calcium (Ca) has antagonistic effects on metal toxicity and studies with some common model species suggest that low dietary and circulating calcium (Ca) levels indicate higher sensitivity to harmful effects of toxic metals. Here we test the generality of this idea with a larger set of bird-species. We collected fecal samples from nestlings of 66 bird species to estimate levels of their dietary Ca and five other macroelement (Potassium K, Magnesium Mg, Sodium Na, Phosphorus P, Sulphur S) by using fecal concentrations as a proxy measure for diet. We found marked interspecific differences in fecal Ca concentration, which correlated positively with Mg and negatively with Na, P and S levels. Lowest Ca concentrations were found in insectivorous species and especially aerial foragers, such as swifts (Apodidae) and swallows (Hirundinidae) indicating potentially high sensitivity to toxic metals. Instead, ground foraging species like starlings (Sturnidae), sparrows (Passeridae), cranes (Gruidae) and larks (Alaudidae) showed relatively high Ca levels. Independent on phylogeny, insectivorous diet and aerial foraging seem to indicate low Ca turnover and potential heavy metal sensitivity. Our results, together with information published on fecal Ca levels and toxic metal impacts, suggest that dietary Ca levels are a promising new tool to evaluate potential metal-sensitivity of bird nestlings, and we encourage collecting such information on wider range of bird species.

2.10.P-We088 Exploring Environmental Chemical Exposure in Seabird Chicks at Two European Breeding Sites Using a Nontargeted Analytical Approach
***Laura Kamp**[1], Elizabeth M. Humphreys[2], Mark A. Taggart[3], Caroline Gauchotte-Lindsay[4], Laurie Savage[4], Eric Stienen[5] and Karen A. Spencer[1], (1)School of Psychology and Neuroscience, University of St Andrews, United Kingdom, (2)BTO Scotland, United Kingdom, (3)Environmental Research Institute, University of the Highlands and Islands, United Kingdom, (4)James Watt School of Engineering, University of Glasgow, United Kingdom, (5)Instituut voor Natuur-en Bosonderzoek (INBO), Belgium*
Chemical pollution of anthropogenic origin affects wildlife in marine habitats across the world. Many environmental chemicals (ECs) can accumulate through the food chain, and long-lived organisms and top predators such as seabirds can suffer particularly severe effects. Seabirds are also threatened by other stressors (i.e., climate change, disease, and shifts in prey abundance). Such pressures are resulting in notable declines in the UK as well as in other European regions. Understanding the role that ECs might play in these biodiversity losses is therefore critical.
While there is much interest in understanding the relationships between ECs and effects, most studies focus on specific groups of chemicals (e.g., metals or organochlorines) using targeted analytical approaches. Most of the research also tends to focus on adult birds – but EC exposure can be particularly harmful in the early stages of life when many important developmental processes are taking place. Therefore, it is important to better understand the specific effects of ECs during pre- and early postnatal life, which can have an impact up to population level.
The aim of this project was to establish comprehensive EC profiles in seabirds breeding at two different European sites: a colony within a national nature reserve in Scotland and a colony in a busy harbour in Belgium, using a non-targeted analytical approach. By sampling from these different sites, a comparison could be made between a more natural environment and a location under strong anthropogenic influence. Work focused on early postnatal exposure in Arctic terns and common terns and possible effects on chick development and health. Both species are long-lived seabirds feeding at a higher trophic level. Samples were screened for different ECs using two-dimensional gas chromatography-time-of-flight mass spectrometry and thus a broad overview of exposure was established.

A better understanding of the impacts of ECs on seabirds will help improve their conservation, enable mitigation of negative impacts and help predict risks to other species foraging in the same habitats. In addition, previously overlooked ECs could be detected with the help of a nontargeted approach.

2.10.P-We089 Exploring VKOR Gene Expression as a Biomarker to Assess Anticoagulant Rodenticide Exposure in Eagle Owl (*Bubo bubo*) Nestlings
***Livia Spadetto**[1], Pilar Gomez-Ramirez[1], Antonio Juan Garcia-Fernandez[2], Mario León-Ortega[3], José Manuel Zamora-Marín[3,4], Sarah Díaz-García[3], Antonio Zamora-López[3,4], José F. Calvo[5], José M. Navas[6] and Azucena Bermejo-Nogales[6], (1)Toxicology Research Group, Faculty of Veterinary, University of Murcia, Spain, (2)Toxicology and Risk Assessment Research Group, Faculty of Veterinary, University of Murcia, Spain, (3)Ulula Research Group, Murcia, Spain, (4)Department of Zoology and Physical Anthropology, Faculty of Biology, University of Murcia, Spain, (5)Department of Ecology and Hydrology, Faculty of Biology, University of Murcia, Spain, (6)Instituto Nacional de Investigación y Tecnología Agraria y Alimentaria (INIA-CSIC), Spain*
Anticoagulant rodenticides (ARs) are toxic compounds widely used against rodents, especially in agricultural and urban areas. Owing to their high toxicity and bioaccumulation capacity, they pose a serious risk to exposed predators, leading to secondary

poisoning. However, the factors determining the level of exposure in nontarget wildlife have been poorly investigated. The vitamin K 2,3-epoxide reductase (VKOR) represents the molecular target of ARs and plays an essential role in the vitamin K cycle and activation of clotting factors. Its isoenzymes vitamin K 2,3-epoxide reductase complex subunit 1 (VKORC1) and VKORC1-like1 (VKORC1L1) catalyze the same reaction but show a different expression ratio according to tissue type and species. Previous studies on VKOR activity in avian species highlight that owls are particularly sensitive to ARs. The Eurasian eagle owl is considered a suitable sentinel species for biomonitoring contaminants in southeastern Spain, where this species is abundant and likely to be exposed to ARs. As the VKOR enzymes are inhibited by ARs, we hypothesized that VKOR gene expression would increase as a compensatory response. In such case, this measure would be a suitable biomarker of exposure and effect to ARs. The aim of the present study is to analyse VKORC1 and VKORC1L1 gene expression in different scenarios with possible sources of ARs contamination. For this purpose, 72 samples belonging to Eagle owl (*Bubo bubo*) chicks from 26 nests were collected in the Region of Murcia (Spain), close to potential sources of ARs pollution (< 2 km). These included fruit tree crops, intensive livestock farms, landfill sites, and human settlements. Some of the sampled nests were located in natural areas (control sites). The results show that the total expression (sum of the expression of VKORC1 and VKORC1L1) is significantly higher in owlets from nests located near residential areas than in control areas ($p = 0.012$). Though not significant, a similar trend is found in owlets from nests in the close vicinity of fruit orchards. These findings suggest that Eagle owl populations living near urban areas are more exposed to ARs, which increases the risk of suffering its harmful effects. Furthermore, this study indicates that VKOR mRNA expression may be a promising biomarker of ARs exposure for Eagle owl as well as for other nontarget species.

2.10.P-We090 Exposure Assessment of Anticoagulant Rodenticides in Liver of Red Foxes (*Vulpes vulpes*) in Slovenia

Vesna Cerkvenik Flajs[1]*, Detlef Schenke*[2]*, Diana Žele-Vengušt*[3]*, Simona Korenjak-Černe*[4] *and Gorazd Vengušt*[3]*, (1)University of Ljubljana, Slovenia, (2)Julius Kühn-Institute Federal Research Centre for Cultivated Plants (JKI), Germany, (3)University of Ljubljana, Veterinary Faculty, Slovenia, (4)University of Ljubljana, School of Economics and Business, Slovenia*

Due to their mass use, anticoagulant rodenticides (ARs) pose a significant environmental problem with toxic effects on nontarget wildlife. For this reason, residues of the first generation ARs chlorophacinone, coumatetralyl, and warfarin and of the second generation ARs brodifacoum, bromadiolone, difenacoum, difethialone, and flocoumafen were monitored in red foxes (*Vulpes vulpes*) in Slovenia to assess their bioaccumulation and the occurrence of secondary poisoning.

In 2019–2022, 148 liver tissue samples were collected from legal and regulated hunting of adult red foxes from all geographical regions of Slovenia. The samples were extracted with methanol/water (2:1, v/v), cleaned-up using a solid supported liquid-liquid extraction, and measured by liquid chromatography-electrospray tandem mass spectrometry (LC-ESI-MS/MS) with reporting limits in the range of 0.5–5.0 ng/g. Residues of at least one rodenticide were detected in 77.7% of the analyzed livers. The second generation ARs bromadiolone, brodifacoum, and difenacoum were most frequently found in 75.0, 51.4, and 18.9% of the samples, respectively. Concentrations of pooled ARs ranged from 1.5 to 2866.5 ng/g with a mean and median value of 601.4 and 350.2 ng/g, respectively. We determined bromadiolone at concentrations of ≥800 ng/g in 16 of 148 fox livers (10.8%) and two of them (1.4%) contained residues >2000 ng/g. The distribution of bromadiolone and brodifacoum showed no significant differences across sex and body mass categories of the animals included in the study. First generation ARs were found in only 9.5% of the samples, the residues were with one exception (coumatetralyl with 55 ng/g) below 10 ng/g. Chlorophacinone and difethialone were not detected. The results of the study demonstrate a serious toxicological risk for red foxes in Slovenia.

To the best of our knowledge, this is the first study to assess the exposure of nontarget animals in the Western Balkan countries to ARs. The findings highlight a potential environmental problem related to persistence, bioaccumulation, and toxicity of ARs in this region and will contribute to the knowledge on the protection of European ecosystems.

2.10.P-We091 Greater Predisposition to Anticoagulant Rodenticide Exposure in Red Foxes (*Vulpes vulpes*) Affected by Canine Distemper Disease

Alberto Carrera[1]*, Pedro María-Mojica*[1]*, Isabel Navas*[2] *and* ***Antonio Juan Garcia-Fernandez***[3]*, (1)Health Sciences, Faculty of Veterinary, University of Murcia, Spain, (2)Health Sciences-Faculty of Veterinary-IMIB, University of Murcia, Spain, (3)Toxicology and Risk Assessment Research Group, Faculty of Veterinary, University of Murcia, Spain*

Anticoagulant rodenticides (ARs) exposure in wild carnivores is a global concern due to their continuous and widespread use worldwide. We studied the prevalence of ARs in liver samples of 25 Red foxes (*Vulpes vulpes)*, 3 European badgers (*Meles meles*), and 2 Genets (*Genneta genneta)* from Alicante (Spanish Levante region) obtained in 2021 and 2022. All samples came from Santa Faz Wildlife Rehabilitation Center (Alicante, Spain) where the necropsies were performed. The most frequent causes of death in wild carnivores in this region are trauma and poisoning by pesticides. However, during this period of study there were several foxes with suspected infectious clinical disease. All commercially available AR active ingredients in Europe were included in this study. So, both first and second generation ARs were analysed by HPLC/MS/TOF in liver samples after a QuEChERS extraction procedure. Apart from the cause of death, the influence of other variables such as age, sex and location were also assessed in ARs liver concentrations. Potential health risk for individuals and populations in the study area have been studied. In relation with this, higher ARs concentrations have been detected in a group of red foxes affected by distemper virus compared to another group of healthy red foxes, mostly killed by trauma. Therefore, the present research aims to explain a possible association between the fact of suffering from an infectious disease and the increase in ARs concentrations of affected animals. Furthermore, we expect to confirm the hypothesis that Red fox (*Vulpes vulpes*) is considered a good sentinel species for the risk of exposure to ARs. All the samples analysed contained ARs and the most detected compounds were difenacoum and bromadiolone (100% of the samples), brodifacoum (93.33%), and flocoumafen (86.67%). Additionally, 53.33% of the animals had at least one second generation anticoagulant rodenticide (SGAR) above the threshold value reported as triggering adverse health effects (200 ng/g). Regarding this, the level of risk in wild mammals in Levante region could be classified as high and worrying. Moreover, we suggest that individuals and populations with weakened health due to other diseases (for example, infectious) could be more prone to high exposure to anticoagulant rodenticides and, very probably, would be more sensitive to suffering serious effects at lower doses of ARs.

2.10.P-We092 High Exposure to Anticoagulant Rodenticides as Cause of Poisoning and Mortality in Bonelli's Eagles from Southestern Spain

Toni Vicedo[1], Pedro María-Mojica[2], Isabel Navas,[3] and ***Antonio Juan Garcia-Fernandez***[4]*, (1)Health Sciences, University of Murcia, Spain, (2)Health Sciences, Faculty of Veterinary, University of Murcia, Spain, (3)Health Sciences-Faculty of Veterinary-IMIB, University of Murcia, Spain, (4)Toxicology and Risk Assessment Research Group, Faculty of Veterinary, University of Murcia, Spain*

Anticoagulant rodenticides (ARs) comprise one of the most toxic groups of compounds currently used worldwide for rodent pest control. Some of them are highly persistent and bioaccumulative. Toxic baits are often, directly or indirectly, ingested by nontarget animals, resulting in secondary poisoning, and affecting frequently apex predators.

Their presence in many species of raptors is quite common, especially in scavenger species serving as sentinel for the presence of these substances in the environment. However, there is little data on the presence of AR in Bonelli's eagle, one of the most endangered eagle species in Spain and with a negative population trend in Europe. This medium-sized eagle feeds entirely on live species that it captures before feeding.
In this study, 17 carcasses of Bonelli's eagles from Valencian Community (Eastern Spain) were necropsied. Both first and second generation ARs were extracted from the livers using a modified QuEChERS technique.

Five first generation ARs (Coumafuryl, Diphacinone, Warfarin, Coumatetralyl, Chlorophacinone) and five second generation ARs (Bromadiolone, Brodifacoum, Difenacoum, Difethialone, Flocoumafen) were analyzed. Analysis of ARs by HPLC-MS revealed that all eagles studied were exposed to at least 6 ARs, out of a total of 10 ARs analyzed, with 8 being the highest number of ARs detected in a sample. Second generation ARs were the most prevalent. 35% of the eagles showed a concentration higher than 200 ng/g of ARs, being compatible with AR poisoning. Bromadiolone and Brodifacoum were the most predominant ARs and they were also the compounds with the highest concentrations, in 94% of the cases.

In conclusion, ARs are widespread in the Spanish Levant, affecting nontarget species and reaching higher trophic levels. The high presence of these compounds in Bonelli's eagles could be a new cause of mortality for this species or could explain other causes of death like the high mortality in power lines and should be taken in account for their conservation. At the same time, the presence of these compounds in the environment represents risks to public health, as the most frequent species in the diet of Bonelli's eagle (rabbits and partridges) are hunted and consumed by humans.

2.10.P-We093 Influence of Seasonality on the Temporal Trend Assessment of Wildlife Exposure to Second-Generation Anticoagulant Rodenticides: A Case Study for UK Common Buzzards (*Buteo buteo*) from 2001 to 2019

Shinji Ozaki*, UK Centre for Ecology & Hydrology (UKCEH), United Kingdom*

Avian predators are widely exposed to second-generation anticoagulant rodenticides (SGARs) by feeding on contaminated prey. Some studies have demonstrated a strong seasonal variation in the exposure of raptors to SGARs, likely linked to seasonal variation in their diet. However, many previous biomonitoring studies have not included seasonality in their models, which might lead to misleading conclusions on the risk assessment of SGARs. In this study, we modelled temporal trends of SGAR residues in Common Buzzards (Buteo buteo) with and without seasonal fluctuation to investigate how the inclusion of seasonality within the model modifies conclusions on temporal exposure trends of wildlife to SGARs.
We used 72 buzzards found dead in the wild in the UK between 2001 and 2019. For each carcass, the month of the collection was recorded, and tissue samples were collected after a postmortem examination. Liver concentrations of five SGARs (bromadiolone, difenacoum, brodifacoum, flocoumafen, and difethialone) were measured. The detection/nondetection in buzzards of each SGAR and summed SGARs (∑SGARs) over time was analysed by logistic models with and without harmonic terms (which explain seasonal fluctuation) and statistically compared. We applied the same approach, using linear models, for liver concentrations of each SGAR and ∑SGARs in the samples excluding non-detect SGAR ones.

Our initial results suggested that the detection of bromadiolone, difenacoum, and ∑SGARs was better explained by logistic models including seasonality, although models without seasonality showed similar temporal trends in detection over the period. In contrast, temporal trends of SGAR liver concentrations were better explained by linear models without seasonality, except for difenacoum whose liver concentrations were better explained by the inclusion of seasonality.
Overall, seasonality influenced the detection/non-detection of SGARs in buzzards but was not important for modelling hepatic concentrations of most SGARs over time when nondetect SGAR samples were excluded from the analysis. Our results indicate that excluding seasonality as a variable might not necessarily lead to misleading conclusions on biomonitoring. However, opportunistic avian predator biomonitoring protocols do not systematically collect samples in the same season or do not systematically exclude non-detect SGAR samples. Therefore, seasonal variation in the detection of SGARs may cause a bias in risk assessment.

2.10.P-We094 Targeted Sampling for Brown Rat Resistances Identification and Incidence in Urban Ecosystems: The City of Madrid

***Azucena Bermejo-Nogales*[1]**, *José Antonio Rodriguez Martin[2], José María Cámara[3], Agustin Cordobés[4] and José M. Navas[1], (1)Instituto Nacional de Investigación y Tecnología Agraria y Alimentaria (INIA-CSIC), Spain, (2)IINIA-CSIC - Spanish National Institute for Agricultural and Food Research and Technology, Spain, (3)Madrid Salud, (4)Lokimica*

Brown rats (*Rattus norvegicus*) are commensal rodent species found in towns and one of the most frequent urban pest. Their control is crucial for authorities in order to avoid health and economic issues. Nowadays, the only effective control method available is the use of anticoagulant rodenticides (ARs) that inhibit the enzyme vitamin K 2,3-epoxide reductase (VKORC1), responsible for reducing vitamin K. The inhibition of VKORC1 prevents the activation of the coagulation factors resulting in animal death by internal bleeding. Resistance to AR is associated to vkorc1 mutations and have been found through random sampling of Pest Control Operators (PCOs) worldwide. In the present study, we aim to introduce targeted sampling procedure as a useful tool for pest controllers' authorities and sanitation companies in the urban environment. Sampling was designed with the aim of inferring the results to the general population of rats in Madrid Central Almond with an area of 4.8 km². The districts were divided into grids of 1000 x 1000 m to ensure the collection of a sufficient number of samples that encompass the largest number of rat colonies. Design also included the selection of sites of at least one segment or section of the sewer system practicable for at least 100 m long. In each collector, six points of sampling of faecal deposits were spaced at least 20 meters to guarantee individuality. Geospatial analysis was done to relate population density, rat warnings, bromadiolone use, and trash production with vkorc1 mutation frequency. A total of 126 stool samples were received from the Department of Vector Control of the City Council of Madrid from 16 neighbourhoods of seven districts. Mutation frequency varies among neighbourhoods and is dispersed along the main central road. The S149I mutation is most frequent in the south and the E155K in the north while double mutant is found in the central district. Interestingly, increase in mutation frequency shows a tendency towards high trash production. The mutation frequency map is an instant moment of what has been done in the past and indicates the areas to change the use of AR and rodent environmental food supply. Therefore, the design of an appropriate sampling would improve control management following resistance evolution over time and space by monitoring the genetics of vkorc1 in the rodent populations.

2.10.P-We095 Pesticides and Biocides in the Danish Population of European Hedgehogs (*Erinaceus europaeus*)

Sophie Lund Rasmussen[1], Katrin Vorkamp[2], Linyan Zhu[3], **Peter Roslev[4]**, *Cino Pertoldi[5] and Jeppe Lund Nielsen[5], (1)University of Oxford, United Kingdom, (2)Department of Environmental Science, Aarhus University, Denmark, (3)Department of Environmental Science, Aarhus University, Roskilde, Denmark, (4)Aalborg University, Denmark, (5)Department of Chemistry and Bioscience, Aalborg University, Denmark*

European hedgehogs (*Erinaceus europaeus*) inhabit most of Denmark. Long-term reduction of suitable habitats causes hedgehogs to increasingly inhabit areas with human occupancy, e.g., gardens, parks, and other recreation spaces, with the potential for pesticide and biocide exposure. In addition, hedgehogs inhabiting rural areas may come into contact with pesticides applied during agricultural practices. The exposure of hedgehogs to potentially toxic chemicals could be a contributing factor to the decline of this species.

Our research studied the occurrence of various pesticides and biocides in European hedgehogs from Denmark and investigated potential risks of exposure by testing for links to age, sex, location, degree of inbreeding, cause of death, and habitat type of the animals.

We used liver samples obtained from dead hedgehogs collected in Denmark in 2016 as part of a citizen science component of The Danish Hedgehog Project. We analysed a selection of commonly used rodenticides (N = 6), insecticides (N =5) and herbicides (N =8) in 115 individuals, using a liquid chromatography-tandem mass spectrometry (LC-MS/MS) method. Furthermore, livers from 17 individuals were selected for non-targeted screening with LC-QToF-MS and GC-Orbitrap-MS.

The targeted analyses showed detection frequencies (DFs) between zero and up to 79% for bromadiolone, with a median value of 12% and an interquartile range (IQR) of 3%-30% across all compounds. Besides bromadiolone, the compounds detected most frequently included the rodenticides coumatetralyl (49%) and brodifacoum (32%) as well as the insecticide imidacloprid (35%). Concentrations varied between nondetected to >2 µg/g. Our preliminary data analysis indicated that the presence of pesticides and biocides did not appear to be affected by sex, age, degree of inbreeding, or habitat type. The DFs were found to differ significantly between localities for difenacoum (Jutland (47%) versus Zealand (22%)), difethialone (Zealand (38%) versus Jutland (16%), and imidacloprid (Zealand (46%) versus Jutland (23%)).

The GC- and LC-based nontargeted analyses revealed 35 and 38 potential pollutants, respectively. Among those were legacy persistent organic pollutants (POPs), such as p,p'-dichlorodiphenyldichloroethane (DDE), hexachlorobenzene (HCB), and polychlorinated biphenyls (PCBs). In addition, several pharmaceuticals were identified.

We conclude that European hedgehogs are exposed to a diverse range of anthropogenic compounds in Denmark.

2.10.P-We096 Relationship between Pesticides and Emergent Diseases in Wildlife Inhabiting Agrosystems: Glyphosate and Myxomatosis in the Iberian Hare

***Alicia Isabel Martínez González*[1]**, *Beatriz Cardoso[1,2], Dayana Montes[1], Rafael Quiles-Zafra[3], Ignacio Garcia-Bocanegra[4], Jose Alberto Viñuelas[5], Pelayo Acevedo[1] and Monica Martinez-Haro[5], (1)Instituto de Investigación en Recursos Cinegéticos (IREC) CSIC-UCLM-JCCM, Spain, (2)University of Porto, Centro de Investigação em Biodiversidade e Recursos Genéticos (CIBIO),*

InBIO Laboratório Associado, Portugal, (3)Agriculture and Environmental Laboratory, Consejería de Agricultura. Junta de Comunidades de Castilla-La Mancha, Toledo, Spain, (4)Departamento de Sanidad Animal, University of Córdoba, Spain, (5)Instituto Regional de Investigación y Desarrollo Agroalimentario y Forestal de Castilla La Mancha (IRIAF), Spain
Pesticide consumption has increase exponentially in the last decades around the world, largely due to its use in agriculture. In this sense, wildlife species inhabiting agrosystems are potentially continuously exposed to a large amount of pesticides. Although pesticides mode of action on target species is often known, their secondary or sublethal effects on wildlife in general are not known but are expected to modulate population dynamics. Another important factor involved in modulating wildlife populations is infectious diseases, especially emerging diseases, which often appear as outbreaks with high mortality rates. In this context, wild lagomorphs, strongly associated with agrosystems, appear as excellent animal models and sentinels of exposure to pesticides and pathogens, due to their ecological relevance as keystone species and their socioeconomic value as game animals. Therefore, this work aimed to study the exposure to pesticides and emerging pathogens on wildlife, using the Iberian hare (*Lepus granatensis*) as a model species. This species is since 2018 hit by a highly virulent emerging disease, myxomatosis. For this purpose, glyphosate residues were analysed together with the seroprevalence of myxomatosis in hunted animals from pesticides-treated and pesticide-free areas during the 2021/22 hunting season in the southwestern Spain. Glyphosate residues were analysed in samples of gastric contents based on a method previously developed for our research team with some modifications for high performance liquid chromatography coupled to triple quadrupole with linear ion trap (Q-TRAP). For myxomatosis, we considered both animals with compatible lesions during necropsy, as well as with antibodies for this virus in serum samples by ELISA techniques. The results are expected to represent a significant scientific breakthrough due to the widespread use of pesticides worldwide, the population decline observed in many wild species associated with agrosystems, and the controversy over chronic toxic effects on nontarget organisms, including their synergistic effects with emerging infectious diseases.

2.10.P-We097 Relationship between the Effects of Pesticides and Disease in Iberian Hare Female Reproduction
***Alicia Isabel Martínez González**[1], Dayana Montes[1], Beatriz Cardoso[1,2], Rafael Quiles-Zafra[3], Maria Angeles Risalde[4], Ignacio Garcia-Bocanegra[4], Jose Alberto Viñuelas[5], Pelayo Acevedo[1] and Monica Martinez-Haro[5], (1)Instituto de Investigación en Recursos Cinegéticos (IREC) CSIC-UCLM-JCCM, Spain, (2)University of Porto, Centro de Investigação em Biodiversidade e Recursos Genéticos (CIBIO), InBIO Laboratório Associado, Portugal, (3)Agriculture and Environmental Laboratory, Consejería de Agricultura. Junta de Comunidades de Castilla-La Mancha, Toledo, Spain, (4)Universidad de Córdoba, Spain, (5)Instituto Regional de Investigación y Desarrollo Agroalimentario y Forestal de Castilla La Mancha (IRIAF), Spain*
In recent decades, species associated to agrosystems have declined significantly worldwide. Numerous factors have been identified as possible causes of these declines, including environmental pollution (largely due to the increase in the use of pesticides in the 20th century). Another important factor involved in modulating wildlife populations is infectious diseases, especially emerging diseases, which often appear as outbreaks with high mortality rates. While the effects of some wildlife infectious diseases on population dynamics are well established, the combined effects that pesticides and pathogens can produce remain largely unknown. Therefore, this study analyses for the first time the independent effects of exposure to pesticides, as well as their combined effects with emerging pathogens, on the population dynamics of wildlife inhabiting agrosystems. More specifically, we have analysed, by histological study, the number of different ovarian follicles in females hunted Iberian hare (*Lepus granatensis*) in pesticide-treated and pesticide-free areas with and without symptoms compatibles with myxomatosis or myxomatosis antibodies during the 2021/22 hunting season in the southwestern Spain. Species affected by this emerging disease since 2018. Preliminary results showed lower number of corpora lutea in individuals from treated areas than pesticides-free areas. In addition, individuals with myxomatosis tended to have lower number of primary follicles, tertiary follicles, atretic follicles and corpora lutea than animals without myxomatosis, although the differences were not significant. Overall, the results suggest that in intensive agricultural areas pesticide exposure could have reproductive effects by decreasing the number of ovarian follicles, effect that can act synergistically with the effect of diseases. We discuss the implications of these results from the perspective of the conservation of this species.

2.10.P-We098 Relationship between the Effects of Pesticides and Disease in Iberian Hare Male Reproduction
*David Martin-Hidalgo[1], Beatriz Cardoso[2,3], Lauro Gonzalez-Fernandez[1], Alicia Isabel Martínez González[4], Rafael Quiles-Zafra[5], Ignacio Garcia-Bocanegra[6], Pelayo Acevedo[2], Jose Alberto Viñuelas[7] and **Monica Martinez-Haro**[7], (1)Grupo de Investigación Señalización Intracelular y Tecnología de la Reproducción (SINTREP), Instituto de Investigación INBIO G+C, University of Extremadura, Spain, (2)Instituto de Investigación en Recursos Cinegéticos (IREC) CSIC-UCLM-JCCM, Spain, (3)University of Porto, Centro de Investigação em Biodiversidade e Recursos Genéticos (CIBIO), InBIO Laboratório Associado, Portugal, (4)Instituto de Investigación en Recursos Cinegéticos (IREC), Spain, (5)Agriculture and Environmental Laboratory, Consejería de Agricultura. Junta de Comunidades de Castilla-La Mancha, Toledo, Spain, (6)Departamento de Sanidad Animal, University of Córdoba, Spain, (7)Instituto Regional de Investigación y Desarrollo Agroalimentario y Forestal de Castilla La Mancha (IRIAF), Spain*
Pesticides and emerging diseases have been identified among the five most important threats to biodiversity globally. Concerning pesticides, there are important shortcomings in the knowledge of secondary or sublethal effects on wildlife and therefore, its potential impact at population level. While the effects of some wildlife infectious diseases on population dynamics are well established, the combined effects that pesticides and pathogens can produce remain largely unknown. In this context, this study analyses the independent effects of exposure to pesticides, as well as their combined effects with emerging pathogens, on the population dynamics of wildlife, using the Iberian hare (*Lepus granatensis*) as a model species. In 2018, the first outbreak of myxomatosis, an infectious disease caused by myxoma virus, was described in Iberian hares in southern Spain. Since then, myxomatosis has threatened hare populations throughout the Iberian Peninsula. Infected animals show severe vascular changes,

including at the testicular level. Testicles were then collected from male hares hunted in pesticide-treated and pesticide-free areas, with and without symptoms compatibles with myxomatosis or myxomatosis antibodies during the 2021/22 hunting season in the southwestern Spain. Testes and epididymis, obtained on the day of capture, were weighted and conserved at 5ºC until processed the following day (12h). Total cauda epididymal spermatozoa were counted, and the percentage of morpho-anomalies determined by eosin/nigrosine stain. A battery of sperm parameters was determined by a computer assisted semen analysis, and by flow cytometry. Preliminary results showed that both factors (pesticides exposure and myxomatosis) appear to affect the parameters analysed, and therefore be key modulating factors in the population dynamics of this species.

2.10.P-We099 Residues of Glyphosate, AMPA, and Glufosinate in Soils, Earthworms, and Wild Small Mammals in Arable Landscapes: A New Case of "Emerging Organic Contaminants"?

*Clémentine Fritsch[1], Colette Bertrand[2], Brice Appenzeller[3], Olivier Delhomme[4], Maurice MILLET[4], Marjolaine Bourdat-Deschamps[5], Sylvie Nélieu[5], Michael Coeurdassier[6], Renaud R Scheifler[1], Sabrina Gaba[7], Vincent Bretagnolle[8] and **Celine Pelosi**[9], (1)UMR 6249 Chrono-environnement, CNRS / Université Bourgogne Franche-Comté, USC INRA, France, (2)INRAE, France, (3)Department of Population Health, Luxembourg Institute of Health, Luxembourg, Luxembourg, (4)UMR CNRS ICPEES 7515, University of Strasbourg, France, (5)Université Paris-Saclay, INRAE, AgroParisTech, France, (6)UMR 6249 Chrono-environnement, CNRS – UBFC, Université de Franche-Comté, France, (7)UMR 7372 CEBC, France, (8)CNRS CEBC, France, (9)INRAE (Institut National de la Recherche Agronomique), France*

Since their registration in the 70's the use of glyphosate-based broad-spectrum herbicides constantly increased, making glyphosate (GLY) one of the most widely applied herbicide worldwide nowadays. Accumulating evidences show that GLY and its metabolite AMPA may be more persistent in the environment and more toxic to biota than expected based on risk assessment in marketing authorization. Recent debates about GLY use mainly focused on human health issues while little is known about risks to wildlife. Glufosinate (GLUF) could be an alternative compound to the use of GLY-based herbicides, but its field ecotoxicology has rarely been studied.

We investigated residues of GLY, AMPA, and GLUF in soils (n = 120 locations), in earthworms (n = 120), and wild small mammals (n = 63 rodents and shrews) sampled in treated (e.g., cereal fields under conventional farming) and nontreated habitats (e.g., hedgerows and cereals under organic farming) over arable landscapes in France. GLY, AMPA, and GLUF were detected in 88%, 58%, and 35% of the soil samples, in 74%, 38%, and 12% of the earthworm samples, and in 64%, 51%, and 44% of small mammal hair samples, respectively. The detection of GLY, AMPA, and GLUF was higher in herbivorous *Microtus* and granivorous *Myodes* voles than in insectivorous *Crocidura* shrews and omnivorous *Apodemus* wild mice. The compounds were found in samples from both conventional and organic cereal fields without significant differences according to the cropping system, as well as in hedgerows and grasslands. GLY and AMPA were more frequently detected and at higher concentrations in soils from cereal fields and hedgerows and in earthworms from cereal fields. The concentrations of GLY were higher in small mammals captured in hedgerows than in cereal fields.

The bioaccumulation of GLY and AMPA was evidenced in earthworms and found greater than expected based on physicochemical features of the compounds. Soil concentrations were lower than Predicted Environmental Concentrations but the maximum GLY concentrations reached values only 2 to 3 times lower than doses showed to have negative effects on earthworms (survival, avoidance).

Showing a ubiquitous soil contamination and chronic exposure of fauna to GLY, AMPA, and GLUF, our findings raise issues about the occurrence of the compounds at landscape scale even in non-treated and semi-natural areas considered as refuges. This study also highlights the potential for transfer of GLY, AMPA and GLUF in terrestrial food webs.

2.10.P-We100 Rice and Pesticides: How Should we Assess the Environmental Risk?

***Ana Lopez Antia**, Miguel Canedo-Arguelles and Silvia Lacorte, Spanish Research Council (CSIC), Institute of Environmental Assessment and Water Research (IDAEA), Spain*

Rice is an essential crop for humans and, at the same time, rice fields are essential habitats for waterbirds. Therefore, the management of rice fields should incorporate bird biodiversity while securing rice production. We propose a field methodology that will generate useful data for better management of rice fields. In the first stage of the project, we characterized multiple rice fields according to environmental features and agronomic factors, and we collected information on the crop yield and bird populations.

The study was performed in the Ebro Delta, an important rice-producing area in Spain and an area of international importance for waterbird conservation. We conducted surveys among farmers to collect information on PPP usage, sowing method (dry vs. wet), soil characteristics, rice variety, field headland management, and yield. For the selected fields we also characterized the surrounding landscape and field headlands. Additionally, bird point counts of 5 minutes duration were performed in each rice field in 3 sampling periods.

We collected information on 76 conventional and 20 organic fields. The average vegetation coverage and width of the field headlands were calculated for each field. Coverage and width were significantly higher ($p \leq 0.001$) in organic fields than in conventional fields. In conventional fields, a total of 21 different active substances were used: 12 herbicides, 6 fungicides, and 3 insecticides. Conventional rice fields were grouped into four categories according to the number of compounds they used (i.e., 0-3; 4; 5-7; 8-12). Glyphosate was used in the field headland of 95% of the conventional fields and 25% used also MCPA.

Regarding treated seeds, 54.7% of the conventional fields used insecticide-treated seeds, and 18.7% used also a fungicide. The number of bird species detected per field and number of individuals per field were significantly higher in organic fields than in conventional fields (both $p \leq 0.001$), which suggests that birds are responding to changes in the rice field (e.g., habitat diversity).

Collected information will be used to build and test risk exposure scenarios. This preliminary analysis is essential to adequately define experimental units for the next stage of the project (i.e., measurement of pesticide residues in environmental samples and analysing the effects of pesticide exposure on birds and invertebrates).

2.11 Filling Gaps for Micro- and Nanoplastic Effects and Risk in Multiple Stressed Aquatic Environments

2.11.T-01 Effects of Nano-, Microplastics, and Temperature on Crustaceans

Felix Biefel[1]*, Susanne M Brander*[2]*, Richard Connon*[3] *and Juergen Geist*[1]*, (1)School of Life Sciences, Technical University of Munich, Aquatic Systems Biology Unit, Germany, (2)Department of Fisheries, Wildlife, and Conservation Sciences, Oregon State University, (3)Department of Anatomy, Physiology and Cell Biology, School of Veterinary Medicine, University of California, Davis*

Effects of micro- and nanoplastic particle exposures on aquatic wildlife are still being explored, while there are knowledge gaps about yet untested interactions with temperature. Especially, the effects of fibers are not well understood. The goal of our studies was to evaluate whether particle sizes, polymer types, and sublethal concentrations impacted organismal responses in the model species *Hyalella azteca* and *Americamysis bahia,* at three temperatures (21-28 °C). Across two studies we exposed *H. azteca* for 96 hours to 0.43 mg/l of fluorescent polystyrene beads of nano- (500 nm) and micro- (1000 nm) size and *A. bahia* for 7 days to cotton, nylon, PES, and HEMP fibers (ca. 4 p/ml and in average 200 µm long), and to PLA and LDPE, as well as to their leachates (1-20 µm, up to 500 p/ml). Following exposure at three temperatures, we evaluated particle uptake, oxidative stress, and multiple behavioral endpoints.

Initial results show high variability in uptake and no translocation of particles or fibers from the gut into adjacent tissue. Mortality was significantly higher following exposure to 500 nm polystyrene beads at the highest temperature of 27 °C than in respective controls without particles. Furthermore, with rising temperature, the uptake of 1000 nm polystyrene particles tended to increase. Fiber ingestion resulted in elevated oxidative stress corresponding with increasing temperature. Whilst no impact on total mobility was observed, videotracking analyses integrating multiple behavioral endpoints allowed for detection of more sublethal effects. Together, our results demonstrate greater effects of particle uptake at higher temperatures. Climate change predicted increases in surface water temperatures may pose greater risk to aquatic organisms with further increases of nano- and microparticles in aquatic ecosystems.

2.11.T-02 How do Microplastics Exacerbate Virus-Related Mortality in a Commercially Valuable Salmonid Species?

Meredith Evans Seeley[1]*, Robert Hale*[2]*, Patty Zwollo*[3]*, Wolfgang Vogelbein*[2] *and Andrew Wargo*[2]*, (1)National Institute of Standards and Technology (NIST), (2)Virginia Institute of Marine Science (VIMS) and William & Mary, (3)William & Mary*

Microplastics are an environmentally ubiquitous threat, coexisting with a variety of natural and anthropogenic stressors. In the aquatic environment, for example, pathogens commonly impact multiple trophic levels and human resources. We evaluated the extent to which microplastics mediate the virulence of an important marine disease (Infectious Hematopoietic Necrosis virus, IHNV) in rainbow trout (*O. mykiss)*. Populations of *O. mykiss* are farmed for human consumption across the U.S. North Pacific, Europe, and Japan, where IHNV can be highly destructive. To evaluate the hypothesis that microplastics modulate population mortality or incidence of IHNV, we conducted a controlled experiment in which trout were chronically exposed to varying doses of microparticles (0, 0.1, 1, and 10 mg L^{-1}) over an 8-week period, with acute IHNV exposure at four weeks. Microplastics used reflected polymers common in aquaculture and wild-caught fisheries: nylon fibers (~10 x 500 µm) used in nets, and ground expanded polystyrene (fragmented to ~20 µm diameter) used in floats. To evaluate if polymers of natural origin (cellulosic plant matter) induce effects, marsh grass (ground to ~20 µm) was included. Mortality was higher when microparticles and IHNV were co-administered than IHNV exposure alone, increasing significantly for nylon fibers at the high concentration and polystyrene at medium concentration. We observed that fish co-exposed to virus and microplastics (particularly nylon microfibers) had a higher viral load and shed than those exposed to virus alone. Importantly, no significant mortality from the presence of any microparticle exposure in the absence of virus co-exposure was observed, underscoring the importance of microplastics as a co-stressor and not just a singular threat. Further, in a second experiment, fish exposed to microfibers chronically prior to IHNV were more susceptible to disease, while microfiber exposure post viral exposure did not augment mortality. We propose that the increase in relative disease virulence arose from increased susceptibility to infection, which may have also enhanced disease transmission between individuals. This work demonstrates that microplastics are an ecologically significant co-stressor for aquatic biota. This may have implications for human diseases transmitted through seafood, and approximate respiratory stressors (particle and virus) for humans, warranting further multidisciplinary research.

2.11.T-03 Multistressor Effects of Chemicals and Microplastics in Fresh-Water Environments

Katie Reilly*, Laura-Jayne Ellis, Jon Sadler and Iseult Lynch, University of Birmingham, United Kingdom*

Microplastics (MP) has been well established as a contaminant of concern, with an increase in scientific and societal interest. The presence of multiple stressors, such as chemical pollutants in combination with MP, poses a complex challenge for ecotoxicology studies to replicate the various pathways of exposures within controlled and simplified testing scenarios to understand the drivers of observed toxicity. *Daphnia magna* are a well-established test organism for chemical testing in freshwater environments.

Standard tests and protocols (for chemical testing) have been established, including the 48-hour acute, and 21-day chronic reproductive, toxicity assays. As a result, there is a wealth of data for chemical effects in *Daphnia* which can be used to establish a baseline response to aquatic pollution stressors, and to rank chemicals based on their toxicity.

Daphnia were initially exposed to three chemicals; triclosan (an antimicrobial), Sodium Dodecyl Sulphate (SDS - a surfactant), and diclofenac (a nonsteroidal anti-inflammatory) which allowed an initial dose response to each of the chemicals to be calculated. To determine the effect of environmental factors, *Daphnia magna* were cultured in three different media (salt only, natural borehole water, and artificial river water with added humic acid as a representative natural organic matter (NOM)) to represent different levels of environmental conditions, before being exposed to the three chemicals again, without or with polyethylene MP (1-4 µm) as a second toxicant. Both acute toxicity with dose response curves, and variability in total protein adsorbed onto the MP particle surfaces at the end of the exposures to chemical and medium mixtures, was ascertained.

We found that variability in toxicity depended on both the exposure scenario and the chemical properties of the pollutants. Triclosan and diclofenac appear to be influenced by co-binding to NOM bound onto the MP particles in this study. SDS readily binds to the surface of the particles due to the amphiphilic nature of the chemical and the hydrophobic surface of the MP, and had elevated toxicity within the exposures containing MP particles, demonstrating a change in exposure pathways as a result of co-exposure. It is essential to consider this at the test design stage to take into consideration the environmental factors that could be drivers for chemical and MP mixture toxicity, to increase the realism of the exposure risk calculations.

2.11.T-04 Combined Effect of Salinity and Leachates of Environmental Plastics on the Copepod *Nitokra spinipes*

*Rocio Soledad Pazos[1], **Zhiyue Niu**[2], Gert Everaert[3] and Ana I Catarino[4], (1)Instituto de Limnología ''Dr. Raúl A. Ringuelet", UNLP-CONICET, Argentina, (2)VLIZ, Ostend, Belgium, (3)Ocean & Human health, Flanders Marine Institute (VLIZ), Oostende, Belgium, (4)Flanders Marine Institute (VLIZ), Oostende, Belgium*

Plastic debris have reached approximately a volume of 8 million tons per year in the oceans and it is necessary to understand the effects on the communities that inhabit them. It is essential to consider that plastic litter comprise not only the polymer that makes them up, but also the various additives that are added during their manufacture and the chemicals that might be sorbed to them from the environment, that are often leached because of their persistence and durability. Coastal areas such as estuaries are transitional zones with natural salinity gradient, that can accumulate plastic litter, and because the release of leachates also depend on such environmental conditions, it is therefore important to assess combined stresses to understand the effects on organisms. The main goal of this study was to analyze the ecotoxicological effect of leachates from environmental and weathered plastics, in two brackish water conditions (two salinities), in a representative model species of planktonic organisms, the harpacticoid copepod *Nitokra spinipes.* Three different environmental samples of PVC, PE, and PP collected in coastal areas from Belgium (North Sea) and Argentina (Río de la Plata estuary) were used for the leachates. The plastics were cut into small fragments (2.5 cm) and the leachates (80 g/L) were prepared in brackish water (BW, salinities of 7 and 15) following standardized method (22°C in dark, 7 d, 80 rpm). After 7 days the leachates were filtrated by 1 and 0.2 µm pore size cellulose filters. The toxicity test to assess the mortality in the copepods was carried out for 96 h following the ISO 14669 protocol, comparing the endpoint among the three polymers and using BW as control (0 % leachates), as well as a positive control using dodecanol. The results indicated a 32% of mortality at 24 h caused by leachates (100% concentration) from PVC, being the mortality of 30% at the end of the experiment ($p<0.05$), at salinity 7. Leachates from PP (2.5% mortality) and PE (7.5% mortality) had no effect on the copepods, compared to the control (5% mortality). The test of ecotoxicological effects of leachates at salinity 15 are currently ongoing. Our results will contribute to assess the combined effect of salinity and leachates of different polymers from environmental stranded plastics, providing information on the complexity of plastics as a diverse group of pollutants with various chemical characteristics, in estuarine ecosystems.

2.11.T-05 Long-Term Effects of Microplastics on a Benthic Community: A Mesocosm Experiment

***Monica Hamann Sandgaard**[1], Claudia Lorenz[2], Nanna B. Hartmann[3], Kristian Syberg[4] and Annemette Palmqvist[5], (1)Department of Science and Environment, Roskilde University, Denmark, (2)Aalborg University, Denmark, (3)DTU Sustain, Technical University of Denmark (DTU), Lyngby, Denmark, (4)Roskilde University, Denmark, (5)Dept. of Science and Environment, Roskilde University, Denmark*

However, little information is available on their long-term effects at higher levels of biological organization. From an ecological point of view benthic organisms play an important role in reworking and irrigating sediments and are important food source for organims at higher trophic levels. Consequently, effects on benthic fauna will potentially affect not only benthic communities and ecosystems but also the pelagic food web though transfer of MPs from benthic organisms to pelagic predators. However, scientific literature on MPs in sediments is limited resulting in knowledge gaps related to population- and community-level effects of MP. While most experimental studies focus on single polymer exposures, it is very unlikely that organisms would be exposed to only single polymers in environment, but they are rather exposed to a suite of different polymers. To address this data gap, we performed a five-week large-scale mesocosm experiment to address potential population- and community-level effects of MP under environmentally relevant exposure conditions. We used a suite of polymers tested at both environmentally relevant concentration and a 1000-fold higher concentration. To address this data gap, we performed a five-week, large-scale mesocosm experiment to address potential population- and comnmunity-level effects of MP exposure to a suite of MPs at an environmentally relevant concnetration (680 MPs L^{-1}) and a 1000-fold higher (6.8×10^5 MPs L^{-1}). We exposed specimen of *Macoma balthica, Corophium volutatror,* and *Monoporeia affinis* in a community structure representing species diversity and abundance in the area of collection. In parallel, we ran complementary experiment for three weeks with *M. affinis* exposed to sediment-associated MPs with the MP mixture at environmental and high concentration, eight additional treatments with each of the single polymers at two different concentrations. Endpoints included survival, growth, and ingestion rate. We found no effects of survival, growth, or significant changes in community structure after five weeks of exposure, nor did we observe effects on survival, growth, and ingestion rate in the complementary experiment. These no-effect results are important to consider in the context of MP risk assessment in sediment.

2.11.P Filling Gaps for Micro- and Nanoplastic Effects and Risk in Multiple Stressed Aquatic Environments

2.11.P-Tu076 Impact of Microplastics on Mussels Under Extreme Climate Conditions

Danae Patsiou[1]*, Zhiyue Niu*[2]*, Gert Everaert*[3] *and Ana I Catarino*[4]*, (1)Institute of Oceanography, Hellenic Centre for Marine Research, Greece, (2)VLIZ, Ostend, Belgium, (3)Ocean & Human health, Flanders Marine Institute (VLIZ), Oostende, Belgium, (4)Flanders Marine Institute (VLIZ), Oostende, Belgium*

Microplastics (MPs) is an emerging contaminant that can affect the marine environment from biota to ecosystems. Co-occurring environmental stressors need to be incorporated into the investigation of the toxicity of MPs, as plastics do not act as isolated stressors in aquatic systems. The present study aims to investigate the toxicity of MPs in combination with thermal stress, under the perspective of environmental relevance and a marine heatwave, in marine mussels, a commercially important organism and a marine pollution indicator species.. In particular, the effect of aged MPs on mussel haemocytes will be investigated after the exposure of mussels to a simulated marine heatwave. The MPs will be artificially aged by sonication and the weathering status of the MPs will be evaluated by the determination of the carbonyl index, an indicator of ageing that is based on the oxidation of polymers such as polyethylene or polypropylene. Mussels will be exposed to a simulated heatwave (i.e., increase of water temperature of 5 ºC) for a 3-day duration. Then the mussel haemocytes will be extracted and exposed in vitro to a set of MPs treatments and different concentrations from low to high levels including environmentally relevant concentrations. The aim of the exposure is to evaluate whether the heatwave increased the mussel sensitivity to MPs, and if MPs toxicity can be attributed to the aging of MPs (compared to pristine unaged particles). Cell toxicity will be evaluated by cell viability, phagocytosis ability, and evaluation of biomarkers through gene expression. The biomarker analyses will include investigation of the expression of genes involved in the oxidative stress, immune and heatshock response. In a warming climate, environmental stressors such as heatwaves will be increasing in frequency, extent, and magnitude creating the need to understand and predict biological responses to short-term extreme events. The present study will contribute to the evaluation of a realistic scenario of the interaction of MPs in the environment with other relevant stressors.

2.11.P-Tu078 Combined Effects of Global Warming and Plastic Leachates from Conventional and Bio-Based Polymers on a Harpacticoid Copepod

Zhiyue Niu[1,2]*, Maelenn Le Gall*[3]*, Marco Curto*[4]*, Elke Demeyer*[5]*, Ana I Catarino*[6]*, Jana Asselman*[2]*, Colin Janssen*[7]*, Hom Dhakal*[4]*, Peter Davies*[3] *and Gert Everaert*[8]*, (1)VLIZ, Ostend, Belgium, (2)Blue Growth Research Lab, Ghent University (UGent), Ghent, Belgium, (3)IFREMER, France, (4)University of Portsmouth, United Kingdom, (5)Centexbel, Belgium, (6)Flanders Marine Institute (VLIZ), Oostende, Belgium, (7)Laboratory for Environmental Toxicology (GhEnToxLab), Ghent University (UGent), Ghent, Belgium, (8)Ocean & Human health, Flanders Marine Institute (VLIZ), Oostende, Belgium*

Global warming and plastic pollution are two human-induced environmental stressors of rising concern due to their potential impact on ocean health. To tackle sustainability concerns on the production of conventional petroleum-based polymers, bio-based polymers, i.e., polymers originated from natural feedstocks, are seen as a potential alternative. However, just as conventional polymers, plastic items from bio-based polymers can leach additives and other associated substances into the (marine) environment. To date the ecotoxicological effects of leachates from bio-based polymers are still unclear, but previous reports have demonstrated that leachates from petroleum-based polymers can induce adverse effects in marine invertebrates. Also, in the environment, organisms are subjected to a myriad of environmental stressors, among which global warming, and the combination of stressors is often not considered in environmental risk assessments. To increase our understanding of the combined effects of plastic leachates from either bio-based or petroleum-based polymers and elevated temperature (global warming), in this work we used the case study of self-reinforced polylactic acid (SR-PLA) and self-reinforced polypropylene (SR-PP), at control (22°C) and elevated water temperatures (25°C). To do so, we exposed newly hatched larvae of a harpacticoid copepod *Nitokra spinipes* to plastic leachates (80 g/L) at each temperature. Our preliminary results indicate that after 6 days exposure, lower larval development ratio (%) was found in 60% v/v of SR-PP leachate ($P<0.05$, Dunnett's test) exposure than no leachate controls at 25 °C, but not in SR-PLA leachate exposure ($P = 0.51$, Dunnett's test). Larvae at elevated temperature (25°C) had a higher mortality compared to control temperature (22°C) ($P<0.05$, ANOVA). We anticipate that our results will contribute to assessing the impacts of bio-based polymers in multiple stressor environments and the use of more realistic scenarios in environmental risk assessment.

2.11.P-Tu079 Disclosing the Effects of Pristine and Weathered Micro- and Nanoplastics Combined with Environmental Contaminants on Fish Intestinal Cells (RTgutGC).

Estefanía Pereira Pinto[1]*, Justin Scott*[2]*, Kendra Hess*[2]*, Jorge Gonzalez Estrella*[3]*, Estefanía Paredes Rosendo*[1]*, Juan Bellas*[4] *and Matteo Minghetti*[2]*, (1)University of Vigo, Spain, (2)Oklahoma State University, (3)School of Civil and Environmental Engineering, Oklahoma State University, (4)Centro Oceanográfico de Vigo - IEO- CSIC, Spain*

Microplastic (MPs, 1 µm - 5 mm) and nanoplastics (NPs, <1 µm) are ubiquitous in the environment. Micro- and NPs in nature are exposed to weathering conditions, including photodegradation, that may modify surface charge and reactivity, and release plastic impurities such as trace metals, additives or solvents. Moreover, MPs/NPs ability to act as vectors of legacy pollutants and modulate the bioavailability, bioaccumulation and toxicity of these contaminants has been highlighted in recent studies. Here, rainbow trout (*Onchorhynchus mykiss)* intestinal cells (RTgutGC) were exposed to polyethylene MPs (pristine and oxidized) and NPs, all UV aged or not. Moreover, to assess the role of MPs/NPs on the bioaccumulation and toxicity of heavy metals and organic pollutants, cells were exposed to MPs/NPs in presence or absence of cadmium and lindane/DDE as a proof of concept. Particles were characterized by Dynamic Light Scattering, zeta potential, Attenuated Total Reflection–Infrared Spectroscropy (ATR-IR), and scanning electron microscopy/energy X-ray spectroscopy. Besides bioaccumulation, toxic effects of MPs and NPs at different concentrations (12.5-200 mg/L) and in absence or presence of Cd (EC10 = 449.64 µg/L) and, separately, a mixture of Lindane/DDE (2000 and 25 µg/L, respectively) on RTgutGC were examined using a multiple endpoint viability assay, simultaneously measuring metabolic activity and lysosomal/cell membrane integrity. Characterization demonstrated that all particles present an incipient stability (-8 to -23 mV), except for the particles coated with Cd that rapidly aggregated (-1 to -12 mV). ATR-IR analyses indicated oxidation and modification of the surface chemistry after exposure to UV radiation. SEM analysis exposed that 6 weeks UV aging of the plastic particles notably altered its surface morphology, presenting more roughness and a damaged surface morphology. Data showed no toxicity on RTgutGC cell lines due to the combination of MPs/NPs with Cd or with the mixture of organics. The presence of MPs/NPs (25 mg/L) on the exposure medium indicated a reduction of cadmium and lindane/DDE bioavailability on RTgutGC cell lines. However, in the present investigation only acute exposure experiments were carried out, being unattainable to conclude that the presence of MPs/NPs cannot increase the toxicity and bioaccumulation of contaminants due to chronic exposure.

2.11.P-Tu080 Microplastics in Cold Water Corals Living up to 948 Meters Deep in an Irish Special Area of Conservation
Alicia Mateos Cardenas*, Aaron Lim and Andrew Wheeler, University College Cork, Ireland*
Microplastic pollution is ubiquitous, and marine systems have especially been studied for their presence. To date, microplastic studies on the deep sea have mainly focused on sediment cores and biota species such as fish and lobsters. Preliminary video data collected by a Remotely Operated Vehicle (ROV) from an earlier project led by the team previously showed that large plastic items are abundant, especially fishing items, in deep water Irish coral reefs from the Porcupine Bank Seabight, currently listed as Special Area of Conservation (SAC). However, there is a data gap in the presence of microplastics in cold water corals of such deep waters. In this study, we show for the first time the presence of microplastics in species of cold-water corals (*Leiopathes* sp. and *Lophelia pertusa*) collected at five sites at depths ranging from 893 to 948 m. Corals were examined on the surface of the coral skeleton and inside the stomach cavity of polyps after tissue digestion. The results from this novel study will be presented showing the different microplastic concentrations accumulated outside/inside the corals, a comparative analysis among species and any potential effects of environmental variables. Overall, cold water coral reefs are a habitat identified for monitoring under the EU Habitats Directive. Therefore, the results from this study will inform national (Irish) and European policy on ocean pollution.

2.11.P-Tu081 Sublethal Effects Induced by Different Nanoplastic Polymers to *Daphnia magna*
Andrea Masseroni[1]*, Marco Fossati*[2]*, Maddalena Collini*[3]*, Camilla Della Torre*[4] *and Sara Villa*[5]*, (1)Department of Earth and Environmental Sciences, University of Milano-Bicocca, Italy, (2)Università degli Studi di Milano, Italy, (3)University of Milano-Bicocca, Italy, (4)Dipartimento di Bioscienze, Università degli Studi di Milano, Italy, (5)Dept. Earth and Environmental Sciences, University of Milano-Bicocca, Italy*
A growing number of studies reports nanoplastics (NPs) capacity to generate potential hazardous effects on organisms, even higher than those induced by microplastics. The main criticisms of these works are related to the tested concentrations, which are higher than the typical environmental levels and the use of only polystyrene (PS).

In this perspective, this study aimed to evaluate the sublethal effects induced by three different NPs polymers (PS-NPs, polyethylene PE-NPs, and polyvinyl chloride PVC-NPs) of a nominal size of 200 nm, to establish whether their toxicity is comparable and if thus the effects of PS-NPs can be used as a proxy for all others.

For each polymer, five environmental relevant concentrations were tested (from 2.5 to 250 µg/L) on the freshwater cladoceran *Daphnia magna*, with 60 individuals exposed for 48 h to each concentration. NPs effects were assessed at the biochemical level investigating the amount of reactive oxygen species (ROS) and the activity of an antioxidant enzyme catalase (CAT), while at the individual level we evaluated the swimming response (distance moved).

Test results indicated that the exposure to different NPs polymers led to different biochemical and individual responses. The 48 h exposure to PS-NPs did not induce either oxidative stress conditions or alteration in the swimming behavior. Statistically significant changes (p-value < 0.05) in ROS levels and swimming distance were observed for PVC-NPs, where the higher concentration (250 µg/L) led to higher ROS content and induced an increased swimming stimulation. For PE-NPs treatment, a sharp decline in ROS was recorded for all the tested concentrations, while no effects were recorded at the individual level.

Our results highlighted that the exposure to environmentally relevant concentrations of NPs could pose sub-lethal effects to *D. magna*, and how these effects could differ with the different tested polymers. It is therefore recommended to conduct further studies on different NPs polymers, to better establish their different toxicity for the achievement of an NPs environmental risks assessment. In particular, the actual strategy to use PS-NPs as a proxy of the other plastic polymers seems not to be feasible, as polystyrene do not appear to be the most harmful NPs polymer.

2.11.P-Tu082 Constrasted Acute Effects of Nanoplastics on *Daphnia* and *Gammarus* Neonates in Comparing Natural Environmental Freshwaters

***Wei Liu**[1], Zijiao Meng[1], Rémi Recoura-Massaquant[2], Arnaud Chaumot[2] and Serge Stoll[1], (1)University of Geneva, Switzerland, (2)INRAE, France*

By 2050, it is expected that 12 billion tons of used plastic will directly go to landfill or be discarded. Once in the environment plastic waste will be transformed into microplastic and nanoplastics (NPLs) via physical, chemical, and biological degradation processes. More concerning shows that nanoplastics are probably more widely distributed and more toxic than microplastics due to their larger surface-to-volume ratio and higher surface reactivity. Despite progress in evaluation of risk assessment, knowledge gaps largely exist understanding the toxicity of nanoplastics in aquatic systems considering nanoplastics surface properties, environmental media characteristics and species ecological traits. In this study, amidine-functionalized polystyrene nanoparticles (PS-NPLs) of different primary sizes of 20, 40, 60, and 100 nm are considered using lake water and mineral water to investigate the behavior and effects in neonate organisms of the plankton *Daphnia magna* and the benthos *Gammarus fossarum*. Key parameters including ζ-potential, z-average diameter, conductivity, polydispersity index, pH, EC_{50} were investigated to gain insight into the relationship between PS-NPLs intrinsic properties, their transformation behavior, water properties and species-specificity in the evaluation of PS-NPLs biological effects on crustacean neonates in natural aquatic environments. The results shown that PS-NPLs with different initial sizes induced a statistically significant mortality of *D. magna* and *G. fossarum* neonates with a dose-time response relationship, and exhibit 1.3-6.5 times higher toxicity in the mineral water than in the lake water. More importantly, ecotoxic effects are found driven by both the surface properties of PS-NPLs and environmental factors. The surface charge is also found the most influential toxicity factor of PS-NPLs on *D. magna* in environmental natural waters, while on *G. fossarum* the aggregation behavior is the stronger explanatory factor. The combination of the characterization of colloidal stability of nanoparticles and effect assessment in environmental natural waters systems in this work evidenced the relationship between colloidal stability of NPLs, exposure water properties, the physiological trait of organisms, and the biological response.

2.11.P-Tu083 Detection of Size-Dependent Physical Effects of Microplastics Using Extended Acute Toxicity Test

***Yukiyo Okazaki** and Norihisa Tatarazako, Ehime University, Ehime, Japan*

In recent years, environmental effect of the microplastics (MP) are increasingly discussed and that ecotoxicity are becoming revealed. In our study, we exposed toxic chemicals to aquatic organisms with and without MP in a closed experimental water system to detect the difference in toxicity values, and the aim is to clarify if the adverse effects of MP exist. If a vector (chemical) effect exists, it is thought that the chemical would be transferred to the organisms more efficiently via MP than via waterborne exposure. We chose pyrene as the test substance, and spherical plastic beads (PB) made of polystyrene and polyethylene with various sizes from 0.2 µm to 3 mm in diameter were used.

In a previous presentation, we showed the result that *Medaka* and *Daphnia* toxicity test (OECD TG 202 and 203) were conducted with pyrene under the presence or absence of PB. If the PB sizes were inedible to the organism, the toxicity was less with the presence of PB compared to absence of those. This may be because the pyrene was sorbed from water to PB and their concentration was decreased, resulting in lower exposure. In the case of the edible size of the PB, they were found in the digestive tract of organisms, but their toxicity remained the same with the exposure result only with pyrene. So no synergistic effects of toxicity due to vector effects were observed.

For the next step, based on the *Daphnia* Acute Toxicity Test (OECD TG202), we additionally continued the observation until the 96th hour with feeding after 48 h. If MP obstructs the gastrointestinal tract and inhibits nutrient absorption, it is thought that *Daphnia* will starve to death within 96 h even if the food is served. Seven types of PB with diameter of 100, 30, 10, 3, 1, 0.46, and 0.19 µm were used for experiment to clarify the physical effects of MP. The PB solution was centrifuged 2 times to separate the medium since it includes dispersant, preservatives, and so on. The amount was weighed by dry weight. From the result, the toxicity of 100 µm did not differ from the control even after 96 h. There was no acute toxicity with PB of the diameter 30, 10, 3, 1 µm at 48 h, but the deaths probably due to starvation were observed after 96 h. Immobilization was observed with 0.46 and 0.19 µm of PB due to adhesion to the body surface, etc.

It was confirmed that there were size-dependent difference in toxic effect of MP by using the test method of feeding and extending the exposure period.

2.11.P-Tu084 Comparison of Ecological Effects of a Diverse Mix of Microplastics with an Equally Diverse Mix of Inert Nonplastic Particles

***Vera de Ruijter**, Xinyi Xie and Albert A. Koelmans, Wageningen University & Research, Netherlands*

Microplastics nowadays can be found throughout the aquatic environment. Consequently, they can be ingested by organisms and experimental work has shown that this could lead to potential negative effects. Many different kinds of negative effects have been reported including physiological stress, cell death, aberrant development, altered lipid metabolism, and intestinal damage. However, most negative effects reported include reduced body and population growth, or an energy reduction. In order to more accurately assess the ecological risk associated with microplastics, a better understanding of effect mechanisms and the key factors triggering them is needed. Currently, it is difficult to compare the impact of various factors on microplastic particle toxicity, as experimental setups differ significantly. However, literature review shows that most important factors determining the toxicity of microplastics include concentration, particle size, and exposure time. Additionally, important co-factors such as species and food availability were underlined. Contrastingly, much less is known about the effect mechanisms underlying adverse effects. Most studies are not able to demonstrate the hypothesized effect mechanisms. While significant evidence exists for the mechanisms 'internal physical damage (including abrasion of the gut) and external physical damage', most evidence exists for "inhibited food assimilation and/or decreased nutritional value", commonly referred to as 'food dilution'. If this mechanism is important, any inert particle would be able to cause it, which is the hypothesis tested here. The model species *Lumbriculus variegatus* was used to compare the effects of an environmentally relevant microplastic mix (ERMP) on growth and survival, with those of a natural, non-polymer solid mix (NS) with equal polydispersity. This way, effects of MP are put in the context of natural particles. Moreover, using volume as an ecologically relevant metric in the dose response testing enables us to test the hypothesized effect mechanism food dilution. As the implications of food dilution are closely linked to food availability, the chronic dose-response tests with both particle types were performed at two levels of sediment organic matter.

2.11.P-Tu085 eDNA Adsorption and Fate on Microplastics

Nicolas David Müller*, Anish Kirtane and Denise M Mitrano, Environmental Systems Science, ETH Zürich, Zürich, Switzerland*

Microplastics (MPs) have been found in virtually every environmental compartment sampled to date. Consequently, there has been increasing research into processes and interactions MPs may undergo in the environment. Environmental DNA (eDNA) has similarly become increasingly discussed due to its uses in determining biodiversity levels and detection of invasive, endangered and rare species. Based on their environmental ubiquity, eDNA and MPs have a high interaction potential, and could be particularly relevant in scenarios with locally high MPs abundance, since MPs could promote long-range transport of eDNA throughout the environment. In these cases, MPs may act as vectors for genetic materials of interest, such as antibiotic resistant genes (ARGs), or DNA sequences that may give insight on MPs origin and transport paths throughout the environment. A better understanding of eDNA
adsorption rates to MPs and sorption isotherms would facilitate assessment of the role MPs play in acting as eDNA vectors. Here we investigated the adsorption of extracellular linear DNA onto MPs.

Three of the most environmentally prevalent polymers were examined; low-density Polyethylene (LDPE), Polyethylenterephthalat (PET), and Polystyrene (PS). Adsorption batch experiments were performed using purified linear extracellular salmon (*Oncorhynchus keta*) sperm DNA prepared in very hard and very soft synthetic freshwaters to assess the influences of water chemistry on adsorption over 24 h. Ionic strength was shown to impact DNA adsorption by electrostatic repulsion, which was reduced in hard water. PET exhibited the highest adsorption capacity when normalizing for MPs specific surface area, likely due to its hydrophilic surface chemistry and the presence of ester groups. Kinetics experiments exhibited fast adsorption during shorter incubation (under 30 min) before eventually reaching equilibrium adsorption capacity after 8 h. Isotherm experiments showed the equilibrium adsorption capacity was reached at DNA concentrations of 10-15 ng μL^{-1}. Overall, we demonstrated that DNA quickly binds to MPs and they could act as an effective vector for environmental genes of interest, such as ARGs, to be transported throughout the environment.

2.11.P-Tu086 A Study on Species Sensitivity Distribution Approaches of Microplastics by using the Highest Observed No-Effect Concentration (HONEC) in Freshwater

Sun-Hwa Nam, Sang A Kim, Tae-Yang Lee and ***Youn-Joo An****, Konkuk University, Korea, Republic of (South)*

Predicted no-effect concentration (PNEC) of chemicals for protecting aquatic ecosystems is derived from the traditional toxicity values (e.g., no observed effect concentration, effective concentration at 10% or 50% effect, or the lowest observed effect concentration) based on guidelines for deriving water quality standards in Europe, Australia and New Zealand, and Canada. However, it is difficult to use only traditional toxicity values for microplastics because most studies have tested only one or two microplastic concentrations and have limited traditional toxicity values. Therefore, it is needed to consider non-traditional toxicity value to get more powerful toxicity data pool for microplastics. In this study, we collected a total of 398 chronic toxicity data of microplastics through various databases and tabulated for fish, invertebrates, algae, and macrophytes). The traditional toxicity values (NOEC and $E(L)C_{50}$) and nontraditional toxicity values (HONEC) were 42% and 58%, respectively. The SSD curve resulted from the inclusion of the nontraditional toxicity values showed weaker HC values, good fitting, and similar spread distribution than the traditional toxicity values pool. We verified applicability of inclusion of the nontraditional toxicity value pool to derive hazardous concentrations for microplastic via inclusion of the nontraditional toxicity value pool.

2.11.P-Tu087 Ecotoxicological Assessment of Microplastics from a New Plasmix-Based Material

Marco Parolini*[1], Beatrice De Felice[1], Stefano Gazzotti[1], Diego Antonioli[2], Valentina Gianotti[2], Michele Laus[2] and Marco Aldo Ortenzi[1], (1)University of Milan, Italy, (2)Università del Piemonte Orientale, Italy*

The development of new strategies to counteract the accumulation of plastics in the environment due to improper or inefficient disposal represents a priority in the waste management. Although most plastics are potentially recyclable, only 15% of the worldwide plastic wastes is currently recycled, while the remaining nonrecyclable part is landfilled or used for energy recovery. In Italy, this heterogeneous mixture of plastic wastes is called Plasmix. To date, Plasmix is landfilled or used for thermal recovery, leading to secondary pollution and loss of economic value for materials that could be reused or recycled. In recent years, we developed an innovative approach based on mechanical recycling aimed at modifying the Plasmix to generate a new Plasmix-based material to be used in the production process. Before being used, this material needs to be tested for its eco-safety because, once in the environment, it can interact with aquatic and terrestrial organisms, mainly after its degradation and/or fragmentation in microplastics. Thus, the present study aimed at evaluating the ingestion and the potential acute and chronic toxicity induced by exposure to different concentrations of microplastics derived from the fragmentation of a Plasmix-based material, toward the freshwater Cladocerad *Daphnia magna* and the earthworm *Eisenia fetida*. The results highlighted that both the model organisms efficiently ingested microplastics. In spite of the ingestion, no effects on Cladoceran and earthworm survival occurred. However, a significant reduction of the reproductive success of *D. magna* treated individuals compared to the control group was noted. In addition, a decrease in body condition and the onset of oxidative stress situation occurred in earthworms. These findings suggest that microplastics generated by materials created by mechanical recycling of plastic waste can affect the health status of aquatic and terrestrial organism, confirming the crucial role of ecotoxicological analyses in the characterization of new materials.

2.11.V Filling Gaps for Micro- and Nanoplastic Effects and Risk in Multiple Stressed Aquatic Environments

2.11.V-01 *Asparagopsis armata* Exudate Combined with Virgin and Mercury-sorbed Polyethylene Microplastics: Histopathology and Byssal Thread Production of the Marine Mussel *Mytilus galloprovincialis*
*Maria Donas-Bôtto Bordalo[1], Cristiana Lopes[2], Andreia Rodrigues[1], Sílvia Pires[2], **Diana Campos**[3], Francesca Coppola[4], Tania Russo[5], Gianluca Polese[5], Amadeu M.V.M. Soares[3] and Hugo C. Vieira[1], (1)CESAM & Department of Biology, University of Aveiro, Aveiro, Portugal, (2)University of Aveiro, Aveiro, Portugal, (3)University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Aveiro, Portugal, (4)Department of Biology & CESAM - University of Aveiro, Aveiro, Portugal, (5)University of Naples Federico II, Italy*
Invasive species and microplastic pollution are two main threats to marine ecosystems. The red seaweed *Asparagopsis armata* is considered a successful invader in the European coasts and is known to exude toxic metabolites with recognized effects in different coastal organisms from cellular to individual levels and consequent implications at the population, community, and ecosystem levels. Microplastics are a significant part of marine debris and can be easily ingested by organisms from different trophic levels. Filter-feeders such as the bivalves are particularly prone to this source of pollution. Also, microplastics can carry several other contaminants (e.g., mercury - Hg), posing an additional impact to marine biota.

This study aimed to evaluate the effects of polyethylene microplastics (PE-MPs) either virgin (PE) or with sorbed Hg (PE-Hg) in the mussel *Mytilus galloprovincialis* under *A. armata* exudate exposure. Mussels were exposed to 6 treatments: control (no exudate nor PE/-Hg), *A. armata* exudate (4%), PE (1 mg/L), PE-Hg (1 mg/L), PE and exudate, PE-Hg and exudate. After 96 h, organisms were checked for the number of produced byssus as a measure of physiological response. Histopathological alterations were also analyzed in the digestive gland and gills. PE-MPs and Hg were quantified in the same tissues.

Microplastic particles were found mainly in the digestive gland, where consequently, the Hg concentration at PE-Hg treatment was also the highest. Although nonsignificant, the mean number of particles was lower in the presence of the exudate when compared to non-exudate-exposed organisms. In contrast, a significant increase in Hg concentration in the digestive gland was found in mussels exposed to the exudate and PE-Hg. Byssal thread production decreased significantly due to exudate exposure, irrespective of the PE-MPs treatment. On the other hand, histopathological results showed that mussels exposed to control treatment presented considerable differences compared to organisms exposed to PE-Hg and/or PE with exudate. These alterations were expressed as: i) cilia loss, hemocytes infiltration, and enlargement of the central vessel in the gills; ii) lipofuscin aggregates and hemocytes infiltration in the digestive tubules. These findings highlight the importance of evaluating the impacts of PE-MPs in the marine environment, and their combined effect with co-occurring stressors, which will be helpful for further evaluation of their ecological risk.

2.11.V-02 Responses of *Mytilus galloprovincialis* in a Multistressor Scenario: Effects of an Invasive Seaweed Exudate and Microplastic Pollution under Global Warming
*Cristiana Lopes[1], Hugo C. Vieira[2], Andreia Rodrigues[2], Sílvia Pires[1], **Diana Campos**[3], Amadeu M.V.M. Soares[3] and Maria Donas-Bôtto Bordalo[2], (1)University of Aveiro, Aveiro, Portugal, (2)CESAM & Department of Biology, University of Aveiro, Aveiro, Portugal, (3)University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Aveiro, Portugal*
Coastal ecosystems are constantly under the influence of a variety of stressors, both natural and anthropogenic, with known consequences to the marine biota. Invasive species are considered a major threat to biodiversity. The red seaweed *Asparagopsis armata* is a highly invasive species, which exudes a cocktail of secondary metabolites as a defence mechanism, with known toxic effects on native organisms. Microplastic pollution is also recognized as an issue of growing concern. Polyethylene microplastics (PE-MP) represent the most common form of microplastic pollution in the marine environment. Given their ubiquity and bioavailability to marine organisms, MPs potentially affect filter-feeders such as the mussel *Mytilus galloprovincialis.* Being ectothermic, these bivalves are also under the threat of global warming. This study aimed to evaluate whether the toxic effects posed by *A. armata* exudate to *M. galloprovincialis* are amplified by the concomitant exposure to these stressors. Mussels were exposed for 96 h to 8 treatments, 4 at 20°C and 4 at 24°C: (i) control (absence of exudate and PE-MP), (ii) 2% *A. armata* exudate (2%), (iii) PE-MP (1 mg/L), (iv) PE-MP and exudate. Biochemical (oxidative stress, damage, and neurotoxicity biomarkers) and physiological (byssus production) parameters were evaluated. Mussels produced the lowest number of byssus under concomitant exposure to the three stressors. Decreased attachment capacity is critical not only at the individual but also at the community level, as the habitat complexity conferred by mussel beds may be compromised. Antioxidant responses were depleted in the gills of organisms exposed to PE-MP and increased temperature, irrespective of the exudate presence, being able to prevent oxidative damage in these scenarios. On the other hand, increased lipid peroxidation was observed in mussels exposed to exudate and warming but not PE-MP. Reduced protein carboxylation was observed in mussels only exposed to exudate. In the digestive gland, nonenzymatic antioxidant responses were activated in mussels simultaneously exposed to 24°C, exudate, and PE-MP, and

oxidative damage was prevented. Neurotoxicity (inhibition of acetylcholinesterase activity) was also observed in the same treatment. In conclusion, simultaneous exposure to these stressors does not necessarily mean an amplification of their single effects. Nevertheless, further studies should be conducted to better understand the mechanisms adjacent to these effects.

2.11.V-03 Combined Effect of Microplastics and Ocean Acidification on Critical Stages of the Sea Urchin (*Paracentrotus Lividus*) Early Development

Juan Ignacio Bertucci[1]*, Ainhoa Juez*[1] *and Juan Bellas*[2]*, (1)Contaminación Marina, Centro Oceanográfico de Vigo - IEO- CSIC, Spain, (2)Centro Oceanográfico de Vigo - IEO- CSIC, Spain*

One of the major consequences of increasing atmospheric CO_2 is a phenomenon known as ocean acidification (OA). This alteration of water chemistry can modulate the impact on marine organisms of other contaminants present in the environment, such as microplastics (MP). The sea urchin *Paracentrotus lividus* is a good indicator of the status of the marine ecosystems, and since it needs to calcify its structures to grow and develop, is also a good model to study the impact of global climate change. The objective of this work was to determine the combined impact of MP and OA on the early development of *P. lividus*, and predict the impact of this particular mixture of contaminants/stressors on the marine environment. In a first set of experiments, sea urchin embryo tests (SET) were conducted to determine growth after 48 h of incubation with two concentrations of MP (1000 and 3000 particles/mL), and under several pH conditions. We found that the inhibition of growth in embryos reared at pH = 7.6 was around 75%. Larvae incubated at 3000 MP particles/mL showed around 20% decrease in growth compared to controls. In a second set of experiments, embryos were exposed to a control treatment (filtered natural seawater), MP (3000 particles/mL), acidified sea water (pH = 7.6), and a combination of MP and acidification (3000 particles/mL + pH = 7.6). After 48, 72, and 96 h measurements of growth and morphometric parameters were taken. Results showed that ocean acidification and MP cause alterations in growth and larval morphology both before and after the larvae start to feed exogenously (around 72 h). This work is part of a larger framework that pursues the utilization of SET for testing multistressor environments, particularly those including factors of global climate change. Through this approach, it has been demonstrated that OA and MP pollution can cause alterations in the morphology and growth of *P. lividus* larvae. The exposure to MP under conditions of OA did not produce an additional effect on growth, but differences were observed at the morphological level related to a decrease in the width of larvae at 48 h. Overall, changes in larvae shape observed at three key points of their development could modify their buoyancy affecting their ability to obtain and ingest food. Therefore, OA and MP pollution might compromise the chances of *P. lividus* to survive in the environment under future scenarios of global climate change, leading to a potential impact on coastal ecosystems.

2.11.V-04 Implications of Single and Combined Acute Exposures to Microplastics and Naphthalene on the African catfish (*Clarias gariepinus*)

Isioma Tongo[1]*, Nosakhare Osazee Erhunmwunse*[2]*, Onize Mary Apeji*[2]*, Samuel Ijewere Okoh*[3] *and Lawrence Ikechukwu Ezemonye Prof*[1]*, (1)Department of Animal and Environmental Biology, University of Benin, Nigeria, (2)Animal and Environmental Biology, University of Benin, Nigeria, (3)University of Benin, Nigeria*

The toxicity of microplastics to aquatic organisms and their potential to induce the toxicity of other contaminants has received increasing attention. There are, however, still very few studies on the effects of microplastics in combination with other environmental contaminants like polycyclic aromatic hydrocarbons (PAHs). Therefore, the current study focused on the acute effects of single and combined exposures to microplastics and naphthalene on the African catfish (*Clarias gariepinus*). The effects of microplastic and naphthalene individually and in mixtures on survival, accumulation, as well as biochemical effects (Total protein and Acetylcholinesterase (AChE)) in the fish were assessed. Juveniles were individually exposed for 96 h to nine (9) treatments **(**control; contained only water), two concentrations of microplastics alone (0.5 mg/L and 2.0 mg/L (low-density polyethylene, LDPE), two concentrations of naphthalene (Nap) alone (20 mg/L and 50 mg/L), and four concentrations of a mixture of microplastics and naphthalene (20 mg/L naphthalene + 0.5 g/L LDPE, 20 mg/L naphthalene + 2.0 g/L LDPE, 50 mg/L naphthalene + 0.5 g/L LDPE and 50 mg/L naphthalene + 2.0 g/L). Results showed no significant differences ($p>0.05$) in the survival rate of the fish exposed to both the single and combined mixtures of microplastics and naphthalene, as nominal differences were observed between the control and treatment groups. Accumulation of the microplastics and naphthalene by the fish in the treatment groups was observed to be concentration dependent for both the single and combined mixtures. Results showed that the LDPE microplastics modulated the impact of naphthalene on the biochemical parameters assessed. The single exposure of *C. gariepinus* to naphthalene and LPDE microplastics, and the combined mixtures of LDPE with naphthalene, significantly inhibited acetylcholinesterase (AChE) activity compared to the control. The single and combined effect of naphthalene and LPDE microplastics induced neurotoxicological response in *C. gariepinus* after 96 h of exposure. Furthermore, the single exposure to naphthalene and the combined exposures also reduced the total protein concentrations in the fish species. These results, therefore, stress the need to further address the role of microplastics in the bioaccumulation and toxicity of other environmental contaminants in fish species.

2.12 Municipal Wastewater: Proxy for Human and Environmental Exposure and Impacts on Soil and Aquatic Ecosystems

2.12.T-01 Emerging Contaminants in Wastewater – European Project on the Occurrence of Chemicals and Adverse Effects

Saskia Finckh[1,2]*, Liza-Marie Beckers*[3]*, Sebastian Buchinger*[4]*, Wibke Busch*[5]*, Eric Carmona Martinez*[1]*, Valeria Dulio*[6]*, Beate Escher*[7,8]*, Henner Hollert*[2]*, Maria Koenig*[7]*, Martin Krauss*[1]*, Eberhard Kuester*[5]*, Warich Leekitratanapisan*[9]*, Leo Posthuma*[10,11]*, Sabrina Schiwy*[2]*, Mechthild Schmitt-Jansen*[5]*, Tobias Schulze*[12]*, Aliaksandra Shuliakevich*[2]*, Etienne Vermeirssen*[13]*, Peter Von der Ohe*[14] *and Werner Brack*[2,15]*, (1)Department of Effect-Directed Analysis, Helmholtz Center for Environmental Research (UFZ),*

Leipzig, Germany, (2)Evolutionary Ecology & Environmental Toxicology, Goethe University Frankfurt, Frankfurt am Main, Germany, (3)Aquatic Chemistry, Federal Institute of Hydrology (BfG), Koblenz, Germany, (4)Biochemistry / Ecotoxicology, Federal Institute of Hydrology (BfG), Koblenz, Germany, (5)Department of Bioanalytical Ecotoxicology, Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany, (6)Institut National de l'Environnement Industriel et des Risques (INERIS), France, (7)Department of Cell Toxicology, Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany, (8)Geosciences, Eberhard Karls University Tübingen, Tübingen, Germany, (9)Ghent University - GhEnToxLab, Ghent, Belgium, (10)National Institute for Public Health and the Environment (RIVM), Netherlands, (11)Department of Environmental Science, Radboud University, Netherlands, (12)Department of Effect-Directed Analysis, Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany, (13)Swiss Centre for Applied Ecotoxicology, Switzerland, (14)German Environment Agency (UBA), Dessau-Rosslau, Germany, (15)Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany
Contamination of our freshwater systems by municipal wastewater carries the risk of adverse effects on aquatic organisms essential for a well-functioning ecosystem. Multiple wastewaters from private households, urban drains, hospitals, and industry containing chemicals of emerging concern, such as pharmaceuticals, personal care products, pesticides, hormones, and transformation products, are typically discharged via wastewater treatment plants into freshwater systems. In this study, sensitive analytical and bioanalytical methods and holistic assessment approaches have been applied to assess complex chemical mixtures in European effluents linking the occurrence of chemicals with adverse biological effects. A set of 56 treated wastewater samples from 15 European countries were investigated using:

1. Chemical target screening of 499 chemicals to identify and prioritise compounds of concern, comparing three different toxic risk assessment metrics (Risk Quotient, Toxic Unit, Hazard Unit).
2. *In vitro* effect-based methods of four cellular endpoints (estrogen-, androgen-, glucocorticoid-, and progestagen receptors) linked with chemical analysis of 79 steropids and phenols to identify and assess endocrine disrupting chemicals.
3. *In vivo* effect-based methods on whole organisms (i.e., growth and PSII inhibition, immobilisation, and mortality) to investigate adverse effects on algae, crustacean and fish.

In the effluent samples 366 chemicals of emerging concern and 42 endocrine disrupting chemicals were detected at concentrations from <1 ng/L to >100 µg/L. Receptor activities were detected in between 14 % and 82 % of the samples, while apical effects (EC_{50} from the concentration-response curve) were measured in 96 % (algae), 51 % (daphnia) and 82 % (fish embryo) of the samples. For endocrine disruptors, measured and predicted bioanalytical equivalent concentrations (BEQ_{bio} and BEQ_{chem}, respectively) were highly correlated and allowed the identification of effect drivers. In summary, integrated monitoring methods and mixture assessment tools indicated a substantial risk of receiving waters from wastewater treatment plant effluents and a substantial mitigation by advanced treatment technologies. Major risk drivers were identified supporting chemical regulation and measures at the source. The integrated approach may be used as a blueprint for future water quality monitoring. One of the bottlenecks is still the lack of measured effect data for major wastewater contaminants.

2.12.T-02 Changes in Chemicals of Emerging Concern in London's Rivers Across the SARS-CoV-2 Pandemic

***Leon Barron**[1], Melanie Egli[1], Helena Rapp Wright[1], Olukemi Oloyede[2], William Francis[1], Rhys Preston-Allen[1], Stav Friedman[2] and Frederic Piel[1], (1)Imperial College London, United Kingdom, (2)Environmental Research Group, Imperial College London, United Kingdom*
The SARS-CoV-2 pandemic has had a huge impact on global urban populations, their activity, and health. However, little is known about impacts of such a public health crisis on urban river ecosystems. The aim of this work was to determine whether significant changes in chemicals of emerging concern (CECs) occurred in rivers located in Greater London (UK) across the pandemic. The objectives were to (a) reliably and rapidly identify and monitor large numbers of CECs at n = 390 sites across 2019, 2020 (during lockdown), and 2021 using two novel direct-injection liquid chromatography mass spectrometry methods for targeted and suspect screening and (b) to interpret changes in CEC concentrations trends and risks in relation to public health data. Out of all 164 CECs monitored, 66 CECs were quantified across all sites using targeted analysis. Pharmaceutical measured environmental concentrations (MECs) decreased during the SARS-CoV-2 lockdown period in 2020 in the R. Thames ($p \leq 0.001$), but then increased to higher MECs in 2021 ($p \leq 0.01$). Across all three years, MECs rose for some antidepressants and antipsychotics and aligned with National Health Service (NHS) medicine prescription data. For the tributary rivers, the R. Hogsmill, Lee, and Wandle were the most impacted across their lengths and predominantly by WWTP discharge. For the R. Hogsmill in particular, it was observed that prescribed pharmaceutical MEC trends generally associated with NHS statistics due to low dilution. Suspect screening based on a library of >1200 compounds revealed a total of 25 additional compounds at the five most-impacted sites. This included several metabolites, for example, high frequency detection of O-desmethylvenlafaxine. Lastly, risk quotients (RQ)>0.1 were calculated for 26 compounds. The highest RQs were for imidacloprid which is mainly used in the UK as a pet parasiticide (medium-high risk at wastewater effluent discharge sites). Selected medications such as antispychotics and antidepressants also rose into higher risk categories. The overall impact of the SARS-CoV-2 pandemic was multifaceted, with short-term changes in CECs observed in rivers during lockdown periods, but impacts were also observed beyond this. With over 10 029 quantifiable CEC occurrences across all samples, this is the largest dataset of its kind both spatially and temporally for Greater London, representing ~16 % of the population of England and a useful case study of the third largest city in Europe.

2.12.T-03 Wastewater-Based Epidemiology to Assess Human Exposure to Multiple Factors Affecting Human Health

***Sara Castiglioni**[1], Noelia Salgueiro-Gonzalez[2], Silvia Schiarea[3], Giulia Salmoiraghi[3], Marco Fossati[4], Carlotta Gennaro[1] and Ettore Zuccato[3], (1)Environmental Health Sciences, Istituto di Ricerche Farmacologiche Mario Negri, Italy, (2)Istituto Mario Negri, Italy, (3)Istituto Mario Negri, (4)Università degli Studi di Milano, Italy*
Wastewater-based epidemiology (WBE) is an innovative methodology enabling the retrieval of epidemiological information from

urban wastewater via the chemical or biological analysis of specific human metabolic excretion products (biomarkers). WBE may provide information at the community level on emerging risky lifestyle habits, the circulation of pathogens (viruses and bacteria), the exposure to contaminants, and the health status. This study aimed to assess multiple factors that may seriously affect human health using WBE. The factors investigated were: licit and illicit drugs use (prescription opioids, new psycoactive substances - NPS); antibiotics use related to antimicrobial resistance. Specific substances were selected according to the requirements requested for applying a WBE approach and were validated as WBE biomarkers. Urban wastewater samples were collected at the inlet of wastewater treatment plants as composite 24 h samples, and were analysed through solid phase extraction and liquid chromatography coupled to tandem mass spectrometry. All analytical methods were validated according to current guidelines and performed well for sensitivity and selectivity. For prescription opioids, human consumption was estimated from mass loads (mg/day/1000 inhabitants) by using specific correction factors that were developed within the present study and took into account urinary excretion rates. Results showed different profiles of use in the north and south of Italy for some substances (e.g., tramadol). The comparison with prescription figures showed a quite good agreement, suggesting that in Italy there is no abuse of prescription opioids as observed in other countries. A list of 43 “priority NPS” was selected for monitoring and 8 were detected in Italy and Europe. Changing profiles of use were found compared to previous studies with an upsurge of the synthetic cathinone 3-methylmethcathinone. The main classes of antibiotics were investigated in urban wastewater influents highlighting the most abundant classes that were fluorochinolones, macrolides, sulfonamides, and tetraciclines. WBE was also applied to follow azithromycin use during COVID-19 pandemic and explore its potential abuse. WBE was a very useful approach to obtain a wide range of information on the health status of a population and was able to identify public health emergencies as the high use of antibiotics and track rapidly emerging risky lifestyle habits as the abuse of new psychoactive substances.

2.12.T-04 Is it Safe to Irrigate Fresh Produce with Reclaimed Wastewater? Evidence from Human Exposure and Risk Assessment Study

***Benny Chefetz**, Jorge Tarchitzky, Vered Mordehay and Evyatar Ben Mordechay, Hebrew University of Jerusalem, Israel*

Irrigation with reclaimed wastewater is a growing agricultural practice. However, this practice exposes the agricultural ecosystem to organic pollutants that were not completely removed during the wastewater treatment. Once introduced into the field these pollutants may be taken up by plants and introduced into the food chain. The current study used Israel as a case study to estimate the unintentional exposure of the population to organic pollutants originating from wastewater. We used up-to-date dietary data and measured the concentrations of organic pollutants in produce representing ~75% of the diet. Human health concerns were estimated using two approaches: the acceptable daily intake (ADI) and the threshold of toxicological concern (TTC).

Leafy vegetables exhibited the highest concentration of organic pollutants; thus the highest human exposure to the wastewater-borne pollutants was for population subgroups consuming high amounts of leafy vegetables, such as vegetarians and Israeli Arabs. For the extreme exposure scenario (calculated as maximum contaminant concentration times the 95th percentile consumption), the anticonvulsant drugs Lamisil, Tegretol, and a therapeutically active metabolite of Tegretol exhibited the highest human exposure levels of 29.1, 27.2, and 19.5 micrograms per person per day, respectively. For the general population and using an average exposure scenario, the above-mentioned anticonvulsant drugs exhibited exposure levels below the ADI and TTC thresholds. However, for the extreme scenario, the exposure level of Tegretol was higher than its ADI level. In addition, the maximum exposure levels of Lamisil and the therapeutically active metabolite of Tegretol were higher than the TTC level for genotoxic compounds.

To reduce the potential risk, it is suggested to exclude leafy vegetables from agricultural water reuse, and/or improve wastewater treatment to completely remove the anticonvulsant drugs Lamisil and Tegretol.

2.12.T-05 Circularity in the Olive Mill Wastewater Management: Evaluation of the Wastewater Treatment From an Ecotoxicological Perspective

***José Nereu Pinto**[1], Andreia Pereira[2], Ana Rita R. Silva[2], Diogo Filipe Nunes Cardoso[1], Amid Mostafaie[1], Fábio Campos[1], Iryna Rehan[3,4], Olga Moreira[3,5,6], Ivã Lopes[7], Daniel Murta[7], Karina Silvério[8], Fátima Carvalho[8], Adelaide Almeida[8], Amadeu M.V.M. Soares[2] and Susana Loureiro[1], (1)CESAM & Department of Biology, University of Aveiro, Aveiro, Portugal, (2)University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Aveiro, Portugal, (3)INIAV – Polo de Inovação da Fonte Boa, Portugal, (4)GeoBioTec Research Center, Faculdade de Ciências e Tecnologia, Universidade Nova de Lisboa, Campus da Caparica, Caparica, Portugal, (5)University of Lisbon, Centre for Interdisciplinary Research in Animal Health (CIISA), Portugal, (6)Associate Laboratory for Animal and Veterinary Sciences (AL4AnimalS), Portugal, (7)Ingredient Odyssey S.A. - EntoGreen, Portugal, (8)Instituto Politécnico de Beja, Rua Pedro Soares (IPBeja)-Campus do IPBeja, Portugal*

Olive oil is widespread in Mediterranean cuisine and represents an ecological challenge as its manufacture entails the generation of vast amounts of liquid and solid waste. Liquid waste – olive mill wastewater (OMWW) – has long been a concern for all olive oil producers. Many wastewater treatment methods have been used, yet no universal solution exists.

The chemical precipitation technique is a novel wastewater treatment method, using a single reagent – lime – that reacts with atmospheric CO_2, resulting in ionic precipitation. This technique will originate treated wastewater and a precipitate (sludge) that might be used mainly in soil amendment. Simultaneously, wastewater can be reused in irrigation, hydroponics, etc. However, the ecotoxicological weight of CPT-treated wastewater (CPT-OMWW) and sludges has yet to be deeply understood, as little work has been carried out. This work aimed to assess the efficacy of CPT for treating wastewater and whether the sludge is ecotoxicologically safe for soil application. For that, a battery of aquatic and soil ecotoxicological assays was performed in both CPT-OMWW and corresponding sludges.

For the ecotoxicological evaluation of both OMWW and CPT-OMWW, four aquatic species (*Raphidocelis subcapitata, Daphnia magna, Danio rerio, Lumbriculus variegatus*) were used. Acute endpoints were obtained for each species, and LC_{50} and EC_{10} values were estimated depending on the species. CPT reduced the toxicity of *D. magna* and *D. rerio (*12.7% and 13.89% LC_{50} OMWW to almost 100% survival at all tested concentrations after CPT). Likewise, *R. subcapitata's* EC_{10} (for average daily growth rate (Day^{-1})) increased after CPT treatment (2.95% to 26%). *L. variegatus* showed no toxicity for OMWW, and that no-toxic pattern continued after CPT treatment.

For the ecotoxicological sludge evaluation, four species (two invertebrates: *Folsomia candida* and *Enchytraeus crypticus,* and two plants: *Lolium perenne and Brassica oleracea*) were used. Sludge was mixed with LUFA 2.2 soil at 0, 0.5, 1, 2, 4, and 8% concentrations. Significant differences from the negative control – no sludge application – were estimated. Sludge did not affect either *F. candida* or *E. crupticus* adult survival at any tested concentration, yet there was a decrease in reproduction for both at 2% and 1% concentrations compared to control. Sludge did not affect seedling (Gemination Index) in either of the tested plant species but, in general, decreased shoot and root biomass in both.

2.12.P Municipal Wastewater: Proxy for Human and Environmental Exposure and Impacts on Soil and Aquatic Ecosystems

2.12.P-Tu088 The First National Scale Evaluation of Total Nitrogen Stocks and Burial Rates of Coastal Sediments Along the West, South, and East Coast of South Korea
Inha Kwon*, Changkeun Lee and Jong Seong Khim, School of Earth and Environmental Sciences & Research Institute of Oceanography, Seoul National University of Science and Technology, Korea, Republic of (South)*
The regulating ecosystem services, such as water purification, etc., that tidal flats provide by nitrogen (N) burial are being increasingly recognized; yet, quantitative estimates remain limited. Here, we first present a nationwide evaluation of total N stocks and burial rates in the Korean tidal flats, based on three-year-long monitoring assessment combined with a remote sensing approach. A total of 20 intertidal flats representing 7 provinces of South Korea were extensively surveyed in 2018–20; West Sea (Gyeonggi, Chungnam, Jeonbuk, and western Jeonnam), South Sea (southern Jeonnam and Gyeongnam), and East Sea (Gyeongbuk and Gangwon). The sediment textural type (sand, mixed, and mud) classified from remotely sensed imagery was significantly correlated to that identified from field data ($p < 0.01$), warranting a nationwide estimate of total N stocks. The estimated total N stocks and burial rates in the tidal flats of Korea were 1.5 Tg N and 7,805 Mg N yr^{-1}, respectively. Total N stocks significantly varied by region, province, morphology, salinity, and land use type adjacent to the corresponding tidal flats. In general, the N stocks of tidal flats seemed to be influenced by the degree of terrestrial N inputs to the ocean, whilst the N stocks were significantly correlated with several physical parameters, such as precipitation ($p < 0.05$) and tide ($p < 0.01$). Sediment properties such as mud content (%) were found to be the key factor in determining the N stocks across 20 intertidal flats ($p < 0.01$). Finally, the economic value of the total N removal was estimated as ~222 million USD yr^{-1} in Korea and ~15 billion USD yr^{-1} globally. Overall, the present work confirms the valuable ecosystem services of tidal flats' cost-efficient N removal capacity, highlighting marine ecosystem services.

2.12.P-Tu089 Health Hazard in the Baltic Sea: The Presence of Total Fluorinated Substances in Various Matrices
Josefine Larsson*[1], Tove Porseryd[1], Katarzyna Smolarz[2], Patrik Dinnetz[1] and Mats Grahn Prof[1], (1)Environmental Science, Södertörn University, Sweden, (2)Institute of Oceanography, University of Gdansk, Poland*
Per- and polyfluoroalkyl substances (PFAS) is a collective name for approximately 5000 synthetic chemicals used in a myriad of products. Their commonness results in large exposure to humans and the environment. PFAS have been associated with cancer, developmental toxicity, immunotoxicity, endocrine disruption, and other health effects. Only a few PFAS have been studied and the currently regulated and monitored are only a small fraction of the total PFAS released into the environment. Wastewater treatment plants (WWTP) represent an important source of marine PFAS pollution. The Baltic Sea is considered a vulnerable ecosystem with low resilience, mainly due to the low number of key species dominating the ecosystem as well as the high level of contamination including PFAS. The aim of this study is to measure the specific concentration by target analysis of a large number of selected conventional and emerging PFAS, at two sites in the Baltic Sea in the vicinity of WWTPs, i.e., the archipelago south of Stockholm and Himmerfjärdens WWTP and in Gdansk the WWTP of Gdansk. PFAS will be measured up-stream the WWTP, at the outlet and in a gradient from the outlet, and in different matrices including water, sediment, plankton, and organisms in Baltic Sea food web. The target analysis will be complemented by measuring extractable organic fluorine (EOF) which will indicate the total amount of PFAS in the environment.

2.12.P-Tu090 Anthropogenic Gadolinium and Pharmaceuticals Along River Rhine From its Alpine Source to the Middle Rhine Region
Maximilian Larisch[1], Stefanie Schmidt[1] and ***Thomas Schiedek****[2], (1)Technical University Darmstadt, Germany, (2)Hydrogeology, Applied Geosciences, Germany*
Gadolinium (Gd) and pharmaceuticals have become a vital part of our everyday life. Gd applications range from high-tech electronics to medical applications, such as magnetic resonance imaging (MRI). MRI contrast agents based on Gd have been used since the late 1980s and have become important for medical diagnostics. After application, the contrast agent (with Gd) is

excreted nonmetabolized with urine and cannot be effectively removed from wastewater by sewage treatment plants. As a result, surface waters in medically advanced countries exhibit anthropogenic generated Gd anomalies (Gd_anth), which can be detected even in drinking water. Long-term and side effects of Gd are under discussion. The most commonly detected pharmaceuticals, such as diclofenac (pain reliever) and carbamazepine (anti-epileptics), show a similar environmental transport pattern. The River Rhine is an important drinking water reservoir in Europe; water quality research is focusing mainly on the lower river part.

In this research, we investigated the occurrence of Gd_anth and pharmaceuticals in Rhine river water from its source to the middle Rhine Region in Germany. In addition, water samples were taken from the most important tributary rivers Aare, Neckar, Main, Nahe, Lahn, and Mosel. All samples (total number 38) were taken within 9 days (mostly within 3 days) during a dry period in September 2021 and hydrochemically characterized by on-site parameters and ion-chromatoghraphy. Quantitative analyses of Gd_anth were performed by ICP-MS (total Gd) and pharmaceuticals by solid phase extraction, derivatization, and GC-MS analyses. The hydrochemical development of the Rhine water reflected the geological background of the catchment and tributary catchments. From all samples only the Rhine source, Lake Toma, was free of Gd_anth. Along the River Rhine remarkable peaks of Gd_anth occurred at the river mouth of Necker, Nahe, Lahn, and Mosel. A strong positive correlation between Gd_anth and diclofenac (R2 = 0.83) as well as Gd_anth and carbamazepine (R2 = 0.81) can be observed, indicating that both Gd and pharmaceuticals may have a common source. This is supported by a correlation between Gd_anth and the respective population size. In general, the Rhine water load increased from the river mouth Aare to the confluence Mosel/Rhine more than 10-fold and reached a load of maximum ca. 2955 kg/a.

2.12.P-Tu091 Monitoring the Metal Particulate in Municipal Wastewater Treatment Plant

*Keunbai Yoo[1], Hayeoun Choi[2], Seonjin Yang[2] and **Byung-Tae Lee**[2], (1)Environmental Analysis Center, Gwangju Institute of Science and Technology, Gwangju, Korea, Republic of (South), (2)Environmental Analysis Laboratory, GIST Research Facilities, Gwangju Institute of Science and Technology, Gwangju, Korea, Republic of (South)*

Due to the development of nanotechnology, particulates are used in various industrial and household chemical products. Due to the increased use of particulates such as nanomaterials, the inflow of particulates into sewage is gradually increasing, raising concerns that environmental exposure of fine particles will cause serious harm to human health and ecosystems. In this study, the treatment efficiency of particulate pollutants was evaluated for each treatment process at three municipal wastewater treatment plants with different treatment processes (A2O, NPR, SBR). The samples were taken from influent, primary treatment, bioreactor, total phosphorus coagulation, filtration, UV disinfection, and effluent. Metal concentrations of 14 elements (Ag, Al, Au, Ca, Cd, Ce, Co, Cu, Fe, Mg, Mn, Ni, Ti, Zn) were measured in the sample. Total metal concentrations were analyzed with acid microwave digestion followed by ICP-MS or ICP-OES. Truly dissolved metals were separated using 10kDa ultracentrifugal filtration and the filtrates were analyzed by ICP-MS. Particulate metals were estimated by subtracting the truly dissolved metals from total metals. Sub micro(<µm) size metal particles were analyzed using spICP-MS to obtain the particle size and concentration. Chelex-100 resin, ion exchange resin, were used to remove excess ions from samples which may hinder the distinction of particle signals from background or ion signal resulting in the high BED (background equivalent diameter).
The municipal wastewater treatment plant with A2O treatment method removed 96.2% of particulates in the bioreactor process. The municipal wastewater treatment plant with NPR treatment method removed 81.5% of particulates in the total phosphorus coagulation process. The municipal wastewater treatment plant with SBR treatment method removed 49.5% of particulates in the total phosphorus coagulation process.

2.12.P-Tu092 Where Does All the Salt Come From: Sources and Dynamics of Freshwater Salinisation in German Rivers

***Theresa Piana**[1], Birgit Valerius[2] and Elisabeth Berger[1], (1)Sozial-ökologische Systeme, University of Kaiserslautern-Landau (RPTU), Germany, (2)Wasser Infrastruktur Ressourcen, University of Kaiserslautern-Landau (RPTU), Germany*

Excessive salinisation of water resources poses a risk to humans and reduces aquatic biodiversity. Salinisation of waterways is understood to have both anthropogenic (e.g., agriculture, mining, road de-icing, wastewater treatment, and industrial discharge) and natural drivers (e.g., geological weathering products, atmospheric salt deposition, and natural saltwater intrusion). Furthermore, climatic conditions affect the volume and dilution capacity of rivers, leading to variations in salt loads.

The magnitude to which of each of these drivers contributes to the salinity of European water bodies is not well understood. In particular, it has not yet been studied how much the increasing amount of metal salts now being used in the wastewater treatment process to reduce phosphate loads, which is one of the goals of the Water Framework Directive, contributes to freshwater salinisation.

To address these knowledge gaps, we compiled a dataset from routine state monitoring programs across all of Germany, covering the 2000 to 2022 timeframe. Using time series analysis, we explored the spatial distribution and temporal development of salinity-related parameters (e.g., electrical conductivity and concentration of salt ions) and related these observations to potential drivers of salinisation (e.g., geology, location of wastewater treatment plants, proximity of roads) using regression models. In order to clarify whether wastewater treatment plants and especially phosphate elimination are significant drivers of salinity, we added hand-collected monitoring data from three waste water treatment plants we monitored for one year.

Our work improves the knowledge of the relative, quantitative contributions of the different drivers to the salinity of German limnic waters, which is crucial for informing regulations and identifying countermeasures. Moreover, our study demonstrates the power of merging monitoring data across states and institutions, serving as an argument for redoubling data standardisation efforts.

2.12.P-Tu093 Possible Future Applications for Nationwide Wastewater Surveillance in the Netherlands
Erwin Roex, *Ana Maria de Roda Husman, Eric Smit and Janneke Verheijen, National Institute for Public Health and the Environment (RIVM), Netherlands*
From the onset of the COVID-19 pandemic in early 2020, a monitoring program for the presence of SARS-COV-2 in domestic sewage influents was set up in the Netherlands. Since September 2020, all 312 Dutch Sewage Treatment Plants were sampled; since November 2021 even 4 times a week, and subsamples are biobanked. Surveillance data are used, next to the results of other surveillance programs, to underpin policy measures. This established infrastructure is the result of a close cooperation in the Netherlands between the Ministry of Health, Sport and Welfare, the National Institute of Public Health and the Environment, and all 21 regional water authorities and is to our knowledge unique in the world.

Now that this infrastructure is in place, it gives the opportunity to monitor all kinds of both biological and chemical parameters, next to SARS-COV-2, on one side reflecting the health status and exposure of the population connected, and on the other hand revealing relevant information regarding compound groups affecting our water quality. Prominent parameters are infectious diseases like polio and influenza, antibiotic resistance, illicit and illegal drug use, and contaminants of emerging concern like PFAS. But which factors are the most relevant in the process of adding parameters to the existing wastewater surveillance? In this poster the potential parameters to be included in the wastewater surveillance are discussed, based on extensive literature study and expert consultations for the different goals and parameters. In this analysis the most important aspects involved are the added value, prospects for action, and ethical and legislative issues.

2.12.P-Tu094 Hazard Screening of Contaminants of Emerging Concern (CECs) in Swedish Surface Waters
Daniel Malnes[1], *Sylvia Waara*[2], *Romain Figuière*[3], *Karin Wiberg*[1], *Lutz Ahrens*[1], *Stephan Köhler*[1] *and Oksana Golovko*[1], *(1)Department of Aquatic Sciences and Assessment, Swedish University of Agricultural Sciences (SLU), Sweden, (2)Department of Environmental and Biosciences, Halmstad University, Sweden, (3)Department of Environmental Science, Stockholm University, Sweden*
Persistent, mobile, and toxic substances (PMTs) have recently garnered increased attention by environmental researchers, the water sector, and environmental protection agencies. One particular concern for the environment is the unknown transport and spatial distribution of PMTs, which can result in PMTs causing toxic effects far from their source. Both assessment factor (AF) and species sensitivity distribution (SSD) methods can be used in component-based methods (CBMs) for environmental hazard assessment (EHA). AF methods are often limited to a few taxonomic groups, thus rarely including all taxonomic groups that have shown occurrence decline in freshwater ecosystems. A relaxed SSD approach can be used in a CBM EHA using all available ecotoxicity data without requirement of a certain number of taxonomic groups. In this study, acute and chronic SSDs were retrieved from literature data for previously quantified contaminants of emerging concern (CECs) in Swedish surface waters (n = 92) and risk quotients (RQ) were calculated. Moreover, to better understand the characteristics of the detected CECs in nonurban lake sites (n =71), these compounds were checked against established criteria for PM(T)s and occurrence in the aquatic environment, respectively. PMT criteria were limited to results after 2017, as that year the definitions were updated by expert authorities. For the CECs with missing SSDs (n = 15 [acute], n = 41 [chronic]), ecotoxicity data were extracted for eight taxonomic groups, and if data were sufficient ($n \geq 3$), SSDs were derived. AFs were used when the ecotoxicity data were insufficient. The retrieved and newly developed SSDs were then used an EHA in the investigated Swedish rivers and lakes. In the rivers, 8 CECs had RQ>1 in at least one location, and 20 CECs posed a moderate risk (0.01 < RQ < 1). Five CECs exceeded ‘no risk to the environment’ in the lake samples. In total, 21 of the 71 detected substances had already been identified as PM(T)/vPvM substances. The remaining CECs were examined for the fulfillment of the PM(T)/vPvM criteria by monitoring data. Detection frequencies (DFs) of previously identified PM(T) substances were compared with CECs within a similar DF range. 16 PM(T)/vPvM substances were detected in nonurban lake samples, and another 7 potential PM(T)s/vPvM substances were detected. Overall, our study shows the importance of studying field data at large spatial scale to reveal potential environmental hazards far from source areas.

2.12.P-Tu095 Emission Estimation of Pharmaceuticals to Wastewater in Urban Areas – Is the Devil in the Detail?
Caterina Zillien[1], *Thijs Groenveld*[2], *Odin Schut*[3], *Leo Posthuma*[4], *Erwin Roex*[4] *and Ad M. J. Ragas*[5], *(1)Radboud University, Netherlands, (2)Environmental Science, Radboud University, Netherlands, (3)Open University, Netherlands, (4)National Institute for Public Health and the Environment (RIVM), Netherlands, (5)Radboud University Nijmegen, Netherlands*
With increasing numbers of chemicals used in modern society, assessing human and environmental exposure to them is becoming increasingly difficult. For example, measuring all >26 000 chemicals registered under REACH is not just technically unfeasible but would also be incredibly expensive. Estimating emissions of chemicals based on production and usage data could offer a more efficient and systematic approach to tackle this issue. However, such modelling exercises typically depend heavily on the quality of the input data. Currently, the optimum level of detail for input data required to derive sound emission estimations is unclear. Compared to other groups of CECs, data on the use of pharmaceuticals are relatively abundant and openly accessible, particularly for prescription drugs used by the general public. We assessed the implications of using different levels of detail in consumption data of 27 active pharmaceutical ingredients (APIs). The dataset used allowed for specification between national and local data, annual and monthly data, data on prescriptions, and usage in health care institutions. For selected pharmaceuticals, also the contribution of over-the-counter sales was evaluated. Furthermore, different routes of administration were considered as well as

the excretion of conjugate metabolites. For some APIs substantial differences in annual per capita prescriptions between local and national scale were observed. Intra-annual variability in local prescription data varied between 5% and 104%. Overall, the general public uses >90% of the total mass of all studied APIs, of which 20% via prescriptions and 80% via OTC sales. Emission estimates were compared to field measurements obtained through passive sampling. Sets of Speedisks were deployed at various locations throughout the municipal sewer system, covering a diverse selection of urban emission sources, including a hospital outlet, elderly home, residential area, student complex, and the local wastewater treatment plant (WWTP). Despite the variability in consumption, field measurements are subject to larger variations in time than emission estimates. When accounting for the excretion of glucuronide metabolites, emission estimations improved substantially even at locations 'upstream' to the WWTP, indicating rapid deconjugation and retransformation into the respective parent compound.

2.12.P-Tu096 Identification of Pharmaceutical Metabolites by Target and Suspect Screening in WWTPs and Their Abatement During Wastewater Treatment

Corina Meyer[1] *and Juliane Hollender*[2]*, (1)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Dübendorf, Switzerland, (2)Environmental Chemistry, Environmental Chemistry, Eawag, Swiss Federal Institute of Aquatic Science and Technology, Dübendorf, Switzerland*

Humans are exposed to a multitude of chemical compounds such as pharmaceuticals, which are upon intake often metabolized in order to increase polarity and facilitate their excretion. Detection of these metabolites in the influent of wastewater treatment plants (WWTPs) can give information on the exposure of a large fraction of the human population, whereas the detection in the effluent can yield indications about the pollution of aquatic systems. Many human metabolites arrive at WWTPs in higher amounts compared to their parents and are in some cases known to have higher toxicity. Nevertheless, many studies exist which analyze the parent compounds or focus on already identified metabolites of single compounds. Therefore, this study aims to identify and analyze metabolites originating from a broad range of pharmaceutical parent compounds by online-SPE-LC-ESI-HRMS/MS in combination with target and suspect screening. For this purpose, untreated wastewater of three Swiss WWTPs equipped with ozonation as a tertiary treatment was sampled for one week in early 2022 during dry weather conditions. The suspect list was generated based on the yearly consumption amounts of parent pharmaceutical compounds in Switzerland. Pharmaceuticals with a consumption amount of more than 100 kg per year or a strongly increasing consumption over the last few years were chosen, yielding 250 parent compounds. To complete the suspect list with the respective human metabolites, literature search, mainly with drugbank and Swiss compendium, was performed. The resulting list encompasses around 1100 metabolites of which 100 were covered by a targeted approach. Feature detection and data analysis were performed by SLAW and R, leading to the identification of several pharmaceutical metabolite compounds with confidence level 2 to 3. In addition to the raw wastewater, samples after every treatment step in the WWTPs were taken to assess the different abatement of parent and respective metabolites. It is anticipated that human phase I metabolites are less efficiently abated during oxidative biological wastewater treatment and ozonation compared to their parents, since they are already oxidized during human metabolism, such that they will be less efficiently attacked by the electrophile oxygen. The results of the ongoing study with focus on metabolites will be presented.

2.12.P-Tu097 Effect-Based Evaluation of Water Quality in a System of Indirect Reuse of Wastewater for Drinking Water Production

Kim Frieberg[1]*, Pablo Gago-Ferrero*[2,3]*, Lubertus Bijlsma*[4]*, Lutz Ahrens*[5]*, Karin Wiberg*[5]*, Felix Hernandez*[4]*, Agneta Oskarsson*[1] *and Johan Lundqvist*[1]*, (1)Swedish University of Agricultural Sciences (SLU), Sweden, (2)Catalan Institute for Water Research (ICRA), Spain, (3)Spanish Research Council (CSIC), Institute of Environmental Assessment and Water Research (IDAEA), Spain, (4)University Jaume I, Spain, (5)Department of Aquatic Sciences and Assessment, Swedish University of Agricultural Sciences (SLU), Sweden*

Freshwater resources are globally under an ever-growing pressure due to high demand and low supply. Furthermore, it is well known how low-level pollution of organic micropollutants can affect freshwater sources. Treated wastewater is often described as point source for this type of pollution. Using treated wastewater as a direct or indirect (via surface water) source for drinking water production therefore comes with a paired risk of presence of chemical pollution as well as presence of pathogenic microbial pollution. In drinking water production, disinfection is a well-established method to combat microbial pollution. It is however known that such treatment can cause formation of disinfection by-products (DBPs) which can induce oxidative stress. In this study, chlorination as a means of disinfection was applied to effluent wastewater indirectly used for drinking water production.

Water quality was assessed for the presence of bioactive compounds in a system of intentional reuse of effluent wastewater in and around the Llobregat River, Barcelona, Spain. Grab water samples included different stages of treated wastewater, recipient surface water, and finished drinking water. Samples were collected in two campaigns, with and without chlorination treatment applied to effluent wastewater. Water quality was assessed in a battery of reporter gene assays using stably transfected mammalian cell lines. Endpoints included estrogen and androgen receptor activity, AhR activity, immune response via NFKβ activity as well as oxidative stress, via the Nrf2 pathway, as a measure of formation of DBPs.
Our results indicate that in this investigated setup, effluent wastewater could be purposely redirected to increase freshwater supply for drinking water production without compromising the quality of finished drinking water. Furthermore, we found chlorination treatment of effluent wastewater to result in three major findings. First, we could not observe an increase in oxidative stress response due to the additional chlorination treatment. Secondly, estrogenic agonistic activity decreased after chlorination treatment and thirdly, we found AhR activity to increase after chlorination treatment.

Some of the results in this study need further investigation to reveal mechanisms behind the specific findings. This study provides important insights for future efforts to increase reuse of treated wastewater as a source for drinking water production.

2.12.P-Tu098 Nicotine in Coastal Waters of the Iberian Peninsula: Environmental Risk and Possible Use as an Indicator of Bathing Water Quality

*Sandra Mozas Blanco[1], Judit Kalman[1], Silvia Diaz-Cruz[2], Andreu Rico[3], Isabel López[3], Salome Martinez Morcillo[4], Miguel Motas[5], Unax Lertxundi[6], **Jose Luis Rodriguez-Gil**[7,8], Gorka Orive[9], Osvaldo Santos[10] and Yolanda Valcarcel Rivera[1], (1)Rey Juan Carlos University, Spain, (2)IDAEA-CSIC, Spain, (3)IMDEA Water Institute, Spain, (4)University of Extremadura, Spain, (5)University of Murcia, Spain, (6)Araba Psychiat Hosp, Spain, (7)University of Manitoba, Canada, (8)Experimental Lakes Area (IISD-ELA), Canada, (9)NanoBioCel Group, Laboratory of Pharmaceutics, School of Pharmacy, University of the Basque Country UPV/EHU, Spain, (10)University of Lisbon, Portugal*

Densely populated coastal areas are highly vulnerable to pollutants from daily human activities. An increasing number of contaminants have been detected in coastal waters highlighting the need to better understand their possible risks. Among these, nicotine has been proposed as a potential marker of anthropogenic contamination due to its ubiquitous presence in coastal areas. Currently, quality of bathing water quality regulations in Europe are only based on microbiological parameters according to Directive 2006/7/EC. The objectives of this study were (1) to determine the presence of nicotine and its main metabolite, cotinine, in three different coastal areas in the south of the Iberian Peninsula, (2) to determine their environmental risks, and (3) to evaluate their usefulness as a water quality indicator. Samples were collected and analysed by liquid chromatography (HPLC) along 16 beaches in the Portugal coast in Lisbon/Algarve, and 30 in Spain: 18 from Cádiz and 12 from Mar Menor (Murcia). The water quality, according to National Bathing Water Information System (Spain) and National Water Resources Information System (Portugal), was evaluated as excellent in 100% of the beaches. Nonetheless, nicotine and cotinine were detected in 97% and 100% of the samples, respectively. For the risk assessment, available chronic toxicity data provided by ECOSAR for both substances were used to calculate the hazard quotient (HQ). To determine the relationship between the microbiological parameters and the concentrations of nicotine/cotinine an analysis of non-parametric contrasts for comparison of medians was carried out. Of all the samples, Veneciola beach in Mar Menor showed the highest hazard (HQ=5) for nicotine, while no risk of cotinine (HQ<0.1) was detected in any area. For nicotine, 14% of the samples presented no risk, 27% low risk and 59% reached moderate risk. No correlation was found between the numbers of bacteria detected and nicotine/cotinine concentrations. This study demonstrates that nicotine and cotinine are ubiquitous contaminants in densely populated beaches, which most likely come from wastewater treatment plant effluents, but also from cigarette butts and human excretion. The risks posed by nicotine can reach high values in peak season. Therefore, further studies should investigate the subchronic and chronic effects of this substance on marine organisms.

2.12.P-Tu099 Characterization of Biological Communities in Systems Affected by Wastewater Treatment Plant (WWTP) Effluent Discharge

*Carlos Silva[1], Joana I Santos[1], Tânia Vidal[1], Susana Silva[2], Fernando J. M. Gonçalves[3], Salomé Almeida[4], Nelson Abrantes[5] and **Joana Pereira**[3], (1)CESAM and Dept Biology, University of Aveiro, Aveiro, Portugal, (2)Department of Biology, University of Aveiro, Aveiro, Portugal, (3)University of Aveiro, Aveiro, Portugal, (4)GeoBioTec and Dept Biology, University of Aveiro, Aveiro, Portugal, (5)Department of Biology, University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Portugal*

Wastewater treatment plants (WWTP) are essential to modern day life; they play a key role in reducing the environmental impact of everyday human activities. However, because WWTPs were mainly designed to reduce organic matter load and disinfect the influent, it is frequent that released treated effluents still bear some contaminants. Whereas most of the mandatory quality assessment standards that WWTPs should meet focus the water compartment (effluent and/or recipient waterway), some of those contaminants might accumulate in the sediment and have an impact in benthic communities in the vicinity of the effluent discharge. Benthic macroinvertebrate and diatom communities are models in this context while also being biological elements used for evaluation of ecological quality under the scope of the European Water Framework Directive (WFD). Herein, we aimed at evaluating the impact (if any) of the effluent in both these communities, learn how their structure changes with distance from effluent discharge, and compare the outcomes of community structure analysis with ecological status classification to appraise on the relative sensitivity of both methods in highlighting responses to effluent-driven contamination. We collected macroinvertebrate and diatom samples, as well as sediment samples for multiresidue analysis, at different distances from effluent discharges in the recipient waterways of three WWTP: immediately upstream the effluent discharge point, immediately downstream the effluent discharge point, and 500 m downstream from the discharge point. Results showed that effluent sourced contaminants accumulated in the sediment (e.g., pharmaceuticals and metals), but also that links to negative impacts in biological communities are not consistently recognized, denoting that the effluent may not be the single most effective stressor constraining communities. A discrepancy was found between the ecological status classification determined on the basis of one or the other community, up to two classification categories, which suggests a high level of specificity of this stressor scenario and highlights the need for a careful selection of biological elements to focus in WFD biomonitoring efforts.

2.12.P-Tu100 Effects of the Antimicrobial Agent Thymol on the Physiological Profile of River Microbiota

*Cristina Gan-Oria, Elisa Langa, Antonio Valenzuela, Natalia Ferrando Lázaro, Guillermo Lorca, Diego Ballestero and **M. Rosa Pino**, Universidad San Jorge, Spain*

Thymol is a natural product derived from the secondary metabolism of plants, being the main monoterpene phenol present in the essential oils of plants belonging to the Lamiaceae family. Thymol presents a wide bioactivity; however, its use as an antimicrobial agent is particularly interesting, as it has been shown to possess antimicrobial properties against several bacteria such as *Escherichia coli*, *Staphylococcus aureus*, *Salmonella thymimurium*, and *Pseudomonas aeruginosa*, among others. Despite the numerous uses of thymol, little is known about its potential impact on the environment, especially on freshwater microbial communities. Microorganisms are essential in river ecosystems, as they form the basis of food chains, and their activity as decomposers contributes to closing the carbon cycle.

The response of a freshwater microbial community from the Gállego river (Zaragoza, Spain) to the effects caused by different concentrations of thymol (0.1, 10, 100, and 1000 µg/mL) for 168 h was evaluated. EcoPlates Biolog™ containing 31 of the most common carbon sources in the environment were used. The data obtained were used to calculate the average well color development (AWCD) as an indicator of population growth and changes in the ability of the microbial community to metabolize substrates.

The microbial community exposed to thymol showed an intense decrease in growth activity compared to the control when exposed to 100 and 1000 µg/mL thymol. However, at 0.1 and 10 µg/mL there was an increased growth effect, suggesting the ability of the microbial community to metabolize this product. The same effect was observed on the ability to metabolize different substrates: while at the lowest concentrations (0.1 and 10 µg/mL), there was hardly any change in the metabolic profile (a slight increase was observed for amines/amides); at higher concentrations (100 and 1000 µg/mL), a decrease in the ability to metabolize almost all substrates, especially carbohydrates and amino acids, was observed.

Results demonstrate that thymol can produce changes in the growth and metabolic profile of river bacteria at concentrations around 0.1 µg/mL, although very high doses of 100 µg/mL are necessary to produce a decrease in microbial activity. Therefore, this product is unlikely to pose an ecotoxicity risk to the environment and is a good alternative to more aggressive antimicrobial products.

2.12.P-Tu101 Impact of the Monoterpene Eugenol on the Physiological Profile of River Microbiota

*Natalia Ferrando Lázaro[1], **M. Rosa Pino**[1], Diego Ballestero[1], Antonio Valenzuela[1], Guillermo Lorca[1], Cristina Gan-Oria[1], Eva Terrado[2] and Elisa Langa[1], (1)Universidad San Jorge, Spain, (2)Universidad de Zaragoza, Spain*

Eugenol is a terpene, found in many plants and their extracts, used in perfumes, excipients, and in current odontology procedures. Thanks to the antiseptics properties of eugenol, an emerging application as antimicrobial compound in combination with commercial antibiotics is raised. Because of this, an environmental toxicity assessment is desirable prior to a more extensive use of this chemical substance.

For this purpose, we evaluated the ecotoxicity of eugenol (0.1, 10, 100, and 1000 µg/mL) on freshwater microbial communities from the Gállego River in Zaragoza, Spain. Biolog EcoPlates® were used to calculate the Average Well Colour Development (AWCD) as an indicator of the entire capacity for degrading 31 of the most common carbon sources found in natural ecosystems.

Results showed a progressive slight decrease in AWCD and metabolite consumption ability for lower concentrations (0.1, 10, and even 100 µg/mL), followed by a complete growth inhibition for the highest dose (1000 µg/mL). Namely, a decrease in the ability to metabolize carbon sources was observed, finding that polymers and carbohydrates were the most affected.
Therefore, this study concludes that, due to the wide range of properties this product offers, its use will increase in the future, and therefore, will land on the environment more often. This assessment allows us to better understand eugenol and how it would impact on the structure of river communities and modify their physiological profile before it happens.

2.12.P-Tu102 Screening Toxicity of Relevant Environmental Mixtures using *Caenorhabditis elegans*

***Fábio Campos**, Amadeu M.V.M. Soares and Susana Loureiro, University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Aveiro, Portugal*

Chemical substances from different sources enter wastewater treatment plants and end up in the environment. Due to effluent and biosolids discharges, pesticides and pharmaceuticals can be found in effluents and therefore in waterbodies or soils. This constitutes a challenging problem for the environment and human health as they occur as complex mixtures (CM) rather than as individual substances. Understanding the toxic effects of such CM remains crucial for proper risk assessment (RA) and public health safety, which are usually carried out separately. From an environmental toxicology perspective, *Caenorhabditis elegans* can be a good model organism for toxicity screening of different CM, for the environment and human health assessment.
In this study, we evaluate the single and joint toxicity of three substances, widely found in Portuguese wastewater effluents, on the survival, feeding, and reproduction rates of *C. elegans*. The chemical substances chosen were the insecticide cypermethrin, the herbicide MCPA, and the over-the-counter pharmaceutical diclofenac, as little is known about the interaction of these chemicals. Concentration addition and Independent Action predictive models were also used to understand the CM's toxicity pattern better. Interactions for synergism or antagonisms were evaluated, looking at deviations from these models.

The results obtained from our study support the importance of *C. elegans* as a model organism to be used jointly for human health and environmental hazard assessment. The fast testing of different endpoints provided different outputs (additivity, synergism, or antagonism) and sensitivities and will unravel the potential MoA of substances or their interactions in CMs, ultimately leading to the development of an adverse outcome pathway.

2.12.P-Tu103 When a Psychiatric Drug Alters the Migratory Behavior of the Critically Endangered Fish *Anguilla anguilla*
Colin Bouchard[1], Valérie Bolliet[2], Stellia Sebihi[2], Cédric Tentelier[1] and ***Mathilde Monperrus***[2]*, (1)UMR ECOBIOP INRA - Université de Pau, France, (2)Université de Pau et des Pays de l'Adour, France*
In the Anthropocene, the current biodiversity losses caused by human activities have various features, from individuals to populations, species, and ecosystems. Chemical pollution is one of the major current threats, especially because Wastewater Treatment Plants do not reduce or treat psychiatric drugs leading to the chemical pollution of aquatic environments. Most of the studies in ecotoxicology focus on the effects on survival or development, losing sight of the potential effects on biodiversity. Individual behavior and the related intraspecific diversity are the main components of it, even though overlooked.

Here, we assessed the effects of a psychiatric drug on the European glass eels' migratory behavior. Glass eels are eel juveniles migrating from the sea towards rivers crossing estuaries and WWTP effluents to colonize hydro-systems. Usually, individuals colonize and distribute themselves from estuaries to upstream river systems leading to changes in local density, which drive sex-ratio and individual growth.

Since we used an anxiolytic, we hypothesized that contaminated individuals would be bolder and less active than control individuals. We put 40 control individuals and 40 individuals contaminated with diazepam at an environmentally relevant concentration through 7-day chronic contamination in a behavioral monitoring tank that mimics a river. This tank is like an annular tank enabling individuals to swim continuously either against the current (i.e., upstream movement) or with the current (downstream movement) and us to study migratory behavior in experimental facilities. We video-recorded around 1-min sequences over 7 days since the depuration of diazepam by glass eels takes 7 days. We also video-recorded the first 15 minutes since individuals hide directly under the gravel at the tank bottom as soon as we placed them in the tank. The time it took them to get out of their shelter is a proxy for their boldness.
We found the anxiolytic contamination led individuals to be bolder but less active than control individuals. The contamination altered their migratory behavior since they swam less at counter-current than control individuals. Finally, the behavioral alterations became more pronounced with time despite the depuration. The behavioral alteration we found may affect the local density and ultimately population processes, but also the local environment since glass eels are predated by several fishes and birds.

2.12.P-Tu104 3,4-Methylenedioxypyrovalerone (MDPV) Sublethal Ecotoxicity Assay on the Microcrustacean *Daphnia magna*
Ariana Pereira[1], Ana Rita Carvalho[1], Bruno Castro[2], Carla Fernandes[3], Maria Tiritan[1], João Soares Carola[4] and ***Cláudia Ribeiro***[1]*, (1)TOXRUN – Toxicology Research Unit, University Institute of Health Sciences, CESPU, CRL, Portugal, (2)CBMA; IB-S, Portugal, (3)University of Porto, Interdisciplinary Centre of Marine and Environmental Research (CIIMAR), Portugal, (4)CITAB, Portugal*
The consumption of psychoactive substances (PAS) has increased in the last years. Among them, synthetic cathinones (SCAT) emerged as a popular group of PAS for recreational purposes. After consumption SCAT enter the sewage systems and reaches the wastewater treatment plants, which are not prepared for their removal, leading to their frequent detection in effluents and aquatic ecosystems. SCAT are designed to change nervous system function, posing unpredictable adverse effects on nontarget organisms. Considering the scarce information available on SCAT ecotoxicity, including 3,4-methylenedioxypyrovalerone (MDPV), it is urgent to assess their toxicity on exposed aquatic organisms. This work aimed to study the ecotoxicity of MDPV using as a model organism the microcrustacean *Daphnia magna*. For that, a sublethal assay using daphniids was carried out at a concentration range of 0.1 to 10 µg/L for 8 days and morphophysiological, behavioral, reproductive, and biochemical effects were evaluated. Results showed a significant increase in the heart size, area, and rate in juveniles at all concentrations tested (day 3). However, on day 8, a significant increase in heart rate was still observed (1 and 10 µg/L) but different responses were observed for heart size and area that showed a significant decrease in adults at the three concentrations studied. MDPV also affected swimming behaviour. Indeed, a significant increase in total distance and active time were observed at 0.1 and 10 µg/L and 10 µg/L, respectively, whereas a significant decrease in swimming speed was noted at 10 µg/L. No changes in reproductive and biochemical parameters were found at the selected concentrations. The present study showed the toxicity of MDPV at sublethal concentrations on morphophysiological and behavioral endpoints. Further studies are ongoing to extend the current knowledge about MDPV toxicity effects on this aquatic organism, concerning its enantiomers.

2.12.P-Tu105 Enantioselectivity in Toxicity of Smphetamine, 3,4-Methylenedioxymethamphetamine and Methylenedioxypyrovalerone on Greshwater Organisms (*Daphnia magna* and *Danio rerio*)
Cláudia Ribeiro[1]*, Ariana Pereira[2], Ondina Ribeiro[3], Ana Costa[1], Virgínia Gonçalves[1], Carla Fernandes[4], Bruno Castro[5], Maria Tiritan[1], Luís Félix[6] and João Soares Carola[7], (1)TOXRUN – Toxicology Research Unit, University Institute of Health Sciences, CESPU, CRL, Portugal, (2)Rua Central de Gandra, CESPU/IUCS/TOXRUN, Portugal, (3)UTAD, Portugal, (4)University of Porto, Interdisciplinary Centre of Marine and Environmental Research (CIIMAR), Portugal, (5)CBMA; IB-S, Portugal, (6)Centre for the Research and Technology of Agro-Environmental and Biological Sciences (CITAB), University of Trás-os-Montes and Alto Douro (UTAD), Vila Real, Portugal, (7)CITAB, Portugal*
The consumption of amphetamines and synthetic cathinones resulted in their widespread occurrence in the environment, raising concern about possible hazardous to nontarget organisms. Their metabolism in humans and biodegradation in wastewaters is stereoselective. Understanding enantiomer-specific toxicity is crucial for risk assessment of chiral contaminants. This study aimed

to investigate the potential enantioselective effects of amphetamine (AMP), 3,4-methylenedioxymethamphetamine (MDMA), and methylenedioxypyrovalerone (MDPV) in *Daphnia magna* and *Danio rerio*.

Daphnids were exposed to three concentrations for the racemate, 0.1, 1.0, and 10.0 µg/L, and two concentrations for the enantiomers (0.1 and 1.0 µg/L) for 8 days and morphophysiological, swimming behaviour, reproductive, and biochemical variables evaluated. For zebrafish assay, fertilized eggs were exposed for 96 h to racemate and enantiomers ranging from 0.02 to 200 µg/L. Embryonic development, malformations, and larvae swimming behaviour were evaluated.
(*R,S*)-AMP and (*R,S*)-MDMA and their enantiomers affected morphophysiological parameters and enantioselective effects were observed even at the lower concentrations. Both substances caused changes in swimming behaviour, but different responses were observed among racemates and enantiomers. No changes in first reproductive events were observed for MDMA whereas AMP racemate stimulated reproduction. (*R,S*)-MDPV caused an increase in heart rate and changes in swimming behaviour.

An increase in the percentage of malformations in zebrafish exposed to (*S*)-MDMA. Changes and enantioselective effects were observed in swimming behaviour. Regarding AMP, an increase in oedema area was observed in organisms exposed to (*R*)-AMP. An increase in larvae size and tail curvature was noted for the racemate. Larvae exposed to (*R*)-AMP showed a higher percentage of malformations and enantioselective effects were observed for swimming behaviour.

Exposure to these substances at environmental reported levels showed to interfere with swimming behaviour, morphophysiological, reproductive,A and biochemical parameters at different developed stages of *Daphnia* and during embryonic development of zebrafish. Enantioselective responses were observed for some parameters.

2.12.P-Tu106 Morphometric Changes in Larval Zebrafish Exposed to Butylone
*Ondina Ribeiro[1], **Cláudia Ribeiro**[2], Luís Félix[3], Sandra Mariza Monteiro[3] and João Soares Carola[4], (1)UTAD, Portugal, (2)TOXRUN – Toxicology Research Unit, University Institute of Health Sciences, CESPU, CRL, Portugal, (3)Centre for the Research and Technology of Agro-Environmental and Biological Sciences (CITAB), University of Trás-os-Montes and Alto Douro (UTAD), Vila Real, Portugal, (4)CITAB, Portugal*
New psychoactive substances (NPS) emerge worldwide and their consumption among young people has been increasing. Human urinary excretion of NPS and its metabolites contribute to their presence in wastewater treatment plants and water bodies. So, their presence in aquatic environments is expected, raising concern about the potential negative effects on nontarget species, like ichthyofauna. Butylone (BTL) is a synthetic cathinone that acts as an entactogen, with psychedelic and stimulant effects in humans, but no data are available concerning potential hazards to fish. Zebrafish (*Danio rerio*) is an animal model widely used in different areas of toxicology research and emerged as a popular model for investigating the potential toxic effects of NPS during early-life stages. Thus, this work aimed to evaluate the potential morphometric effects of BTL in zebrafish larvae.

For that, 10 embryos with approximately 3 hours postfertilization (hpf) were exposed for 96 hpf to different concentrations of BUT (0.01, 0.1, 1, 10, and 100 µg/L). Three replicates were performed for each concentration. After the exposure period, morphometric measurements (larva size, eye area, yolk area, oedema area, head area, and tail curvature) and malformation evaluations were assessed in larvae. Concentrations were selected to include environmental reported levels and higher concentrations to get insights about BTL toxicity.
Overall, a decrease in the larvae size (0.1, 1, and 10 µg/L), eye area (10 µg/L), and head area (0.01, 0.1, 1, 10, and 100 µg/L) was observed in comparison with the control group. Contrarily, we observed an increase in tail curvature (0.1 and 1 µg/L) and malformations percentage (like deformations in the tail, yolk sac oedema, and pericardium oedema) for 0.1, 1, 10, and 100 µg/L BTL concentrations.

These results show that BTL can interfere with morphometric parameters during embryonic zebrafish development even at environmental levels. Teratogenic effects in organisms' development can affect fish swimming and even their survival. Additional studies are been done to confirm these effects of BTL in fish.

2.12.P-Tu107 Effects of Methamphetamine Exposure on the Zebrafish Embryonic Development
*Ondina Ribeiro[1], Diane Pereira[2], Cláudia Rubio[2], **Cláudia Ribeiro**[3], Luís Félix[4] and João Soares Carola[5], (1)UTAD, Portugal, (2)School of Life Sciences and Environment, University of Trás-os-Montes and Alto Douro (UTAD), Portugal, (3)TOXRUN – Toxicology Research Unit, University Institute of Health Sciences, CESPU, CRL, Portugal, (4)Centre for the Research and Technology of Agro-Environmental and Biological Sciences (CITAB), University of Trás-os-Montes and Alto Douro (UTAD), Vila Real, Portugal, (5)CITAB, Portugal*
Illicit drugs are a global concern with significant direct and indirect adverse impacts on human health and wildlife. Among them, methamphetamine (METH) is a psychostimulant that is widely used as a recreational drug. Increased worldwide consumption and incomplete metabolization in the human body have led to the appearance of METH in the aquatic environment mainly via wastewater effluent discharge, with potential effects in nontarget organisms. Early development stages of aquatic organisms, like fish, are prone to adverse effects caused by toxins. Hence, zebrafish (*Danio rerio*) presenting semitransparent embryo has been increasingly used as a key model to study developmental biology and to assess the toxic effects of psychoactive substances during the early stages of embryonic development. Therefore, the goal of this work was to evaluate METH effects on the embryonic development of *D. rerio*.

Zebrafish embryos with approximately 3 hours postfertilization (hpf) were randomly exposed for 96 h to different concentrations of METH (0.05, 0.5, 5, 25, and 50 µg/L) and the effects on embryonic development parameters were evaluated, namely cumulative mortality (7, 24, 48, 72, and 96 hpf), spontaneous movements (24 hpf), heart beats (48 hpf), and hatching rate (72 hpf). For each concentration, three replicates were performed and a control group.
Preliminary data showed that METH exposure has no effects during embryonic development, for spontaneous movements and hatching rate of zebrafish embryos. However, a slight increase in cumulative mortality and a decrease in heartbeats were observed at different concentrations of METH.

Our data indicated that METH does not affect the studied parameters of embryonic development; however, it can reduce the heart rate and increase mortality. These experiments provide a baseline for the study of the toxicity of METH during the zebrafish's early life stages. Nevertheless, additional studies are required about METH to better assess the potential risk for fish namely in the first stages of fish embryonic development because these changes can affect greatly their survival.

A**2.12.P-Tu108 A Class of their Own? Water-Soluble Polymer Pollution Impacting a Freshwater Host-Pathogen System**
Charlotte Robison-Smith[1]*, Eve Tarring*[2]*, Numair Masud*[3] *and Joanne Cable*[3]*, (1)Biosciences, Cardiff University, United Kingdom, (2)Chemistry, Cardiff University, United Kingdom, (3)Cardiff University, United Kingdom*
Microplastic pollution is a major ecological threat for aquatic ecosystems. A primary route of freshwater microplastic pollution is wastewater, where wastewater treatment plants (WWTP) fail to effectively remove microplastics (MPs) before effluent reaches river systems. This has fuelled the debate on whether 'intentionally added MPs' or primary MPs should be banned under UK/EU REACH chemical regulation and restriction. Primary MPs, often added to personal care products (PCPs), are beginning to see restrictions on their uses, but water-soluble polymers (WSP) have so far slipped through the net for global chemical regulation. Despite the widespread occurrence of WSP in the cosmetic and food industries, there are no regulations for their use. In addition to their prevalence in PCPs, the predominant use of WSP is attributed to wastewater treatment itself, where they are applied directly to aid removal of contaminants. As a result, reports of WWTP effluents with high WSP concentrations (up to 7 mg/L) are emerging, yet the environmental implications of these chemicals are poorly understood. There is new evidence of the sublethal effects of WSP, where physiological changes have been observed for freshwater invertebrates and neonate zebrafish, implying WSP may be inducing stress. Investigating the interaction of these chemicals with other biological stressors over longer exposures is imperative to determine the potential risk of WSP for freshwater ecosystems.

Utilising a host-pathogen model system, this study assesses the impact of two mass produced WSPs on fish welfare, specifically host growth, metabolic rate, and disease susceptibility, thereby defining the interaction with a second stressor (i.e., the pathogen). Analytical methods such as matrix-assisted laser desorption/ionisation-time-of-flight (MALDI-TOF) will be applied to further examine the fate of these chemicals *in vivo,* achieving an interdisciplinary investigation into their effects on this freshwater ecological model. This is the first study of its kind investigating the chronic impacts of this neglected polymer class on a freshwater vertebrate. If negative effects of these polymers are encountered individually or in a multistressor scenario with disease, we hope that this research would encourage the consideration of WSP under UK/EU REACH, and increase awareness of these emerging contaminants globally.

2.12.P-Tu109 Ecotoxicological Characterization of Wastewaters from Different Origins Obtained After Using the Chemical Precipitation Technique
Ana Rita R. Silva[1]*, José Nereu Pinto*[2]*, Andreia Pereira*[1]*, Amid Mostafaie*[2]*, Diogo Filipe Nunes Cardoso*[2]*, Iryna Rehan*[3,4]*, Olga Moreira*[3,5,6]*, Ivã Lopes*[7]*, Daniel Murta*[7]*, Karina Silvério*[8]*, Fátima Carvalho*[8]*, Adelaide Almeida*[8]*, Amadeu M.V.M. Soares*[1] *and* ***Susana Loureiro***[2]*, (1)University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Aveiro, Portugal, (2)CESAM & Department of Biology, University of Aveiro, Aveiro, Portugal, (3)INIAV – Polo de Inovação da Fonte Boa, Portugal, (4)GeoBioTec Research Center, Faculdade de Ciências e Tecnologia, Universidade Nova de Lisboa, Campus da Caparica, Caparica, Portugal, (5)University of Lisbon, Centre for Interdisciplinary Research in Animal Health (CIISA), Portugal, (6)Associate Laboratory for Animal and Veterinary Sciences (AL4AnimalS), Portugal, (7)Ingredient Odyssey S.A. - EntoGreen, Portugal, (8)Instituto Politécnico de Beja, Rua Pedro Soares (IPBeja)-Campus do IPBeja, Portugal*
With the increase in human population, more waste has been generated, leading to several environmental concerns. Consequently, more than ever, for a sustainable planet, it is urgent to transform waste into valuable by-products by treating, reusing, or recycling it. This is one of the aims of the project NETA-"New Strategies for WasteWater Treatment" (Portugal2020): to valorize different wastewaters (WW) by transforming them into valuable resources, namely hydric and nutrient resources.

Different methods have been developed to treat wastewater, usually combining biological, chemical, and physical processes (e.g., wastewater treatment plants). One alternative method being successfully explored is the chemical precipitation technique (CPT). In CPT, one reagent ($Ca(OH)_2$) is added to the WW, that by ionic precipitation, will originate treated water and the formation of a precipitate (i.e., a sludge-like product). This method might be considered effective for WW treatment due to its low cost, quickness, and ease of use on a large scale. Considering the need for effluent and sludge environmental discharges, it is important to understand the efficacy of this technique as WW treatment, looking at their physicochemical characteristics, jointly with their ecotoxicological profile.

Thus, in the present study, the aim was to evaluate CPT's efficacy in treating WWs from different origins – industrial/domestic/urban – from an ecotoxicological perspective. As case studies, different WWs were used: 1) olive mill WW,

2) cheese whey WW, and 3) WW from multiple sources (receiving both domestic, slaughterhouse, and livestock WW). For all these WWs, ecotoxicological assays were conducted for both untreated and CPT-treated WW. Acute immobilization was assessed for the crustacean *Daphnia magna,* and hatching rate, survival, and malformations for the zebrafish *Danio rerio*. The results showed that toxicity was reduced for both species after CPT treatment, compared with untreated WW, overall displaying high survival rates to all tested concentrations, except in the cheese whey wastewater (with mortality at 75% and 100% of WW for *D. magna*).

These results confirm the efficacy of using the CPT technique in (some types of) WWs from an ecotoxicologically perspective. Results also highlight that the source of WW will define the quality and toxicity of the originated CPT-treated WW, and that chemical analysis by themselves are not sufficient to define the safety and disposal of WWs.

2.12.P-Tu110 Context Dependent Behavioral Responses of Arabian Killifish to Sertraline and Predator Alarm Cues
Asma Al Shuraiqi[1] *and Michael J Barry*[2]*, (1)Biology, Sultan Qaboos University, Muscat, Oman, (2)Sultan Qaboos University, Muscat, Oman*
The release of pharmaceuticals from waste treatment plants poses a major threat to aquatic ecosystems downstream of receiving waters. The antidepressant sertraline has been detected in surface waters at concentrations up to 80 ng/L and can also accumulate in sediments and aquatic organisms. Several studies show that sertraline can affect the behavior of fish at concentrations as low as 5 ng/L. Neuroactive pharmaceuticals such as sertraline can alter fish behavior leading to maladaptive responses and increasing the risk of succumbing to predators. The aim of the present study was to measure the effects of environmentally relevant concentrations of sertraline on the swimming, foraging and mating behavior of Arabian killifish (*Aphanius dispar*) in the presence and absence of alarm cues (kairomones) from predatory dragonfly larvae.

Groups of 12 male *A. dispar* were exposed for 60 days to two different concentrations of sertraline (5 ng/L, 50 ng/L, or a freshwater control), in glass aquariums (40 × 30× 30 cm) holding 20 L of water. There were four replicates of each treatment. The behavior of the fish was measured in three experiments: (1) Shoaling behavior. The swimming behavior of groups of one, three or five fish was recorded before and after the addition of a dragonfly alarm chemical. (2) Exploratory behavior: The swimming and foraging behavior of three killifish was recorded in a complex arena (80 x 80 cm) containing three different habitats, before and after the addition of a dragonfly alarm chemical. (3). Attraction to female killifish.

Overall responses to sertraline exposure and predator alarm were strongest when single fish were measured, suggesting that solitary fish assessed the threats as greatest when they were alone compared to being in shoal. In the habitat preference test fish preferred the vegetation, and this preference increased following addition of alarm chemical. Sertraline did not affect female preference.

2.12.P-Tu111 Evaluation of the Effects of Metoprolol on Microalga *Monoraphidium pusillum* and Fish *Poecilia* sp.
Alma Sobrino-Figueroa[1]*, Omar Jímenez Hernández*[2] *and Sergio Alvarez-Hernandez*[3]*, (1)Hydrobiology, Universidad Autonoma Metropolitana Iztapalapa, Mexico, (2)Hydrobiology, Universidad Autónoma Metropolitana-Iztapalapa, Mexico, Mexico, (3)Hidrobiology, Universidad Autónoma Metropolitana-Iztapalapa, Mexico, Mexico*
Metoprolol drug inhibits the stimulating effect of catecholamines on the heart, being the priority drug for consumption by the population in Mexico to treat hypertension. In wastewater in Mexico, the presence of metoprolol in concentrations of 1530 ng L^{-1} has been identified. Due to the fact that the consequences of Metropolol in aquatic organisms are not completely known, in this study an evaluation of the effects of Metoprolol in the microalgae *Monoraphidium pusillum* in their growth, its content of pigments and macromolecules and in the fish *Poecilia* sp. its oxidant, neurotoxic effects, and alterations in the macromolecule content were determined. A bioassay was carried out where the microalgae were exposed to five concentrations of the drug (20, 40, 60, 80, 100 mgL^{-1}) for 72 h, to determine the EC_{50} (Probit). Subsequently, it was carried out a sublethal bioassay with microalgae to evaluate Chlorophyll, Carotene, and macromolecule content. The fish were exposed to five concentrations of the drug (20, 40, 60, 80, 100, 250 mg L^{-1}) for 96 h, to determine the LC_{50} (Probit). Afterwards, a sublethal bioassay was performed to evaluate the degree of lipid peroxidation, the activity of the enzyme Acetylcholinesterase, and the concentrations of macromolecules. The EC_{50} values (72 h) in the microalgae and for the fish LC_{50} (48 h and 72 h) are in the limit of EC_{50} 10 mg L^{-1} $\leq$ 100 mg L^{-1} indicating that Metropolol is a harmful compound for these organisms (GHS, ONU 2011). In the tests with microalgae, an increase of between 5% to 43% in the concentration of pigments and from to 27% in macromolecules were observed. In the fish the Metoprolol had an oxidative effect, AChE inhibition, proteins, and carbohydrates decreased with increasing drug concentration. Metropolol had greater harmful effects on the fish *Poecilia* sp. exposed to sublethal concentrations.

2.12.P-Tu112 Toxicity of Three Types of Surfactants in Aquatic Organisms of Different Trophic Levels
Alma Sobrino-Figueroa[1]*, Vivian Crespo Albarran*[2] *and Alberto Perez-Rojas*[3]*, (1)Hydrobiology, Universidad Autonoma Metropolitana Iztapalapa, Mexico, (2)Hidrobiologia, Universidad Autonoma Metropolitana Iztapalapa, Mexico, (3)Universidad Autonoma Metropolitana Iztapalapa, Mexico*
Surfactants are synthetic compounds used in the manufacture of detergents; generally anionic surfactants are the most used, but the use of cationic and noncationic surfactants is increasing, because they are present in personal care products. These compounds are toxic to aquatic organisms, since they destabilize cell membranes, affecting survival, and they also alter essential functions such as respiration, feeding, and growth. In this study, an evaluation of the toxicity of 3 surfactants was carried out: Lauryl Alkylsulfonate (anionic LAS), Cetyltrimethyl Ammonium Chloride (cationic), and Triton X (nonpolar) in aquatic organisms of

different trophic levels (microalgae, cladocerans, and fish), to determine which species is more sensitive to these compounds. The microalgae *Monoraphidum pusillum*. and *Pseudokirchneriella subcapitata*, six species of cladocerans: *Chydorus* sp, *Ceriodaphnia dubia*, *Daphnia exilis*, *Daphnia magna*, *Moina macrocopa* and *Simocephalus mixtus* and two species of fish *Danio rerio* and *Poecilla* sp. were exposed to 5 concentrations of surfactants (for 48 hours for cladocerans and 96 hours for tests with microalgae and fish). With the mortality data obtained, the Lethal Concentration 50 (LC_{50}) was determined (Probit method). The sensitivity of the species was determined by comparing their LC_{50} values. The LC_{50} values obtained in the tests with LAS varied from 0.04 to 110 mg L^{-1}, with Cetyltrimethyl Ammonium Chloride from 0.032 to 2.99 mg L^{-1}, and with TX from 4.3 to 48.029 mg L^{-1}. The most toxic surfactant for the 10 species was the cationic surfactant and the least toxic the nonpolar. Cladocerans were the most sensitive organisms to surfactants. The species most sensitive to surfactants were *Pseudokirchneriella subcapitata* and *Daphnia exilis*. The degree of toxicity of these compounds ranged from highly toxic to harmful, according to the Globally Harmonized System (GHS).

2.12.P-Tu113 Drinking Water Production – What Are the Risks From Dumping RO-Concentrates and Antiscalants into the Aquatic Environment?

Carolin Anna Cecile Bertold[1], Florian Gigl[1], Anja Rohn[2], Gerhard Schertzinger[2], Alexander Sonnenburg[2], Beat Schmutz[3], Sebastian Egner[3], Dominic Armbruster[3], Oliver Happel[3], Henner Hollert[1,4], ***Sarah Johann[1]*** *and Sabrina Schiwy[1], (1)Goethe University Frankfurt, Department Evolutionary Ecology and Environmental Toxicology, Frankfurt am Main, Germany, (2)IWW Water Centre, Germany, (3)TZW DVGW (German Water Centre), Germany, (4)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany*

To ensure high drinking water quality, modern techniques like membrane-filter like reverse osmosis (RO) technologies are constantly applied and optimized. During the water purification process, concentrates that contain highly concentrated salts, RO-additives, and partly micropollutants are produced. Subsequently, these concentrates are discharged either directly or indirectly into surface water. The potential impact of these discharges has not yet been fully investigated. The RO-additives and antiscalants (AS) are needed to elongate the membrane lifetime. Once leaked into the environment, their high complexation ability could lead to sediment sealing and enhance the migration of heavy metals. Also, AS shows a low biodegradability and could aggravate phosphate, contributing to eutrophication. In the *KonTriSol* project, various AS active substances, AS technical products, and RO-concentrates were tested to be supplied with a more precise statement on the effect of the RO-concentrate discharge on the environment. The *KonTriSol* project aims to develop a comprehensive bioassay battery for the ecotoxicological assessment of AS and concentrates, evaluate the effects of AS active ingredients in complex mixtures and concentrate treatment strategies. Additionally, concentrate discharge conditions should be optimized. For a comprehensive ecotoxicological evaluation, AS active ingredients, AS technical products, RO-concentrates, and treatment strategies were tested in a biotest battery, with acute (on daphnids, fish and algae) and mechanism-specific endpoints (genotoxic-, PFAS-like-, endocrine-activity). We found that AS and its technical products have no endocrine or genotoxic effects but exhibit acute toxic effects toward daphnids, especially algae. As there are toxic effects already present in potentially environmentally relevant concentrations, AS discharge could have a potential harm on the environment. The first results show that RO-concentrates containing AS can exert an (low) acute toxic effect on daphnids and fish (algae toxicity data yet to come). It must be considered that the concentrates are diluted when discharged into the environment, which will lower the effects. With the knowledge about the ecotoxicological properties of RO-concentrates and AS, concentrate discharge conditions into the environment can be optimized, thus preventing damage to the aquatic environment.

2.12.P-Tu114 Ecotoxicity of Combined Exposure of Antibiotics and Biofilms to *Xenopus laevis* Larvae

Alexandre Thibodeau[1]*, Florence Mouchet[2], Maïalen Barret[2], Xuan Van Nguyen[1], Laury Gauthier[2] and Eric Pinelli[2], (1)INP Toulouse, France, (2)UMR5245 CNRS-UT3-INPT Laboratoire Ecologie Fonctionnelle et Environnement, France*

Over 40 different antibiotics are found in wastewater treatment plant effluents (WWTP) and freshwater (FW) ecosystems, usually in mixture. They are rejected in environment through different sources at low concentration. Organisms in freshwater such as wild animals and biofilms (multicellular community of microorganisms) are constantly exposed to antibiotics. To understand ecotoxicology of antibiotic cocktails in environment, this experiment has been conducted to assess combined effects from antibiotic cocktails and various biofilms with different exposure scenarios in more environmental relevant conditions. In accordance with international standard ISO 21427-1 Guidelines, *Xenopus laevis* larvae have been exposed 12 days to 10 $\mu g.L^{-1}$ to cocktail 1 (six antibiotics) or cocktail 2 (three antibiotics) reported on EU Watchlist (ciprofloxacin, azithromycin, amoxicillin, erythromycin, trimethoprim, sulfamethoxazole), and with or without biofilm (from WWTP outlet, or from FW). Morphometric parameters (length, growth rate), genotoxicity (micronucleus induction), and oxidative stress biomarkers data have been collected in larvae exposed in different conditions compared to control. After 12 days, morphometric parameters decreased for larvae exposed to antibiotic cocktail 1 + biofilms present (WWTP or FW). Genotoxicity has been reported in larvae exposed to biofilm (WWTP or FW) and with cocktail 2 + WWTP biofilm. Based on current data from this study, hypotheses can be drawn on ecotoxicity of biofilms but need further research. Oxidative stress biomarkers analysis is currently ongoing. Investigations of potential link between gut microbial communities and genotoxicity would be explored by further analysis of microbial diversity in gut larvae and biofilms.

2.12.P-Tu115 The Challenges of the Risk Assessment of Textile Wastewater

Mira Goßen*, Evolutionary Ecology & Environmental Toxicology, Goethe University Frankfurt, Frankfurt am Main, Germany*

During textile wet-processing, which includes garment dyeing, thousands of chemicals are used with different toxic potentials and modes of action. Alone the used textile dyes contain several toxic and stable compounds. If these are released into the water system, by discharging untreated or inadequately treated wastewater into rivers, this has serious implications for human and environmental health, as can currently be observed in major producing countries such as India. However, the impacts of industrial wastewater on organisms and the environment are difficult to assess because of the complex composition and mixture of chemicals, including potentially degraded products, which might be more toxic than the parent compounds. In addition, the high salt concentration in textile wastewater can lead to the salinization of rivers, which could negatively impact freshwater organisms and change the toxic potential of the substances. Thus a realistic risk assessment requires the use of holistic and impact-oriented methods. Chemical analysis cannot fully detect the complexity of substances, so in this study, the wastewater samples from a textile dyeing plant in India were analysed both chemically and ecotoxicologically. Based on the data from the chemical target screening using liquid chromatography– high-resolution mass spectrometry (LC-HRMS, compounds belonging to three main classes could be found: substances from textile wet production, pesticides, and pharmaceuticals. In addition to the analyses of the textile effluents, the toxic potential of five reactive azo dyes used in the dye factory was also investigated using various endpoints. The toxic potential varied widely among these dyes. For example, the acute toxicity in zebrafish larvae after 120 hpf exposure was 4.5 times higher for the reactive azo dye ME3B red compared to yellow GD3R. As described, the high salt concentration in textile effluents is also an additional stressor, especially for freshwater organisms. Toxicity studies with and without the addition of salts showed an increase in toxicity in different organisms in the mixture compared to exposure to salts or dyes alone.

2.12.P-Tu116 Integration of Effect-Based Methods in the Development of Textile Wastewater Technologies

***Jan Halaunia**, Mira Goßen, Nicole Jennifer Goede, Henner Hollert and Sabrina Schiwy, Evolutionary Ecology & Environmental Toxicology, Goethe University Frankfurt, Frankfurt am Main, Germany*

Only 3% of the water on earth is freshwater and therefore a limited resource. In addition, factors such as the growing population or pollution from agriculture and industrial wastewater are leading to an increased scarcity of freshwater resources. Due to its high population density and increasing industrialization, India is particularly affected by the consequences of freshwater scarcity. The textile industry is one of India's most important economic sectors and is one of the main producers of industrial wastewater worldwide. In addition, textile wastewater is particularly difficult to treat due to the high number of different chemicals (e.g., reactive azo dyes) and high salt concentration. Therefore, there is a need to develop wastewater treatment technologies that meet the requirements of treating complex textile wastewater. The EfectroH$_2$O project is developing a new wastewater treatment technology that combines advanced oxidation processes (AOP) for the removal of micropollutants and capacitive deionization (CDI) for selective salt removal and recovery. The development will be accompanied by effect-based methods, as chemical analysis alone cannot detect the toxic potential of mixture effects or metabolites to investigate the efficiency of the new technology. For this purpose, a synthetic textile wastewater is produced in the laboratory based on data from the wastewater of the textile industry MS/Rohini, Erode in Tamil Nadu, India. The synthetic wastewater contains the five dyes Red GDN, Navy GDG, Red ME3B, Yellow GD3R, Black GDNN [2.9 g/L] and a salt mixture [7 g/L] of $NaHCO_3$, Na_2SO_4, NaCl, $CaCl_2$, and $MgCl_2$. The toxic potential of the synthetic textile wastewater will be tested on a laboratory scale before and after treatment with the newly developed technology. The acute toxicity is analyzed using freshwater model organisms in different trophic levels (Algae, Daphnids, and Fish embryo). The first results show that *Daphnia magna* has a lower EC_{50} value (2.03 g/L saltmix and 0.75 g/L dyemix) than *Danio rerio* (2.34 g/L and 0.88 g/L). The main sublethal effects in *D. rerio* were fin deformations, edema, and prevention of hatching. Moreover, the data for the acute toxicity with algae *Raphidocelis subcapitata* and specific endpoints for genotoxicity will be available at the conference.

2.12.P-Tu117 Evolution of the Endocrine-Disrupting Activity of BPA and Analogues During Aqueous Ozone- and •OH-Based Oxidation

***Alberto Cruz-Alcalde**[1], Oriol Porcar-Santos[1], Laia Navarro-Martin[2], Marta Casado[2], Marta Gual-Gimeno[2], Tugstenio Lima[2] and Carme Sans[1], (1)Department of Chemical Engineering and Analytical Chemistry, University of Barcelona, Spain, (2)Department of Environmental Chemistry, Spanish Research Council (CSIC), Institute of Environmental Assessment and Water Research (IDAEA), Spain*

As a result of their proven, endocrine-disrupting effects, bisphenol A (BPA) is currently a restricted chemical in different world regions. The immediate solution for companies using this compound in their manufacturing processes has been its replacement by other bisphenol analogues, such as BPF, BPS, BPAF, and BPC, among others. However, several previous studies have revealed endocrine-disrupting effects of these substitutes over organisms similar to those exerted by BPA. In this research, the endocrine-disrupting activity of BPA and some of its mostly employed substitutes was studied before and after both ozone and hydroxyl radical oxidation-based treatments of aqueous solutions containing these chemicals. The gene expression responses of the model organism zebrafish have been used for toxicological evaluation.

The selected compounds were BPA, as well as the analogues BPS, BPAF, and BPC-Cl. Zebrafish eggs were obtained by natural mating of adult individuals, which were collected at approximately 17 h postfertilization (hpf), then rinsed and finally checked for fertilization. Embryos were placed in six multiwell plates and their exposure to several concentrations of selected bisphenols was conducted from 4 to 5 days postfertilization (dpf). After RNA extraction, the endocrine disrupting effects were evaluated by comparing the expression of different genes of the control well (i.e., not containing bisphenols) with the different concentrations that were selected.

Results revealed that the gene displaying the highest expression was the estrogenic gene cyp19a1b. The concentrations evaluated were 0.5, 2.5, 5, 25, and 50 mM. In the case of BPA, to cite an example, the highest expression of gene cyp19a1b compared to the control was observed at a concentration of 25 mM. The lower expression observed after exposure to concentrations of 50 mM was attributed to an increase of nonspecific toxicity, according to the observed decrease of the swim bladder inflation rates.

The evaluation of toxicity evolution over ozone- and •OH-based treatments, performed by means of these techniques, gives further insights into treatment characterization, providing practical knowledge to assist in the selection of the optimal treatment conditions for these water treatment technologies.

2.12.P-Tu118 Detoxification of Wastewater Plant Effluents by Soil Aquifer Treatment Methodologies

Claudia Sanz[1], Marta Casado[2], ***Laia Navarro-Martin***[2] *and Benjamin Pina[1], (1)Environmental Chemistry, Spanish Research Council (CSIC), Institute of Environmental Assessment and Water Research (IDAEA), Spain, (2)Department of Environmental Chemistry, Spanish Research Council (CSIC), Institute of Environmental Assessment and Water Research (IDAEA), Spain*

Despite all the efforts carried out in Wastewater Treatment Plants (WWTP), their effluents contain a number of chemicals, many of them classified as contaminants of emerging concern, such as pharmaceuticals and personal care products, steroid hormones, surfactants, industrial chemicals, and pesticides. Many of these chemicals are well known to have endocrine disrupting properties (such as estrogenicity) and dioxin-like activity which are capable to alter the general development, metabolism and endocrine system of organisms living downstream. In the present study, we have investigated the efficiency of three mesoscaled Soil Aquifer Treatment (SAT) systems equipped with reactive barriers (RB), containing different proportions of sand and organic fillings and associated to a sandy aquifer, to reduce toxicological risks. SATs were fed with secondary effluents from an operating WWTP during two consecutive campaigns timed before and after the 2020 summer vacation period. Fifteen water samples were collected from the WWTP effluent, after every RB, and at the end of the aquifer. Transcriptomic analyses of zebrafish embryos exposed to the corresponding extracts revealed a wide range of toxic activities in the WWTP secondary effluents. Our results demonstrated that the associated responses were reduced by more than 70% by SAT, achieving control levels in some cases. Similar results were obtained when human HepG2 hepatic cells were tested for cytotoxic and dioxin-like responses. Toxicity reduction appeared to be partially determined by RB composition and/or SAT managing, and it correlated with the removal of certain CECs by SAT, as monitored by nontarget semiquantitative LC-HRMS analysis. In conclusion, SAT appears to be a very promising technical approach for efficiently reducing the effects of recalcitrant pollutants from WWTP secondary effluents on the environment and human health

2.13.P New Approaches and Methodologies for the Future Direction of Pollinator Health and Safety

2.13.P-Mo133 Tissue Specific Investigation of the Detox Gene Inventory of *Apis mellifera* After Exposure to Coumaphos, Malathion, and their Metabolites

Janin Rösner[1]*, Tobias Pamminger[2] and Ralf Nauen[2], (1)Early Environmental Safety, Bayer AG - Crop Science Division, Germany, (2)Bayer AG - Crop Science Division, Germany*

Pollinators such as honeybees are among the most ecologically important insects because they play a major role in plant reproduction, thus contributing to the functioning of various ecosystems. In recent years high annual losses of insect pollinators were reported, which have been linked to various environmental stressors including the exposure to pesticides. Consequently, it is important to gain a deeper understanding of the detoxification mechanisms of the honeybee and thus the factors driving honeybee sensitivity toward pesticides.

In this study we focus on a range of established detoxification enzymes including the cytochrome P450s, which are known to mediate tolerance to pesticides in the honeybee. In order to identify potential genes involved in pesticide detoxification we determined the expression profiles of candidate genes suspected to be involved in pesticide detoxification in different honeybee tissues prior to, and following exposure to the pesticides coumaphos and malathion, and their metabolites coroxon and malaoxon. Next we investigated the causal involvement of these enzymes by performing acute contact toxicity tests with adult honeybees exposed to the pesticides with and without enzyme group specific inhibitors.

We found that some genes had particularly high transcript levels in excretory tissues. These include genes encoding for cytochrome P450 monooxygenases such as *CYP9Q3*, which is already known to be involved in the detoxification of neonicotinoid insecticides, and some *MRP4* genes, which encode proteins of the family of ATP-binding cassette (ABC) transporters and are known for their involvement in export of pesticides and their metabolites. Also, a single glutathione-S-transferase gene (*GstD1*) had increased transcript levels in the Malpighian tubules and the fat body of the honeybee.

In addition, some *MRP4* genes as well as genes encoding for cytochrome P450 monooxygenases, such as *CYP4C1* and *CYP4C3,* were upregulated in response to pesticide treatment, and the combination of pesticides of interest with some synergists resulted in increased mortality. In summary, this study represents a first overview of the tissue-specific distribution of expression of detox genes and their response after exposure of coumaphos, malathion, and their metabolites in the honeybee and provided mechanistic support for the causal involvement of cytochrome P450 monooxygenases, carboxylesterases, and ABC transporters in detoxification of pesticides.

2.13.P-Mo134 Using Machine Learning for Trait-Based Predictions of Insecticide Toxicity to Wild Bee Species

Magdalena M. Mair[1]*, Maximilian Pichler[2] and Tobias Pamminger[3], (1)Statistical Ecotoxicology, University of Bayreuth, Germany, (2)Theoretical Ecology, University of Regensburg, Germany, (3)Bayer AG - Crop Science Division, Germany*

Honeybees (*Apis mellifera*) are traditionally the main focus of pollinator risk assessment. However, wild bee species are often more vulnerable to stressors than honeybees, and it is unclear whether the current application of safety factors to exposure thresholds can offer them enough protection. The revised guidance on the risk assessment of plant protection products on bees addresses this issue by incorporating some wild bee species (e.g., bumble bees of the genus *Bombus* and solitary bees like *Osmia* spp.) as standard test organisms into the requirements for the registration of plant protection products in the EU. The problem however remains the same: Even if we know how several bee species are affected by a chemical, we still do not know whether this adequately protects all other wild bee species. *In silico* techniques that enable chemical toxicity estimation for untested pollinator species based on a mix of chemical properties and bee traits are promising tools to address this task.

We present here a flexible machine learning model (Boosted regression tree) trained to predict LD50 values of insecticides to untested bee species using a combination of the chemicals' molecular fingerprints and physicochemical properties, and bee species specific traits including ecological characteristics, size measurements, taxonomic information and known detoxification genes (cytochromes P450). We show how machine learning models combined with explainable artificial intelligence (xAI) can be used to derive hypotheses on bee-chemical trait combinations leading to particularly toxic or non-toxic outcomes. We argue that this trait-based approach is a promising addition for assessing the risk of chemicals to wild bee species that cannot be tested in the lab, and will improve our mechanistic understanding of insecticide toxicity.

2.13.P-Mo135 Ecological Traits Interact with the Landscape Context to Determine Bees' Pesticide Tisk
Jessica Knapp[1]*, Charlie Nicholson*[2]*, Ove Jonsson*[3]*, Joachim de Miranda*[4] *and Maj Rundlöf*[2]*, (1)Lund University, Sweden, (2)Department of Biology, Lund University, Sweden, (3)Department of Aquatic Sciences and Assessment, Swedish University of Agricultural Sciences (SLU), Sweden, (4)Swedish University of Agricultural Sciences (SLU), Sweden*
Widespread contamination of ecosystems with pesticides threatens nontarget organisms. However, the extent to which life-history traits alter pesticide exposure and resulting risk in different landscape contexts remain poorly understood. We address this for bees based on pesticide concentrations in pollen and nectar collected by *Apis mellifera, Bombus terrestris* and *Osmia bicornis*, representing extensive, intermediate, and limited foraging trait types across a gradient of agricultural land use. We found extensive foragers (*A. mellifera*) experienced the highest overall pesticide risk – additive toxicity-weighted concentrations. However, intermediate (*B. terrestris*) and limited (*O. bicornis*) foragers' risk estimates responded to the landscape context, resulting in increased pesticide risk with more agricultural land. Furthermore, pesticide risk correlated among bee species and between pollen and nectar food sources, demonstrating the potential for proxies useful in pesticide risk assessment. Our work provides foraging trait and landscape-dependent information on the identity, level and frequency of pesticides bees encounter in agricultural landscapes. Such information is fundamental for developing a more holistic and realistic environmental risk assessment and essential for taking action to meet policy goals to reduce the pesticide-related risk for bees and other pollinators.

2.13.P-Mo136 Solitary Bees and Pesticide Exposures: A Model Approach
Amelie Schmolke[1]*, Nika Galic*[2]*, Vanessa Roeben*[3]*, Thomas G Preuss*[3]*, Mark Miles*[4] *and Silvia Hinarejos*[5]*, (1)Waterborne Environmental, Inc., (2)Syngenta Crop Protection, Basel, Switzerland, (3)Bayer AG - Crop Science Division, Germany, (4)Bayer AG - Crop Science Division, United Kingdom, (5)Sumitomo Chemical Agro Europe SAS, France*
Solitary bees, including both wild and managed populations, are important pollinators of crops and wildflower communities. Solitary bees can potentially be exposed to pesticides via multiple routes of exposure which may differ between species and between solitary bees and the Western honey bee (*Apis mellifera*) which is currently used as surrogate for risk assessments across bee species. Species-specific traits may additionally interact with the potential for exposures and effects, including, for instance, phenology, reproductive rates and flower preferences. We are presenting a population model for solitary bees in agricultural landscapes, SolBeePop. The model was developed to simulate a variety of species by using species-specific ecological traits as model parameterisations. Model parameterisations for several species (*Osmia bicornis*, *O. cornifrons*, *O. cornuta*, *O. lignaria*, *Megachile rotundata*, *Nomia melanderi*, and *Eucera (Peponapis) pruinosa*) were compiled from the literature whereby data availability varied by species. Exposures to a pesticide through multiple exposure routes can be considered, such as nectar, pollen, direct spray and nesting materials. Effects are implemented using a simplified toxicokinetic-toxicodynamic model, BeeGUTS, adapted specifically for adult bees while an exposure-response functions is applied to simulate effects to developing in-nest life stages. We calibrated and validated the model with control data from semifield studies conducted with *O. bicornis*. We applied the model across the model species to assess the impacts of different trait combinations on population dynamics as well as population-level effects. The model provides a valuable tool for higher-tier pesticide risk assessments across species of solitary bees in agricultural landscapes.

2.13.P-Mo137 Predicting Pollen and Pesticide Occurrences at National Scales Using Citizen Science Monitoring Data
Bas Buddendorf[1]*, Hans Baveco*[2]*, Alison Gray*[3]*, Jozef van der Steen*[4] *and Ivo Roessink*[2]*, (1)Environmental Risk Assessment, Wageningen Environmental Research (WUR), Netherlands, (2)Wageningen Environmental Research (WUR), Netherlands, (3)University of Strathclyde, United Kingdom, (4)AlveusAB, Netherlands*
Honeybees (*Apis mellifera* L.) are one of the key species providing pollination for crops and a variety of other flowering plants. The quality of the environment is paramount for the well-being of honeybee colonies, as landscapes with a too low forage quality can be detrimental to colony performance. In addition, such landscapes have been linked to an increase in frequency and intensity of pesticide use, thus providing an extra stress. In order to survey landscape quality, there is a need for a general approach that allows for an assessment of likely crop diversity and the prevalence of pesticides in an area over the course of a season.

Data on pollen and pesticides were collected in five apiaries in Austria and four apiaries in Denmark using a standardised protocol. Two types of geo data were used to extract predictor variables. Firstly, sites were chosen to cover different landscapes based on CORINE landscape classes. Secondly, the cumulative degrees Celsius above 10°C after the 1st of January in 2019 was used as a predictor variable for pollen (as a proxy for plant phenology).

Prediction of the probability of a pollen family or a pesticide being present in a location (i.e., multiclass classification) can be achieved using random forests, a machine learning technique. Each time an observation in the training data is passed through a classifier tree it is placed into a certain outcome category (predicted outcome); each tree can lead to a different outcome for the same sample. Next, from the ensemble of classifiers (i.e., the forest) an estimated probability is given for a sample being a member of a certain category, as the proportion of all the trees that predict that category for the sample (observation).

Predictive maps were created of: 1) pollen diversity, and 2) pesticide diversity. Sparse training data lowered the performance of the models. Nonetheless, the predictions seem to match with an expectation of lower numbers of pesticides in areas with a higher floral diversity. In a follow-up project, data will be collected in all 27 EU countries. Hence the models can be updated, and it is expected this will result in models that can be used to make risk maps for pollen and environmental pollutants that can be used by, for example, beekeepers to find suitable locations for their apiaries. Moreover, these maps will show, in time and space, where mitigation measures may be needed, allowing authorities and managers to take efficient and targeted action.

2.13.P-Mo138 *In vitro* Impacts of Acute and Chronic Exposure to λ-Cyhalothrin and Spinetoram on the Honeybee (*Apis mellifera*) Larvae

Kyongmi Chon[1], *Ji-Yeong Choi*[1], *Juyeong Kim*[1], *Bo-Seon Kim*[1], *Chang-young Yoon*[2] *and Jin-A Oh*[1], *(1)Toxicity and Risk Assessment Division, National Institute of Agricultural Sciences, Korea, Republic of (South), (2)Toxicity and Risk Assessment Division, Rural Development Administration, Korea, Republic of (South)*

λ-Cyhalothrin is a pyrethroid insecticide that interferes with the nervous system of insects, which is effective against aphids. A recent study reported that λ-cyhalothrin influenced the performance and the activity of learning and memory, and reduced homing ability of honeybees. Spinetoram is a spinosyn insecticide that targets the insect nervous system of the nicotinic acetylcholine (nACh) receptors and γ-aminobutyric acid (GABA) gated ion channels. The honeybee exposed to spinetoram showed a reduction of sugar solution consumption compared to the control, which can potentially impact the health and growth of honeybee colonies. As there are limited studies about the potential impact of both pesticides on honeybee larvae relative to adult bees, we investigated the acute and chronic toxicities of λ-cyhalothrin and spinetoram on honeybee larvae reared *in vitro*. The 72 h LD50 values of λ-cyhalothrin and spinetoram were 0.058 (0.051-0.066) and 0.026 (0.01-0.045) µg a.i/larva, respectively. In the chronic toxicity test, the LD50 at D22 of λ-cyhalothrin and spinetoram were 0.040 (0.033-0.046) and 0.017 (0.014-0.019) µg a.i/larva, respectively. The chronic NOED of λ-cyhalothrin and spinetoram was 0.0125 µg a.i/larva. All λ-cyhalothrin treatment groups had an adult deformation rate of higher than 30%, exhibiting a significant difference compared with solvent controls in a dose-dependent manner. Similarly, spinetoram treated bees exhibited significantly more deformities in comparison to the solvent control. The acute and chronic LD50 values estimated in our study suggests both pesticides are highly toxic to bee larvae. Both pesticides significantly increased the deformation rates of emerging bees. Our results would provide some important findings for the lethal and sublethal effects of these insecticides on honeybee larvae. Further in-depth understanding is needed to confirm the effect of both pesticides based on molecular mechanisms.

2.13.P-Mo139 Flupyradifurone: Systemic Butenolide, Persistent and Bioaccumulation in Honeybee Hives and Hummingbirds in British Columbia, Canada

Christine Bishop[1], *John E. Elliott*[2], *Alison J Moran*[3] *and English G Simon*[4], *(1)WILDLIFE RESEARCH DIVISION, Environment and Climate Change Canada, Delta, Canada, (2)Environment and Climate Change Canada, Canada, (3)Rocky Point Bird Observatory, Victoria, Canada, (4)Forestry and Conservation Science, University of British Columbia, Canada*

In Canada, new regulations for the use of imidacloprid were implemented in April 2021 on high bush blueberry crops. Imidacloprid use was reduced from two sprays per year to one spray and only after bloom drop. There was no change to use of flupyradifurone, a systemic butenolide that was introduced since 2015, and it is rapidly replacing imidacloprid for aphid control. Although flupyradifurone is less acutely toxic to invertebrates it is sprayed at almost 10 times the application rate as imidacloprid. In the Fraser River valley in British Columbia blueberry crops are rapidly expanding in acreage. Flupyradifurone is now being detected at concentrations an order of magnitude above imidicloprid levels in honeybee nectar, honey, and hummingbird urine. Flupyradifurone concentrations were as high as 418 ppb in nectar, 156 ppb in honey, and 43.9 ppb in hummingbird urine among 12 study sites in a gradient from within 200 m to 22 km from blueberry crops. EU maximum residue levels acceptable in honey for flupyradifurone were also exceeded in samples of honey from hives within 200 m and up to 2km of blueberry crops.

2.13.P-Mo140 30 Day Acute and Chronic Honeybee Test with Microbials

Eugenia Soler[1], *Emmanuelle Verge*[2], ***Carmen Gimeno***[3] *and Josep Antoni Aguilar-Alberola*[3], *(1)EUROFINS TRIALCAMP, SLU, Alcacer, Spain, (2)Eurofins Agroscience Service Ecotox GmbH, Niefern-Öschelbronn, Germany, (3)Eurofins Trialcamp, Spain*

For microbial testing, two guidelines are available, OPPTS 885.4380 and OECD 67. Both are very general and do not give enough details on test design, endpoints, or validity criteria.

Nowadays, acute (oral and contact) and chronic toxicity tests based on OECD 213, 214, and 245 are conducted for the registration of new or existing microbial products in the market. However, it is necessary to develop new methodologies to fulfil the demands of microbial testing in ecotoxicology.

We are sharing our previous findings and working hard, together, with the ICPPR Microbials and bees working group (launched at the ICPPR 2017). As a group, we are working on several approaches and methodologies to establish new guidelines in the near future**.**
This poster presents one approach to keep the bees alive for 30 days with less than 20% mortality. Under this approach studies can be run.

2.13.P-Mo141 Underestimated Adverse Effects of Entomopathogenic Nematodes to Bees
Angélique Rüfenacht[1], Lars Straub.[1], Daniela Grossar[2] and ***Lukas Jeker****[3], (1)Vetsuisse Faculty, Institute of Bee Health, Switzerland, (2)Agroscope, Switzerland, (3)WBF / ZBF, Agroscope, Switzerland*
There is a great interest in finding sustainable alternative plant protection products to safeguard biodiversity and our ecosystem. Entomopathogenic nematodes (EPNs) have received much attention as an alternative biological-control agents to conventional synthetic agrochemicals. However, as nematodes are considered natural enemies, national authorities often approve commercial products based on limited or no data. Here we show for the first time that foliar exposure to a commercial EPN product can significantly reduce honeybee survival and that the nematodes can successfully replicate within the carcasses of adult bees. Following an adjusted EPA protocol for assessing the toxicity of chemical residues on foliage, we exposed newly emerged adult honeybees (*Apis mellifera*) and larvae of the greater wax moth (*Galleria mellonella*) for up to 96 h to a low (0.25 Mio/m^2) and medium (0.5 Mio/m^2) field realistic concentration of *Steinernema carpocapsae*. Daily mortality was recorded over four days and nematode reproduction was assessed in all dead individuals. The date revealed that, *S. carpocapsae* exposure significantly reduced wax moth larvae survival (both p's < 0.001), resulting in an increased mortality rate of 80% across both treatment groups compared to controls. Likewise, both the low and high concentrations of *S. carpocapsae* significantly reduced honeybee survival (both p's < 0.001). However, the data revealed a dose-dependent effect wherein the high exposure led to a significantly higher mortality rate (55%) than the low (43%) when compared to the controls. Nematode reproduction was significantly higher in the wax moths compared to the honeybees (p<0.001), yet no significant difference was observed between the low and high treatment groups for either species (p>0.56). Average nematode reproduction per individual wax moth and honeybee was 126 695 and 4370, respectively, representing a 29-fold increase in the wax moth compared to honeybees. The data provide clear evidence that *S. carpocapsae* exposure can impose negative lethal effects as well as reproduce in honeybees. Considering the vast lack of data regarding potential adverse effects of EPNs on nontarget pollinating insects, our results underline the urgent need to act cautiously when considering foliar application of EPNs on crops. Further research is required to adequately address the potential risk of EPNs to bees and other NTA's pollinating insect species regarding foliar and soil application.

2.13.PC New Approaches and Methodologies for the Future Direction of Pollinator Health and Safety

2.14 New Developments in Sediment Ecotoxicology and Risk Assessment

2.14.T-01 Effect of Chronic Exposure of Sediment-Associated Neurotoxic Pharmaceutical Sertraline on the Reproduction of Benthic Deposit Feeder, *Tubifex tubifex*
Wing Sze Chan*[1], Martina Santobuono[1], Elettra D'Amico[2] and Henriette Selck[1], (1)Roskilde University, Denmark, (2)INM, Roskilde University, Denmark*
Among the emerging contaminants, pharmaceuticals are considered one of the most pertinent substances that may pose threats to aquatic ecosystems. Pharmaceuticals are designed to be directed at specific metabolic and molecular pathways. Thus, they are assumed to still be biologically active when entering the ecosystem and may therefore result in unpremeditated impacts on nontarget organisms. One of the most widely used selective serotonin reuptake inhibitors, sertraline (antidepressant), is regularly found in aquatic environments. However, knowledge about effects of this sediment-associated pharmaceutical in benthic invertebrates is insufficient. The present study examined the impacts of chronic exposure (28d) (3.3, 33, 330 µg/g) of sediment-associated sertraline on reproduction in the deposit-feeding oligochaete, *Tubifex tubifex*. Sertraline significantly decreased growth and survival of *T. tubifex*. Worms exposed to higher sertraline concentrations had a lower reproduction rate indicated by a significantly lower number of cocoons produced. Worms exposed to environmental relevant concentrations have shown a reduction in growth in exchange for an increased reproduction rate. The presented results indicate that sertraline has negative impacts on *T. tubifex*'s survival, growth, and reproduction. However, information regarding molecular and behavioural changes leading to growth and reproduction impacts of invertebrate under chronic sertraline exposure is still inadequate; further research into chronic toxicity is therefore advocated.

2.14.T-02 From the Sediment into the Biomass: Microplastic Uptake in a Protected Sediment Dwelling Species
Flora Rendell-Bhatti*[1], Elma Lahive[2], Colin Bull[3], Richard Cross[2], Gbotemi Adediran[2] and Ruairidh Cox[2], (1)Biological and Environmental Sciences, University of Stirling, United Kingdom, (2)UK Centre for Ecology & Hydrology (UKCEH), United Kingdom, (3)University of Stirling, United Kingdom*
Plastic contamination of freshwater ecosystems is widely distributed, with hotspots of increased abundance in deposited sediments. Benthic animals occupying these depositional habitats such as lamprey larvae contribute to ecosystem processes, including nutrient cycling. However, whether protected vulnerable species such as these are exposed is a pertinent question when trying to understand the consequences of plastics in the natural environment. Interactions between plastics and freshwater biota are regularly being documented, and its integration into aquatic food webs provides a route for remobilisation and trophic transfer. This study analyses microplastic loadings in paired samples of sediments and lamprey larvae to allow a direct comparison of microplastic loadings, using micro-Fourier transform infrared spectroscopy. We detect microplastics in all samples

of lamprey and paired sediment, ranging in abundance from 1.00 to 27.47 particles g^{-1} in dry lamprey gastrointestinal tract tissue, and 0.40 to 105.41 particles g^{-1} in dry sediment. The most encountered polymer types in lamprey from their immediate habitat were polyurethane, polyamide, and cellulose acetate. Microplastic abundance in lamprey was not correlated with that of the surrounding sediment, suggesting that either specific polymer types are retained or other factors such as larvae residence time within sediment patches may influence biological uptake. It is crucial to understand the fate and transport of microplastic contamination, thereby identify potential stressors to populations. However, this is often limited by the collection of threatened species and the analytical challenges to quantify smaller-sized plastics in complex organic matrices. We overcome these challenges to provide novel findings, which reveal microplastic particles found above the limit of detection in all samples. To the best of our knowledge, this is the first study to document microplastic contamination of lamprey larvae and surrounding sediment, contributing another potential stressor to the population status of this vulnerable species. This highlights the importance of considering microplastics in both sediment and the benthic community in integrated sediment quality assessments.

2.14.T-03 Conducting Chronic Sediment Toxicity Studies to Reduce Uncertainty for Plant Protection Products

Alan Samel[1]*, Nanditha Billa*[2]*, Inma Buendia*[3] *and David Funk*[4]*, (1)Global Regulatory Sciences, FMC Corporation, Newark, (2)Eurofins Agroscience Services, (3)FMC Corporation, Denmark, (4)Stream Ecology, Stroud Water Research Center*

In Europe, a tiered approach is used to demonstrate low risk to nontarget organisms to register a plant protection product. For the aquatic risk assessment, a tiered approach is used to demonstrate low risk to organism(s) that may be exposed *via* off-field movement (i.e., spray drift, runoff, drainage). As per guidance from the European Food Safety Authority (EFSA) Aquatic Guidance Document (2013), tier 1 single species are tested, and endpoints are adjusted using assessment factors (AF) to derive regulatory acceptable concentrations (RAC). The RACs are then compared to Predicted Environmental Concentrations (PEC) in the water or sediment to derive PEC/RAC ratios. If l risk is not demonstrated using the results from one or two surrogate test organisms, additional testing can be conducted. This can be in the form of additional single species tests in the laboratory to derive a geometric mean (Tier 2A) or a species sensitivity distribution (Tier 2B), or mesocosm studies (Tier 3). The endpoint used in the final risk assessment uses the results from multiple single species tests as either the HCx (hazard concentration) from a Species Sensitivity Distribution (SSD) or the Geometric Mean of the No Observed Effects Concentration (NOEC) study endpoints from laboratory tests or as a No Observed Adverse Effect Concentration (NOAEC) from the mesocosm tests. A lower assessment factor may be applied because the number of diverse species tested reduces the uncertainty around interspecies sensitivity.

A higher tier risk assessment provided in this poster uses endpoints from chronic laboratory studies conducted on a wide variety of freshwater and marine aquatic benthic invertebrates exposed to sediment spiked with a plant protection product. The objective is to lower the uncertainty by increasing the number and diversity of sediment organisms tested. This approach to resolving long-term risk to sediment organisms is especially challenging considering the vastly different feeding traits, life history patterns, and life cycles for each organism tested. For this reason, there have been few if any attempts made to conduct a higher tier long-term multi-single species test program for plant protection product registration. In this poster, the methodology and results of the higher tier tests are presented. The long-term study program with eight sediment invertebrate organisms was successfully conducted resulting in a higher RAC, with a greater degree of certainty.

2.14.T-05 Extending a Quantitative Weight of Evidence Approach to Include 'Omics in Sediment Quality Assessment: The Case Study of a Venice Lagoon Canal

Martina Cecchetto[1]*, Elisa Giubilato*[1]*, Cinzia Bettiol*[1]*, Marco Picone*[1]*, Annamaria Volpi Ghirardini*[1]*, Fabiana Corami*[2]*, Massimo Milan*[3]*, Ilaria Bernardini*[3]*, Valerio Matozzo*[3]*, Davide Asnicar*[3]*, Antonio Marcomini*[1] *and Elena Semenzin*[1]*, (1)University Ca' Foscari of Venice, Italy, (2)National Research Council (CNR), Institute of Polar Science (ISP), Italy, (3)University of Padua, Italy*

In the context of ecological risk assessments, it is now well-established that ecosystem health status should be assessed based on a broad range of indicators possibly tailored to the characteristics of a specific waterbody. This holds also true in the sustainable management of dredged sediment, for which a thorough characterization is desirable so that neither the dredged area nor the destination site would result impaired.

The combination of different scientific evidence within a quantitative Weight of Evidence (QWoE) approach seemed then a valuable tool to expand the existing knowledge on the quality of bed sediment from a canal subject to future dredging in the Venice Lagoon. To this end, a series of experimental investigations were carried out. Data from the chemical characterization of inorganic and organic contaminants in one-metre sediment cores converged into a single line of evidence (LoE). Sampled sediment provided the exposure matrix for a battery of ecotoxicological bioassays, bioaccumulation tests, and biomarker analyses. The exposure and effect investigations constituted three more LoEs. Given its modularity and with the intent of reaching a better-supported risk characterization, the QWoE methodology for sediment quality assessment borrowed from Regoli et al. (2019) was extended to eco-toxicogenomics analyses. A new LoE based on the evaluation of whole-transcriptome effects of chemical exposure on bivalves was then introduced in the quantitative framework. For each of the five LoE, a set of algorithms helped in summarizing high dimensional data into synthetic hazard quotients with a relative class of hazard (from absent to severe), which are then aggregated to quantitatively infer the level of risk.
Hazard in the investigated sites was classified from slight to major, revealing a deterioration in sediment quality for sites closer to Porto Marghera industrial area. QWoE proved to be effective in summarizing a large amount of heterogeneous data, taking into account exposure to and effects of sediment at different levels of the organism functioning. Although, the integration of data into

a quantitative WoE implies a trade-off between the synthesis and the loss of information from individual LoEs. Moving backward, from the final class of hazard to the original data contributing to each LoE, is hence fundamental to correctly support risk assessment and regulatory decision-making.

2.14.P New Developments in Sediment Ecotoxicology and Risk Assessment

2.14.P-We102 Lead Sinkers in Sediments Impact Aquatic Snails

*Steven Droge[1], Ernst-Jan Otten[2], Edwin Peeters[3], Marie-Claire Boerwinkel[4], Nico van den Brink[5] and **Ivo Roessink**[6], (1)Environmental Risk Assessment, Wageningen Environmental Research (WUR), Netherlands, (2)Dept. of Aquatic Ecology and Water Quality Management, Wageningen University & Research, Netherlands, (3)Aquatic Ecology and Water Quality Management, Wageningen University & Research, Netherlands, (4)Team of Environmental Risk Assessment, Wageningen Environmental Research (WUR), Netherlands, (5)Dept of Toxicology, Wageningen University & Research, Netherlands, (6)Wageningen Environmental Research (WUR), Netherlands*

Loss of sinkers by sports fishermen and remnants of lead shot cause a build-up of lead in aquatic environments. Although mostly sinking to the sediment, part of the lead dissolves to the water phase, and ingestion of solid lead poses a direct risk to birds. As a result, a 2021 ECHA proposal calls to phase-out lead in sport fishing and hunting. This will be decided upon in 2023. To assess the potential impact of lead in Dutch surface waters, a literature review comprising the amount of lead lost by sports fishermen, measurements of dissolved lead in surface waters, and effect concentrations was performed. This review was complemented by an experimental study to assess the impact of lead on aquatic snails.
The available data on measured lead concentrations in Dutch surface waters showed that yearly average values of freely available dissolved lead are below the Dutch water quality limit (JG-MKE) of 1.2 µg/L. Species Sensitivity Distributions in literature indicate that aquatic snails are amongst the most sensitive organisms, with reported NOEC values of 12 µg/L. In addition, a laboratory fate study with 4 pellets in 500 mL overlying water reported that at neutral pH conditions dissolved lead concentrations can exceed the JG-MKE. Consequently, we investigated the leaching potential and impact of 3 ,mm lead sinkers on the aquatic snail *Physella acuta,* with and without sediment. Twenty-eight days of exposure to 4, 20 or 100 lead sinkers (1 month pre-aged) did indeed exceed the JG-MKE, and sediment treatments reduced growth of the snails compared to the controls. The lowest treatment matching 108 cm^2 lead per m^2 sediment surface (lead comprising 1.1% of the sediment surface) indicates that in stagnant waters this might lead to environmental concern.

2.14.P-We103 Drivers of Spent Gunshot Bioweathering in Wetlands

***Lukasz J. Binkowski**[1], Anna Potysz[2], Jakub Kierczak[2] and Barnett A. Rattner [3], (1)Institute of Biology and Earth Sciences, Pedagogical University of Krakow, Poland, (2)Institute of Geological Sciences, University of Wrocław, Wrocław, Poland, (3)US Geological Survey*

Waterfowl hunting entails releasing large quantities of lead (Pb) gunshot into wetlands that can result in exposure and poisoning of wildlife, and environmental contamination. Pb shot remains in use for waterfowl hunting in many countries. Pellets deposited in wetlands are almost always submerged, with physicochemical and biological factors that result in bioweathering. We undertook a simplified *in vitro* approach to determine the extent to which organic matter and the presence of native microorganisms affected dissolution of major elements (Pb, Sb, and As) in shot. We examined the surface of gunshot by microscopy, and the efficiency and dynamics of weathering (proxied by pellet weight loss and elemental leaching efficiency) in different environmental conditions over a 60-day period. This study consisted of 4 treatment groups (10 replicates) that simulated some conditions that may be found in wetlands: 1) natural river water (RWA), 2) sterilized extract of pond sediments (SPS), 3) extract of pond sediments (APS), and 4) artificial root exudates (ARE). Elements were leached in proportion to their concentration in shot, with quantity of Pb being greatest, followed by Sb and As. Dissolution of Pb from shot differed among treatments. With the exception of the SPS and APS treatments, leaching of Sb and As differed between RWA and ARE treatments, but not between SPS and APS treatments. The greatest leaching was noted in the ARE group. One would presume that Pb, Sb, and As were homogeneously distributed in shot, and this was verified in part by findings of significant and strong relationships of total leaching among elements (Pearson correlation analysis, $r > 0.9$ for all comparisons). We conclude that spent Pb shot has the potential to result in long-term contamination at some heavily hunted sites. The leaching of elements from spent gunshot can vary greatly depending on environmental conditions. Native microorganisms may play a stimulating role in weathering, but in comparison to other constituents of the matrix, this influence seems to be rather small. Such information will assist in the evaluation of the long-term risks posed by spent gunshot deposited on wetlands.

2.14.P-We104 Does Pre-Exposure to Sediment Spiked with Arsenic Influence the Effects of PMMA on *Hediste diversicolor?*

***Marta Silva**[1], Miguel Oliveira[2], Dick Vethaak[3], Concepción Martínez-Gómez[4], Mónica Almeida[2], Etelvina Figueira[5] and Adilia Pires[5], (1)University of Aveiro, Department of Biology, Aveiro, Portugal, (2)University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Aveiro, Portugal, (3)DELTARES, Netherlands, (4)Instituto Espanol de Oceanografía (IEO-CSIC), Spain, (5)University of Aveiro, Aveiro, Portugal*

In many coastal systems, sediment contamination is a relevant problem, where metal(loid)s can be found in higher concentrations than in the water column. These pollutants have been found in high concentrations in the tissues of marine invertebrates, altering enzymatic activities. For example, arsenic (As) is a toxic metalloid shown to impact behavioural and biochemical parameters, like neurotransmission and oxidative status, in polychaetes.

In the environment, organisms are exposed to a variety of contaminants, such as plastics, which have been a research focus in recent years. In marine ecosystems, they break down into micro- and nanoplastics (NPs); however, there are few studies on NPs effects in benthic invertebrates. Polymethyl methacrylate (PMMA) effects on marine organisms are still mainly unknown, particularly in polychaetes, which are key species with relevant roles in their environments. To the authors' knowledge, no studies have addressed the role of metal pre-exposure in worms' response to PMMA NPs. This study aims to understand how organisms living in contaminated areas may have their response to NPs modulated, assessing behavioural and biochemical endpoints in *Hediste diversicolor*.

Specimens of ***H.*** *diversicolor* were collected in a reference site of Ria de Aveiro and, after acclimation, 80 organisms were distributed in 8 aquaria and exposed, for 10 d, to 0 and 0.625 mg As/kg of sediment. Afterwards, 10 organisms per experimental condition were selected for the behavioural and biochemical assays, while 30 organisms from the control conditions and 30 from the As exposure were randomly distributed per experimental condition (0, 0.5, and 5 mg PMMA/kg) exposed for 10 d.

Behavioural data displayed no differences between conditions; however, data from PMMA NPs suggest a decrease in cholinesterase activity after the exposure to As. Superoxide dismutase was shown to be significantly increased in As pre-exposed organisms exposed to PMMA NPs, but not enough to prevent damage. Protein carbonylation was demonstrated to be significantly increased in pre-exposed organisms exposed to 0.5 mg PMMA NPs/Kg.

Obtained results demonstrated that As pre-exposure conditions influence the effects of PMMA NPs at the biochemical level. Thus, considering the increased concentration of plastics in marine environments, and the possible interactions of plastics with other pollutants, these types of studies should be performed considering the most common environmental contaminants.

2.14.P-We105 Mercury in European River Sediments and Climate Change

John van Tol*, Soil & Groundwater, TAUW bv, Capelle a/d IJssel, Netherlands*

Practically all EU countries have committed themselves to the minimization of mercury releases when signing the "Minamata Convention." Further obligations result from marine protection and EU regulations. According to the European Environmental Agency (EEA) mercury presents the biggest risk in rivers, lakes, and oceans where it is readily absorbed by animals and bioaccumulates in the aquatic foodchain.

The EU Water Framework Directive defines the chemical status of water bodies by complying with environmental quality standards (EQS) for selected chemicals. For many regulated parameters the EQS are exceeded only within a few water bodies. However, the situation for mercury is different. In Germany, for example, mercury presents a practically ubiquitous problem in surface waters. This is in line with findings from many EU member states: recent monitoring data show that out of approximately 111 000 surface water bodies in the EU nearly 46 000 are not meeting mercury levels set to protect fish-eating birds and mammals.

As for many persistent organic pollutants related to various activities in the catchment areas of Europes large river basins, it is difficult to trace back the origin and the migration pathways of mercury. Historical primary sources are often abandoned. However, remaining soil and sediment deposits act as long-term secondary sources to the environment. For a number of (former) large industrial sites we have seen clear accumulation of mercury in river sediments. This is of great relevance as aqueous organisms are in direct contact with sorbed mercury sorbed in the sediment or dissolved in the porewater. Another threat is the further mobilization of particle bound mercury with flood events increasing both in frequency and in intensity due to climate change.

In our presentation we will discuss the fate and transport and the environmental risks of mercury in fluvial systems in Europe with particular regard to the increased environmental risks of heavy flood events. We will focus on systematic approaches for investigating historical sediment deposits in rivers, backwaters and floodplain soils and their dislocation in extreme flood events. We will illustrate this with a number of cases from sites in Germany, Spain, and the Netherlands. Detailed mapping and inventory studies in our opinion provide essential input for the following risk assessment and management steps in order to improve the chemical and ecological status of EU water bodies.

2.14.P-We106 Assessing the Environmental Risk of Sediments from Areas of Natural Interest Through Applying Weight-of-Evidence Approach: A New Environmental Management Tool?

Manuela Piccardo[1]*, Verdiana Vellani*[2]*, Serena Anselmi*[3]*, Eleonora Grazioli*[3]*, Monia Renzi*[2] *and Stanislao Bevilacqua*[2]*, (1)Dipartimento di Scienze della Vita, Università di Trieste, Italy, (2)Dipartimento di Scienze della Vita, Università di Trieste; CoNISMa-Consorzio Interuniversitario per le Scienze del Mare, Trieste, Italy, (3)Bioscience Research Center sr, Italy*

Aquatic sediments act as sinks for physical and biological debris, along with a variety of organic and inorganic pollutants. As they play a pivotal role in the functioning of aquatic ecosystems, assessing their ecological quality and pollution levels is essential for environmental management and marine biodiversity conservation. Yet, sediment quality monitoring, as implemented in most European directives, still relies on distinct assessments (e.g., physical-chemical, ecotoxicological, biological), lacking a unifying framework for a comprehensive analysis of the associated environmental risk.

Here, we applied an integrated approach to environmental risk assessment of sediment samples collected at Natura 2000 sites in the Gulf of Trieste (N Adriatic Sea, Italy) within the project MITFISH-N2K (FEAMP 1.40 - 2014-2020). The aim was to test

whether this approach (usually applied in potentially polluted contexts) may represent a new effective tool for monitoring the health status of sediments in protected areas.
The Weight-of-Evidence (WOE) approach proposed by Regoli et al. (2019) was used to build a multidisciplinary characterization combining different lines of evidence (LOE): the traditional lines of chemical characterization (LOE1) including 61 compounds (from "nonpriority" to "priority and hazardous" according to EC Directive 2008/105), the investigation of ecotoxicological properties of sediments (LOE4) through a series of bioassays following standardized protocols (involving algae, sea urchins, and amphipods), combined with the assessment of the ecological status of benthic communities (LOE5) based on the latest m-AMBI index.

LOE1 showed several compounds exceeding thresholds at nearshore sites (with corresponding moderate to very high-risk ratings) and low or no risks at more distant sites. No risk for any site emerged based on LOE4, suggesting the potential limitations of laboratory bioassays and underlining the need for an additional line of evidence to measure putative effects on resident populations (LOE5), which are the only biological components experiencing medium- and long-term exposure and adaptation processes. The outcomes of this study will provide useful insights on the potential of the WOE approach to become a new management tool for areas of natural interest.

2.14.P-We107 Ecotoxicological Effects of Sediment Pollution in the Estuaries of Elbe and Odra
Safia El Toum[1]*, Inna Sokolova*[2] *and Susanne Heise*[1]*, (1)Hamburg University of Applied Sciences (HAW), Germany, (2)University of Rostock, Germany*
Estuaries are among the most productive ecosystems in the world and are critical to the life history and development of many aquatic species. Historic and ongoing sediment contamination remains a major concern for many estuarine sediments. Many pollutants (e.g., metals and POPs) adsorb to sediments and persist for long periods of time. Depending on their bioavailability, which itself may change with environmental conditions, these contaminant mixtures may exert adverse effects on aquatic organisms. Thus, it is crucial that sediment contamination in estuaries and its biological and ecological significance be properly assessed. One objective within the Blue Estuaries project (BluEs) is to estimate the ecological stress from sediment-bound contaminants in the Elbe and Odra estuaries. For this purpose, surface sediments were sampled frequently at several sites over the course of two years. The sampling sites (8 in the Elbe estuary; 5 to 7 in the Odra Delta) were chosen along a presumed contamination gradient in both estuaries. To detect the ecotoxicological effects of the sediment samples, a biotest battery was applied comprising assays in direct sediment contact (*Arthrobacter globiformis, Caenorhabditis elegans*) and with elutriates (*Raphidocelis subcapitata, Aliivibrio fischeri,* and *Daphnia magna*). The biotest responses were subsequently classified into different toxicity categories. In combination with the bioassays, an analysis of the meiobenthos composition (Nema-Spear-Index) was determined at the freshwater sites to assess the quality of the local biological communities. In addition to the determination of TOC and grain size fractions, the sediment samples were chemically analysed for heavy metals, 16 EPA PAHs, PCB, HCB, DDX, HCH which characterize the industrial history of both catchments. Preliminary results of the chemical analyses confirmed higher concentrations of historical contaminants in the Elbe estuary than in the Odra for all contaminants except PAHs which were higher in the Szczecin Lagoon. Highest ecotoxicological effects were observed with the algae growth inhibition test in the most upstream area of the Elbe Estuary and with the bacterial direct sediment contact test in the Szczecin Lagoon. An integrated assessment of chemical, ecological and ecotoxicological data will be carried out and presented in the poster.

2.14.P-We108 Different \Rivers, Common Problems – Linking Chemical and Ecological Status in Polluted Sediments of Three Different European River Basins
Sebastian Hoess[1]*, Lieven Bervoets*[2]*, Hanne Hetjens*[3]*, Sonja Faetsch*[4]*, Johannes Teuchies*[5]*, Jeanette Rotchell*[6]*, Raf Elst*[7]*, Walter Traunspurger*[8]*, Els Ryken*[7]*, Will Mayes*[9]*, Susanne Heise*[4] *and Paul Walker*[10]*, (1)Ecossa, Starnberg, Germany, (2)University of Antwerp, Belgium, (3)Biology, Antwerp University, Belgium, (4)Hamburg University of Applied Sciences (HAW), Germany, (5)Biology, University of Antwerp, Belgium, (6)University of Hull, United Kingdom, (7)Flanders Environment Agency, Sint-Denijs-Westrem, Belgium, (8)Bielefeld University, Germany, (9)Environmental Science, Hull University, United Kingdom, (10)Labs and Analytical, Socotec, Burton on Trent, United Kingdom*
Contaminated sediments are still a major obstacle to achieve good chemical and ecological status in aquatic ecosystems, with the consequence that less than half of the EU's water bodies are in good status. Due to contaminant effects on sediment dwelling organisms, sediment-associated contamination contributes to disruption of the whole aquatic ecosystem because of benthic-pelagic food web coupling, which is a natural component of nutrient cycles influencing benthic and pelagic food webs and by that the ecological status. Weight-of-evidence (WoE) approaches, such as the sediment quality triade, using various lines of evidence (LoE) based on chemical, toxicological, and ecological information, can help to reliably determine sediment quality and to identify cause-effect relationships and thus allow a more effect-directed decision making in water management. However, there is a lack of specific pollution-sensitive metrics, and many macroinvertebrates in data of the EU water framework directive are not exclusively endobenthic and are to a large extent exposed rather to contamination in the water phase. These shortcomings may lead to misinterpretations of cause-effect relationships and, in the worst case, to inappropriate water management actions. Sediment-based LoEs (sediment quality guidelines; sediment toxicity tests; endobenthic bioindicators) might be more appropriate to reliably determine sediment quality and predict the risk of contaminated sediments for the aquatic ecosystem.

The EU Interreg project "Sullied Sediments" aimed to provide the tools for sediment assessment to enable better risk assessment and reduce economic costs. Therefore, contaminated sediments were sampled at three different river basins in Germany (Elbe), UK (Humber) and Belgium (Scheldt) over a period of 21 months (9 sites; 6 sampling campaigns) for analyzing physicochemical properties, potentially toxic chemicals, ecotoxicity, and the endobenthic invertebrate fauna. As LoEs, the toxic potential based on sediment quality guidelines (LoE1), the ecotoxicity based on a toxicity test battery (bacteria, algae, nematodes) (LoE2), and chemical stress-sensitive biotic indices based on endobenthic macro-invertebrates (Biotic Sediment Index; BSI) and meio-invertebrates (NemaSPEAR[%]-index) (LoE3) were applied. The aim of this study was to evaluate the sediment quality triad as a tool for a more reliable and, thus, better decision making for water managers.

2.14.P-We109 Integrated Assessment for Sediment Quality along the West Coast of Korea Based on Chemistry, Toxicology, and Ecology: Application of eDNA Analysis

***Junghyun Lee*[1]**, *Seongjin Hong[2] and Jong Seong Khim[3], (1)School of Earth and Environmental Sciences & Research Institute of Oceanography, Seoul National University of Science and Technology, Korea, Republic of (South), (2)Department of Marine Environmental Science, Chungnam National University, Daejeon, Korea, Republic of (South), (3)Seoul National University of Science and Technology, Korea, Republic of (South)*

Over the past few decades, the west coast of South Korea including various estuarine and coastal regions has been experienced environmental deterioration by persistent toxic substances (PTSs) due to industrialization and urbanization. We investigated the long-term changes of benthic microbial communities which adversely affected by PTSs (PAHs, styrene oligomers (SOs), nonylphenols (NPs), and heavy metals) and potential toxicities (AhR- and ER-mediated potencies and bioluminescence inhibition) in sediments from 10 sites of major estuarine and coastal regions in west coast from 2010 to 2018. Two perspectives were highlighted in this study, strengthening logistics of a comprehensive assessment in time (long-term; 2010–18) and space (inland vs. coastal comparison; for 5 regions). In general, compositions of bacterial communities varied spatiotemporally, but significant timely similarities were observed in community structure. Although bacterial compositions generally varied among or within regions, some phyla, such as Proteobacteria (29%), Actinobacteria (13%), and Chloroflexi (13%), were consistently predominant among locations. Alpha diversity of certain bacterial groups, such as Bacteroidetes and Firmicutes, revealed positive correlations ($p < 0.05$) with concentrations of certain metals, including lead (Pb) and chromium (Cr). The diversity of bacterial communities was not significantly correlated with salinity, AhR-, ER-mediated activities, and concentrations of APs. Overall, the results suggested that the sediment bacterial community could be one potential proxy component to address the pollution status in the integrated sediment assessment.

2.14.P-We110 Characterizing a Novel Passive Dosing Device Based on 3D Printing for Sediment Toxicity Tests

***Nathalie Iris Grau*[1]**, *Andreas Schäffer[2] and Felix Stibany[2], (1)Institute for Environmental Research, RWTH Aachen University, Institute for Environmental Research, Germany, (2)Institute for Environmental Research, RWTH Aachen University, Germany*

The ecotoxicological assessment of hydrophobic organic compounds (HOC) is connected to a series of difficulties. Due to their physicochemical properties HOC strongly sorb to organic material, test vessels, test organisms, and other surfaces. This might lead to an underestimation of the exposure concentration. Especially in sediment toxicity tests of HOC, the strong sorption might result in extremely low freely dissolved pore-water concentrations. For these substances, passive dosing (PD) is one suitable method, as it provides a reliable and constant exposure concentration of the test compound over the whole test duration. Potential losses due to sorption over time can be compensated through the inert reservoir loaded with the HOC and, thus, allows for full control of the pore-water concentration. PD reservoirs can be made from different materials (often silicone) and can have a variety of shapes. Typically, O-rings, tubes, or sheets are used. However, in sediment toxicity tests these standard shapes become problematic due to their small surface area and inhomogeneous distribution in the sediment. Therefore, in the present study, a complex form was designed *in silico* for a homogeneous distribution throughout the sediment, with a high surface-to-volume ratio (17,7 cm^2/cm^3) to ensure fast release kinetics. For the production of the device, a casting form was 3D-printed using a transparent, food-grade polylactic acid filament which was then casted with a food-grade, transparent 2-component silicone. The uptake kinetics of the model compound dodecylbenzene was determined as well as the release kinetics in pure water and in a water-sediment-system. The uptake of dodecylbenzene in the novel PD device was higher than in commonly used O-rings (20 % vs. 14.5 % (w/w)). This leads to the conclusion that the used silicone has a sufficient buffer capacity and might be a suitable material for PD. The loading time until saturation (6 hours) is comparable to that of O-rings. Next steps are the testing of different HOC and the adaptation of standard sediment toxicity tests with the new device.

2.14.P-We111 Ecotoxicological and Chemical Assessment of Seasonally Collected Lake Suspended Particulate Matter

***Rébecca Beauvais*[1]**, *M. Carmen Casado-Martinez[2] and Benoit J.D. Ferrari[2], (1)Ecotox Centre, Switzerland, (2)Centre Ecotox, Switzerland*

Monitoring suspended particulate matter (SPM) provides rich additional information on the sediment compartment in surface waters. In this project, we studied the quality of SPM with both ecotoxicological and chemical approaches over two sampling periods in a deep peri-alpine lake. We expected to see seasonal differences in link with lake dynamics, e.g. algal blooms and senescence or level of tributaries' particles input. To test this, we collected SPM in Lake Geneva over two successive periods of 4-5 months in sediment traps deployed at 30-m depth. After the integration period, trapping tubes were recovered and brought to the laboratory. Under standard conditions, we exposed laboratory-reared larvae of the insect *Chironomus riparius* directly in the tubes to assess effects on growth, emergence success and on the expression of over 15 biomarker genes. In addition, we conducted a standard mortality and growth inhibition bioassay with the ostracod *Heterocypris incongruens*. Lake SPM samples were characterized by physico-chemical analyses (grain-size, total organic carbon, S, N, and P contents and metal concentrations, including Hg) and submitted to nontargeted liquid chromatography–high resolution mass spectrometry (LC-HRMS). SPM-exposed larvae were digested for analysis of potentially bioaccumulated contaminants (e.g., metals, pesticides). While lake SPM of both sampling seasons inhibited chironomid emergence, larval growth was not impaired compared to the control. We observed a strong effect on the ostracod growth for the first sampling and a severe mortality for the second. For the concentrations of metals in the exposed chironomid larvae, we did not see a difference between the two seasons. However, gene expression profiling was able to discriminate between samples from the first and the second campaign. By Orbitrap (LC-HRMS), we detected over 1000 compounds, 510 of which were common between the two seasons. Overall, thanks to both approaches, we could discriminate seasonal differences in the quality of Lake Geneva SPM. Quantitative analyses of targeted organic contaminants (ongoing) will provide a better understanding of the bioavailability of chemicals of concern in Lake Geneva. Further sampling campaigns will aim to decrease the period of integration of particles and enhance the frequency of the sampling to gain additional knowledge on the dynamics of lake SPM and the importance of the fate and effects of anthropogenic chemicals in aquatic ecosystems.

2.14.P-We112 Sediment Avoidance Behaviour Test with Lumbriculus Variegatus as a Novel Screening Tool for Hazard Assessment

Jacqueline Hilgendorf[1], *Diogo Filipe Nunes Cardoso*[2], *José Nereu Pinto*[3], *Ana Eduardo Rodrigues*[2] *and Susana Loureiro*[3], *(1)Department of Biology & CESAM-Centre for Environmental and Marine Studies, University of Aveiro, Aveiro, Portugal, (2)Department of Biology & CESAM-Centre for Environmental and Marine Studies, University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Aveiro, Portugal, (3)CESAM & Department of Biology, University of Aveiro, Aveiro, Portugal*

Sediments play an important role in the environmental partitioning of chemicals in aquatic ecosystems as they can act as a sink for lipophilic and persistent chemicals. This can lead to the exposure and bioaccumulation of substances in sediment organisms, key in aquatic trophic chains. Nevertheless, studies on sediment hazard assessment are still scarce, leading to the possible underestimation of the general chemical threat in the environment.

Hazard assessment is mainly based on short-term acute exposures using lethal endpoints as observed effects. However, more sensitive endpoints are necessary to improve our understanding of how chemicals impact our ecosystems. Behavioural assays represent an essential alternative, providing a faster and typically more sensitive response to chemical exposure than conventional sublethal endpoints like reproduction and growth. However, studies for behavioural assessment, especially for sediment-dwelling species and the oligochaete *Lumbriculus variegatus* in particular, are still scarce.

Avoidance behaviour tests are useful behavioural tools to assess the contamination of soils, linking individuals to the habitat function of soils. They represent rapid and cheap experiments to evaluate whether organisms perceive the presence of chemicals and escape to noncontaminated soils as a response. This study adapted the soil avoidance test design for the aquatic sediment compartment and tested it with *L. variegatus*. Three chemicals, a pharmaceutical, a pesticide, and a metal, known to be persistent in the sediment, were chosen for the experimental setup. Test boxes were divided into two compartments, where contaminated and uncontaminated sediments were placed on each side of the box. Ten *L. variegatus* were added where this division took place to give them an equal chance of choice. Data will then be used to calculate the avoidance percentage along with the capability of sediments to keep their habitat function. In this study, we show that these assays can be used to get a fast, accurate and easy-to-evaluate response to chemical stress using the sediment-dwelling species *L. variegatus.*

2.14.P-We113 Biotransformation of Sediment-Associated Cyclic Volatile Methyl Siloxanes (cVMSs) by Benthic Invertebrates

Elettra D'Amico[1], *Martina Santobuono*[2], *Wing Sze Chan*[2] *and Henriette Selck*[2], *(1)INM, Roskilde University, Denmark, (2)Roskilde University, Denmark*

Hydrophobic organic contaminants (HOCs), such as the cyclic volatile methyl siloxanes (cVMS, log K_{ow} >5), sorb to particles in the water column and eventually accumulate in sediments often to levels much higher than in the overlying water. The half-life of the most common cVMS in sediment is longer than in water: half-life; D4: 3.9 days in water, 365 days in sediment; D5: 70.4 days in water; 3100 days in sediment. However, results from our laboratory demonstrate lower half-lives in sediment inhabited by the estuarine polychaete, *Capitella teleta,* and the freshwater oligochaete, *Tubifex tubifex* due to a high biotransformation capacity. Deposit-feeding invertebrates, such as *C. teleta* and *T. tubifex,* colonize and thrive in organically polluted areas where they reach high densities (e.g., >100.000 pr m^2). A high biotransformation capacity, as shown for several Persistent Organic Pollutants, may explain their ability to live in organically polluted areas. However, information on the mechanisms involved in the biotransformation processes is limited. Further, it has been found that *C. teleta* genome showed the presence of 96 functional cytochromes and xenobiotic response elements (XREs) following PAH exposure.

The aim of this study was to determine the mechanisms controlling biotransformation of sediment associated cVMSs by benthic invertebrates. The freshwater oligochaete, *T. tubifex*, and the estuarine polychaete, *C. teleta,* were exposed to sediment spiked with radiolabeled D4 (Octamethylcyclotetrasiloxane) for 28 days. We found no impact on survival, probably due to biotransformation of the parent compound to polar metabolites and a fast elimination. Furthermore, *C. teleta* and *T. tubifex* reduced sediment concentration of D4 faster compared to microbial degradation. ECOD and EROD *in vivo* analysis were used to assess the potential activation and increased activity of CYPs both in *C. teleta* and *T. tubifex* exposed to D4 to test the hypothesis that both species are able to break down sediment associated D4 through biotransformation.

2.14.P-We114 Toxicity of Historic Oil Deposits on Marine Organisms: Preliminary Acute Toxicity Results

Joanna Joanna Uzyczak[1], *Paula Milliken*[1], *Phoebe Eddon*[1], *Marta Vannoni*[2] *and Clare Hynes*[3], *(1)Ecotoxicology, Centre for*

Environment Fisheries and Aquaculture Science (Cefas), United Kingdom, (2)Ecotoxiclogy, Centre for Environment Fisheries and Aquaculture Science (Cefas), United Kingdom, (3)Chemistry, Centre for Environment Fisheries and Aquaculture Science (Cefas), United Kingdom
Oil pollution can be caused by any spillage of crude oil or its refined products. However, the largest and most damaging pollution events usually involve spills of petroleum or heavy 'bunker' fuel from collisions of tankers f. The Greek tanker *Eleni V* was cut in two by the French vessel Roseline in foggy conditions off the southeast coast of England May 6, 1978. The collision caused the release of approximately 5000 tonnes of heavy fuel oil (HFO), polluting nearly 20 miles of the Norfolk coast and a significant amount of oil was buried in deep trenches in local beaches. In February 2021 Storm Darcy caused significant coastal erosion and re-exposed and mobilised these 40-year-old buried historic deposits. This study evaluates long-term environmental impact of residual oil from the event. Chemical analyses were performed to confirm residual polycyclic aromatic hydrocarbons (PAHs) still present in the sediment. Toxicity studies using the bacteria screening assay Microtox, the copepode *Tisbe battagliai* (48 hours mortality test), and the polychaete *Arenicola marina* (10 days sediment toxicity test) were performed to assess residual toxicity of the deposit.

Historic deposits were analysed for PAHs and alkanes by Gas Chromatography Mass Spectrometry (GC-MS). Results were compared with original *Eleni V* reference oil with samples showing 85% reduction of total PAHs and 70% of total alkanes. Acute toxicity results obtained with water accommodated fraction (WAF) for the bacterial assay Microtox and the copepode *T. battagliai* indicated limited toxicity of the deposits with EC50s > 100g/l. A 10 day *A. marina* sediment toxicity test was performed mixing oil deposits with reference sediment (up to 25%). Results showed no significant mortality compared to the control groups. Changes in feeding behaviour were observed indicating that the organisms were undergoing challenging conditions.
Acute toxicity results indicate that there is low likelihood of acute toxicological effects in both water column and sediment associated with the historic deposits. This is likely due to a reduction of total PAHs with time in the oil deposits compared to the original crude oil. Nevertheless, sublethal endpoints need to be further investigated to understand if organisms in the surrounding areas could be chronically impacted by the eroded deposits. More studies, on sediment dwelling organisms in particular, would be beneficial to exclude potential long- term impacts on organisms.

2.14.P-We115 Organic Biomarkers as Indicators of Urban, Industrial, and Sewage Contamination in a Subtropical Estuary (Santos, SE Brazil)
Cristian Taboada Timoszczuk[1]*, Satie Taniguchi*[2]*, Bianca Sung Mi Kim*[1]*, Rafael Andre Lourenço*[2]*, Rubens Figueira*[1] *and Marcia Caruso Bícego*[2]*, (1)University of São Paulo (USP), Brazil, (2)Oceanography, University of São Paulo (USP), Brazil*
Santos and São Vicente estuarine complex is one of the main estuaries of Brazil, with great economic and industrial importance, mostly related to the presence of the Santos Port and the Cubatão Industrial Complex, that include mainly chemical, metallurgical, and petrochemical factories. Over the years, the intense discharge of effluents from urban, industrial, and port activities have contributed to many environmental problems observed on the area. In this context, the assessment of the level of contamination of this environment was proposed, based on the evaluation of organic markers, such as aliphatic hydrocarbons (AHs), polycyclic aromatic hydrocarbons (PAHs), and sterols, in superficial sediment samples (n = 19) collected from different regions of the estuary and in the adjacent Bertioga channel. Results indicated higher concentrations of PAHs in the estuary (1176 – 32153 ng g^{-1}), probably related to industrial activities, compared to the channel (534 – 6786 ng g^{-1}). PAH distribution was similar among samples, with predominance of PAHs from pyrolytic sources that include oil and diesel combustion and vehicular emissions. AH results indicated petroleum contamination on all samples, with high concentrations of unresolved complex mixture (UCM) that oil is related to intemperized oil. N-alkanes distribution indicated mixed sources, with a strong signature of natural hydrocarbons (C25, C27, C29 and C31) from the adjacent mangrove vegetation, mainly in Bertioga Channel. Coprostanol indicated urban sewage contamination in all samples, with concentrations between 0.03 and 10.4 µg g^{-1}. Although the environmental concern and efforts to control anthropogenic emissions into the marine environment have been increasing, the pollution by organic pollutants is still very relevant in one of the most important industrial and port areas of the Latin America.

2.14.P-We116 First Assessment of (Anti)Estrogenic Activity in Sediment Core from a Mangrove in Rio de Janeiro State, Brazil
Stella Melgaço de O.Pinto[1]*, Allan Argolo*[2]*, Cássia de Oliveira Farias*[3]*, Michelle Passos Araújo*[3]*, Nara de Oliveira Rodrigues José*[3]*, Ana Clara Coimbra Abreu*[3]*, Mário Luiz Gomes Soares*[4]*, Filipe de Oliveira Chaves*[4]*, Brunna Tomaino*[5]*, Cláudia Hamacher*[3]*, José Antônio Baptista Neto*[6] *and Daniele Maia Bila*[7]*, (1)Fluminense Federal University, Rio de Janeiro, Rio de Janeiro, Brazil, (2)Doutorado em Engenharia Ambiental - DEAMB, Universidade do Estado do Rio de Janeiro, Brazil, (3)Laboratório de Geoquímica Orgânica Marinha - LAGOM, Universidade do Estado do Rio de Janeiro, Brazil, (4)Núcleo de Estudos em Manguezais - NEMA, Universidade do Estado do Rio de Janeiro, Brazil, (5)Instituto Marés, Brazil, (6)Universidade Federal Fluminense, Brazil, (7)Departamento de Engenharia Sanitária e Meio Ambiente - DESMA, Universidade do Estado do Rio de Janeiro, Brazil*
Paraíba do Sul River is very important to the water supply, industrial uses, and irrigation in Rio de Janeiro state (Brazil). It receives raw sewage, industrial wastewater, agricultural runoff, among others along its way. Mangroves are ecosystems of extensive relevance, and it is also a depositional environment. Sediments can act as sinks of contaminants and the geochronological study can provide valuable information on the contamination history and consequences of anthropic occupation. Bioassays have been used in sediment cores to assess paleotoxicology or to reconstruct each layer's estrogenic activity. However, assessing estrogenic activity in sediments is challenging because it is a complex matrix. Using an antiestrogenic assay allows

acknowledging if there are compounds in samples inhibiting the estrogenic activity by the YES (Yeast Estrogen Screen) assay. A sediment core was collected in a mangrove at the Paraíba do Sul estuary. It was sliced every 2 cm up to 20 cm and sectioned every 5 cm up to 1 m. This first analysis comprised the first 12 layers, up to 30 cm. Fine content (silt and clay), total organic carbon, and total nitrogen were determined. Samples were freeze-dried and extracted by sonication and solid-phase extraction. The estrogenic and antiestrogenic activities were assessed using the Yeast Estrogen Screen with *Saccharomyces cerevisiae*. To our knowledge, this study is the first screening assessment of estrogenic activity in a sediment core from a mangrove. The sediment core presented C/N molar ratio values of 25.75 ± 3.97 and fine content of 58,20%± 4.91. Estrogenic activity was observed only in the first layer (0.09 ng/g Eq-E2). The antiestrogenic activity was qualitatively observed in eight layers, the most superficial ones, from 0 to 8 cm, and also in 10-12, 16-18, 20-25, and 25-30 cm. This suggests that antagonism might have masked the estrogenic activity of those layers. The chromatographic analysis will be held in the following steps to analyze which compounds are causing the antiestrogenic activity, as well as the dating analysis.

2.14.P-We117 Chronic Exposure of Sediment-Associated Sertraline Leading to Endocrine Disruption in the Benthic Polychaetas *Capitella teleta*

***Martina Santobuono*[1]**, *Wing Sze Chan*[1], *Elettra D'Amico*[2] *and Henriette Selck*[1], *(1)Roskilde University, Denmark, (2)INM, Roskilde University, Denmark*

In the past few decades, the consumption of antidepressants has increased. When these pharmaceuticals are metabolized in the human body, a percentage of the parent compound and some metabolites are released to the environment via the down-the-drain pathway to the waste water treatment plants (WWTP). Thus, this is the main driver of antidepressants' contamination in the environment. Normally, antidepressants are detected in the range of ng L^{-1} and µg L^{-1}. Since they are designed to have a biological effect at low concentrations, they might pose a risk to native species, especially if exposure lasts for extended periods. Antidepressants, like sertraline (Log *Kow* 5.3), can sorb to particles in the water and subsequently accumulate in sediments with potential impact on sediment-dwelling organisms. Polychaetas are key organisms inhabiting benthic environments and, among them, *Capitella teleta* is widespread in estuarine organically enriched areas.

Since antidepressants are known to function as neurotoxic chemicals and endocrine disruptors, the aim of this work was to evaluate if sediment-associated sertraline has an impact on growth and reproduction in *Capitella teleta*. Polychaetas were exposed to five concentrations of sertraline (0, 0.3, 3.3, 33, and 100 µg/g dry wt), from day five posthatching until reaching maturation. Although not significant, worm growth rate showed a trend to increase when exposed to the lower concentrations of sertraline 0.3, 3.3, 33 µg/g dry wt. The increased growth was associated with a shorter time to reach maturity and time to first reproduction. Hence, our findings suggest that sediment-associated sertraline, at environmentally relevant concentrations, can disrupt *Capitella teleta* maturation and the timing of reproduction. Thus, studies on sediments-associated contaminants are fundamental to fully comprehend chemical´s repercussions into the environments. Further research is needed to investigate the mechanisms underlying these effects.

2.14.P-We118 Methods for Removal of Matrix Effect and Cytotoxicity in the Estrogen Activity Assay (YES) for Sediment Sample

Louise Felix[1], *Allan Argolo*[1], *Giselle Gomes*[2], *Ana Dalva de Oliveira Santos*[3], *Danieli Lima da Cunha*[3], *Marília Teresa Nascimento*[3], *Estefan Monteiro Fonseca*[3], *José Antônio Baptista Neto*[3] *and* ***Daniele Maia Bila*[1]**, *(1)UERJ - Universidade do Estado do Rio de Janeiro, Rio de Janeiro, Brazil, (2)University of Aveiro, Aveiro, Portugal, (3)UFF - Universidade Federal Fluminense, Rio de Janeiro, Brazil*

Pollution of aquatic ecosystems with emerging contaminants is a growing concern. Among these, endocrine disruptors (EDCs) are substances that can alter the endocrine system of living beings even at low concentrations. Its physicochemical characteristics indicate affinity with organic particles; therefore the study of detection methods in sediments is very important. Estrogenic EDCs can be evaluated by the *in vitro* Yeast Estrogen Screen (YES assay), which is based on the expression of the human estrogen receptor that has been incorporated into the yeast, *Saccharomyces cerevisiae*, genome. Despite being a well-established assay for chemical substances, this technique shows high interferences on the response and cytotoxicity of the yeast when associated with complex environmental
matrices. For that reason, this study aimed to evaluate sediment sample preparation methods using solid phase extraction to remove cytotoxic compounds in the *in vitro* YES assay. It is being tested four methodologies for sample preparation. The first one (M-I) is based on the exclusive use of Strata-X cartridge on solid-phase extraction (SPE). The second method (M-II) is based on the use of EDTA for metal removal. Another methodology used (M-III) was based on clean-up sample using Strata-SAX cartridge on SPE. The last one tested (M-IV), is the association of both two last methods tested. All approaches used showed good viability on YES assay to quantify EQ-E2 (ng L-1). The M-I showed 0.68 ng L-1 EQ-E2 while the cytotoxicity was 96%. On M-II, the Eq-E2 was 0.39 ng L-1 expressing 95% of cytotoxicity, M-III 0.71 ng L-1 Eq-E2 and no cytotoxicity was observed. The last method M-IV expressed 0.37 ng L-1 Eq-E2 and no cytotoxicity. Concerning the numerical quantification of Eq-E2 on environmental samples, the last method tested showed a decreasing evaluation, which can be associated with some lost on the process. Even though M-III and M-IV were able to remove all cytotoxicity, the first one were considered better because it used less laboratorial insume and showed more expressive response on EQ-E2. The isolated use of EDTA for metal removal was not enough to reduce all the cytotoxicity, while the SAX cartridge showed good results on cytotoxicity removal. It was concluded that the combined use of cartridges on SPE was the most viable technique for evaluating the estrogenic activity of sediment samples with the YES assay.

2.14.V New Developments in Sediment Ecotoxicology and Risk Assessment

2.14.V-01 RNA-seq Analysis of Transcriptome Response to Cadmium-Based Sediment Ecotoxicity using *Glyptotendipes tokunagai*

Ihn-Sil Kwak[1], *Won-Seok Kim*[1], *Ji-hoon Kim*[1], *Boobal Rangaswamy*[2] *and Tae-Sik Yu*[2], *(1)Department of Ocean Integrated Science, Chonnam National University, Yeosu, Korea, Republic of (South), (2)Fisheries Science Institute, Chonnam National University, Yeosu, Korea, Republic of (South)*

High-throughput transcriptomics data have shown substantial information to disclose the complex molecular responses to pollutant toxicities. Here, chironomid's transcriptome analysis studied the ecotoxicological effects of cadmium (Cd), one of the prominent metal pollutants in the freshwater environment. The midges *Glyptotendipes tokunagai*, due to their relevance in the benthic sediments, opted for the insight on concentration and time-dependent molecular responses and tolerance mechanism to the toxic effects of Cd. We treated chironomids in sediments with three concentrations (low - 0.35 $mg.kg^{-1}$, medium - 3.35 $mg.kg^{-1}$, high - 10.70 $mg.kg^{-1}$) of cadmium chloride ($CdCl_2$) for 1-10 day intervals. We observed evident changes in the gene expression and pathway regulations comparatively higher at the high Cd concentration and longer duration (10 days). The complete transcripts represented 10275 significantly expressed genes with an average length of 795 bp. Gene set enrichment analysis indicated the progression of differentially expressed genes (DEGs). Cd exposure in 1-day duration pronounced upregulated genes in autophagy and signal transduction which mediates ion homeostasis, receptor binding, and cytoskeletal protein regulation. Further, downregulation in metabolic pathways intervenes in molecular functions. Extended exposure (10 days) tends to the upregulated metabolic pathways, cofactors biosynthesis, cuticle metabolism, and detoxification response inducing glutathione metabolism and catalytic activity. Network mapping using the STITCH database predicted the interaction of encoded proteins of stress response and tolerance mechanism reliable to the effect of Cd toxicity in the sediments. The transcriptome of chironomids portrayed the signal transduction-based cellular regulation, and stress response in 1 day samples, further adapting the tolerance mechanism via detoxification phases to withstand prolonged toxic effects.

2.15.P Pollutant-Induced Perturbations of Host-Associated Microbiomes as Both Indicators and Modulators of Environmental Toxicity

2.15.P-Th117 Fungicide and Insecticides can Alter the Microbial Community on the Cuticle of Honeybees

Fabienne Reiß[1], *Antonia Schuhmann*[2], *Leon Sohl*[3], *Markus Thamm*[2], *Ricarda Scheiner-Pietsch*[2] *and Matthias Noll*[4], *(1)Microbiology, Coburg University of Applied Sciences and Arts, Coburg, Germany, (2)Behavioral Physiology and Sociobiology, Julius Maximilian University of Würzburg, Germany, (3)Fan, Coburg University of Applied Sciences and Arts, Coburg, Germany, (4)Coburg University of Applied Sciences and Arts, Coburg, Germany*

Honeybees are crucial for our ecosystems as pollinators, but the intensive use of plant protection products (PPPs) in agriculture poses a risk for them. PPPs do not only affect target organisms but also affect nontargets, such as the honeybee *Apis mellifera* and their microbiome. This study is the first that aimed to characterize the effect of PPPs on the microbiome on the cuticle of honeybees.

We chose PPPs which have frequently been detected in bee bread and studied their effects on the cuticular microbial community and function of the bees. The effect of the fungicide Difcor®, the insecticide Steward®, the combination of both (mix A) and the fungicide Cantus® Gold, the insecticide Mospilan® and the combination of both (mix B) were tested. The honeybees (*A. mellifera carnica*) were collected from a hive of the departmental apiary at the University of Würzburg and transferred into cages. Feeding solutions were provided via prepared 2 mL cups. Doses were chosen based on their corresponding residue values found in the field. Feeding solution consists of 30% sugar water and addition of respective PPP. After nucleic acid extraction from the bees' cuticle, bacterial 16S rRNA gene and fungal transcribed spacer region gene-based amplicon sequencing were carried out. Additionally, quantification of bacterial and fungal gene copy numbers were done by quantitative PCR using the same primers. The treatment with Steward® significantly affected fungal community composition and function. Bacterial cuticular community composition of bees treated with Cantus® Gold, Mospilan® and PPP mix B differed significantly from the control. In addition, Mospilan® on its own significantly changed the bacterial functional community composition. Cantus® Gold significantly affected fungal gene copy numbers, community and functional composition. Our results demonstrate that PPPs show adverse effects on the cuticular microbiome of *A. mellifera* and suggest that PPP mixtures can cause stronger effects on the cuticular community than a PPP alone. This may have far reaching consequences for the health of honeybees.

2.15.P-Th118 Copepod-Associated Microbiome as Biosensors of Pollutant Exposures in the Marine Environment

María Paula Carrillo Losada[1], *Mar Luna Manteca*[2], *Claudia Sanz*[2], *Núria Trilla*[2], *Naiara Berrojalbiz*[2], *Jordi Dachs*[2], *Carlos Barata*[2] *and Maria vila-Costa*[2], *(1)Environmental Chemistry, Institute for Environmental Diagnosis and Water Studies (IDAEA-CSIC), Spain, (2)Environmental Chemistry, Spanish Research Council (CSIC), Institute of Environmental Assessment and Water Research (IDAEA), Spain*

Trace amounts of thousands of manmade organic pollutants (OPs) and hydrocarbons reach seawaters mainly through run-off, riverine, and diffuse atmospheric inputs. The fraction of marine dissolved organic matter (DOM) accounted by OPs remains unknown due to the analytical complexity to analyse both pools. However, this assessment is important because OPs are hydrophobic, and thus tend to accumulate in marine biota at higher intracellular concentrations than in seawater. Copepod-associated bacterial communities can be used as natural sensors of OPs exposures although is a subject seldom studied. Previous works have described copepod-associated microbiomes in different marine environments and locations, and although there is some research on the factors regulating copepod-associated microbiome, they are mostly focused on their role on microbial production, biogeochemical cycles and diversity maintenance. The aim of this research is to study how OPs and other different environmental factors modulate copepod-associated microbiomes (size of copepod, location, physic-chemical conditions) in an Atlantic Ocean transect, in order to detect specific taxa in the microbiomes that can be used as natural biosensors of pollutant exposures in the marine environment. Samples of copepods and seawater were collected during an Atlantic Ocean transect crossing latitudes between Vigo (Spain) to Punta Arenas (Chile). DNA was extracted and 16S rDNA was sequenced using a paired-end 250 Illumina system to characterize copepod-associated and seawater microbiomes, and pollutants were measured in the seawater from the same sampling locations. Taxonomic composition of copepod-associated microbiomes was dominated by *Gammaproteobacteria, Actinobacteria,* and *Alphaproteobacteria*; remarkably, *Vibrio* spp. were present at high abundances, mostly in big copepods and northern/central locations. Significant differences were seen in the bacterial communities of big and medium size copepods, and between different stations. Copepod-associated microbiome was different to that of the seawater, and shared more taxa with particle-attached microbiomes compared to free-living bacteria. During the next months, changes in community structures in copepod-associated microbiomes will be correlated to *in situ* concentrations of selected organic pollutants and other environmental parameters relevant in the marine environment to detect potential taxa of interest of marine OPs exposures.

2.15.P-Th119 Microbiota Alterations in Three Passerine Birds Under Environmental Metal Exposure

Lyydia Irmeli Leino*, Miia J. Rainio and Tapio Eeva, Department of Biology, University of Turku, Finland*

Industrial activities such as smelters emit various heavy metals into the environment. These metals are known to affect the physiology and fitness of wild birds. However, the indirect effects of metal exposure on bird health via changes in the microbiota have not been studied. As microbiota plays a vital role in bird health, there is a need to investigate whether microbial composition can be altered by metal pollution. To address this knowledge gap, we observed the effects of anthropogenic metal pollution on the nest and gut microbiota of three common passerine birds: great tits (*Parus major*), blue tits (*Cyanistes caeruleus*), and pied flycatchers (*Ficedula hypoleuca*). These species were studied near a copper-nickel smelter, where high levels of Cu, Ni, As, Cd, and Pb are found in the environment. We inspected 30 nests per study species from metal-polluted and unpolluted areas to collect data on breeding variables. Furthermore, we took nest swabs and nestling fecal samples, the latter of which were split for microbial (16S rRNA sequencing) and metal (ICP-OES) analyses. Our preliminary findings suggest that there were no significant differences in the microbial alpha diversity of the nests between species or pollution groups. However, it seems that the microbial community compositions (β-diversity) in the nests differed between polluted and control sites, depending on bird species. Differential abundance analysis indicates that the abundance of Proteobacteria may be decreased in the polluted nests of blue and great tits, but not in pied flycatchers. The observed differences in the nest microbial communities between bird species and pollution groups may be explained by differences in metal tolerance between bacteria and variations in nest materials. In the future, it is necessary to perform experimental manipulations with metal mixtures to entangle the possible causality between metal pollution and microbial composition. Further investigations are required to determine the consequences of metal exposure for wild avian health and fitness via microbiota alterations.

2.15.P-Th120 Effects of Agricultural Management on the Gut Microbiota of the Iberian Hare

Monica Martinez-Haro*[1], Xavier Triadó-Margarit[2], Rafael Mateo Soria[3], Jose Alberto Viñuelas[1] and Emilio O. Casamayor[2], (1)Instituto Regional de Investigación y Desarrollo Agroalimentario y Forestal de Castilla La Mancha (IRIAF), Spain, (2)Microbial Community Ecology, Centre for Advanced Studies of Blanes (CEAB, CSIC), Spain, (3)Wildlife Toxicology, Instituto de Investigación en Recursos Cinegéticos (IREC) CSIC-UCLM-JCCM, Spain*

The gradual shift from traditional agriculture toward more mechanized market agriculture that took place during the 20th century has led to a major change in the traditional agricultural landscape worldwide. This agricultural intensification, focused on increasing crop yields, has led, on the one hand, to an important homogenization of the landscape due to land consolidation and, on the other hand, the entry of more and more pesticides and fertilizers in the environment. In broad terms, this agricultural intensification has been associated with the loss of plant diversity, as well as a significant decline in wildlife species associated with agrosystems worldwide. In the case of pesticides, although their mode of action is often known in the target species, their secondary or sub-lethal effects on wildlife are still unknown. We face, therefore, the need to causally link knowledge about the molecular actions of pesticides to their possible interference with biological processes, in order to develop reliable predictions about the consequences of the use of pesticides. Among the effects of pesticides, a growing number of studies in recent years have described their potential to alter the composition of the host-associated gastrointestinal microbial communities, which in turn contributes critically to a variety of host metabolic and immune functions. Effects that may have an impact on animal health, and thus represent key modulating factors at the population level. Using the Iberian hare (*Lepus granatensis*) as study model, this work was aimed to study the effect of agricultural management based on the use of pesticides on the gut microbiota. For this purpose, the microbial community of hares hunted in pesticides-treated and pesticides-free areas during the 2018/19 hunting season in the central Spain was studied in gut samples. Our results showed that agricultural management is capable of altering the gut microbiota, suggesting that more research is needed to understand the potential repercussions of this alteration at the population level.

2.15.P-Th121 Effects of Zinc Contamination on Arbuscular Mycorrhizal Fungal Function in Urban Horticulture

Miles Bate-Weldon*, Katie Field and Jill Edmondson, Plants, Photosynthesis and Soil, School of Biosciences, University of Sheffield, United Kingdom*

By 2050 the global population is likely to be approaching 10 billion people, 70% of whom are expected to live in cities. Food production needs to increase in order to meet demand; however due to climate change, agricultural land currently in use may become unsuitable for crop production. The utilisation of urban soils to increase food production at a local scale may have a role to play in contributing to food security in the future. However, the soils in urban allotments, which have become increasingly popular in recent times, are susceptible to high levels of Zn deposition from industry and transport, as well by land management practices such as the application of manures and fertilisers. Zn is an essential micronutrient for plant growth and development but at high concentrations, Zn can have detrimental impacts on plant health and productivity. Additionally, the prevalence of Zn in the soil is thought to affect soil health by influencing the diversity of the soil microbial communities, including symbiotic microorganisms such as arbuscular mycorrhizal fungi (AMF). AMF form symbioses with the roots of most plants and can improve host plant resistance to stresses such as heavy metal toxicity while simultaneously increasing access to soil nutrients such as inorganic phosphorus and water, in return for host plant-fixed carbon. However, the impact of the distinct properties of allotment urban soils on the functionality of AMF has remained uninvestigated. By measuring key plant traits and tracking AMF function using isotope tracers, we investigated the effects of environmentally relevant Zn concentrations in soil on the phenotypic characteristics of the plant and resource exchange between peas and AMF. Our results show Zn may affect the function of AMF in urban soils, and the subsequent yields of crops grown in urban environments, as well as how the symbiosis between AMF and the plant may allow the plant to cope better with the additional heavy metal stress.

2.15.P-Th122 The Gut Microbiome Causally Contributes to Interspecific Differences in Pesticide Sensitivity
***Charlotte Theys*[1]*, Julie Verheyen*[1]*, Lizanne Janssens*[2]*, Nedim Tüzün*[2]*, Maxime Fajgenblat*[2] *and Robby Stoks*[2]*, (1)Biology, KU Leuven, Belgium, (2)KU Leuven, Belgium*
Explaining interspecific differences in pollutant sensitivity is key to increase the predictive power of ecotoxicology. Recently, not only organismal traits, but also the gut microbiome has been hypothesized to be a potential factor in shaping host tolerance to pollutants. This generates the hypothesis that the gut microbiome may provide an additional predictive factor of pollutant sensitivity, complementary to the trait-based approaches in ecotoxicology. Therefore, we investigated the causal role of the gut microbiome in shaping differences in pesticide tolerance between two conspecific damselfly species. A reciprocal gut microbiome transplant experiment was performed between larvae of the less pesticide-tolerant *Ischnura elegans* and the more tolerant *I. pumilio*. Subsequently, recipient larvae were exposed to the organophosphate insecticide chlorpyrifos or a solvent control. The gut microbial community of both species included pesticide-degrading bacteria, and showed besides fixed species differences also species-specific responses to the pesticide. Consistent with our hypothesis, the gut microbiome contributed causally and predictably to the difference in tolerance between both species. Indeed, the most sensitive donor-recipient combination to the pesticide was when *I. elegans* recipient larvae received an *I. elegans* donor gut microbiome, whereas the least sensitive combination was when *I. pumilio* recipients received an *I. pumilio* donor gut microbiome. The mixed donor-recipient microbiome combinations had an intermediate tolerance. Our results therefore provide the first proof-of-principle that the gut microbiome may serve as an additional predictive factor of species differences in pollutant sensitivity next to species traits in ecotoxicology.

2.15.P-Th123 The Role of the Host-Associated Microbiome in Host Tolerance and Cross-Tolerance to Pollutants
***Marlies Van de Maele*[1]*, Lizanne Janssens*[2] *and Robby Stoks*[2]*, (1)Biology, KU Leuven, Belgium, (2)KU Leuven, Belgium*
Populations that are exposed to a pollutant can evolve tolerance to this pollutant. Tolerance to one pollutant can increase tolerance to another pollutant, so-called cross-tolerance. Understanding patterns of cross-tolerance is important as populations are increasingly exposed to multiple pollutants. While host mechanisms of (cross-)tolerance are well studied, it remains untested whether the host's microbiome may also play a role in driving cross-tolerance by lowering the toxicity of pollutants for the host. In this study, we therefore studied the host-associated microbiome community as underlying mechanism of its host's (cross-)tolerance. We build on an experimental evolution trial in which *Daphnia magna* evolved tolerance to the pesticide chlorpyrifos which was associated with cross-tolerance to the pesticides malathion and carbaryl, while it did not change the tolerance to the pesticide esfenvalerate and reduced the tolerance to the pesticide imidacloprid and the pharmaceutical fluoxetine. We determined the whole body microbiome community composition of two chlorpyrifos-sensitive clones and two chlorpyrifos-tolerant clones after 4-days exposure to a control treatment or a sublethal concentration of one of the above pollutants. In the control treatment, the chlorpyrifos-sensitive and -tolerant clones had a different bacterial community composition supporting the idea that changes in the microbiome contributed to the evolution of tolerance to chlorpyrifos in the host. While exposure to the organophosphates chlorpyrifos and malathion did not change the bacterial community composition of the chlorpyrifos-tolerant clones, it did cause a compositional change in the bacterial community of the chlorpyrifos-sensitive clones, suggesting that the chlorpyrifos-tolerant clones have a microbiome with bacteria that can thrive under organophosphate exposure as they can degrade these pesticides. These bacteria may contribute to the host's tolerance to chlorpyrifos and cross-tolerance to malathion. Our study hereby provides the first experimental indication that the host-associated microbiome plays a role in not only the host's tolerance but also cross-tolerance to pollutants. In addition, our results show pollutant-specific shifts in the microbiome community composition whereby the microbiomes of both chlorpyrifos tolerance types were strongly affected by exposure to carbaryl and imidacloprid, yet not significantly affected by exposure to esfenvalerate and fluoxetine.

2.16 Soil Function and Biodiversity: Impacts and Resilience Under Stressed Environments

2.16.T-01 C and N Mineralization in Metal Mine Tailings Technically Recovered versus Spontaneously Colonized by Vegetation as Indicator to Assess Soil Functionality
***Matias Ceacero-Moreno*[1]*, José Álvarez Rogel*[2]*, Héctor M. Conesa Alcaraz*[3]*, Juan J. Martínez-Sánchez*[3] *and M. Nazaret*

Gonzalez-Alcaraz[2], *(1)Agronomic Engineering, Universidad Politécnica de Cartagena, Cartagena, Spain, (2)Agronomic Engineering, Technical University of Cartagena, Spain, (3)Technical University of Cartagena, Spain*
Metal mine wastes from ore processing are among the most hazardous residues (e.g., high metal(loid) levels, extreme pH, high salinity, organic matter/nutrients deficiency). These wastes are often deposited in open-air piles (mine tailings). Classic-restoration approaches (technical reclamation) usually involve topsoil capping aiming to create a "new soil" above wastes and then afforestation. These options have been questioned in (semi)arid regions due to ecosystems inability to be self-sustaining. An alternative, based on nature-based solutions principles, is to promote the growth of plants directly in mine wastes (phytomanagement by phytostabilization). This contributes to create the so-called fertility islands that may promote plant-soil feedbacks and ecosystem functioning. If tailings pose immediate risks (e.g., structural collapse, close to urban areas), the necessary financial/technical means should be made available for immediate technical restoration. However, if conditions are not so extreme, the spontaneous succession of plants directly growing in mine wastes has some advantages (e.g., plants adaptation to local climate/substrate conditions, high natural value, improved long-term sustainability). Previous works showed that the direct growth of native plants in tailings can provide functional soil-vegetation systems. This study aimed to evaluate whether technically reclaimed (capping and afforestation) and spontaneously colonized metal(loid) mine tailings' soils differ on carbon and nitrogen transformation activities. For this, C and N mineralization rates (following OECD guidelines) were evaluated in soil samples collected in spring 2022 in areas with both shrubs and pine trees in two mine tailings from SE Spain: a tailing technically reclaimed by capping and afforestation, and a tailing spontaneously colonized by plants directly growing in mine wastes. The results showed that both tailings differed in their C transformation activity, showing the technically reclaimed tailing greater capacity to mineralize C. However, in the case of N, both tailings showed similar mineralization rates. Furthermore, the soils under shrubs were the ones reaching greater mineralization scores in the technically reclaimed tailing, while the contrary occurred in the tailing spontaneously colonized by vegetation with greater mineralization scores in soils under pine trees. The latter may suggest that the type of vegetation is modulating soil functioning.

2.16.T-02 Biocides Containing Façade Eluates Alter Soil Microbial Community Composition and Activity
Fabienne Reiß[1], *Nadine Kiefer*[2], *Stefan Kalkhof*[3] *and Matthias Noll*[4], *(1)Microbiology, Coburg University of Applied Sciences and Arts, Coburg, Germany, (2)Department for Bioanalysis, Coburg University of Applied Sciences and Arts, Coburg, Germany, (3)Institute for Bioanalysis, HAW Coburg, Germany, (4)Coburg University of Applied Sciences and Arts, Coburg, Germany*
Combinations of biocides are commonly added to building materials to prevent microbial growth and thereby cause degradation of the façades. These biocides reach the environment by leaching from façades and pose an environmental risk. Studies regarding the effects of those on the soil microbiome are relatively scarce. Our previous study showed that combined entry of biocides frequently used in building materials into the soil had tremendous effects on active soil microbial communities and their associated functions, even though overall soil parameters such as soil respiration and soil physicochemical parameters were unaffected.
This study aimed to characterize the effect of façade eluates on the soil microbial community composition and function. Therefore, eluates from samples without biocides and samples containing both in-can and film preservatives were generated within a natural weathering experiment and introduced to soil microcosms outdoors. After the leaching experiments, the eluates were diluted since only a few percent of the horizontal rainfall is biocide-containing façade runoff. To resemble the realistic scenario at the buildings, eluates were added with every rain event to the soil microcosm. Samples were treated with Bromodeoxyuridine (BrdU) one day before sampling to mark active proliferating members of the soil microbiome. After 29 and 53 days of incubation samples were drawn. Those samples were investigated by BrdU immunocapture technique in combination with pair-end Illumina sequencing to differentiate the total and active bacterial and fungal microbiomes. Bacterial and fungal gene copy numbers were quantified via Real-Time PCR analysis. Moreover, soil chemical parameters, soil respiration, biocide, and biocidal degradation product concentrations were determined and compared to the control (incubation with rain water). The resulting data set is then analyzed using multivariate statistics. In addition, a functional annotation for bacteria and fungi is conducted using the FungalTraits and FAPROTAX database.

No effects on soil physicochemical parameters and overall soil microbial activity could be observed. BrdU immunocapture technique in combination with pair-end Illumina sequencing is currently in progress and will show if there are any species-specific effects on active and total soil microbial community. We suspect that, similar to the last study, changes in the microbial community were also caused by the treatment with eluates.

2.16.T-03 Increased Temperature Enhances Toxicity From Contaminant Stress in a Widespread Collembola Species With Different Thermal Adaptation
Silje Marie Kristiansen[1], *Hans Petter Leinaas*[2], *Cornelis A.M. van Gestel*[3] *and Katrine Borga*[2], *(1)Department of Biosciences, University of Oslo, Norway, (2)University of Oslo, Norway, (3)Amsterdam Institute for Life and Environment (A-LIFE), Vrije University Amsterdam, Netherlands*
Springtails (Collembola) are important components of soil ecosystems worldwide, and may be exposed long-term to anthropogenic contaminants. As global air temperature continues to increase, it is likely that it will affect ectotherms' responses to contaminant stress. Populations inhabiting different climates may respond differently to higher temperature, as their adaptation to utilize ambient heat likely differ. Our aim was to document whether sublethal effects on Collembola exposed to an insecticide depend on the ambient temperature. Additionally, we aimed to determine effect from the thermal adaptation of the study organisms on their response.

One temperate and one arctic originated population of *Hypogastrura viatica* (Collembola) was exposed dietary to two sublethal concentrations of imidacloprid and a control, at 10, 15, 20, or 25°C. The exposure lasted from 0 to 1500 day-degrees (days*temperature), allowing comparisons between temperatures. Each experimental unit contained 25 juveniles, and each treatment had 12 replicates, of which 4 were harvested at three different life stages. We studied among other the traits survival, growth (body size) and egg production.

Dietary exposure to imidacloprid resulted in sublethal effects for both populations at 10 and 15°C (>85% survival), while the highest concentration of 0.16 mg/kg dry bark was lethal at 20°C and 25°C (approx. 50-70% survival). The effect was stronger for the temperate population. The growth pattern for both populations showed little or no effect on the body size at an early age, but a strong reduction in body size at a high adult age, which was increasing with increasing temperature. A decrease in egg production in arctic *H. viatica* was caused by imidacloprid exposure of the highest concentration, but without any apparent interaction from ambient temperature. Contrastingly, the toxic effect on egg production was temperature-dependent for temperate *H. viatica,* for which higher temperature resulted in a stronger decrease in number of eggs laid.

Unlike the arctic population, the temperate population is adapted to efficiently utilizing a warm summer climate by increasing egg production at increasing temperature. The energy cost of high egg production might cause the temperate population to be more sensitive to other stressors when the temperature is high. Knowledge on how other factors affect toxicity from contaminant stress can contribute to a more relevant risk assessment in the future.

2.16.T-04 Eco-Indicators Sensitivity Distribution (EcoSD): A Systematic Approach to Redefining the Species Sensitivity Distribution (SSD) for Ecosystem Services Approach in Soil Ecological Risk Assessment

Hamzat Fajana[1]*, Eric Lamb*[2] *and Steven Siciliano*[1]*, (1)University of Saskatchewan, Canada, (2)Saskatchewan University, Canada*

Soil ecological risk assessment is usually based on toxicological endpoints of individual soil invertebrates and plant species, with little consideration for soil ecological processes. For example, the Species Sensitivity Distribution (SSD) is helpful in the tiered ecological risk assessment (ERA) approach. Still, this approach needs to be improved by considering key soil ecological processes that are directly linked to ecosystem services. The ecosystem services (ES) approach has gained recognition because it directly relates the effect of environmental stressors on service providers to human wellbeing. Therefore, this study aims to propose and describe a concept, the Eco-indicator Sensitivity Distribution (EcoSD), that employs data from ecological indicator responses to chemicals in deriving ecotoxicity thresholds that will protect vulnerable ecosystem processes and services in a terrestrial ecosystem. The EcoSD is like an SSD but based on ecological indicators rather than individual species. EcoSD is conceived to fit into the existing ERA as an initial step of the tired approach, accommodate site-specific assessment for different land use, and incorporate a dose-response approach to deriving an ecologically safe limit or threshold to protect the ecosystem.

2.16.T-05 Upcycling Agricultural Co-Products to Improve Soil Quality and Ecosystem Services in Sustainable Agriculture

Catarina Correia de Lemos Malheiro[1]*, Marija Prodana*[1]*, Diogo Filipe Nunes Cardoso*[1]*, Sara Cristiana Lopes Peixoto*[1]*, Pedro Monteiro*[1]*, Ana Rita R. Silva*[1]*, Fábio Campos*[1]*, Pedro Sarmento*[2]*, Gloria Pinto*[1]*, Carla Patinha*[3]*, Daniel Murta*[4,5]*, Amadeu M.V.M. Soares*[6]*, Rui Morgado*[7] *and Susana Loureiro*[1]*, (1)CESAM & Department of Biology, University of Aveiro, Aveiro, Portugal, (2)Escola Profissional de Agricultura e Desenvolvimento Rural de Vagos, Portugal, (3)GeoBioTec & Department of Geoscience, University of Aveiro, Aveiro, Portugal, (4)Ingredient Odyssey S.A. - EntoGreen, Portugal, (5)CiiEM – Centro de Investigação Interdisciplinar Egas Moniz, (6)University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Aveiro, Portugal, (7)CESAM and Department of Biology, University of Aveiro, Aveiro, Portugal*

During the last decades, a Green Revolution took place in agriculture, triggered by significant advances in scientific knowledge and characterized by fast increases in production yields, essential for a flourishing population. Still, this intensification in agricultural production has led to environmental deterioration, imperiling the delivery of ecosystem services. Moreover, food supply chains also face an increasing problem of food loss and waste, further contributing to environmental unsustainability. Therefore, a new revolution is urgent to ensure food security, one that is rooted in novel sustainability paradigms such as efficiency and circularity. Technological innovations focus on the use, transformation, and valorisation of agroindustrial byproducts into innovative products aimed to ameliorate soil functioning, reduce fertilizer dependence, and maintain ecosystem integrity, such as agro-waste-based fertilizers (AWBF). Bearing this in mind, our study used an ecosystem services approach to evaluate the effectiveness and environmental impact of an AWBF derived from the digestion of vegetable co-products by *Hermetia illucens* larvae (product under development). In a greenhouse production system, a randomized block experiment with four treatments was established: 1) reference (no fertilization), 2) NPK plus horse manure, 3) NPK plus AWBF, and 4) AWBF alone. An integrated assessment included: tomato productivity and quality (provisioning services), mesofauna and microbial communities biodiversity (regulating services), functionality of microbial communities (supporting services), *in situ* feeding activity of soil organisms (supporting services), and soil retention function (regulating services). Overall, our results showed that tomato yield was significantly higher in the soil amendments with NPK and manure and AWBF alone. The feeding activity of soil fauna did not differ between treatments and low average percentages of feeding activity were observed, which can be related with lower abundance of soil fauna. Nevertheless, a stimulatory effect in soil enzymatic activity was observed, in the case of AWBF and NPK and AWBF-treated soil. As for soil retention function, AWBF did not pose risk to freshwater organisms. Our multidisciplinary approach showed that AWBF might be considered an appropriate and environmentally safe fertilization management option for tomato production, improving the sustainability of terrestrial and aquatic ecosystems.

2.16.P Soil Function and Biodiversity: Impacts and Resilience Under Stressed Environments

2.16.P-Mo142 Arbuscular Mycorrhizal Fungi as Microbial Indicators to Characterize Soils and Their Use Intensity

Fritz Oehl[1] *and Ewald Sieverding*[2]*, (1)Agroscope, Switzerland, (2)Hans-Ruthenberg Institute, University of Hohenheim, Germany*

Arbuscular mycorrhizal fungi (AMF; Mucoromyceta) are an important component of fertile soils, as they support several key soil functions: for instance they improve plant growth and health, stabilize soil aggregation, enhance rainwater infiltration, and retain macro- and micro nutrients in the upper soil layers. Currently, approximately 350 AMF species are known worldwide. This number is steadily increasing, since new molecular technologies allow identifying new as yet undescribed species. During the last 20 years, we studied the diversity of these fungi in a series of natural or agricultural soils, in different continents, under different climatic conditions, at different altitudes, and subjected to different conventional or organic farming and soil tillage practices. We found that worldwide multiple AMF species as well as the overall AMF community structure can be used as powerful indicators in various aspects such as agricultural sustainability, soil fertility, water and nutrient budgets, or soil degradation due to overuses or climate change. About 2-80 species were detected in natural and agricultural soils depending - among other factors - on climate, land use type and intensity, plant species diversity and specific soil parameters. In arid soils, only Glomeraceae, Diversisporaceae, or Paraglomeraceae species were detected. Under semiarid to humid conditions, also Acaulosporaceae and Gigasporaceae species occur, but they are generally more sensitive to high fertilization levels than Glomeraceae species, and often they are less common in neutral to alkaline soils. In a wide range of soils types, e.g. ,Tschernosems, Luvisols and Ferralsols, a high AMF diversity can be found even under intensive agricultural production, as long as the majority of the fungi have suitable living conditions during the vegetation periods. Herbicide and even repeated fungicide applications might then have only minor effects on the AMF communities in the soils. Their diversity can, however, be dramatically decreased, especially when the plant root and hyphal network is periodically disturbed by harsh tillage practices, when plants suffer due to increasing droughts, or when specific weeds or entire weed communities are periodically eliminated by chemical measurements.

2.16.P-Mo143 Evaluation of Antibiotics and Copper Mixture Effects on Test Organisms, Natural Soil Microbial Communities, and Plant Growth: An Ecological Study at Different Hierarchical Levels

Alessandra Narciso[1]*,* ***Chiara De Carolis***[1]*, Paola Grenni*[2]*, Andrea Visca*[2]*, Gian Luigi Garbini*[2]*, Ludovica Rolando*[2]*, Livia Mariani*[1]*, Jasmin Rauseo*[3]*, Luisa Patrolecco*[3]*, Tanita Pescatore*[4]*, Francesca Spataro*[5]*, Maria De Los Angeles Bustamante Muñoz*[6]*, Cristina Aurora Alvarez-Alonso*[6]*, Maria Adelaide Iannelli*[7]*, Giovanna Frugis*[7] *and Anna Barra Caracciolo*[8]*, (1)Italian National Research Council - Water Research Institute (CNR-IRSA), Italy, (2)CNR-IRSA Rome, Italy, (3)National Research Council- Institute of Polar Science (ISP-CNR), Italy, (4)National Research Council (CNR), Institute of Polar Science (ISP), Italy, (5)National Reasearch Council Institute of Polar Sciences, Montelibretti, Italy, (6)Department of Agrochemistry and Environment, Miguel Hernández University, Alicante, Spain, (7)Institute of Agricultural Biology and Biotechnology, National Research Council (IBBA-CNR), Italy, (8)Water Research Institute - Italian National Research Council IRSA-CNR, Italy*

Livestock manure is a common used organic fertilizer; however, recent investigations have demonstrated it can be a source of heavy metals (e.g., copper) and antibiotics (ABs) for agroecosystems. Copper (Cu) is used in organic farming at high concentrations (30-800 mg/kg) as antifungal, and toxic effects to biota are not excluded. For this reason, agricultural soils can be environmental sinks of ABs and Cu, which can be accumulated in plants and eventually pass through the food chain to animals and humans. AB presence in soil can exert a selective pressure which promotes antibiotic resistant bacteria spread and related resistance genes.

The aim of this work was to increase knowledge on this issue, using an ecological approach at various hierarchical levels. Firstly, ecotoxicological standard tests were performed, with *Aliivibrio fischeri*, *Lepidium sativum,* and *Daphnia magna,* to evaluate acute effects of copper and antibiotics (alone or in mixture) in terms of effective doses (e.g., EC_{50}). Subsequently, soils amended with manure/digestate and spiked with copper alone (30 mg/Kg) or in combination with three common antibiotics (sulfamethoxazole and ciprofloxacin, 7.0 mg/kg each) in presence/absence of *Lactuca sativa* were studied in microcosm experiments.
The effects on natural soil microbial communities were evaluated in terms of abundance (DAPI count), viability (% Live cells /Live+Dead), enzymatic activity (Dehydrogenase activity) and community structure (NGS). Moreover, plant growth (biomass of roots and aerial part) was evaluated.

AB effective concentrations (SMX, EC_{50}:194.06 mg/L and CIP EC_{50}:250.10 mg/L) were higher than environmental ones. The EC_{50} found for Cu (0.78 mg/L) was significantly lower than concentrations found in agroecosystems, suggesting a risk for natural biota. Moreover, additive detrimental effects were recorded in ABs and Cu mixtures.

Soil natural microbial communities were partially affected by Cu presence; however, in organic amendments and plant co-presence, microbial communities were not affected by copper toxicity. Microbial community structure analyses evidenced significant differences between different conditions. Analyses of ABs and Cu bioaccumulation in lettuce tissue are in progress.

2.16.P-Mo144 LDPE and Biodegradable Plastics Differentially Affect Plant-Soil Nitrogen Partitioning and Dynamics in a *Hordeum vulgare* Mesocosm

Michaela K. Reay[1]*, Lucy M. Greenfield*[2]*, Martine Graf*[3]*, Charlotte E.M. Lloyd*[1]*, Richard P. Evershed*[1]*, David R. Chadwick*[2] *and Davey L. Jones*[2]*, (1)Organic Geochemistry Unit, School of Chemistry, University of Bristol, United Kingdom, (2)School of Natural Sciences, Bangor University, United Kingdom, (3)Bangor University, United Kingdom*

Micro- and macroplastics are emerging contaminants in agricultural settings, yet their impact on nitrogen (N) cycling and partitioning in plant-soil-microbial systems is poorly understood. Furthermore, the long-term impact of increasing macroplastic and microplastic loading from plastic mulching on ecosystem services is relatively unknown. This includes the microbially mediated N transformations, which is central to agricultural productivity. In this mesocosm-scale study, spring barley (*Hordeum vulgare* L.) was exposed to macroplastic (1 cm) or microplastic (<500 µm) produced from low density polyethylene (LDPE) or biodegradable (PLA/PBAT 15%/85% *w/w*) plastic mulch at concentrations equivalent to 1, 10, and 20 years of plastic mulch film use. Partitioning of ^{15}N-labelled fertiliser into plant biomass, soil, and leachate yielded a partial mass balance. Soil-N partitioning and microbial assimilation was probed via compound-specific ^{15}N-stable isotope analyses of soil microbial protein. Dose-dependent decreases in plant ^{15}N uptake occurred with increased leached nitrogen for LDPE microplastic, due to changes in physical pore flow pathways. Assimilation into soil microbial protein was higher for biodegradable plastics, which we associate with early-stage biodegradable plastic degradation. Microbial assimilation in the presence of LDPE was a function of abiotic impacts on leaching, with suppression of inorganic N transformations. While microplastics and macroplastics altered soil N cycling, the limited impacts on plant health indicated the threshold for negative effects was not reached at agriculturally relevant concentrations. However, changes in soil N cycling and available N will impact nitrogen use efficiency and soil organic matter dynamics. Thus, the differing impacts of conventional and biodegradable macro and microplastics must be considered in risk assessments for agricultural plastics.

2.16.P-Mo145 Adverse Effects of Agrochemicals on Methanotrophy Examined in a Toxicity Assay with Methane Oxidizing Bacteria

*Asbjørn Bøcker[1], Niels Iversen[1] and **Peter Roslev**[2], (1)Department of Chemistry and Bioscience, Aalborg University, Denmark, (2)Aalborg University, Denmark*

Biological methane oxidation by high-affinity methanotrophic bacteria in soils is the only known biological process that can remove methane (CH4) from the atmosphere. Methanotrophic bacteria play a vital role in the global carbon-cycle and could potentially mitigate increases in global methane emissions. Aerobic methanotrophic bacteria belong to a small number of bacterial lineages, and a key characteristic is the synthesis of methane monooxygenase enzymes which catalyze the oxidative attack of the otherwise stable CH4 molecule. Methane monooxygenases are unique and enable methanotrophic bacteria to grow on CH_4 as their sole source of carbon and energy. Due to their unique cellular metabolism, methane oxidizing bacteria are sensitive to a number of environmental disturbances including natural and anthropogenic toxicants. This study developed a new toxicity assay to investigate adverse effects of toxicants on aerobic methanotrophic bacteria, and screened common agrochemicals for effects on methanotrophy. A range of methanotrophic bacteria were screened for responsiveness and the facultative methanotrophs *Methylocapsa aurea*and *Methylocystis hirsuta* were selected for a toxicity assay with methanotrophic bacteria (TOX-MOB). TOX-MOB is based on growth and activity measurements in 96-well microplates after incubation with CH4 and the endpoints are growth rates, electron transfer system (ETS) activity and production of reactive oxygen species (ROS). Ten concentrations of each compound were examined and 18 potential toxicants were examined including antibiotics, pesticides, biocides, and metals. The responses of *M. aurea* and *M. hirsuta* were compared with results obtained in parallel experiments with the bioluminescent reference bacterium *Aliivibrio fischeri*. The results showed that EC10, EC20, and EC50 values obtained in the TOX-MOB assay were lower for 16 of 18 test compounds suggesting that methanotrophic bacteria are inhibited at lower concentrations than standard bacterial test organisms. For example, growth and energy metabolism in methanotrophic bacteria were affected by elevated concentrations of compounds such as zinc, copper, the herbicide bentazon, the herbicide degradation product 3,4-dichloroanilin, and the fungicide tebuconazole. The results suggest that the TOX-MOB assay is an ecologically relevant toxicity assay, and that methane oxidizing bacteria in soils are potentially adversely affected by compounds commonly used in modern agriculture.

2.16.P-Mo146 Initial Soil Microbial Colonizers Following Fresh Crude Oil Spill Incident

***Chidinma Peace Okafor**[1] and Chioma Blaise Chikere[2], (1)University of Port Harcourt, Nigeria, (2)Department of Microbiology, University of Port Harcourt, Nigeria*

Crude oil pollution is an ecological perturbation that disrupts the biodiversity of the affected environments. This study investigated the availability of microbial isolates capable of withstanding the change in physicochemical parameters occasioned by the spill. The study also sought to identify those isolates capable of early colonization and utilization of the crude oil pollutant shortly after the spill at the 12" Santa Barbara spill site, a wetland, in Nembe Local Government Area (L.G.A) of Bayelsa State, Nigeria (4°31'60" North, 6°16'60" East). Physicochemical parameters were determined according to regulatory protocols in Environmental Guidelines and Standards for the Petroleum Industry in Nigeria (EGASPIN). Microbial isolates were isolated using the enrichment technique and tested for crude oil degradation abilities using the redox-dye (2,6-Dichlorophenolindophenol) protocol. The high performing degraders were then identified using the 16S rRNA Sanger sequencing method and phylogenetic tree constructed to determine species relatedness. The mean extractable total petroleum hydrocarbons (TPH) content of 17 000 mg/kg, which is above the 5000 mg/kg intervention limit of the Nigerian Upstream Petroleum Regulatory Commission (NUPRC). The site also had an average pH of 6 and heavy metals levels within acceptable limits. The high degraders identified in the study included mainly species of *Pseudomonas* and *Acinetobacter* which are typical crude oil polluted sites microflora and presumably novel bacterial genera. This preliminary study suggests adequate presence and richness of microbial isolates for *in situ* bioremediation given the remoteness and sensitivity of the spill site.

2.16.P-Mo147 Microbial Indicators of Stress in Crude Oil-Impacted Soils

***Chidinma Peace Okafor**[1] and Chioma Blaise Chikere[2], (1)University of Port Harcourt, Nigeria, (2)Department of Microbiology,*

University of Port Harcourt, Nigeria
Soil environments impacted by crude oil pollution adversely affect ecological functions in such environments. The use of microorganisms especially bacteria afford an easy and timely understanding of the pollutant effects on soil biodiversity. Crude oil spill is a frequent occurrence in the Niger Delta region of Nigeria and some spills have been left unattended hence constituting chronic exposure of the resident microflora. For this study, physicochemical parameters were analyzed to determine the concentration of extractable total petroleum hydrocarbons (TPH) and polycyclic aromatic hydrocarbons (PAHs) in the soil. Shotgun/whole genome sequencing from ZymoBIOMICS services was used to determine the identity and functionality of the resident microflora in the soil microbiome. Using the OMICS dashboard of the BIOCYC, pathways were reconstructed and the significant stress related genes included genes for starvation, heat shock, DNA damage, osmotic stress, oxidant detoxification, and pH tolerance. The findings show strong correlation between pollutant presence and increase in microbial stress genes.

2.16.P-Mo148 Whole Genome Sequencing Reveals a Wide Range of Virulence and Antibiotic Resistance Determinants in Oil-Polluted Soil Microbiome
Chioma Blaise Chikere[1], *Memory Tekere*[2] *and Blaise Ositadinma Chikere* [3], *(1)Department of Microbiology, University of Port Harcourt, Nigeria, (2)Environmental Sciences, University of South Africa, South Africa, (3)Biodiversity/Environment, Shell Petroleum Development Company (SPDC), Nigeria*
Crude oil pollution is an endemic environmental problem in the Niger Delta Region, Nigeria, and as such impacted soil ecosystems over the years have been subjected to colossal biodiversity crises. The emergence of antimicrobial resistance (AMR) and virulence factors in oil-polluted soil microbiome has really not been a major research focus in this region. Following increasing evidence-based reports from our recent investigations of the worrisome presence of many AMR genes in hydrocarbon-degrading bacteria (HDB), the present study employed high-throughput sequencing technique to evaluate the diversity of these genes in the environment. Axenic cultures of HDB from the soil contaminated with 4,923 – 51,780 mg/kg of total petroleum hydrocarbons (TPH) were repeatedly screened by enrichment in 1% crude oil- and naphthalene-Bushnell Haas (BH) broth and isolates with enhanced degradation potentials were selected on BH agar. DNA extraction was performed using ZymoBIOMICS-96 MagBead DNA kit while Nextra DNA flex library prep kit was used to prepare sequencing libraries. Raw sequence reads were trimmed to remove low quality fractions and adapters. Antimicrobial resistance and virulence factor gene identification were performed with Diamond sequence aligner. Genome analysis by composition barplots at strain level revealed the presence of *Pseudomonas nitroreducens* (42.52%), *Ochrobactrum intermedium* (37.7%), *O. intermedium* 2745-2 (19%), *O. intermedium* M86 (0.5%), *Pseudomonas* sp. (0.3%), and *P. nitroreducens* NBRC 12694 (0.2%). Thirty seven antibiotic resistance genes affiliated more with *Ochrobactrum intermedium* than other strains with aminoglycoside 2´-N-acetyltransferase AAC (2´)- IIa gene having read counts of 40 as the predominant determinant followed by class C extended spectrum beta-lactamase OCH-1 with 37 read counts. *Pseudomonas nitroreducens* had 5 different AMR genes that were mainly multidrug efflux transporter permease subunit complexes with read counts of 1 to 4. Virulence factors detected were 1,239 and all affiliated with *Ochrobactrum intermedium* (predominant one being glutamate synthase NADPH large chain with 1,031 read counts) and *Pseudomonas nitoreducens* (that had 'still frameshift probable component of chemostatic signal transduction system' with 405 read counts). Consequently, we conclude that oil-impacted soil ecosystems in this economic haven may possibly pose serious public health risks as important reservoirs of AMR genes and virulence factors.

2.16.P-Mo149 Could Nature Successfully Trigger Soil Functional Processes in Metal Mine Tailings or Do We Always Need a Manmade Restoration Intervention?
Matias Ceacero-Moreno[1], *José Álvarez Rogel*[2], *Héctor M. Conesa Alcaraz*[3], *Juan J. Martínez-Sánchez*[3] *and M. Nazaret Gonzalez-Alcaraz*[2], *(1)Agronomic Engineering, Universidad Politécnica de Cartagena, Cartagena, Spain, (2)Agronomic Engineering, Technical University of Cartagena, Spain, (3)Technical University of Cartagena, Spain*
Metal mine wastes from ore processing are among the most hazardous residues (e.g., high metal(loid) levels, extreme pH, high salinity, organic matter/nutrients deficiency). These wastes are often deposited in open-air piles (mine tailings). Classic-restoration approaches (technical reclamation) usually involve topsoil capping aiming to create a "new soil" above wastes and then afforestation. These options have been questioned in (semi)arid regions due to ecosystems inability to be self-sustaining. An alternative, based on nature-based solutions principles, is to promote the growth of plants directly in mine wastes (phytomanagement by phytostabilization). This contributes to create the so-called fertility islands that may promote plant-soil feedbacks and ecosystem functioning. If tailings pose immediate risks (e.g., structural collapse, close to urban areas), the necessary financial/technical means should be made available for immediate technical restoration. However, if conditions are not so extreme, the spontaneous succession of plants directly growing in mine wastes has some advantages (e.g., plants adaptation to local climate/substrate conditions, high natural value, improved long-term sustainability). Previous works showed that the direct growth of native plants in tailings can provide functional soil-vegetation systems. This study aimed to evaluate how and to what extent technically reclaimed (capping and afforestation) and spontaneously colonized metal(loid) mine tailings soils differ in functional aspects. For this, a complete seasonal monitoring program (physical, chemical, physicochemical, and biological soil parameters) was carried out during 2022 in two mine tailings from SE Spain: a tailing technically reclaimed by capping and afforestation, and a tailing spontaneously colonized by plants directly growing in mine wastes. Both tailings store similar type of mine wastes and were restored/abandoned at the same time. In each tailing monitoring plots were establised in areas with both shrub-herbaceous and tree vegetation. Among others, in each study season, a battery of biological parameters (in)directly related to soil functionality was measured: respiration (in situ soil CO_2 emission), fauna feeding activity (bait lamina), microbial biomass carbon/nitrogen, dehydrogenase activity, enzymes activity related to soil biogeochemical cycles (e.g., β-glucosidase, N-acetyl-β-glucosaminidase, protease, urease, acid phosphatase).

2.16.P-Mo150 Bioconversion of Olive Pomace by *Hermetia illucens* Larvae to an Organic Fertilizer - The Soil Health and Safety Perspective

Amid Mostafaie[1], José Nereu Pinto[1], Andreia Pereira[2], Marija Prodana[2], Sara Cristiana Lopes Peixoto[1], Ana Rita R. Silva[1], Ivã Lopes[3], Daniel Murta[3], Susana Loureiro[1] and ***Diogo Filipe Nunes Cardoso[1]****, (1)CESAM & Department of Biology, University of Aveiro, Aveiro, Portugal, (2)University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Aveiro, Portugal, (3)Ingredient Odyssey S.A. - EntoGreen, Portugal*

Bioconversion of various organic wastes by black soldier fly (BSF) larvae can be an alternative method instead of conventional organic waste treatments and disposal. *Hermetia illucens* is an insect with high protein and fat content, a short lifecycle, and high bioconversion rates. Thanks to these properties, it can play a crucial role in waste management. Organic waste, such as olive pomace, which has phytotoxic characteristics mainly due to phenolic compounds, is an obstacle for the olive oil industry in terms of waste management. Bioconversion of olive pomace by BSF larvae can be a suitable alternative, while olive pomace can feed BSF. However, the generated frass from BSF's metabolic activities during the biodigestion (larvae faeces, exuviae, and organic processed material) has been widely studied and successfully applied as an organic fertilizer. To the best of our knowledge, this is the first work that assessed the frass from the biodigestion of olive pomace. The study aimed to evaluate the safety aspect of BSF frass produced from the biodigestion of olive pomace as an organic fertilizer, using soil health and quality indicators. The effects on soil organisms were assessed by incorporating frass into the natural LUFA 2.2 soil at six application rates (from 0.3 to 9.6 %w/w) and two distinct incubation periods (2 and 32 days of soil incubation with OF), conducting ecotoxicological assays with terrestrial invertebrates (OECD reproduction assays with *Folsomia candida* and *Enchytraeus crypticus*) and plants (phytotoxicity bioassays with *Lolium perenne and Brassica oleracea*). Plant experiments were based on two methodologies, confirming seedlings' emergence and growth in soil and aqueous extracts. Soil enzymatic activity was assessed at the same application rates of frass and three incubation periods (2, 32, and 64 days). Results demonstrated no adverse effect on soil invertebrates' survival and reproduction. Phytotoxicity tests indicated a significant increase in the germination index of *L. perenne* on day 32 of incubation compared with day 2. Overall, enzyme activity stimulation was observed by increasing the concentration of frass applied in the soil (starting from 2.4, or 4.6 % w/w). While this study provided a comprehensive evaluation of the safety aspect of bioconverted olive waste by BSF to organic fertilizer, more in-depth understanding is still required before environmentally safe and sustainable applications of the frass.

2.16.P-Mo151 Collembola Locomotion Behavior Test: An Alternative Method to Assess the Impacts of Pesticides on Soil Collembolans

Felipe Ogliari Bandeira[1], Paulo Roger Lopes Alves[2], ***Vitor Pereira Vaz[3]****, William Gerson Mathias[1], Philippe Juneau[4] and David Dewez[5], (1)Departamento de Engenharia Sanitária e Ambiental, Universidade Federal de Santa Catarina, Brazil, (2)Federal University of Fronteira Sul, Chapecó, Brazil, (3)Sciences de l'Environnement, University of Quebec at Montréal, Canada, (4)Department of environmental Sciences, University of Québec à Montréal, Canada, (5)Departement de Chimie, University of Québec à Montréal, Canada*

In soil ecotoxicology, the effects of pesticides on nontarget soil invertebrates are mainly assessed by standardized protocols of acute and chronic toxicity tests. Although the standard assays are practical and useful for ecological risk assessment approaches, they do not address the impacts of pollutants on the locomotion of organisms. The ability to move is essential for collembolans to search for food, avoid predators, and reproduce. In this work, we propose a novel method to assess the potential impacts of pesticides on the locomotion behavior of collembolans *Folsomia candida*. Initially, collembolans were exposed to an Entisol artificially contaminated with a commercial formulation of the insecticide imidacloprid. The soil was spiked with a contaminated aqueous solution to achieve a final concentration of 0.1 mg active ingredient kg^{-1} dry soil. A control treatment containing only distilled water was also prepared. The control and the contaminated soil had their moistures adjusted to 60% of the soil water holding capacity. Ten collembolans (20-22 days old) were inserted in each experimental unit. Three replicates were prepared for each treatment. Collembolans were fed with *Saccharomyces cerevisiae*. After seven days of exposure, the soil of each replica was flooded, and collembolans were gently transferred to a clean culture plate (charcoal/plaster of Paris substrate), where they remained for 24 h to acclimatize. Then, 10 collembolans randomly selected from each group had their locomotion recorded in a video for one minute. For this, the collembolans were individually transferred to a new culture plate in which a high-resolution camera recorded their movements. The videos were analyzed in the software Kinovea® to calculate the total walked distance. The mean walked distance ($n = 10$) of the exposed group was compared to the control group through Tukey's HSD test ($p < 0.05$). We observed that collembolans exposed to 0.1 mg kg^{-1} had reduced locomotion ($p = 0.00045$) compared to the nonexposed ones. A 31% reduction in the walked distance was found when comparing the mean distance of the control (19.9 ± 4.5 cm) with the contaminated group (13.7 ± 4.9 cm). The decrease in the collembolans' locomotion is probably due to the neurotoxic nature of imidacloprid, which is known to cause neuronal overexcitement and paralysis in exposed organisms. The results confirm the new method's effectiveness as an alternative to the standard avoidance behavior test.

2.16.P-Mo152 Rare Earth Elements (REE) Toxicity on Soil Invertebrate's Population and Microbial Decomposition in West African Soil

Hamzat Fajana *and Steven Siciliano, University of Saskatchewan, Canada*

Rare earth elements (REE) are metals crucial to the green economy because they are used for several commercial purposes. Global REE production accounted for around 280,000 metric tons of rare earth oxides in 2021, and Africa has a significant deposit of rare earth elements. However, very few studies have reported the toxicity of REE to soil fauna and ecological processes in African soil. Therefore, this study reported the toxicity of three REEs; Lanthanum (La), Neodymium (Nd), and Niobium (Nb), including Nickel (Ni) as a model industrial metal on soil invertebrates and ecological processes. Here, we exposed the soil oribatid mites, *Oppia nitens* and collembola, *Folsomia candida* to these metals in three West African soils from Nigeria and the Republic of Benin. We also measured soil microbial decomposition via a filter paper experiment. As a result, these REEs reduced the mite and collembola population across the three soils and also caused a significant reduction in microbial decomposition. This study's result provides one of the first sets of data on REE toxicity to soil invertebrates in West African soil. It will set the stage for soil ecological risk assessment of REE in West Africa.

2.16.P-Mo153 Impact of Initial Body Weight of *Eisenia fetida* on Main Parameters Mortality, Body Weight Change, and Reproduction in OECD 222 Earthworm Reproduction Testing

*Eiko Wagenhoff[1], Eva Aderjan[1], **Andreas Duffner**[1] and Oliver Körner[2], (1)Eurofins Agroscience Services Ecotox GmbH, Niefern-Öschelbronn, Germany, (2)Edmund-Rumpler-Strasse 6, Germany*

OECD guidelines for environmental risk assessment (ERA) of plant protection products for nontarget soil organisms have been published to meet criteria such as reproducibility and comparability. In order to increase standardisation and to reduce variability in the data sets, the test organisms should meet certain criteria. These criteria include certain life stage(s), age, or other important life history parameters such as sexual maturity or body weight with respect to earthworms in OECD 222 (2016) tests. For the earthworm *Eisenia fetida*, the initial weight of animals used in these tests should be between 300 and 600 mg.

The main objective of this poster is the assessment if this range is appropriate or if the initial weight of the adult earthworms have an impact on the main parameters (mortality, body weight change, and reproduction) that need to be determined in the tests. To test this, an OECD 222 test was run in untreated artificial soil using “light” (300-350 mg) and “heavy” (550-600 mg) mature worms. In a second step, the impact of initial body weight on toxicity of the reference item boric acid to *E. fetida* was investigated using “light” and “heavy” mature worms. Adult mortality and body weight change were determined after 28 days and the number of juveniles was assessed after 56 days. The results are presented and discussed in the light of standardisation and ERA.

2.16.P-Mo154 Single and Combined Effects of Metal-Based Fungicides on Eisenia fetida **under Different Climatic Change Scenarios**

*Hussain Kaka[1], Prosper Ashibudike Opute[2] and **Mark Maboeta**[1], (1)North-West University, South Africa, (2)Department of Animal and Environmental Biology, University of Benin, Nigeria*

This study evaluated the ecotoxicity of metal-based fungicides under the current global change scenarios. It sought to determine the response of *Eisenia fetida* to copper oxychloride (CuOx) and mancozeb (MnZn) under varying temperatures (20°C and 25°C) and soil moisture content regimes (30% and 50%). The concentrations for CuOx were 200, 500, and 1000 mg/kg and MnZn, 44, 850, and 1250 mg/kg in single and binary mixtures. The test assessed mortality, growth, avoidance behaviour, and reproduction as biological endpoints following standardized protocols (ISO and OECD). The mortality rate in all single-exposure groups was below 10% in all the treatment conditions except CuOx1000. In the mixture exposure groups, the mortality rate only exceeded 10% in the CuOx1000 and CuOx1000 + MnZn1250 mg/kg groups in all the temperature-moisture combinations. However, the mortality rate exceeded 10% only in the CuOx500 + MnZn850 mg/kg treatment at 20°C30%. In the CuOx and MnZn treatment groups, the relative growth rates decreased with increasing concentration. In both CuOx and MnZn treatment concentrations at 20°C30% and 25°C50% conditions, avoidance response behaviour was above 80% throughout the 48-h exposure except in the CuOx200 mg/kg, MnZn44 mg/kg and the binary mixture of CuOx200+MnZn44 mg/kg. The reproduction of the exposed earthworms across all treatment groups was concentration-dependent and influenced by the varying temperatures and soil moisture conditions. There were no juveniles or cocoons in the CuOx1000 mg/kg treatment at 25°C30%, thus indicating that copper oxychloride may be more toxic than mancozeb, especially in drought conditions (increased temperature and reduced moisture). The binary mixture of CuOx and MnZn had no synergistic effect across all treatment conditions. This study found that different temperature and soil moisture level altered the ecotoxicity of CuOx and MnZn. Therefore, climate change is likely to significantly impact the outcomes of metal ecotoxicity to earthworms and their ecological activities.

2.16.P-Mo155 Effect of Macroplastic on Soil Percolation and Infiltration Rate: A Lysimeter Test using Artificial Rainfall on Samples from the Central Norwegian Coast

***Zuzanna Maria Sledz**[1], Jakob Bonnevie Cyvin[2] and Francis Chantel Nixon Prof[1], (1)Geography, Norwegian University of Science & Technology (NTNU), Norway, (2)Norwegian University of Science & Technology (NTNU), Norway*

Mausundvær is a group of remote, protected islands located along the outer coast of central Norway, where large amounts of ocean plastic waste are known to accumulate due to a bend in the North Atlantic Current . Previous studies have shown that soil accumulating just above the upper tide level on Mausundvær contain up to 70% (dw/dw) of plastic, with a range down to approximately 10%. In this study, core-samples will be taken from selected areas with a broad range of plastic concentrations. Each sediment core will then be exposed to an artificial rain experiment and percolation tested using a lysimeter in a laboratory setting. Finally, all samples will be dried and the concentration of macroplastics quantified for each core.
Expected results will document the impacts of macroplastic concentration on infiltration and percolation of water through organic-rich coastal soils, and on drying rates. Results will be discussed in relation to existing research on how plastic might affect the decomposition of organic matter and therefore the carbon cycle. A critical discussion of methods and protocols will also be presented.

2.16.P-Mo156 The Resilience of Soil Systems Toward Microplastics

***Hafeez Ur Rehman**, Luca Nizzetto and Rachel Hurley, Norwegian Institute for Water Research (NIVA), Norway*

The impact of microplastics (MPs) on soil health and fertility has been a hot topic for the last couple of years. However, the effect of MPs on soil resilience has not yet been investigated, particularly when comparing the effects of different MP materials. A threshold of resilience is needed to improve our understanding of how MPs influence soil resilience. We hypothesize that MP exposure influences soil properties and functioning, and accumulation will negatively impact the resilience of soil systems. In this study, we are performing a laboratory experiment using varying concentrations of MPs in soils and measuring changes in bulk density, porosity, organic matter, pH, and water-holding capacity of soils. These changes will be tracked across several time intervals over several months to understand how soils respond and potentially recover from the addition of microplastics as a disturbance. The ratio of postdisturbance and predisturbance will be considered to evaluate soil resilience. This will include the development of approaches to evaluate soil resilience in the context of persistent and particulate contamination. The preliminary results of the experiment will be presented as a poster during the SETAC conference.

2.16.V Soil Function and Biodiversity: Impacts and Resilience Under Stressed Environments

2.16.V-01 Ag2S NP Accumulation in the Mealworm *Tenebrio molitor* and the woodlouse *Porcellio scaber*: Are Single-Species Tests a Good Predictor of Indoor Mesocosm Experiments?

Zahra Khodaparast[1], *Cornelis A.M. van Gestel*[2], *Ana Rita R. Silva*[3], *Geert Cornelis*[4], *Elma Lahive*[5], *Amaia Green Etxabe*[5], *Claus Svendsen*[5], *Marta Baccaro*[6], *Nico van den Brink*[7], *Neja Medvešček*[8], *Sara Novak*[9], *Anita Jemec Kokalj*[9], *Damjana Drobne*[9], *Kerstin Jurkschat*[10] *and Susana Loureiro*[3], *(1)University of Aveiro, Aveiro, Portugal, (2)Amsterdam Institute for Life and Environment (A-LIFE), Vrije University Amsterdam, Netherlands, (3)CESAM & Department of Biology, University of Aveiro, Aveiro, Portugal, (4)Soil and Environment, Swedish University of Agricultural Sciences (SLU), Sweden, (5)UK Centre for Ecology & Hydrology (UKCEH), United Kingdom, (6)Wageningen University & Research, Netherlands, (7)Division of Toxicology, Wageningen University & Research, Netherlands, (8)Department of Biology, Biotechnical Faculty, University of Ljubljana, Slovenia, (9)University of Ljubljana, Biotechnical Faculty, Slovenia, (10)Department of Materials, Oxford University, United Kingdom*

Silver nanoparticles (Ag NPs) are used in everyday applications, ending up in wastewater treatment plants (WWTPs) and accumulating in sewage sludge. Because of the high sulfide concentration in WWTPs, AgNPs are likely transformed into Ag_2S. Upon application of biosolids onto agricultural land, as fertilizer, exposure of terrestrial organisms to Ag_2S is inevitable. The objective of this study was to validate the prediction of toxicokinetics of Ag in invertebrates exposed to Ag_2S in multispecies indoor mesocosm experiments from earlier single-species tests (Khodaparast et al., 2021; Talaber et al., 2020). The mealworm *Tenebrio molitor* and the woodlouse *Porcellio scaber* were exposed in mesocosms together with plants (*Triticum aestivum* L.) and earthworms (*Lumbricus rubellus*). The organisms were kept for 28 days in soil columns which contained a 10 cm top layer spiked with 10 µg Ag g^{-1} dry soil as Ag_2S NPs or $AgNO_3$ and a bottom layer of clean soil. The soil columns were watered daily with artificial rainwater. The organisms were collected at different sampling times (0, 7, 14, and 28 days), purged for 24 h, and then frozen, dried, and acid digested to measure the total Ag concentration. The soil pore water was also extracted to measure total and dissolved Ag concentrations. A one-compartment model was used to estimate the Ag uptake kinetics. Although Ag_2S NPs dissolved much less than $AgNO_3$, the dissolution of Ag_2S NPs in the soil pore water extracted from the mesocosm test was higher than during the single-species test. In the case of mealworms, the uptake rate constants from $AgNO_3$ in both tests, single-species and mesocosm experiments, were similar regardless of exposure time. But Ag from Ag_2S NPs was taken up faster in mealworms during the mesocosm experiment compared to single-species tests. For woodlice, the uptake rate constant of Ag from $AgNO_3$ in single-species tests was significantly slower than in mesocosm tests and woodlice did not bioaccumulate Ag from Ag_2S NPs in both single-species and mesocosm tests. To conclude, the single-species tests may not be an accurate predictor for the Ag uptake in mealworms and woodlice under more realistic exposure conditions of a mesocosm. But this does not mean that single-species tests could not be used as a fast screening approach to assess the possible bioaccumulation of chemicals in biota before other more complex tests can be conducted.

2.16.V-02 Earthworms under Plastic Debris and Environmental Stress. The Case of Agricultural Microplastics

Esperanza Huerta Lwanga[1], *Dana Bashkir*[2], *Paul Domin*[1], *Paolina Garbeva*[3], *Alice Wang*[1], *Giulia Bonjiorno*[1], *Violette Geissen*[1] *and Coen Ritsema*[1], *(1)Wageningen University & Research, Netherlands, (2)Koblenz University, Germany, (3)NIOO-KNAW*

Earthworms, known as soil ecosystem engineers and soil health indicators, are in danger when soil emergent pollutants are present. In agricultural systems microplastics are found in the soil when plastic mulches are used, or when compost is applied. Although it is known how high concentrations of microplastics impact earthworm abundance and diversity, scarce information is provided when extreme environmental conditions are present. Therefore, the aim of this study was to evaluate the performance of earthworms under extreme environmental conditions with and without microplastics and with and without plants.

More than 100 experiments were performed with 3 soil types, 3 plastic types, and 3 earthworms' ecological categories. We observed how with low microplastics concentrations environmental conditions play a key role. Preliminary results indicate how anecic and epigeic earthworms are the most vulnerable, and endogeic earthworms are the most resilient ones, and multispecies were also very resistant. Plant performance seems to be dependent on environmental conditions and earthworms' performance. More results will be later provided.

2.17.P Toward a Better Understanding of Chemical Biomarker Responses in Aquatic Organisms

2.17.P-Tu119 Living under CO_2 Pressure: Investigation of Some Oxidative Stress Enzymes and Metabolic Markers in Two Calcifying Mollusks from the CO_2 Vent of Ischia Island (Italy)

Lorenzo Federico[1], *Silvia Giorgia Signorini*[2], *Marco Munari*[3] *and Camilla Della Torre*[4], *(1)DISAT, Italy, (2)Department of Biosciences, Università degli Studi di Milano, Italy, (3)Integrated Marine Ecology, Università di Padova, Italy, (4)Dipartimento di Bioscienze, Università degli Studi di Milano, Italy*

The effects of ocean acidification (OA) are becoming one of the main investigative targets for understanding the anthropogenic impacts on the marine environment. Particularly, we focused on naturally acidified systems, such as the CO_2 vents at Ischia Island (Italy), as a natural laboratory to study the long-term effects of OA on two calcifying organisms: *Patella* spp., which are long-time residents in the vents systems, and *Mytilus galloprovincialis*, that occur only as juveniles in the vents. Our aim was to understand the potential mechanisms underpinning the tolerance processes occurring in response to OA in these calcifying taxa.
We investigated the activity of electron transport system and the glycogen content as parameters related to metabolic capacity, the activity some antioxidant enzymes (CAT, SOD, GST, and GPx), the oxidative damage such as lipid peroxidation, and the extent of valves decalcification. Our results show that limpets seem adapted to OA, and, in these organisms, low pH conditions do not trigger significant oxidative stress; on the contrary, mussels show strong decalcification of valves, alteration of the antioxidant system and a reduction of glycogen content. This suggests that early stages of acclimation to OA might involve the imbalance of osmoregulation and a significant energy consumption in order to survive at low pH.

2.17.P-Tu120 Pinpointing the Effects of Oceanic Pollutants in Blue Sharks (*Prionace glauca*) with High-Throughput Transcriptomics

Tiago Filipe da Silva Simoes[1], *Emma Sehlhoff*[2], *Luís Alves*[1], *Naima H. Verberne*[3], *Judith Risse*[3], *Sandra Smit*[3], *Ken Kraaijeveld*[2], *Marco F.L. Lemos*[1], *Dick Roelofs*[4] *and Sara Novais*[5], *(1)Polytechnic of Leiria & MARE, Portugal, (2)Department of Bioinformatics, University of Applied Sciences Leiden, Leiden, Netherlands, (3)Wageningen University & Research, Netherlands, (4)KeyGene, Netherlands, (5)Instituto Politécnico de Leiria, Portugal*

The blue shark (*Prionace glauca*) is a cosmopolitan species, being one of the most widely distributed and heavily caught pelagic shark species across the globe. As a top predator with a long life span, this species is very prone to accumulate high levels of oceanic pollutants through bioaccumulation and biomagnification processes. The detoxification of most pollutants is performed in their liver, which is one of the largest organs in these species. With the use of transcriptomics methodologies for whole gene expression profiling, a more global assessment of the health status of an organism can be achieved through an understanding of the functional pathways that are responding to pollutant exposure. Thus, this study aimed to assess the influence of different contaminants' body burden (metals and POPs) in the liver transcriptional profiling of *P. glauca,* for an improved understanding of the organisms' mechanisms to cope with different ocean contamination scenarios. As very little genomic information was available for *P. glauca*, and to improve quality and coverage of the gene expression profiling results, the genome of the species was for the first time assembled and annotated using PacBio HiFi data and both long- and short-read RNA sequencing data from different tissues. To achieve the goal of this study, RNA from the liver of 21 juvenile male blue sharks caught as bycatch in swordfishing vessels was sequenced and mapped against the assembled genome. The transcriptional profiles were then analysed against the contaminant levels measured in the same tissue following a multivariate correlational analysis. The top 120 correlated genes were selected and clustered. A GO enrichment analysis of each cluster demonstrated lipid and fatty acid metabolism to be positively correlated to metal levels and several regulatory mechanisms negatively correlated to these elements. Sharks are believed to possess an extremely adaptive immune system, and a general positive correlation between immune system related genes (e.g., immunoglobulins) and POPs levels was also highlighted in this study. This study underlines the relevance of 'omics data to better understand the overall effects of contamination in real exposure scenarios and the importance of similar studies for monitoring the marine environment. Furthermore, the blue shark genome will be a valuable resource and expand the capacity for in-depth molecular investigation on elasmobranchs, shark immunity, and vertebrate evolution.

2.17.P-Tu121 Fish Scale Hormone Concentrations as a Nonlethal Biomonitoring Tool for the Assessment of Chronic Stress and Endocrine Disruption

Emily Kennedy[1] *and David M. Janz*[2], *(1)Toxicology, University of Saskatchewan, Canada, (2)Western College of Veterinary Medicine and Toxicology Centre, University of Saskatchewan, Canada*

Fish serve as an essential resource to the human population and thus their conservation is of extreme importance. Nonlethal biomonitoring tools are invaluable in the accomplishment of such goals as they allow for the collection of information without adversely impacting populations at risk. Within the past decade the use of fish scale cortisol concentration as a nonlethal method for the assessment of chronic stress in teleost fishes has been explored. This has been highly successful with scale cortisol concentration now shown to increase in response to a variety of chronic stressors such as increased water temperatures, physical stressors, and fin injury. However, alongside cortisol the stress response is mediated by additional steroid hormones. This can include DHEA, an androgen and precursor steroid capable of influencing the conversion of cortisol to the inactive metabolite cortisone. Therefore, to expand upon this approach we quantified cortisol, cortisone, and DHEA in control and stressed rainbow trout (*Oncorhynchus mykiss*) scales and serum. Increases in cortisol, cortisone, and DHEA observed in stressed trout scales were not reflected in serum samples, adding evidence to the practicality of scale hormone concentrations in chronic stress assessment. In a second study we successfully quantified scale progesterone, testosterone, and 11-ketotestosterone alongside cortisol in rainbow trout to allow for the additional assessment of alterations to reproductive endocrinology. This study identified negative relationships between scale cortisol and testosterone, a relationship often used to quantify the adverse effects of stress on reproduction. The addition of reproductive steroids to our repertoire also presents an opportunity for future identification of other sources of endocrine disruption in fishes such as that induced by chemical contaminants. Thus, while these methods are still under development, our results provide promising evidence of the practicality of fish scale hormone concentrations for the nonlethal biomonitoring of teleost fishes.

2.17.P-Tu122 Diatom Role in River Ecological Assessment: Linking Diatom Diversity Determined by Molecular Methods to Some Environmental Features

Panayiota Pissaridou[1], Athina Papatheodoulou[2], Gregoris Notarides[1], Juan Antonio Villaescusa[3], Antonio Camacho[4], Antonio Picazo[4], Vitor Gonçalves[5], Maria Jose Villena[3], Marlen I Vasquez[1] and ***Eleni Christoforou****[1], (1)Cyprus University of Technology, Limasol, Cyprus, (2)I.A.CO Ltd Environmental and Water Consultants, (3)Laboratorios Tecnológicos de Levante S.L, (4)Cavanilles Institute of Biodiversity and Evolutionary Biology, (5)Universidade dos Açores*

Anthropogenic pollution is deemed as the primary source of stressors threatening freshwater aquatic ecosystems. The extensive use of fertilisers, the release of wastewater, and the artificial alteration of the surrounding land can be reflected in the physicochemical characteristics of riverine water. In turn, this can have adverse effects on the biotic communities like diatom assemblages. These organisms are considered valuable bioindicators due to their swift response to environmental changes displayed in their assemblage composition. The importance of this information lies in understanding the impact imposed by stressors on the river quality.

The WAT-DIMON project aims at the creation of a novel genomic test for identifying European benthic diatoms through DNA metabarcoding techniques which can improve and expediate freshwater bioassessment. Extracted results can then be compared with the ambient physicochemical parameters, aiming at the evaluation of the environmental impact of stressors and early treatment response.

For this work, epilithic diatom samples have been collected from rivers at 52 sampling sites across four biogeographical regions in Europe, and their physicochemical parameters were measured. DNA barcodes were amplified using specific primers for diatoms and sequenced using Illumina MiSeq. Bioinformatics analysis was then performed using the DADA2 pipeline to quality-filter the sequences and identify the diatom species using the Diat.Barcode reference database. Lastly, nonmetric multidimensional scaling (NMDS) was performed to investigate the relationship between diatom assemblages and river characteristics.

The preliminary results show a variation in the diversity between the river samples. Furthermore, the NMDS ordination revealed dissimilarity between the diatom assemblages of the different biogeographical regions. The river type (Intermittent – periodically cease flow and Perennial – continuous flow) and the pH also seemed to influence the diatom assemblages. Even though these results suggest an influence of the physicochemical parameters on the diatom assemblages, they are nonconclusive and will be further analysed.

2.17.P-Tu123 Using a Translocation Experiment with Feral Brown Trout to Investigate AnthropogenicImpacts on Fish

Fabian Weichert*[1], Jörg Ahlheim[2], Werner Brack[2,3], Mario Brauns[4], Markus Brinkmann[5], Dorian D. Dörge[6], Barbara Feldmeyer[7], Patrick Fink[4,8], Markus Hecker[5], Sarah Johann[3], Sven Klimpel[6,7], Martin Krauss[2], Markus Pfenninger[7], EL Joachim Sturve[9] and Henner Hollert[3], (1)Evolutionary Ecology & Environmental Toxicology, Goethe University Frankfurt, Frankfurt am Main, Germany, (2)Department of Effect-Directed Analysis, Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany, (3)Department Evolutionary Ecology & Environmental Toxicology, Goethe University Frankfurt, Frankfurt am Main, Germany, (4)Department of River Ecology, Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany, (5)Toxicology Centre, University of Saskatchewan, Canada, (6)Integrative Parasitology and Zoophysiology, Goethe University Frankfurt, Frankfurt am Main, Germany, (7)Senckenberg Biodiversity and Climate Research Centre, Germany, (8)Department of Aquatic Ecosystem Analysis and Management, Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany, (9)Biological and Environmental Sciences, University of Gothenburg, Sweden*

Water bodies are impacted by a constantly growing number of pollutants that are present in complex mixtures. The ecological effects of exposure to these mixtures are most often difficult to assess, as impact-oriented *in situ* studies that take realistic scenarios into account are scarce.

This study aims at investigating the impacts of multiple chemical stressors on feral fish by analysing biomarker and transcriptomic response patterns in locally adapted and translocated individuals. Complemented by comprehensive chemical analysis, this study will strengthen the understanding of the causal relationships between environmental pollution and ecological impacts.

At three sites, following a gradient of anthropogenic influence along a well-studied small river (Holtemme) in Central Germany, feral brown trout (*Salmo trutta fario*) were caught with hand-held electrofishing gear and caged at the same locations. Furthermore, fish from a reference site were relocated and caged at two sites upstream and downstream of the wastewater treatment plant (WWTP) Silstedt. Each of the five groups comprised 24 fish distributed in three cages.

After 21 days of exposure, fish were euthanised, exsanguinated and organs were dissected. Tissue and blood samples will be analysed using a broad battery of well-established enzymatic and non-enzymatic biomarkers indicative of oxidative stress, xenobiotic metabolism, immune response and neurological disturbance.

Furthermore, transcriptomic patterns will be investigated by next-generation sequencing to identify underlying molecular pathways of physiological response processes.

Simultaneous with the caging, time-integrated water samples were taken using Large-Volume Solid Phase Extraction at each sampling site. These samples undergo targeted high-resolution LC-MS and bioanalytical analysis to identify compounds that drive toxicity.
Preliminary results show that fish caged downstream of the WWTP exhibited higher mortality during exposure time than at the other two sites. The liver somatic index was significantly lower in the group of fish relocated from the reference to the downstream site, which might indicate elevated energy consumption during the experiment.

2.17.P-Tu124 Can sub-lethal effects of plastic ingestion be assessed by phthalates concentration and molecular biomarkers in stranded Manx shearwaters, Puffinus puffinus?

Patricia Pereira Serafini[1], *Leandro Bugoni*[2], *Isadora N.L. Piccinin*[3], *Gabriel D. Nascimento*[3], *Alice Pereira*[4], *Marcelo Maraschin*[3], *Luciana Gallo*[5], *Marcela M. Uhart*[6], *Daína Lima*[7], *Bárbara Righetti*[3], *Jacó Mattos*[3], *Clei Piazza*[3], *Cristiane K.M. Kolesnikovas*[8], *Ralph E.T. Vanstreels*[6], *Afonso Celso Dias Bainy*[3] *and Karim Hahn Luchmann*[9], *(1)Laboratory of Biomarkers of Aquatic Contamination and Immunochemistry (LABCAI), Universidade Federal de Santa Catarina, Brazil, (2)Universidade Federal do Rio Grande (FURG), (3)Universidade Federal de Santa Catarina, Brazil, (4)Projeto Albatroz, (5)Consejo Nacional de Investigaciones Científicas y Técnicas - CONICET/SENASA, (6)University of California, Davis, (7)UFSC, Brazil, (8)Associação R3 Animal, (9)DECT, Universidade do Estado de Santa Catarina, Florianópolis, SC, Brazil*

Seabirds are considered sentinels of marine ecosystems as they reflect environmental changes. Plastic pollution is one of the greatest challenges for marine conservation, and nearly all living seabirds will ingest plastics at some point in their life. Additives (e.g. phthalate esters) can leach from plastics and because seabirds often retain plastic items for extended periods in their digestive tract, they could be vulnerable to the adverse effects of chronic exposure to these compounds. In this study we evaluated molecular biomarkers in stranded Manx shearwaters (*Puffinus puffinus*) as a tool to assess sub-lethal effects of plastic ingestion. Age class, sex, body mass, and plastic presence were registered for all birds. The transcript levels of genes involved in xenobiotic biotransformation including aryl hydrocarbon receptor (*AhR*), cytochrome P450 1A5-like (*CYP1A5*) and UDP-glucuronosyl-transferase (*UGT1*); genes related to endocrine disruption as estrogen receptor alpha (*ESR1*); and genes responding to metabolic stress as heat shock protein 70 (*HSP70*) were measured in the liver from 79 fresh carcasses of birds (11% with plastic) stranded along the coast of southern Brazil from 2016 to 2021. Plastic additives (Dibuthyl phthalate - DBP, Dimethyl phthalate – DMP, and Diethylhexyl phthalate - DEHP) were also quantified by gas chromatography with flame ionization in the uropygial gland from 25 birds (8% with plastic). Overall, 11 of the 104 seabirds sampled had ingested plastic found during necropsy. Of these 11 shearwaters, 55% were males and all were juveniles. The best-fitting generalized additive models (GAM) found associations between the transcript levels of *AhR* and *UGT1* genes responding to bird age class, sex, mass, and plastic presence. Slightly higher transcript levels of both genes in animals with plastic showed a potential positive association. Additives were detected in 10 seabirds for DBP, 2 seabirds for DMP, and 12 for DEHP. GAMs best fitting models showed associations between DEHP concentration and the factors sex and plastic presence. Although preliminary, our findings imply the need to further investigate sublethal effects of plastics, as well as their influence on birds' metabolism and response to environmental xenobiotics. This study provides baseline data for the conservation of seabirds in an area where plastic pollution is increasing.

2.17.P-Tu125 Isotopic variation in response to the combined chemical exposure and temperature

Roque Gastón Alurralde[1,2], *Sophie Steigerwald*[1], *Andrius Garbaras*[3], *Sebastian Abel*[1], *Ann-Kristin Eriksson-Wiklund*[1], *Anna Sobek*[1] *and Elena Gorokhova*[4], *(1)Environmental Science, Stockholm University, Sweden, (2)Baltic Marine Environment Protection Commission HELCOM, Finland, (3)Mass Spectrometry Laboratory, Center for Physical Science and Technology, Lithuania, (4)Department of Environmental Science, Stockholm University, Sweden*

Stable isotope signatures for carbon ($\delta^{13}C$) and nitrogen ($\delta^{15}N$) are widely used in trophic ecology and ecotoxicology for the trophic positioning of consumers. The approach relies on 'predictable' isotope fractionation in the consumer tissues relative to their diet, with the physiological condition of the animals having a relatively low effect on the fractionation. However, when chemical and nonchemical stressors affect the physiological status, these signatures may also be affected due to responses in biochemical rates and altered pathways, with downstream effects on fractionation.
Understanding the effects of various stressors, such as chemical pollution and temperature, on the isotopic signatures is essential for their interpretation. Departing from the premise that sublethal chemical exposure distorts fractionation and isotopic signatures via altering metabolic rate, we aimed to assess stable isotope variation as an indicator of toxic effects under different thermal conditions. Here, using a passive dosing system with no food, we exposed *Daphnia magna* to the combined effects of polycyclic aromatic hydrocarbons (PAHs; acenaphthene, fluorene, phenanthrene, and fluoranthene as a mixture) and temperature (20°C, 23°C, and 25°C). We used the chemical activity concept to address the effects of the PAH mixture and relate the chemical exposure and temperature effects to the metabolic alterations in the daphnids. We measured $\delta^{13}C$ profiles, mortality and protein content and established their dose-response relationships (E*a*50) for different chemical activities in the range of 0.01 to 0.1 and the three thermal conditions.
At all temperatures, a depletion of $\delta^{13}C$ was observed with increasing chemical activity in a dose-response fashion. Moreover, the E*a*50 values were temperature-dependent, decreasing from 0.08 at 20°C to 0.05 at 23°C and 0.06 at 25°C. In addition, low protein content and high mortality coincided with low $\delta^{13}C$ values, supporting the view that isotopic fractionation is affected by metabolic depression. Understanding non-dietary isotopic variability in a multi-stressor context improves the interpretation of stable isotope signatures in environmental assessment.

2.17.P-Tu126 Fatty acid profiles in blubber samples from humpback whales (Megaptera novaeangliae) between feeding (Southern Ocean) and breeding and calving areas (NE Brazil)

***Cristian Taboada Timoszczuk*[1]*, Satie Taniguchi*[2]*, Josilene da Silva*[2]*, Luciano Dalla Rosa*[3]*, Eduardo Secchi*[3]*, João Carlos Gomes Borges*[4]*, Salvatore Siciliano*[5]*, Paula Baldassin*[6] *and Rafael Andre Lourenço*[2]*, (1)University of São Paulo (USP), Brazil, (2)Oceanography, University of São Paulo (USP), Brazil, (3)Federal University of Rio Grande FURG, Brazil, (4)Fundação de Mamíferos Aquáticos, Brazil, (5)FioCruz, Brazil, (6)Instituto BW para a Conservação e Medicina da Fauna Marinha*
Humpback whales (*Megaptera novaeangliae*) in the southern western hemisphere feed during summer and autumn in the Southern Ocean and the southern coast of Chile and migrate northwards to mate and reproduce in northeast region of Brazil (known as Stock A) and in the Caribbean region (Stock G). The energy expended during this displacement is enormous and cause a loss of approximately 20-40% of their blubber layer, since the humpbacks are fasting from the calving and breeding areas until their returns to feeding sites. In order to evaluate possible changes on the superficial blubber layer composition, samples from stranded whales (n=20) in Brazilian Coast and biopsies (n=81) from specimens around Antarctic Peninsula were collected to assess fatty acids. Results indicated the predominance of similar fatty acids in the samples collected in the breeding and feeding areas, with highest concentrations of monounsaturated fatty acids (MUFA) and saturated fatty acids (SFA), with C18:1ω9, C16:0, C16:1ω7, C14:0 and C18:1ω7 as the compounds with the highest contributions. Samples from the northeastern and southeastern Brazilian coast presented a relatively higher contribution of long-chain polyunsaturated fatty acids (PUFA), such as C22:5w3 (DPA), C22:6w3 (DHA) and C20:5w3 (EPA) compared to Antarctic samples, even though the average EPA/DHA ratio was quite similar to krill (*Euphausia superba*), the main prey for the humpback whales sampled in this study. The fatty acid profile differences can be directly related to the metabolization of the lipid layer during the feeding and fasting period although individual aspects such as gender and age should be considered to better understand how this highly migratory species adapts during migration.

2.17.P-Tu127 Linking Hepatic Residues of Anticoagulant Rodenticides in Wild Freshwater Fish with in vivo Determined Effect Levels

***Hannah Schmieg*[1]*, Hannah Schrader*[1]*, Julia Regnery*[2]*, Hermann Ferling*[1]*, Stefanie Jacob*[3]*, Anton Friesen*[3] *and Julia Schwaiger*[1]*, (1)Bavarian Environment Agency, Germany, (2)Federal Institute of Hydrology (BfG), Koblenz, Germany, (3)German Environment Agency (UBA), Dessau-Rosslau, Germany*
Second-generation anticoagulant rodenticides (SGARs) remain the most often used biocides to control pest rodents such as house mice or brown rats despite bearing high risks of unintentional poisoning of wildlife and being classified as persistent, bioaccumulative and toxic (PBT). Consequently, these compounds will continue to be detected regularly in an ever-increasing number of non-target organisms. While primary and secondary poisoning of terrestrial and avian species such as small mammals and raptors are well known, little data exists on fate of SGARs in the aquatic environment and to an even lesser extent regarding possible ecotoxicological effects associated with this exposure levels. Although recent studies found AR residues in livers of freshwater fish in the magnitude of ng/g, it is currently not possible to link these hepatic AR concentrations to possible lethal or sub-lethal effects.

In order to determine the relevance of reported SGAR residues in wild freshwater fish and to assess their risk of AR poisoning, we conducted *in vivo* experiments feeding rainbow trout (*Oncorhynchus mykiss*) defined doses of the SGAR brodifacoum in a flow through system. In a first experiment, one-year old fish (ca. 250 g) were exposed individually to brodifacoum-spiked feed for 15 d whereas in a second experiment one and a half year old trout (ca. 650 g) were exposed in groups to the SGAR for 60 d. Lower brodifacoum doses were chosen based on the limit of quantification of brodifacoum, intermediate doses based on the concentration of active ingredients in rodenticide baits and higher doses represent reported effect levels in other species. Sampling of fish every 15 d allowed tracking brodifacoum concentrations in liver, serum, and filet, and occurring effects over the course of time. Notably, the duration between brodifacoum uptake and observed effects took 15 d and was considerably longer than reported for other vertebrates. Brodifacoum reduced the vitamin K level and inhibited the coagulation in rainbow trout. Disturbed haemostasis resulted in haemorrhages in gills, pseudobranchs and other organs leading to severe anaemia and mortality. Effects on coagulation occurred at an average brodifacoum concentration of ca. 150 ng/g hepatic tissue. The results emphasize, that acute standard biotests are not suitable to observe effects of chronically acting AR on fish and would substantially underestimate potential effects.

2.17.P-Tu128 The Use of Comparative Transcriptomics Field Studies to Assess the Effects of Multiple Stressors on Fish

***Camilo Escobar Sierra*[1] *and Kathrin Lampert*[2]*, (1)University of Cologne, Germany, (2)Zoology, University of Cologne, Germany*
European running waters are affected by several multiple stressors (MTS) which can have detrimental effects on the fish fauna. In such MTS scenarios, it remains highly challenging to unravel the particular effects of a stressor on the species of interest. Furthermore, the challenge is amplified by the traditional approach of studying the effects of MTS relying on controlled small- and meso-scale experiments. In these experiments, the organisms are exposed to different levels and combinations of stressors and their effects are measured as the organism's survival or at the physiological level with a limited set of targeted physiological markers. When limiting the MTS studies to manipulative and targeted physiological studies, the effects of stressors on other physiological pathways or the effects of underlying stressors combinations in natural habitats may pass undetected. In this context, the use of comparative transcriptomics in the field has the potential to assess the effects of MTS in the entirety of an organism's gene expression, pinpoint particular stressors of interest, and even understand the mechanisms and underlying genetic pathways of the adaptation to stress. To validate the approach of comparative transcriptomics for MTS study in natural populations of fish, here we present evidence of differential gene expression in *Gasterosteus aculeatus* that correlate with different levels of anthropogenic stressor conditions in the river Boye (Germany). We chose one river transect with natural cover and mainly agricultural influx and two field sites in an urban and industrial landscape that showed higher nutrient and salinity concentrations. For each site, we did Illumina high throughput mRNA sequencing of three specimens and performed a differential

gene expression analysis. We found a set of significantly differentially expressed candidate genes between the fishes of the different transects. A gene ontology analysis of these genes showed an enrichment of gene expression in the pathways related to response to osmoregulation in both transects with higher urban and industrial land cover and higher concentrations of chloride. Following a similar research design, the transcriptome response analysis of the native and endangered fish species *Cottus rhenanus* is ongoing, and results will be presented in the poster. Our case studies showcase the comparative transcriptome approach potential to understanding fish adaptation under MTS vironments in natural habitats.

2.17.P-Tu129 Evaluation of physiological and morphological endpoints combined with the conventional endpoint of algal toxicity: application to five disinfection by-products characteristic of a chlorinated effluent

***Théo Ciccia*[1]**, *Pascal Pandard[2], Nastassia Urien[1], Leo Lafay[1], Philippe Ciffroy[1] and Anne Bado-Nilles Dr[3], (1)Laboratoire National d'Hydraulique et Environnement (LNHE), Electricité de France (EDF) R&D, Chatou, France, (2)Institut National de l'Environnement Industriel et des Risques (INERIS), France, (3)Umr-I 02 Sebio, Institut National de l'Environnement Industriel et des Risques (INERIS), France*

The toxicity of a contaminant present in the environment is usually assessed with standardized bioassays focusing on only one or a few specific endpoints on the organism/individual level, such as survival, growth, reproduction or development. These endpoints allow us to determine the toxicity of a specific substance on organisms, but, in that case, information on the mode of action on the subcellular level is partial or missing. In this work, the individual toxicity of five disinfection by-products (DBPs) characteristic of a chlorinated effluent (monochloroacetic acid MCAA, dichloroacetic acid DCAA, trichloroacetic acid TCAA, bromochloroacetic acid BCAA and 1,1-dichloropropan-2-one 1,1-DCP) was evaluated on the green microalgae *Raphidocelis subcapitata*. In addition to a classic growth inhibition approach (OECD TG 201), flow cytometry technics were investigated to better understand the physiological performance of the green microalgae. Some cellular biomarkers, such as metabolic activity, cellular viability, mitochondrial membrane potential, oxidative stress, lipid content, chlorophyll *a*, green autofluorescence, size and complexity, were developed to determine sublethal responses and the mechanisms of action which could explain the effects measured on the population growth.

Results showed that 1,1-DCP, a DBP for which few information is available in the literature, was the most toxic substance for growth inhibition endpoint followed by AMCA≥ATCA>ABCA>ADCA. Concerning the cellular parameters studied, all of them showed similar patterns in response to the exposure to the 5 DBPs except for metabolic activity. Green autofluorescence, size, intracellular complexity, neutral lipid content and oxidative stress significantly increased during the experiment, whereas mitochondrial membrane potential showed no changes for any DBP and at any time for the five DBPs. Furthermore, a decrease in chlorophyll *a* (photosynthetic activity) was observed at 72h. In another way, metabolic activity presented some dissimilarity between compounds with a significant decrease observed after 48h of exposure to MCAA and 1,1-DCP, whereas the other DBPs led to a significant increase in metabolic activity after 48h and 72h of exposure. Based on these observations, we proposed a hypothetical comprehensive figure representing the relationships between the cellular parameters observed during the study leading to growth inhibition after exposure to DBPs.

2.17.P-Tu130 The combined effect of stress and diazepam on facultative migration of European glass eel (Anguilla anguilla): development of endocrine and molecular markers

Stellia Sebihi[1,2], Marie Morere[1], Colin Bouchard[1], Pascale Coste[1], ***Mathilde Monperrus*[1]**, *Maren Ortiz-Zarragoitia[3] and Valérie Bolliet[1], (1)Université de Pau et des Pays de l'Adour, France, (2)CBET+ Group, Research Centre for Experimental Marine Biology and Biotechnology Plentzia Marine Station PIE Areatza z/g, Spain, (3)CBET+ Group, Research Centre for Experimental Marine Biology and Biotechnology Plentzia Marine Station PIE, Spain*

The European eel (*Anguilla anguilla*) population has received considerable attention in recent decades due to its significant decline. This catadromous species presents a facultative diadromy and glass eels display a large panel of estuarine migratory tactics, ranging from residency in marine water, to various degrees of upstream colonization through estuarine and freshwater ecosystems. These different patterns of migration can have a strong impact on the fate of the population because individuals remaining downstream mostly develop into males, whereas individuals colonizing upstream develop mainly into females. Recent results suggest that glass eels presenting a low probability to migrate in experimental facilities may be more stressed or more sensitive to stress than migrant individuals. Estuaries are considered stressful environments and represent a major sink for various contaminants usually considered as powerful stressors depending on their concentrations. Among these chemicals, benzodiazepines, found in relatively high concentrations in effluents of wastewater treatment plants, can induce a number of neuroendocrine alterations in exposed fish. However, paradoxically, they also may counteract the stress responses in fish due to their anxiolytic effect.

The aim of this work was to investigate the effect of the stress and diazepam at environmental doses on the European glass eel by developing stress markers. Stress hormones analysis were developed by LC-MS-MS to determine cortisol, cortisone, 11-deoxycortisol, and 11-deoxycorticosterone production in glass eel individuals. In addition, transcriptomic markers were detected using a non-targeted approach, by RNAseq. These molecular and endocrine markers were analyzed on glass eels contaminated or not with diazepam, and exposed or not to a 2 minutes mechanical stress. Both stress markers were monitored with time (after 15, 30, 60 and 120 min) to evaluate the combined effect of stress and diazepam in glass eel.

The developed stress markers could then be applied to address stress in migrant and non-migrant glass eels to understand the determinism of migration.

2.17.P-Tu131 Co-variation of metallothionein expression levels and cadmium tolerance in Gammarus fossarum field populations.

Auréline Lalouette[1], *Arnaud Chaumot*[1], *Nicolas Delorme*[1], *Laura Garnero*[1] *and Davide Degli Esposti*[2], *(1)UR RiverLy - ECOTOX, Laboratoire d'écotoxicologie INRAE, France, (2)Laboratoire d'écotoxicologie INRAE, France*
Metallothioneins (MTs) are low molecular weight proteins rich in cysteine notably involved in the detoxification of non-essential metals. In aquatic invertebrates, MTs have been identified as potentially being involved in population adaptation to metal exposure in the contaminated environment. In one field population of the crustacean *Gammarus fossarum* naturally exposed to geochemical sources, we have previously documented an increased tolerance to cadmium (Cd) in adult organisms which can be transmitted to their offspring by means of parental effects. The objective of our study was first to generalize this result to a larger set of field populations in naturally contaminated headwater streams, and second to establish a possible correlation between *Gfoss*MTs expression and tolerance of different life stages based on organisms either freshly collected in the field or after laboratory maintenance in Cd-free conditions (6 months). For this, 11 natural populations of *G. fossarum* from Cd contaminated and uncontaminated rivers were collected after a fine *in situ* characterization of Cd bioavailability (active biomonitoring). We assessed concomitantly Cd tolerance (mortality tests) and the expression levels of *Gfoss*MTs measured by RT-qPCR in the gills and caeca of adult males and in neonates. The results show at different dates of the year, Cd tolerance during mortality tests of Cd-contaminated populations, and a clear correlation with the expression levels of one MT, namely *Gfoss*MT1 of the different batches of individuals. This covariation was also supported by a parallel decrease of tolerance and MT expression in the gills during maintenance in Cd-free water. Furthermore, a transmission of tolerance to unexposed offspring was confirmed. Interestingly, while similar levels of *Gfoss*MT1 expression were observed under control conditions in neonates born from sensitive *vs* tolerant genitors, we observed a higher induction of this expression in neonates from tolerant populations under Cd re-exposure in the laboratory. This pattern leads to a discussion of the plasticity mechanisms that appear to support the modification of sensitivity in exposed natural populations.

2.17.P-Tu132 Ecotoxicological State Assessment of Fish and Bivalves
Nathalie Wessel[1], *Vincent Roubeix*[1], *Farida Akcha*[1], *Tifanie Briaudeau*[2], *Melanie Brun*[1], *Thierry Burgeot*[1], *Urtzi Izagirre*[3] *and Aourell Mauffret*[1], *(1)IFREMER, France, (2)University of the Basque Country (UPV/EHU), Spain, (3)UNIV BASQUE COUNTRY, Spain*
In the context of the different Marine frameworks, France implemented since 2017 an ecotoxicological monitoring on bivalves and flatfishes, namely the SELI program, on two hot spots of chemical contamination in the French Atlantic and Channel marine waters: the Loire and the Seine bays.

The present work aimed to i) develop ecotoxicological indicators for the Marine Strategy Framework Directive (MSFD) evaluation for bivalves and flatfishes (interpretation and integration/aggregation tools) and ii) integrate ecotoxicology and chemistry on different matrices (biota, sediment) on the Seine bay for the Ospar Quality Status Report (QSR).
In the Seine Bay, common sole (*Solea solea*), dab (*Limanda limanda*), and flounder (*Platichthys flesus*) were sampled during a unique campaign in September 2018. Moreover, blue mussels (*Mytilus edulis*) were collected during the annual campaign of the French mussel watch program in February 2019. In the Loire bay, two campaigns were conducted: soles were sampled in September 2017 and 2020, and mussels in February 2018 and 2021. A panel of ecotoxicological parameters, among the ICES recommendation list, were assessed in organisms. They targeted different toxic endpoints (general stress, neurotoxicity, genotoxicity, cytotoxicity) and PAH exposure (only for fishes).

The ecotoxicological integration tools allowed the evaluation of the general health status of each species and area. The results showed that flounder and mussel achieved “Good environmental status” as defined under MSFD, while sole and dab were affected by the chemical contamination.

The chemical-biological assessment conducted on the Seine Estuary allowed for the integration of the different ecotoxicological parameters, and the chemical concentrations in fish, bivalve and sediment, for several geographical units. The closest estuary unit seemed to be the most impacted with the highest percentages of both chemicals and biological effects at unacceptable levels, followed by a decrease with the distance from the coast.

These results highlighted the biological impacts of the chemical pressure in the two studied areas, particularly on fish. The sole seems to be more sensitive to pollution than the other flatfish species, putting forward the need of specific thresholds.

This work supports the need for a long-term monitoring on mobile and sessile species to allow trends assessment. Other toxicological endpoints should be investigate, such as immunotoxicity or endocrine disruption.

2.17.P-Tu133 Transcriptional Biomarkers of Toxicity – An Applied Perspective from Studies on Bivalves
Gustaf Magnus Oskar Ekelund Ugge[1], *Ullrika Sahlin*[1], *Annie Jonsson*[2] *and Olof Berglund*[1], *(1)Lund University, Sweden, (2)University of Skövde, Sweden*
Gene transcripts may have great potential as early warning biomarkers by representing how an organism copes with chemical stress before harm arises at higher organizational levels. A major challenge is however to distinguish transcriptional stress responses from background noise and baseline variability. Using bivalves as study organisms, we assessed sensitivity, variability, and robustness in six putative transcriptional biomarkers of general stress; catalase, glutathione-S-transferase, heat shock proteins 70 and 90, metallothionein and superoxide dismutase. This was performed through a systematic review and meta-analysis on bivalves in general, and through laboratory studies on the freshwater mussel *Anodonta anatina*.

For the meta-analysis, we extracted reported transcriptional responses (n = 396) from 22 selected studies and incorporated them into Bayesian mixed effects models to test overall responses with and without tissue, exposure concentration (transformed to toxic unit) and exposure time as moderators. In the main experimental study, *A. anatina* (n = 40) were exposed for 96 h to a high-resolution concentration gradient of Cu (0.13 – 1 600 µg/L). Relative expression of selected transcripts was measured by RT-qPCR, and concentration-response relationships were fitted relative the measured Cu concentrations in both water and tissue.

According to the meta-analysis, the estimated overall response in a bivalve upon arbitrary metal exposure was an expected 65 % increase in relative expression. The effect was however inflated by publication bias toward reporting positive responses, and when corrected for bias, expected responses were close to zero. Furthermore, there was general implication of monotonic concentration-response relationships in *A. anatina* upon Cu-exposure. Modelled responses however saturated at relatively low magnitudes, and only three transcripts in gills exceeded a 2-fold change within the exposure range. In contrast, the meta-regressions offered little support for concentration-dependent responses across species and exposure scenarios. In practice, high background noise may obscure the small effects even at high exposures, and this problem can only be expected to increase upon extrapolation between different species and exposure scenarios.

Our results will be discussed in terms of sensitivity and robustness to critically address the idea of universal application of these transcripts as biomarkers of general toxicity.

2.17.P-Tu134 Proposition of Reference Range for Genotoxicity Biomarkers in Stickleback by Considering Season and Biotic Factors

Amélie Cant[1], Cleo Tebby[2], Jean-Marc Porcher[1], Alain Geffard[3], Cyril Turiès[1], Marc Bonnard[3] and ***Anne Bado-Nilles[1]****, (1)UMR-I 02 INERIS-URCA-ULH SEBIO, France, (2)INERIS, France, (3)Umr-I 02 Sebio, University of Reims Champagne-Ardenne (URCA), France*

Biomarkers may reflect a causal relationship between the exposure to chemicals and early impact on organisms. To be employed in freshwater biomonitoring programs at a large scale, natural variability ranges of biomarkers need to be considered. Indeed, the characterisation of reference values faces to limits, such as the influence of confounding factors and the difficulty to find a reference station associated to no or low anthropogenic pressures. Among biological parameters used, the assessment of environmental genotoxicity represents a major challenge due to the wide range of substances which are known to have genotoxic properties on aquatic species. However, the lack of knowledge about the impact of confounding factors on genotoxicity responses can complexify the assessment of freshwater genotoxic risk. The aim of the study was to establish reference baseline values considering potential biotic (sex and length of fish) and abiotic (season) factors. DNA strand breaks, oxidative lesions to DNA (Fpg-sensitive site), DNA content variation, and erythrocyte mortality and density were assessed over a one-year period on the three-spined stickleback, *Gasterosteus aculeatus*, from an outside artificial pond, using the comet assay and flow cytometry. Both Fpg-sensitive site, DNA content and erythrocyte mortality presented sex-dependent seasonal variation. Only Fpg-sensitive site and erythrocyte necrosis were impacted by the fish size. DNA strand breaks and erythrocyte density were not affected by these factors. This work has improved knowledge of erythrocyte biomarkers variability and proposed the first projection of reference range carried out by a mathematical model previously developed. The variability explained by these models, as well as its predictive capacity, vary according to the biomarker considered. The prediction was well represented by the three confounding factors for biomarkers of erythrocyte mortality and chromosomal damages but could be improved by considering other abiotic parameters. A field exposure outside of stickleback breeding periods, with a homogeneous sample (sex ratio and size) should be preconized to improve the genotoxicity assessment. Overall, these results represent the first attempt to define reference ranges for biomarkers of genotoxicity in the stickleback, which will be useful to compare future data from studies of freshwater environments under biomonitoring scopes.

2.17.P-Tu135 Variability of Metallothionein Expression in Field-Populations of *Gammarus fossarum* Living in Long-Term Chronic Cadmium Contamination Contexts: Basal Levels, Sensitivity, and Transgenerational Effects

Auréline Lalouette[1]*, Arnaud Chaumot[1], Nicolas Delorme[1], Laura Garnero[1] and Davide Degli Esposti[2], (1)UR RiverLy - ECOTOX, Laboratoire d'écotoxicologie INRAE, France, (2)Laboratoire d'écotoxicologie INRAE, France*

Metallothioneins (MTs) are proposed as biomarkers of metal exposure because MT-synthesis is often induced when organisms are exposed to environments contaminated by heavy metals. Nevertheless, in natural populations, the basal sensitivity of biomarkers is not currently fully characterised whereas it can be variable due to adaptation phenomena and/or influence of past exposure of organisms (acclimatation) or transgenerational effects (parental exposure). This source of variability can make problematic risk assessment in biomonitoring when correlations between the dynamics of metallic exposure and MTs expression in collected organisms have to be drawn. In this way, this study in the sentinel freshwater species *Gammarus fossarum* wants to better understand the plasticity of MT-expression in populations exposed to historical metallic contamination, especially in naturally contaminated river due to geochemical sources. A data mining of recent transcriptomic resources in *G. fossarum* followed by experimental validation by RT-qPCR allowed us to identify two MTs, *Gfoss*MT1 and *Gfoss*MT2, the first one which responds strongly to Cd exposure in laboratory conditions. Our objectives were to investigate the variability of MT-expression in 13 *G. fossarum* field populations, notably living in long-term chronic Cd contamination contexts, by 1) determining the co-variation between *Gfoss*MT1 expression levels of different life stages and Cd bioavailability in the field, 2) examining whether basal levels of *Gfoss*MT1 expression in organisms maintained in laboratory are dependent on the exposure history of population origin, and 3) characterising under common Cd exposure in controlled conditions the sensitivity of *Gfoss*MT1 expression of populations with different metallic exposure histories. Our results confirm that *Gfoss*MT1 is overexpressed in naturally populations exposed to historical Cd contamination and suggest that long-term exposure over several generations affects the sensitivity of *Gfoss*MT1 expression to Cd exposure. Our study evidences in the case of *Gfoss*MT1 expression can be the object of adaptive transgenerational processes occurring during historical exposure in field populations.

2.17.PC Toward a Better Understanding of Chemical Biomarker Responses in Aquatic Organisms

Track 3 Environmental Chemistry and Exposure Assessment: Analysis, Monitoring, Fate and Modeling

3.01 Advances in Bioaccumulation Science and Assessment

3.01.T-01 A Tiered Approach for Screening Chemicals for Biomagnification Potential in Air-Breathing Organisms
***Alessandro Sangion**[1,2], James M Armitage[3], Liisa Toose[1], Ester Papa[4] and Jon A. Arnot[1,5], (1)Arnot Research and Consulting Inc. (ARC), Canada, (2)University of Toronto, Canada, (3)AES Armitage Environmental Sciences, Inc, Canada, (4)DiSTA, University of Insubria, Italy, (5)Department of Pharmacology and Toxicology, University of Toronto, Canada*
Regulatory programs seek to protect human and environmental health and, as a part of hazard assessment, often categorize chemicals according to their persistence (P), bioaccumulation (B), and toxicity (T) properties. For air-breathing organisms, biomagnification is related to the octanol-air partition ratio (K_{OA}) in addition to the octanol-water partition ratio (K_{OW}), In current REACH guidance, chemicals with log $K_{OA} \geq 5$ and log $K_{OW} \geq 2$ are considered to have bioaccumulation potential in air-breathing organisms. Critical caveats to these screening criteria are the assumptions that (i) the chemical is efficiently absorbed from the diet, (ii) it is nondissociating (i.e., a neutral organic chemical), and (iii) there is no biotransformation. A better metric to assess bioaccumualtion in air-breathing organisms is the biomagnification factor (BMF), defined as the fugacity ratio (applicable to nonionic compound) or the activity ratio of the organism to its diet. As recently outlined by the ECHA working group on toxicokinetics in the "Bioaccumulation assessment of air-breathing mammals: a discussion paper", physiologically-based biokinetic (PBK) models, describing processes such as chemical absorption, distribution, metabolism (biotransformation), and excretion (ADME), can be used to simulate whole body concentrations at steady-state and calculate the BMF. Here we present a tiered approach for screening organic chemical bioaccumulation in air-breathing organisms. The tiered approach progresses from conservative screening-level assumptions based on K_{OW} and K_{OA} to more realistic conditions for chemical properties, internal distribution and biotransformation.

The screening results show a progressive decrease in the chemical activity based biomagnification factor (BMF_a) from Tier 0 (K_{OA} and K_{OW} only) where 84% of the chemicals predicted as potentially B to Tier 3 when ED, bio-partitioning and dissociation are included in the simulation and 77% of the chemicals have an estimated $BMF_a > 1$. Tier 4 shows significantly different results when biotransformation is included in the simulations; biotransformation is by far the main elimination pathway for most chemicals reducing the number of chemicals with $BMF_a > 1$ to ~ 2% of the original dataset.

This study shows the key role of biotransformation in bioaccumulation assessment for air-breathing organisms and highlights the need for reliable biotransformation data to effectively categorize chemicals for B hazard.

3.01.T-02 High Throughput Prediction of Hepatic Clearance Using Isolated Perfused Fish Livers in Diverse Chemical Mixtures
***Matthew Schultz**[1], Zoey Bourgeois[1], Jordan Comfort[1], Jonathan Karl Challis[2], Jenna Cantin[1], Sophia Krause[3] and Markus Brinkmann[1], (1)Toxicology Centre, University of Saskatchewan, Canada, (2)Lethbridge Research and Development Centre, Agriculture and Agri-Food Canada, Canada, (3)Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany*
Chemical risk assessment often focuses on screening substances for criteria of persistence, bioaccumulation potential, and toxicity (PBT). Of these criteria, bioaccumulation potential presents unique challenges in effective risk assessment due to the difficulty associated with testing compounds that undergo biotransformation. This difficulty is compounded by the diversity of chemical classes of interest, such as pharmaceuticals, ionizable organic compounds (IOCs), or complex mixtures within the environment. Presently, bioaccumulation assessment relies upon costly whole animal *in vivo* exposures, or new approach methodologies (NAMs) such as *in vitro* assays coupled with *in vivo-in vitro* extrapolation (IVIVE). These approaches have been used to reduce both animal use and uncertainty within assessment frameworks such as REACH, however further refinement is needed to establish the high-throughput predictive tools that are desired by modern chemical legislation. One such refinement involves the use of the isolated perfused rainbow trout liver model at an intermediate level of biological organization. This model can deliver a physiologically relevant measure of hepatic clearance and thus help build an estimate of bioaccumulation potential. In the present study, the hepatic clearance of a diverse mixture of chemicals found within the US EPA's Non-Targeted Analysis Collaborative Trial (ENTACT) trial, as well as nine psychotropic drugs were measured in both isolated perfused trout livers and isolated primary hepatocytes (RT-HEP). Samples were analyzed using liquid-chromatography-high-resolution-mass-spectrometry (LC-HRMS) to semiquantitatively measure individual chemicals within mixture and calculate hepatic extraction fraction. Our results show that the combination of the isolated perfused liver model with mixtures is a powerful predictive tool for investigating bioaccumulation potential across a vast range of chemicals. Coupled with IVIVE modeling, this approach can achieve high-throughput screening of contaminants with minimized animal use and greater certainty than previous studies.

3.01.T-03 Elimination Resistant: Characterising Multicompartment Toxicokinetics of Thiacloprid in *Gammarus pulex* Using Bioconcentration and Receptor Binding Assays

Johannes Raths[1], *Linda Schinz*[2], *Annika Mangold-Doring*[3] *and Juliane Hollender*[4], *(1)Environmental Chemistry, Eawag, Swiss Federal Institute of Aquatic Science and Technology, Dübendorf, Switzerland, (2)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Dübendorf, Switzerland, (3)Wageningen University & Research, Netherlands, (4)Environmental Chemistry, Environmental Chemistry, Eawag, Swiss Federal Institute of Aquatic Science and Technology, Dübendorf, Switzerland*

Neonicotinoid insecticides act as agonists of the nicotinic acetylcholine receptors (nAChRs) and induce symptoms of neurotoxicity. In aquatic invertebrates, delayed toxicity is a common phenomenon for neonicotinoids. Further, recent studies observed slow and incomplete elimination of neonicotinoids in amphipods suggesting multicompartment kinetics. However, a mechanistic link between receptor binding and toxicokinetic modelling has not been demonstrated yet.

The incomplete elimination of thiacloprid in the freshwater amphipod *Gammarus pulex* was studied in several toxicokinetic approaches, comprising an extended elimination phase, concentration dependence and pulsed exposure experiments. Further, experiments were complemented with studies on the binding of thiacloprid to nAChRs using *in vitro* and *in vivo* receptor binding assays. Based on the results of the experiments, a toxicokinetic-receptor model was developed to predict the uptake and elimination kinetics of thiacloprid in *G. pulex*.

The performed experiments confirmed the incomplete elimination of thiacloprid in *G. pulex*. The elimination resistant fraction (0.18 to 0.39 µmol/kg wet weight) was independent of exposure concentration and the number of exposure pulses. Based on the receptor binding assays, irreversible binding to the nAChRs was demonstrated to be the major cause of elimination resistance. Accordingly, the toxicokinetic-receptor model consisted of a membrane protein (i.e., nAChR) compartment and a structure compartment. Internal thiacloprid concentration data of various experiments were used to calibrate and validate this toxicokinetic-receptor model.

The present study elucidated the toxicokinetic mechanisms of thiacloprid accumulation in *G. pulex*. Additionally, we provided the tools to assess toxicokinetics including receptor binding. Our results could help in understanding the delayed toxic effects caused by neonicotinoids. Furthermore, we want to raise awareness towards the long-term toxic effects following the irreversible binding to nAChRs where regulatory solutions are needed.

3.01.T-04 Using Multimodal Passive Samplers for the Estimation of Risk and Bioaccumulation in *Gammarus pulex*

Alexandra Kate Richardson[1,2], *Stephen Stürzenbaum*[3], *David Cowan*[3], *David Neep*[4] *and Leon Barron*[5], *(1)Analytical, Environmental & Forensic Sciences, King's College London, United Kingdom, (2)Environmental Research Group, Imperial College London, United Kingdom, (3)King's College London, United Kingdom, (4)Agilent Technologies, Inc., United Kingdom, (5)Imperial College London, United Kingdom*

A six-month monitoring study for contaminants of emerging concern in an urban river, London UK (River Wandle) using a miniaturised 3D printed passive sampling devices (3D-PSDs) is presented. The 3D-PSDs were manufactured from a methacrylate-based resin and held up to five individual 9 mm sorbent disks. The sampling rates (R_s) of three different sorbents (HLB (divinylbenzene-co-N-vinylpyrrolidone), anion exchange, and cation exchange) were assessed in the laboratory over 10 days at low exposure concentrations (50 and 100 ng L^{-1}) in artificial freshwater (AFW). The sampling rates ranged from 0.3 to 12.3 mL day^{-1}, 0.3 to 18.8 mL day^{-1}, and 2.0 to 81.0 mL day^{-1} for HLB, anion and cation sorbents, respectively. The 3D-PSDs (n = 15 individual sorbent disks across three devices per sorbent) were deployed for seven days per month from July to December 2021. Appropriate field blanks were used during deployment and retrieval, and water samples were collected at three timepoints over the 3D-PSD deployment. The benthic invertebrate *Gammarus pulex* was collected every month, co-occurring with 3D-PSD deployment and retrieval. All matrices were analysed using a highly sensitive liquid chromatography-tandem mass spectrometry (LC-MS/MS) method.

Across all matrices, 94 unique compounds were detected, seven of which are watch list compounds. Of these, 14 compounds are common to all matrices, 38 were common to all sorbents, and 19 compounds were common to both the 3D-PSDs and *G. pulex*. Concentrations on the sorbent disks ranged from 0.004 ng $disk^{-1}$ (mephedrone) to 6.7 ng $disk^{-1}$ (imidacloprid), 0.02 ng $disk^{-1}$ (roxithromycin) to 5.0 ng $disk^{-1}$ (acetamiprid), and 0.02 ng $disk^{-1}$ (thiacloprid) to 6.3 ng $disk^{-1}$ (imidacloprid) for HLB, anion and cation sorbents, respectively. The inclusion of the anion and cation phases increased the chemical sampling space by 23 compounds. In the *G. pulex*, concentrations ranged from 3.8 ng g^{-1} (lidocaine) to 127 ng g^{-1} (citalopram), median = 10.2 ng g^{-1}. Risk quotients (RQs) and toxic units (TU) were calculated for all compounds. Imidacloprid was found to have medium to high RQs derived from water and 3D-PSD data and high TU calculated in *G. pulex*. High correlations were found between the effect and toxic units calculated using the *G. pulex* data and mass on 3D-PSD. Multivariate analysis was applied to the *G. pulex* and 3D-PSD data to determine relationships with a view to move toward the prediction of *G. pulex* concentrations from the 3D-PSD data.

3.01.T-05 Strengthened Role of New Approach Methods (NAMs) in Bioaccumulation Assessment under REACH

Doris Hirmann[1], *Anu Kapanen*[1], *Jane Caley*[1], *Tomasz Sobanski*[1], *Christian Schlechtriem*[2], *Eric Verbruggen*[3], *Gabriele Treu*[4] *and Juliane Ackermann*[4], *(1)European Chemicals Agency (ECHA), Helsinki, Finland, (2)Bioaccumulation & Animal Metabolism, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany, (3)National Institute for Public Health and the Environment (RIVM), Netherlands, (4)German Environment Agency (UBA), Dessau-Rosslau, Germany*

In recent years, a number of New Approach Methods (NAMs) were developed as alternatives to the bioaccumulation fish tests according to OECD TG 305. The revised ECHA PBT guidance document clarifies their role in the bioaccumulation assessment and testing strategy. Bioconcentration factors (BCFs) with the aquatic invertebrate *Hyalella azteca* according to the new OECD test guideline, which is scheduled to become available in 2023, can be directly compared against the REACH Annex XIII criteria on bioaccumulation to conclude on bioaccumulative ('B') and very bioaccumulative ('vB'). The results can furthermore be used to conclude on 'not B' or 'not vB', unless there are reasonable doubts that a fish BCF would have exceeded the 'B' or 'vB' thresholds, respectively. In this case, further supporting information is needed. Regarding the *in vitro* methods with fish hepatocytes and liver S9 (OECD TG 319A,B), there is still a lack of practical experience on their performance, and results should be used together with other information to conclude on bioaccumulation. For studying the biotransformation potential of substances in air-breathers, assays with material from mammalian species, such as primary hepatocytes and liver S9, could be used. An ECHA initiated working group on bioaccumulation assessment based on air-breathing species proposed such *in vitro* methods as intermediate tier in a tiered approach to assess the bioaccumulation potential in air-breathing species, with the aim to avoid vertebrate tests as far as possible. Also in this case more experience on its performance is needed, and results should be used together with other information to conclude on bioaccumulation. Assays to determine the rate of hepatic clearance are also used for the assessment of human health systemic toxicity to convert a nominal concentration measured *in vitro* to the equivalent external dose used *in vivo*. Further developments of these assays should aim to combine the needs of both bioaccumulation and hazard assessment for systemic toxicity endpoints. Furthermore, guidance is now available on how to interpret elimination half-lives from toxicokinetic (OECD TG 417) and human biomonitoring studies as indicators of biomagnification. With the update of the ECHA PBT guidance document in 2023, the role of NAMs in bioaccumulation assessment is clarified and advice given on their application in a regulatory context.

3.01.P Advances in Bioaccumulation Science and Assessment

3.01.P-Th124 Intelligent Sampling in Standard *in vivo* Toxicity Studies to Complement Bioaccumulation Assessments in Mammals

*Heike Laue[1], Miriam Leon Paumen[2], Delina Lyon[3], Aaron Redman[4], **Gordon Sanders**[5], Leslie J. Saunders[3] and Blanca Serrano Ramón[6], (1)Givaudan Schweiz AG, Switzerland, (2)ExxonMobil Biomedical Sciences, Inc., Machelen, Belgium, (3)Concawe, Brussels, Belgium, (4)ExxonMobil Biomedical Sciences, Inc., (5)Givaudan International SA, Vernier, Switzerland, (6)ECETOC, Brussels, Belgium*

Traditionally, a fish bioconcentration factor has been employed to determine the propensity of chemicals to bioaccumulate in organisms in the environment. The requirement to perform a separate assessment of bioaccumulation in terrestrial air-breathing species was introduced in the 2017 revision of the Guidance on Information Requirements and Chemical Safety Assessment, Chapter R.11: PBT / vPvB assessment (v3.0) but without technical guidance on how to develop/achieve such an assessment, beyond partitioning-based screening criteria.   the ECETOC workshop on Bioaccumulation in Air-Breathing Organisms, held at the SETAC Copenhagen meeting (May, 2022) a tiered assessment approach was proposed and openly discussed, starting from *in silico* screening, progressing to *in vitro* biotransformation assays, then to *in vivo* mammalian studies, as a last option in the event that reasonable doubt remains regarding air-breather bioaccumulation potential. This poster will propose and discuss the merits of smart sampling approaches within standard *in vivo* repeated dose toxicity studies, currently required from Annex VIII and above in REACh. Biological fluids (e.g., plasma, urine), organs, and tissue samples are routinely collected during *in vivo* studies for analytical screening of parent chemicals and their metabolites. These data could be leveraged to develop further weight-of-evidence with respect to body distribution and elimination half-lives of chemicals, both of which are relevant to the bioaccumulation endpoint. The approach respects the "Reduction" principle of the 3Rs, in that more useful data are derived from the same number of test animals since the analytics would be performed on relevant samples obtained from existing standard test protocols (e.g. OECD 407, 408, 421, 422). It is believed that the information derived from this smart sampling approach using amended test guidelines would lead to a significant reduction in the need for separate follow-up targeted bioaccumulation testing in laboratory mammals.

3.01.P-Th125 OECD TG 319B: Comparison of Biotransformation Rates of Organic Chemicals in Liver S9 Subcellular Fractions from Common Carp and Rainbow Trout

*Lu Hostettler[1], **Gordon Sanders**[2], Karen Jenner[3], Heike Laue[1] and Andreas Natsch[1], (1)Givaudan Schweiz AG, Switzerland, (2)Givaudan International SA, Vernier, Switzerland, (3)Givaudan UK Ltd, United Kingdom*

Bioaccumulation in aquatic species in the regulatory assessment of chemicals usually involves the *in vivo* determination of the bioconcentration factor (BCF) in fish (OECD TG 305). Whereas different fish species are recommended *in vivo*, the validated *in vitro* methods using hepatocytes and liver S9 fractions (RT-S9) to determine biotransformation rates (OECD TG 319 A/B) and the *in vitro-in vivo* extrapolation (IVIVE) models have been developed for rainbow trout. For regulatory purposes, different geographical regions may have particular species preferences. As such, complimentary validation work may be required on alternative species to establish OECD 319A/B fit-for-purpose.

The goal of this study was to compare the biotransformation rates of organic chemicals between trout and carp S9 fractions and to compare the predicted BCFs. Substrate depletion assays were performed with 23 different chemicals in carp-S9 (CC-S9) and RT-S9 including pyrene as reference. TG 319 B was slightly modified for the CC-S9: the incubation temperature was 18°C and the pH of the phosphate buffer pH 7.4. Decrease of the test chemicals was analysed by GC-MS.

Four chemicals were not significantly biotransformed in either system and one additional chemical not in RT-S9. For the remaining chemicals, $CL_{IN\ VITRO,\ INT}$ ranged from 0.04 to 4.01 mL/h/mg protein in CC-S9 (n=19) and from 0.09 to 16.77 mL/h/mg

protein in RT-S9 (n = 18). Four of these chemicals were biotransformed slower in CC-S9 by a factor of 3 to 16, while for the majority of chemicals the differences were within a factor of 2. Predicted BCFs using a new empirical regression model which was built with $CL_{IN\ VITRO,\ INT}$ determined in CC-S9, measured log Kow values and in vivo BCFs determined in common carp, were similar to BCFs which were predicted with a general regression model (i.e., RT-S9 $CL_{IN\ VITRO,\ INT}$), log Kow and mixed species BCFs). In addition, a revised IVIVE model from Nichols et al. 2013 was applied to predict BCFs using CC-S9 and RT-S9 data as input with minor adaptations for carp.
The dataset indicates that the differences in $CL_{IN\ VITRO,\ INT}$ between common carp and rainbow trout are, for the majority of chemicals, within the same range as differences between various batches of RT-S9 and that species matched models do not substantially improve the BCF predictions. In summary, predicted BCF using RT-S9 biotransformation rates may be used to assess bioaccumulation in a "general" fish species.

3.01.P-Th126 Is Nanoplastic-Sorbed Tributyltin Bioavailable to Marine Organisms?
***Jason Raymond**[1], Monica Felipe Sotelo[1], Charles Sission[2] and Maya Al-Sid-Cheikh[1], (1)University of Surrey, United Kingdom, (2)Applied Spectra, Inc.*
Plastic pollution in our oceans has become one of the most prominent human impacts on the environment over the last few decades. Degradation of plastic debris and the resulting formation of micro- (MP) and nanoplastics (NP) have prompted global interest in modelling the behaviour and environmental impacts of these smaller particles in the environment. Plastic particles are both known to be up taken by marine organisms and have the potential to act as a vector for harmful co-contaminants. But how much of the sorbed contaminant is available to the organism? Can the contaminant reach otherwise inaccessible areas of tissue due to the permeation power of the plastic particle?

One of the co-contaminants of interest is tributyltin (TBT), a legacy aquatic pollutant previously used on the underside of marine vessels as an anti-fouling agent. Toxicity is exhibited to bivalves exposed to concentrations as low as 1 ppb, and the strong affinity to suspended particles in the ocean makes it a perfect candidate to model its variable bioavailability.

In this research, a robust new method for the spatial quantification of TBT in mussel tissue by laser ablation–inductively coupled plasma–mass spectrometry (LA-ICP-MS) was developed. Wild blue mussels (*Mytilus edulis*) were exposed to a combination of TBT and 3 various sizes of polystyrene nanoplastic (PS-NP) for 24 h, followed by a 2-week depuration period. Total aqueous and uptaken TBT at several time points were determined by ICP-MS. Given limited availability of matrix-matched reference materials, matrix-matched standards for environmentally realistic concentrations were prepared in house with a combination of spiking, cryogrinding, embedding, and cryosectioning. Whole mussel sagittal sections were mapped via 50 µm-height line scans at a speed of 300 $\mu m s^{-1}$. In addition to spatial determination of tin (Sn), maps also were produced for common metal imbalance indicators: copper (Cu), zinc (Zn), manganese (Mn), magnesium (Mg), and iron (Fe).

3.01.P-Th127 Can Nanoplastics Carry Harmful Organotins into Aquatic Organisms?
***Jason Raymond**[1], Monica Felipe Sotelo[1], Rachida Bance-Soualhi[1], Carol Crean[1] and Maya Al-Sid-Cheikh[2], (1)University of Surrey, United Kingdom, (2)Department of Chemistry, University of Surrey, United Kingdom*
Plastic pollution in our oceans has become one of the most prominent human impacts on the environment over the last few decades. Degradation of plastic debris and the resulting formation of micro- (MP) and nanoplastics (NP) have prompted global interest in modelling the behaviour of these smaller particles in the environment. MPs have been shown to act as a vector for harmful co-contaminants via chemical and physical adsorption. However, information regarding the adsorption capacity of NPs is somewhat limited, despite their greater penetration power through biological membranes and their larger surface area.

Tributyltin (TBT) is a legacy aquatic pollutant, previously used on the underside of marine vessels as an antifouling agent. Toxicity is exhibited to bivalves exposed to concentrations as low as 1 ppb. TBT has a strong affinity to suspended marine particles such as sediments and plastics. Whilst bound, TBT has an extended half-life of 40 years and therefore exists most in benthic sediments. However, plastic particles are significantly less dense than sediment and may allow for the remobilisation of TBT.

In this research, 3 size classes of Nanopolystyrene (PS-NP) spheres were produced with diameters spanning the nano- range (40.09 ± 0.14, 483.75 ± 1.79 and 765.52 ± 9.18 nm). These PS-NPs were used in combination with ICP-MS and MP-AES during adsorption experiments to explore the kinetics and thermodynamics of TBT adsorption by PS-NP within 4 water matrices including natural sea water (NSW, 32 psu), brackish water (IW, 16 psu), artificial sea water (ASW, 32 psu), and a pH 8 buffer in Milli-Q water. The impacts of other environmental factors such as salinity and PS particle size were also investigated. The majority of TBT adsorption occurred within the first 3-6 hours of mixing. Langmuir and Freundlich isotherm models were plotted for each water and polystyrene particle matrix, with distribution coefficients (K_D) ranging between 192.1 ± 8.8 Lg^{-1} and 2852.8 ± 290.9 Lg^{-1}. It was found that the Freundlich isotherm model provided the most accurate fit to experimental data. The greatest adsorption was observed with the smallest plastic particles and in brackish water. This suggests that nanoplastics have a greater potential to act as a vector for the transportation of TBT over microplastics, and that adsorption is restricted by the presence of competitive salts.

3.01.P-Th128 Assessing Bioaccumulation Potential of Pharmaceuticals Using Rainbow Trout Liver S9 Intrinsic Clearance
***Lisa Ann Constantine**[1], Raman Sharma[2] and Angela C Doran[2], (1)Pfizer, (2)Pdm, Pfizer*

The OECD 305 is a widely used, standard test guideline for measuring bioaccumulation of chemicals in fish. This test requires a significant number of fish, is expensive, and time-consuming. Therefore, researchers from various government, industry, and academic institutions have dedicated a significant amount of time and resources over the last decade to develop standard methods and models based on *in silico* and *in vitro* approaches to predicting bioaccumulation in fish. *In vitro* systems derived from fish liver tissue were used to predict biotransformation, a key factor in understanding the bioaccumulation of chemicals in fish.
A major scientific accomplishment in this area of research was the development and validation of OECD 319B, "Determination of in vitro intrinsic clearance using rainbow trout liver S9 subcellular fraction (RT-S9)", adopted June 2018.

Neutral organic chemicals were used to develop and evaluate the OECD 319B Guideline; therefore, additional research is required to evaluate and optimize the extrapolation model for use with ionic organic chemicals (IOCs), such as pharmaceuticals. The procedures as outlined in the guideline were used to determine in vitro intrinsic clearance rates for several pharmaceuticals. These rates were then used to estimate fish BCF values for comparison with the *in vivo* fish BCFs determined as per the OECD 305 Guideline. The predicted BCF values derived from the *in vitro* approach are presented along with the *in vivo* BCF data.

3.01.P-Th129 Evaluation of the Ema Trigger for Fish BCF Testing: Evaluation of Log D and Fish Bcf Data for Several Pharmaceuticals

Lisa Ann Constantine[1], *Todd Davidson*[2], *Jim Ryan*[3], *Joan G. Tell*[4], *Natalie Burden*[5], *Andreas Haener*[6], *David Dolan*[7] *and Gemma Janer*[8], *(1)Pfizer, (2)Bristol Myers Squibb, (3)Environment, Health and Safety, GSK, United Kingdom, (4)MSD, (5)NC3Rs, London, United Kingdom, (6)Group SHE, F. Hoffmann-La Roche Ltd, Basel, Switzerland, (7)Amgen, (8)Novartis Pharma, Spain*
As per the European Medicines Agency (EMA) Guideline for Environmental Risk Assessment of Medicinal Products for Human Use, a fish bioconcentration study is triggered in Phase I for pharmaceuticals having a log Kow >4.5 to support screening for Persistence, Bioaccumulation, and Toxicity (PBT) and in Phase II for pharmaceuticals having a log Kow >3 to assess bioaccumulation potential. The recommended protocol for bioaccumulation is OECD Test Guideline 305: Bioaccumulation in Fish, Aqueous and Dietary Exposure. Based on the standard OECD 305 sampling schedule, approximately 200 fish per study may be required to determine steady-state (BCFSS) and kinetic (BCFK) bioconcentration factors following fish exposures to a low- and high-test concentration and a negative control. As per the draft revision of the EMA guideline, released for consultation in 2018, when log Kow is ≥3 the potential for secondary poisoning should be evaluated by first determining the experimental fish BCF, and when the resulting BCF is >100 L kg-1, a secondary poisoning assessment is required. Considering the potential for fish to metabolize and excrete xenobiotics and the number of animals required for a standard BCF test, the BCF values for several pharmaceuticals were evaluated to understand whether existing data support the current log Kow trigger of 3 for BCF testing. In the interest of animal welfare, BCF data were also evaluated to determine if study design could be limited to a single test concentration and still provide a good estimate of the BCF while reducing the number of fish required. Based on the data presented, increasing the log Kow trigger for BCF testing from 3 to 4 is proposed, and use of a single test concentration to evaluate bioaccumulation potential is recommended.

3.01.P-Th130 Toxicokinetics and Biotransformation in *Eisenia fetida*: Comparison of a Short Exposure Design with the Standard OECD Bioaccumulation Study

Oihane Del Puerto Bengoetxea, *Syngenta Crop Protection, Basel, Switzerland*
In bioaccumulation studies for risk assessment, a kinetic bioaccumulation factor (BAF_k) is calculated as the ratio between the uptake rate constant and the elimination rate constant assuming first-order kinetics. This implicitly also assumes that it is not needed to reach steady state conditions, and thus the kinetic bioaccumulation does not depend on the duration of the experimental uptake and elimination phases and not on the exposure concentrations. If this holds true, then the kinetic bioaccumulation factor could be estimated based on a shorter experimental time than the one suggested by the OECD guideline. However, we do not know if the key assumption on steady state is generally true and consequently, we do not know how reliable BAF_k estimates from shorter experiments would be. If the BAF_k could reliably be estimated from a shorter experiment, it would substantially decrease the costs and time of experimental work. Hence, the aim of the present study is to compare results from a short experimental design and the usual bioaccumulation study design following OECD.

A laboratory study was carried out in which single *Eisenia fetida* earthworms were exposed to three organic compounds with different physicochemical properties (Log P between 2-4). The study consisted of two parallel experiments named "short" and "long". The short experiment consisted of 7 days of exposure in the uptake phase and 14 days in the elimination phase, whereas the exposure duration of the long experiment in the uptake phase was set to 21 days followed by 14 days elimination phase. The compounds were extracted from soil, porewater, and whole earthworms and quantified by liquid chromatography coupled with mass spectrometer. A one-compartment TK model was fitted to estimate uptake and elimination rate constants and BAF_k were derived. In addition, a suspect screening approach was used to detect possible metabolites and estimate biotransformation rate constants.

Kinetic rate constants and BAF_k values were obtained from the short and long experiments for the same compound and compared between the experimental designs and across the test compounds. We compare the suspected metabolites and the respective enzymatic pathways of the different test compounds. Finally, we will also discuss the feasibility and consequences of decreasing the experimental duration for the reliability of estimates of kinetic rate constants and the respective kinetic bioaccumulation factors.

3.01.P-Th131 Organ-Specific Biotransformation in Salmonids: Insight into Enzyme Kinetics and Micropollutant Clearance

Marco Enrique Franco[1], *René Schönenberger*[1], *Juliane Hollender*[2,3] *and Kristin Schirmer*[1,4,5], *(1)Environmental Toxicology, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Dübendorf, Switzerland, (2)Environmental Chemistry, Environmental Chemistry, Eawag, Swiss Federal Institute of Aquatic Science and Technology, Dübendorf, Switzerland, (3)ETH Zürich, Institute of Biogeochemistry and Pollutant Dynamics, Zürich, Switzerland, (4)Environmental Systems Science, ETH Zürich, Zürich, Switzerland, (5)School of Architecture, Civil and Environmental Engineering, EPFL, Lausanne, Switzerland*

For aquatic animals, like fish, bioaccumulation assessments have largely focused on the biotransformation capacity of the liver, as the organ responsible for a large proportion of the biotransformation activity. However, limited information exists regarding extrahepatic biotransformation and its potential influence in estimating bioaccumulation parameters. To explore the ability of different organs to support biotransformation processes, we isolated S9 subcellular fractions from the liver, intestine, gills, and brain of rainbow trout (*Oncorhynchus mykiss*) and brown trout (*Salmo trutta*), and conducted comparative evaluations of biotransformation enzyme kinetics and intrinsic clearance of two micropollutants: the fungicide azoxystrobin and the pharmaceutical propranolol. In addition, pyrene was included as a well-studied reference chemical. Our observations suggest significant phase I and II constitutive enzyme activity in all organs of both species, particularly for CYP1A and Glutathione-*S*-transferase (GST), respectively. CYP2B and UDP-glucuronosyltransferase (UGT) displayed similar activity magnitude in the liver and the intestine. For rainbow trout in specific, CYP2B displayed the highest activity in the gills. Neither CYP2B nor UGT were detected in the brain. All chemicals tested were biotransformed by liver S9 fractions. However, interspecific differences were observed regarding the ability of different organs to biotransform the compounds. Significant extrahepatic biotransformation was observed for pyrene, mainly in brown trout. However, extrahepatic biotransformation in this species was not significant for the two tested micropollutants. In rainbow trout, both the intestine and the brain appeared to biotransform azoxystrobin. Similarly, propranolol appeared to be biotransformed by the intestine and gills. Altogether, these observations provide evidence that extrahepatic biotransformation may depend on the presence of tissue-specific enzymes and their ability to interact with chemicals. Thus, considering the biotransformation potential of different organs could help in refining the estimation of bioaccumulation parameters during environmental hazard and risk assessments.

3.01.P-Th132 A Comparison of *in vitro* Metabolic Clearance of Various Regulatory Fish Species Using Hepatic S9

Megan Zercher[1], *Diane Nabb*[1], *Jason Coral*[2] *and Karla M. Johanning*[3], *(1)FMC Corporation, Newark, (2)FMC Corporation, (3)KJ SCIENTFIC*

In vitro metabolic clearance rates are used in a combination approach with QSAR modeling and *in vivo* testing with whole organisms for bioaccumulation predictions. However, estimations from QSAR modeling are predicated from databases and suffer from variability of data from inconsistent testing protocols and variations of tested species. OECD 319B is an *in vitro* assay that only covers rainbow trout hepatic clearance. Despite accuracy in whole organisms, fiscal limitations, temporal limitations, and new mandates from the European Union regarding animal welfare are noteworthy drawbacks for *in vivo* testing. Herein, we elucidate the concordance of rainbow trout hepatic S9 fractions to other regulatory species, considering the potential differences in metabolism between warm- and cold-water species. In addition to analyzing the *in vitro* clearance rates of seven chemicals crossing multiple classes of chemistry and modes of action, the S9 exposure methods were refined, generating a more robust and accurate method. The rainbow trout in vitro S9 clearance rates of 4-nonylphenol, amitraz, chlorpyrifos, fenthion, pyrene, and S-indoxacarb are equal or superior to that of other tested species. These results indicate that rainbow trout S9 fractions have the potential to be used as surrogates for multiple piscine species of regulatory concern when predicting BCFs. Further, we show that Carp and Fathead Minnow showed similar metabolism to Rainbow Trout and can be used as warm water species for predicting BCF. This research can be leveraged prior to or in place of initiating a TG305 BCF study to aid in selection of the appropriate regulatory model.

3.01.P-Th133 Use of Primary Rainbow Trout Hepatocytes to Determine *in vitro* Intrinsic Clearance for Bioaccumulation Assessment in Fish

Anett Ullrich[1], *Tanja Krimmling*[1], *Melissa Thiede*[1], *Heike Laue*[2], *Lu Hostettler*[2] *and* ***Dieter Runge***[1], *(1)Primacyt Cell Culture Technology GmbH, Germany, (2)Givaudan Schweiz AG, Switzerland*

In order to improve *in silico* predictions of chemical bioaccumulation in fish, methods are needed to estimate hepatic biotransformation and incorporate this information into established computational models. One promising approach involves the measurement of intrinsic clearance using *in vitro* biotransformation systems derived from liver tissue. The OECD Test Guidelines (TG) 319A and B support this approach and therefore contribute to alternative methods to animal experiments in context of the 3Rs.

Primary Rainbow trout hepatocytes (*Oncorhynchus mykiss*) were isolated from animals kept under controlled environmental conditions and cryopreserved. Cells remained a high viability after thawing over a time frame of at least 2-3 years and kept viabilities above 90 % under shaking conditions (1000 rpm, 14 °C) for metabolism and depletion assays in suspension cultures. The metabolites of three main Cytochrome P450 reactions as well as glucuronidation and sulfation reactions were quantified.

Furthermore, the *in vitro* intrinsic clearance was determined with the reference chemical Pyrene (0.025 µM) using the cells in substrate depletion assays according to the OECD TG
319 A with direct comparison to heat-inactivated hepatocytes as negative control. Incubations were performed with $2*10^6$ viable cells/mL for up to 15 minutes at 11 °C. Pyrene concentration was analyzed by GC-MS with anthracene as internal standard for quantification. The measured *in vitro* intrinsic clearance values ($CL,_{IN\ VITRO},_{int}$ of 2.78-5.41 $mL*h^{-1}*10^6\ cells^{-1}$) were comparable to results from the international ring trial. These $CL,_{IN\ VITRO},_{int}$ can be used to extrapolate to the whole body biotransformation rate to estimate a BCF (bioconcentration factor) using *in vitro* to *in vivo* extrapolation models or as direct inputs in physiologically based toxicokinetic models (PBTK) for fish bioaccumulation assessment.

Primary hepatocytes from Rainbow trout and other fish species, e.g., Atlantic salmon or Common carp, as well as from other species like chicken or duck, are becoming increasingly important *in vitro* models as alternatives to animal testing in the field of environmental toxicology, in particular, for bioaccumulation assessment.

3.01.P-Th134 Kinetics of Uptake and Elimination of Complex Drug Mixture in Zebrafish (*Danio rerio*)
Klaudija Ivanković, *Jelena Dragojević, Ivan Mihaljević, Tvrtko Smital, Marijan Ahel and Senka Terzić, Division of Marine and Environmental Research, Ruder Boskovic Institute, Croatia*
Active pharmaceutical ingredients (APIs) belong to the most frequently detected categories of emerging environmental contaminants in the aquatic environment. However, in contrast to the large number of reports dealing with the occurrence and fate of APIs in abiotic environmental matrices, data on their concentrations in aquatic organisms are still relatively scarce. In this context, it is essential to understand and assess their bioconcentration potential as well as the uptake and elimination kinetics of APIs at realistic conditions, including environmentally relevant concentration levels and simultaneous exposure to complex mixtures of APIs.
In this work, bioconcentration and elimination of 20 different APIs, covering a wide range of therapeutic categories and physicochemical properties, were studied under controlled laboratory conditions using zebrafish (*Danio rerio*) as a model organism. The exposure was performed at a concentration of 10 µg/L of each API in the mixture and involved a 7-day uptake period followed by a 7-day purification period. Samples of fish and water were collected daily and analyzed using a thoroughly validated multiresidue LC/MS methodology for both matrices, which allowed sensitive and accurate determination of APIs and their biotransformation products. To verify the preset exposure concentrations, water samples were processed immediately, while whole fish samples were frozen using liquid nitrogen, cryogrinded, and stored at -80 ˚C until analysis. The results showed that the kinetics of API uptake was relatively fast, reaching a plateau for most of the APIs within 7 days. However, the bioconcentration factors of selected target APIs varied in a rather wide range. The most pronounced bioconcentration was observed for sertraline, oxazepam, and desloratadine with bioconcentration factors (BCF) reaching 55, 22, and 15, respectively. The bioconcentration of APIs was associated with a slight to moderate increase in CYP1A and CYP3A activity in API-exposed fish. The elimination of APIs, after 7 days of exposure was also relatively fast and reached rather low levels (≤ 5% of the maximum) within the first 2-3 days. The exception was azithromycin, caffeine, and desloratadine whose residual concentrations on the 7th day were around 27%, 18%, and 7%, respectively.

3.01.P-Th135 Intrinsic Labelling to Track and Quantify Bioaccumulation and Tissue Distribution of Nanoplastic in Biological System: Case Study of Rainbow Trout
Maya Al-Sid-Cheikh[1], *Joyce Ang*[2], *Gareth T.W. Law Prof*[3], *Theodore Henry*[4], *Steven Rowland*[5], *Marc-Andre Cormie*[6] *and Richard Thompson*[7], *(1)University of Surrey, United Kingdom, (2)Department of Chemistry, University of Helsinki, Finland, (3)Chemistry, University of Helsinki, Finland, (4)Heriot-Watt University, United Kingdom, (5)University of Plymouth, United Kingdom, (6)Earth Science, University of Oxford, United Kingdom, (7)Plymouth University, United Kingdom*
Radiolabelled NP have been successfully used to overcome the significant limitations for quantifying carbon-based contaminants in environmental and biological media and to facilitate work at low limits of detection. For instance, nuclear techniques such as the quantitative whole-body autoradiography (QWBA) offer the possibility for direct visualization of intra-organ radiolabelled-particle concentrations. In the study presented here, we radiolabelled the carbon-backbone of the NP by synthesizing ^{14}C-labeled nanopolystyrene particles (*n*PS, 20 and 250 nm), and then exposed Rainbow trout to these particles, measured the biokinetics and quantified NP tissue distributions via QWBA. The aim of the study was to compare how toxicokinetic and tissue distribution of nanopolystyrene would differ at different dosing and times of exposure. We used environmentally realistic *n*PS concentrations (15 ppb) and concentrations 17 times higher (250 ppb) for low and high dosing, respectively. This allowed us to test the hypothesis that Rainbow trout, a commercially important fish, might uptake, absorb, and depurate NP differently at different dosing and exposure times. Our experiments showed that, even at a concentration of 15 µg L^{-1}, *n*PS accumulated rapidly within the lumen of the digestive tract in fish, but that accumulation in internal tissues including skeletal muscle (i.e., fillets) was minimal. Tissue and faeces toxicokinetics show differences between acute and short-chronic exposures and suggest differences in accumulation and depuration. Once the fish transferred to clean food pellets only, the radioactive particles were depurated relatively rapidly from the fish. The potential for both sizes of *n*PS to transfer in the circulatory system is suggested by their presence (although at minimal levels of detection), revealed on the QWBA, in bones, eyes, skin, kidney. This emphasizes the advantages of using radiolabelling techniques in the study of Contaminants of Emerging Concerns (CEC). The use of radiotracers will help to further the understanding of bioavailability, bioconcentration, bioaccumulation, biotransformation, and biomagnification of organic CEC (e.g., NP, p-phenylenediamine (PPD) additives, Perfluoroalkyl and Polyfluoroalkyl Substances (PFAs), Tributyl tin) in biota. The type of data that this approach produces is critical to inform risk assessments to develop policies surrounding those chemicals.

3.01.P-Th136 Cross-Species Evaluation of Bioaccumulation Thresholds for Air-Breathing Animals
Leslie J. Saunders[1] *and Frank Wania*[2], *(1)Concawe, Brussels, Belgium, (2)Department of Physical and Environmental Sciences, University of Toronto, Canada*
In air-breathing organisms, an organic chemical's susceptibility for elimination via urinary excretion and respiratory exhalation can be judged based on the octanol–water partition ratio (K_{OW}) and the octanol–air partition ratio K_{OA}, respectively. Current regulations specify that chemicals with K_{OW} <10^2 and K_{OA} <10^5 may be screened as nonbioaccumulative in air-breathers. These thresholds are based on model simulations of bioaccumulation in food webs with primarily large warm-blooded, carnivorous mammals as top predators. Their ability to eliminate chemicals may differ greatly from animals with different feeding habits, thermal physiology, or metabolic activity. It therefore remains possible that current K_{OW} and K_{OA} thresholds are not protective of all air-breathing species. Here we used a model-based approach to derive threshold values consistent with a biomagnification factor equal to 1 for 140 different mammals, birds, and reptiles. Animals with lower rates of respiration (e.g., manatees, sloths) and those ingesting a high lipid diet (e.g., polar bears, carnivorous birds) were predicted to be able to biomagnify chemicals with K_{OA} below 10^5. This was also the case for several cold-temperature acclimated reptiles due to lower reported respiration rates and internal temperatures. Protective K_{OA} thresholds for each animal group were determined to be <$10^{4.80}$ (mammals), <$10^{4.70}$ (birds), <$10^{4.75}$ (reptiles at >25°C), and <$10^{3.35}$ (reptiles at ≤25°C). For all animals, urination alone was not efficient to prevent biomagnification of any organic chemical as we found no K_{OW} below which a chemical cannot bioaccumulate in air-breathers. For chemicals with a K_{OW} below 10^1, we found that biomagnification of persistent chemicals was constrained by the water-air partition ratio (K_{WA}) rather than the K_{OA}. Differences in physiology may need to be considered when assessing bioaccumulation in air-breathing species.

3.01.P-Th137 *In vitro* Approach to Refine Bioconcentration and Biotransformation Predictions of Organic Persistent Pollutants Using Cell Lines
Paloma de Oro-Carretero[1] *and Jon Sanz-Landaluze*[2], *(1)Analytical Chem., Complutense University of Madrid, Madrid, Spain, (2)Analytical Chem., University Complutense of Madrid, Madrid, Spain*
Understanding the processes of bioaccumulation and biotransformation in an organism, and the relationship between them is crucial for assessing the toxicity and therefore the regulation of chemical compounds. In recent years, there has been a strong interest in developing efficient and cost-effective tools that use alternative *in vivo*, *in vitro,* and *in silico* assays to predict human health effects, reducing animal testing. The tests with primary hepatocyte (RT-HEP) and S9 fractions (RT-S9) of rainbow trout, with a substrate depletion approach, has been validated (OECD TG 319 A and 319B) to estimate the biotransformation rate and refine BCF predictions using *in vitro*-*in vivo* extrapolation (IVIVE). However, these extrapolations and assumptions (e.g., the free concentration is fully bioavailable to the cell and only for the metabolization process and not considering the bioaccumulation in *in vitro* systems) continues to over- or underestimate BCF values comparing with those obtained by official OCDE 305 bioaccumulation test guide (https://doi.org/10.1002/etc.4791). Therefore, to improve *in silico* predictions, further experimental data is needed to understand all the mechanisms involved in these processes.
The studies presented here are based on the determination of the substrate concentration in the medium and inside the cells, as well as that of its major metabolites to assess the bioavailable concentration and the actual biotransformation rate. These determinations are carried out at different times of the assay in aim to model the behaviour and kinetics of the substrate and its metabolites depletion and formation, respectively. Liver cell lines such as HepG2 (human hepatoma) or ZFL (zebrafish liver) are used in these assays because they allow assessment of cell bioavailable concentration and biotransformation; evaluation in animals other than fish; longer incubations (up to 72 h) that allow evaluation of compounds with slower metabolism rates; as well as their continuous use without the need for animal experimentation.

The results shown focused on PAHs and PBDEs, known persistent organic pollutants (POPs), as well as that of their mayor metabolites (OH-PAHs, OH-BDEs, and MeO-BDEs), contribute to the improvement of IVIVE models to reduce animal suffering trials and to a better understanding of the metabolic pathways and toxicity of POPs.

3.01.P-Th138 Relationship Between the BMF and BCF
Frank Gobas[1], *Nicole Berg*[1], *Aaron Redman*[2] *and Thomas Parkerton*[3], *(1)Resource & Environmental Management, Simon Fraser University, Canada, (2)ExxonMobil Biomedical Sciences, Inc., (3)EnviSci Consulting*
The Bioconcentration Factor (BCF) has played a key role in identifying the bioaccumulation potential of organic substances in aquatic organisms. However, the BCF has some key limitations, including its onerous and difficult measurement in laboratory tests (especially for very hydrophobic substances); limited domain of applicability (i.e., water breathing organisms only); and lack of thermodynamically or biologically relevant criteria values that can be used to determine if a substance is truly bioaccumulative. These limitations have become more apparent with the increasing variety of chemicals that are being assessed today and cause both over and underestimations of the bioaccumulation potential of chemical substances that are best avoided. It has been proposed that the biomagnification factor (BMF) is a more generally applicable metric (i.e. applies to water and air-breathing organisms) with thermodynamically and biologically relevant criteria values, that can be measured in laboratory based tests that are simpler than BCF tests and can also be derived from field data. One of the key questions for using the BMF in bioaccumulation assessments is how the BMF compares to the BCF and what this means for bioaccumulation assessment. To address this question, we compiled data from 252 dietary and 350 aqueous bioaccumulation studies in fish for a wide range of substances in fish to (i) investigate the relationship between the BCF and the BMF for the same substance in the same fish species; and (ii) to investigate methods for deriving the BCF from the results of dietary bioaccumulation tests. The results of this

analysis show that BCFs in fish can be derived from BMFs in fish with good precision, but that simple empirical correlations between the BCF and BMF are of limited use for bioaccumulation assessment.

3.01.P-Th139 A Food Web Bioaccumulation Model for Quantifying the Dietary Exposure to Persistent Organic Pollutants of Beluga Whales from the St. Lawrence Estuary, Quebec, Canada

Jenny Oh[1], *Leslie J Saunders*[2], *James M Armitage*[2,3] *and Frank Wania*[1,2], *(1)Department of Chemistry, University of Toronto, Canada, (2)Department of Physical and Environmental Sciences, University of Toronto, Canada, (3)AES Armitage Environmental Sciences, Inc, Canada*

The elevated levels of persistent organic pollutants (POPs) in beluga whales (*Delphinapterus leucas*) of the St. Lawrence Estuary (SLE), classified as an endangered species, may be linked to their current population stagnation, despite many recovery efforts. However, a quantitative assessment of the bioaccumulation of POPs in the aquatic food web leading up to the SLE beluga whales has not yet been done. Therefore, further understanding the diet of the SLE belugas and modeling the bioaccumulation of contaminants through their food web may help shed light on the pathways of dietary exposure of these whales. Here, we construct a food web with feeding relationships and diet compositions of male and female SLE beluga whales using previously reported stomach contents data and staple isotopic ratio measurements (i.e., $\delta^{13}C$, $\delta^{15}N$) in beluga muscle tissue. Eleven potential prey species of the belugas were identified, whose feeding relationships, diet composition, and trophic position were estimated from the diets reported for each species in the literature. Using these feeding preference matrices of the aquatic food web and organism-specific characteristics collected from the literature, we parameterized a previously published food web model, which utilises a mass balance approach to calculate steady-state concentrations of lipophilic chemicals in each of the organisms. The final assembled food web model includes phytoplankton, zooplankton (copepods and krill), seven invertebrate species, nine fish species, and different age classes and sexes of beluga whales (adult and juvenile male, adult and juvenile female, infants). We applied the model to quantify the bioaccumulation of polychlorinated biphenyls and perfluoroalkyl sulfonamides in the food web of the SLE belugas. We also compare the predicted results with measured concentrations of these compounds in the whales and other aquatic species of the SLE to evaluate model performance.

3.01.P-Th140 Using *in silico* Bioaccumulation Models: Review and Comparison of the EPI Suite BCFBAF and EAS-E Suite BET

Liisa Toose, M.Sc.[1], *Jon A. Arnot*[1], *Alessandro Sangion*[1] *and James M Armitage*[2], *(1)Arnot Research and Consulting Inc. (ARC), Canada, (2)AES Armitage Environmental Sciences, Inc, Canada*

Bioaccumulation (B) assessments using various methods, data, metrics, and classification criteria are routinely conducted as a part of chemical regulatory programs. Various screening-level tools are available that incorporate measured and estimated B metrics. The BCFBAF module in EPI Suite v4.11 has two models, BCFWIN fragment-based approach and the 2003 Arnot & Gobas bioconcentration (BCF) and field bioaccumulation factors (BAFs) model. The Bioaccumulation Estimation Tool (BET) is a screening-level mechanistic modelling system integrated in the Exposure And Safety Estimation (EAS-E) Suite platform. The BET is based on mass balance bioaccumulation models in the BAT ver.2.0 including representative food webs (aquatic and terrestrial) and ecological receptors (plants, invertebrates, fish, birds, and mammals). Typical lab test animals are also included, i.e., fish and rat. B-metrics including BCF, BAF and Biomagnification Factor (BMF) for both neutral and ionogenic chemicals, such as PFAS can be predicted for all organisms.

A bioaccumulation database of field and laboratory B metrics has been collected and reviewed. Over 400 organic neutral and ionogenic chemicals spanning partitioning space and biotransformation half-lives have been included. The physical chemical properties were obtained from within each modelling system.

The models give similar preliminary predictions of logBCF, though using differing approaches. Expanding the database to include all the BCFBAF training set chemicals will give further insight into the predictive ability of the BET. The BET predicts slightly higher logBAFs up to a value of 5 or 6 and lower values above that, though still well above any threshold values. BET captures decreased bioaccumulation of IOCs.

Preliminary analysis shows that Aquatic BMFs are predicted with slight positive bias (0.88) and low RMSE (10.16). We hope to present analysis of terrestrial BMFs predicted by the model as well.

We compared a regression-based model with a mechanistic model and achieved similar results. Extending B-assessments to include BMFs from both aquatic and air-breathing organisms is useful for identifying hazards of a wider variety of chemicals. *In silico* tools such as the EAS-E Suite BET can be utilized to guide these assessments with confidence.

3.01.P-Th141 Localising Organic Contaminants and their Biotransformation Products in Whole Body Cross-Sections of Aquatic Invertebrates Using Two Mass Spectrometry Imaging (MSI) Techniques

Johannes Raths[1], *Fernanda Endringer Pinto*[2], *Christian Janfelt*[2] *and Juliane Hollender*[3], *(1)Environmental Chemistry, Eawag, Swiss Federal Institute of Aquatic Science and Technology, Dübendorf, Switzerland, (2)Department of Pharmacy, University of Copenhagen, Copenhagen, Denmark, (3)Environmental Chemistry, Environmental Chemistry, Eawag, Swiss Federal Institute of Aquatic Science and Technology, Dübendorf, Switzerland*

Elucidation of spatial and organ specific distribution of drugs in an organism by mass spectrometry imaging (MSI) is an intensively applied method in medical sciences. A transfer of this method toward environmental chemistry would allow the

localisation and discrimination between parent contaminants and their biotransformation products (BTPs) in nontarget organisms, such as the aquatic amphipod species *Gammarus pulex*. Further, MSI allows the analysis of multiple compounds within the same sample. The present study aimed to assess the spatial distribution of organic contaminants and their BTPs in the tissue *G. pulex* by applying different MSI and dissection methods, complemented by online solid phase extraction coupled with liquid chromatography and high resolution tandem mass spectrometry (online SPE-LC-HRMS/MS).
Specimens of *G. pulex* were exposed in water containing a mixture of pesticides (cyprodinil, fluopyram, terbutryn) and pharmaceuticals (carbamazepine, citalopram, diclofenac). Whole body cryosections (16 µm thickness) were analysed by matrix-assisted laser desorption ionisation (MALDI-) MSI or by desorption electrospray ionization (DESI-) MSI. Additionally, extracts from dissected and nondissected gammarids were analysed online SPE-LC-HRMS/MS to confirm the internal concentrations of different compartments.

The whole body internal concentrations determined by LC-HRMS/MS ranged from 2.5 µg/g (citalopram) to 14 µg/g (cyprodinil). Five of the six compounds (except diclofenac) could be detected using DESI-MSI whereas only three (citalopram, cyprodinil, terbutryn) could be detected using MALDI-MSI. The parent compounds generally followed a rather uniform distribution in the amphipod tissue, indicating a passive diffusion driven bioaccumulation. Several BTPs of terbutryn and cyprodinil were detected in the gastrointestinal system of the cross-sections analysed by MALDI-MSI. The observation was supported by the LC-HRMS/MS analysis of dissected specimens. This revealed the intestine to be the main biotransformation site in gammarids.

The present study demonstrates the suitability of MSI for investigations on the spatial distribution of organic contaminants and biotransformation sites in *G. pulex*. However, both applied methods required relatively high tissue concentrations and DESI-MSI appeared to be the more sensitive method. Further improvements would be needed to address environmental concentrations.

3.01.P-Th142 Determination of Engineered Nanomaterial Bioavailability in Amphipods Using Haemolymph Isolation and Single Particle ICP-MS

Sebastian Kuehr*, Li Xie and Anastasia Georgantzopoulou, Norwegian Institute for Water Research (NIVA), Norway*

Currently, tiered approaches using invertebrates are discussed to avoid animal tests for regulatory bioaccumulation assessement such as the fish bioaccumulation tests (OECD TG 305). The *Hyalella azteca* bioaccumulation test (HYBIT) has been succesfully used in a series of bioaccumulation studies with engineered nanomaterials (ENMs). However, due to the small size of the amphipod, it is not possible to distinguish the ENMs in the intestinal content from the real incorporated, bioavailable fraction (ENM in the tissue or body fluids). Even if a concept for a tiered assessment scheme based on ENM-HYBIT that takes this ambiguity into account with adjusted endpoints exists, further data on the bioavailability of the tested ENMs are of high value. However, imaging techniques for the localization of tissue-incorporated ENMs require sophisticated time- or cost-intensive analytical methods or very high exposure and body burden concentrations (e.g., correlative microscopy or micro X-ray fluorescence imaging).
Within this study, a microcapillary based simple method that can be used in any laboratory was developed isolating the haemolymph of exposed amphipods. *H. azteca* was exposed to AgENMs and $AgNO_3$ (ionic comparison group). After exposure, the haemolymph from 20 animals per replicate was collected, pooled, diluted, and analyzed for the presence of AgENMs using single particle Inductively Coupled Plasma-Mass Spectrometry (spICP-MS). By this, we were able to measure AgENMs in the haemolymph, despite the small sample volume. The measured AgENMs showed a strong comparability in size to the particles measured in the exposure medium. Ag in particulate form was also found in the haemolymph from the $AgNO_3$ treatment, but these were a different size and their size distribution was more heterogeneous. This indicates the formation of secondary particles, as has already been described for other species after $AgNO_3$ exposure.

The results show that the method developed is suitable for assessing the bioavailability and tissue translocation of ENMs. Secondary particles (particles generated by precipitation of Ag in the medium or in the organism) as well as pseudoparticles can be identified by comparison with spICP-MS measurements of the exposure media. This approach provides valuable insight that can support data interpretation from the ENM-HYBIT to provide a higher degree of certainty for the assessments.

3.01.P-Th143 Mobilization of POPs in Humpback Whales from Feeding Areas Around the Antarctic Peninsula and Strait of Magellan and Migration, Breeding, and Calving Grounds on the Brazilian Coast

Josilene da Silva*, Satie Taniguchi, Marcia Caruso Bícego, Rosalinda Carmela Montone and Rafael Andre Lourenço, Oceanography, University of São Paulo (USP), Brazil*

The Southern Hemisphere humpback whales (*Megaptera novaeangliae*) face the longest migration distances and fasting periods that reflect the composition of the lipophilic contaminants to which they are exposed. To evaluate these changes, persistent organic pollutants (POPs) were determined in blubber samples of humpback whales around the Antarctic Peninsula (n=46), in the Strait of Magellan, Chile (n =22), and off the Brazilian coast (n = 38). The similarity in the PCB and HCB contents in the individuals from feeding (Stock G) and breeding (Stock A) grounds indicates that they may have been contaminated while feeding in higher latitudes. In the whales around the Antarctic Peninsula, the predominance of tetrachlorobiphenyl PCBs with a marked presence of di- and tri-biphenyl congeners was evident. The whales that feed in the Strait of Magellan showed a slight predominance of 5Cl biphenyls as a consequence of their feeding on subantarctic krill species but also on small fishes and galatheid crabs that could be contaminated by industrial activities in Chile. The dominance of 5-6Cl congeners in the whales of Stock A in Brazil and the lack of 3-4Cl congeners is probably related to the extreme physiological changes during fasting when whales mobilize blubber reserves and metabolize lighter congeners or by transferring them to their calves, even though they can feed opportunistically along migratory routes.

3.01.P-Th144 Mercury and Selenium Concentrations, and Selenium:Mercury Molar Ratios in Embryos of Three Placental Viviparous Shark Species (Carcharhinus leucas**, *Carcharhinus limbatus*, and *Carcharhinus plumbeus*)**

Jessica Dutton[1]*, Bethany M Deacy*[2] *and Brian P Jackson*[3]*, (1)Biology, Texas State University, (2)Riverside Technology, Inc., National Marine Fisheries Service, Southeast Fisheries Science Center, Panama City, (3)Earth Sciences, Dartmouth College, Hanover*

Embryos from placental viviparous shark species accumulate high concentrations of mercury (Hg) due to maternal transfer; however, the resulting impacts on embryonic development are not known. It has been argued that selenium (Se), an essential trace element, has a protective effect against Hg toxicity if the Se:Hg molar ratio is >1:1; therefore, sharks may be protected against the adverse health effects of Hg exposure during embryonic development if Se is in molar excess of Hg. The goal of this study was to 1) investigate the inter- and intraspecies variability in Hg and Se concentrations, and Se:Hg molar ratios in muscle, heart, brain, liver, and kidney of bull shark (*Carcharhinus leucas*), blacktip shark (*Carcharhinus limbatus*), and sandbar shark (*Carcharhinus plumbeus*) embryos, and 2) compare the Hg and Se concentrations, and Se:Hg molar ratios in muscle and liver of each embryo to the values for their corresponding parent. Mercury concentrations were measured using a Direct Mercury Analyzer and Se concentrations were determined using microwave acid digestion and ICP-MS analysis. Three pregnant bull sharks (n = 16 embryos), four pregnant blacktip sharks (n = 20 embryos), and four pregnant sandbar sharks (n = 37 embryos) were included in this study. For all species, the mean ranking of embryo Hg tissue concentrations was muscle > heart > kidney > brain > liver. Bull shark embryos had the greatest mean muscle, heart, brain, and liver Hg concentrations, whereas blacktip shark embryos had the greatest mean liver Hg concentration. There was no clear tissue ranking in Se concentrations; however, the mean concentration was greatest in the kidney in all species. Among species, mean embryonic muscle and liver Hg concentrations were between 10.6% to 21.8% and 0.33% to 0.68% of the parent's mean muscle and liver concentration, respectively, whereas Se was between 206% to 404% and 46.6% to 114%, respectively. For all species, the mean embryonic Se:Hg molar ratio ranking was liver (167-613:1) > kidney > brain > muscle > heart (28-72:1). Sandbar shark embryos had the greatest mean liver, heart, brain, and kidney Se:Hg molar ratios, and lowest muscle Se:Hg molar ratio. In comparison, mean muscle and liver Se:Hg molar ratios were just above 1:1 in parental tissues of each species. The high Se:Hg molar ratios indicate that Se may have a protective effect against Hg toxicity during embryonic development, reducing the adverse effects of Hg on growth and development.

3.01.P-Th145 Integrated Assessment and Testing Strategy for Bioaccumulation Assessment Under REACH: New Pathways to Weight-of-Evidence

Anu Kapanen[1]*, Doris Hirmann*[1]*, Jane Caley*[1]*, Christian Schlechtriem*[2]*, Eric Verbruggen*[3]*, Gabriele Treu*[4] *and Juliane Ackermann*[4]*, (1)European Chemicals Agency (ECHA), Helsinki, Finland, (2)Bioaccumulation & Animal Metabolism, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany, (3)National Institute for Public Health and the Environment (RIVM), Netherlands, (4)German Environment Agency (UBA), Dessau-Rosslau, Germany*

With the update of the ECHA PBT guidance in 2023, the integrated assessment and testing strategy for bioaccumulation assessment was revised to take account of the technological and scientific progress in recent years. A number of New Approach Methods (NAMs) were developed as alternatives to the fish BCF test (OECD TG 305). In the future, the freshwater amphipod *Hyalella azteca* bioconcentration test (HYBIT) should be considered, where possible, to avoid vertebrate testing. Hyalella BCF values can be compared against the REACH Annex XIII criteria for bioaccumulation, i.e., bioaccumulative ('B') and very bioaccumulative ('vB'). The result can furthermore be used to conclude on 'not B' or 'not vB'. If it cannot be excluded that due to the lower lipid content of the amphipods the bioaccumulation potential of a substance may be underestimated compared to fish, further information is needed. For highly hydrophobic substances, the dietary exposure bioaccumulation fish test (OECD TG 305) has been suggested. The ECHA PBT guidance recommends that the elimination rate constants derived from fish feeding studies should be used to estimate aquatic BCF using the methods described in Annex 8 of OECD TG 305 and its related Guidance Document. Furthermore, lipid correction for the biomagnification endpoint is discussed. Growth correction is supported and further explained. It is noted that high molecular weight is no longer accepted as an indicator for hindered uptake. Biomagnification and corresponding elimination half-life are the key endpoints for bioaccumulation assessment of terrestrial and air-breathing organisms. According to the ECHA PBT guidance document, the use of mammalian *in vitro* tests for the estimation of biotransformation rates is a promising pathway to be developed further to support bioaccumulation assessment with air-breathing organisms. Moreover, the PBT guidance document gives advice on the interpretation of elimination half-lives derived from toxicokinetic studies according to OECD TG 417 and human biomonitoring studies. In addition to that, the revised guidance document includes also more detailed guidance on the use of field and biomonitoring data, assessment of ionisable substances and surfactants. The poster gives an overview of the new pathways to weight-of-evidence covered by the updated ECHA PBT guidance document with respect to bioaccumulation assessment.

3.01.P-Th146 Integrated Strategy for the Assessment of Aquatic and Terrestrial Bioaccumulation

Christian Schlechtriem[1]*, Verena Kosfeld*[2]*, Monika Nendza*[3]*, Daniel Frein*[4] *and Caren Rauert*[4]*, (1)Bioaccumulation & Animal Metabolism, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany, (2)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany, (3)Analytisches Laboratorium, Germany, (4)German Environment Agency (UBA), Germany*

A concept for an intelligent crosscutting assessment strategy for bioaccumulation in the context of the prospective assessment of substance regulations (chemicals, plant protection products, biocides, and pharmaceuticals) incorporating the findings from previous projects of the UBA, the ECHA, and other institutions is presented. The strategy permits the protection of the environment at an early stage against accumulating substances, especially against accumulation in the food chain and with regard to the risk of secondary poisoning. Hazard-based and risk-based assessment approaches are considered. A more efficient and accurate identification of bioaccumulative substances will permit an improved identification of substances with PBT and/or vPvB properties. In addition, the strategy will help to advance alternative methods to the existing tests with vertebrates (e.g. OECD 305) and to integrate them into the assessment, including the investigation of their uncertainties. Such alternative testing and assessment methods are required and can be useful in several regards: They are meant to minimise the use of animal testing, can enable improved informative value for extrapolation to ecosystems and transferability to species other than those tested. This will result in more reliable estimates based on less data and indicate for which substances or groups of substances further studies are required for a robust assessment. The further development of existing screening models, such as IVIVE (*in vitro* to *in vivo* extrapolation), PBTK (Physiologically Based Toxicokinetic), and mass balance models that are used for the estimation of bioaccumulation in fish and terrestrial vertebrates, is required in order to identify bioaccumulative substances early and reliably. As part of a UBA funded project the application of the screening models and alternative methods are currently critically assessed in order to enable their future use as part of the regulatory bioaccumulation assessment of substances. The limitations of the various screening models (e.g., applicability domain for specific substance properties) and alternative test methods are to be identified.

3.01.P-Th147 Consolidation of Log Kow Estimates by Consensus Modelling

***Monika Nendza**[1], Verena Kosfeld[2] and Christian Schlechtriem[3], (1)Analytisches Laboratorium, Germany, (2)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany, (3)Bioaccumulation & Animal Metabolism, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany*

The octanol/water partition coefficient log *K*ow is a key parameter for assessing the environmental fate and effects of chemicals. The log *K*ow may be determined experimentally; more often it is calculated. Different methods can sometimes perform better and sometimes worse for different target chemicals, and none of them is consistently superior. Variability may be caused by differences in the applicability domain related to, for example, training set coverage and descriptor relevance. Correct representation of chemical structures needs to consider ionisation, tautomerism, etc.

Comparison of results from different *in silico* methods for log *K*ow estimation and valid experimental data, e.g., Chemistry Dashboard (US EPA, 2022) including EPI Suite and OPERA, ECHA registered substances (ECHA, 2022), ChemSpider featuring ACD/Labs and ChemAxon (Royal Society of Chemistry, 2022), T.E.S.T. (US EPA, 2020), ChemProp providing Consensus, ReadAcross and LSER models (UFZ Department of Ecological Chemistry, 2022), LSERD (Helmholtz Centre for Environmental Research-UFZ, 2017), OCHEM (eADMET, 2022), indicate the need to consolidate variable, possibly conflicting, results.

Calculations of multiple log *K*ow for test chemicals including classical POPs, PCB, PAH, siloxanes, flame retardants, PFAS, pesticides, pharmaceuticals, fragances, biocides, surfactants, UV-filter, plasticizer, antioxidants, phenols, parabens, etc. were analysed to recommend complementary estimation methods. The output is a set of multiple independent methods for log *K*ow estimations, including guidance on how to use the methods. Consensus modelling, i.e., the mean of multiple log *K*ow values, including valid experimental data and estimates calculated independently by different methods, such as group contribution, fragmental, atomic values, topological descriptors, or LSER (linear solvation energy relationships), is generally expected to provide the most reliable log *K*ow predictions. The benefits of the suggested approach are consolidated log *K*ow that are robust and scientifically credible, reliable, and reproducible, as well as cost efficient.

3.01.P-Th148 The Use of *in vivo* and *in silico* Methods for the Bioaccumulation Assessment of Hydrophobic Organic Compounds

***Goksu Celik**[1], Stefan Stolte[2] and Marta Markiewicz[2], (1)Institute of Water Chemistry, Technical University Dresden, Dresden, Germany, (2)Institute of Water Chemistry, Technical University Dresden, Germany*

Heterocyclic polyaromatic hydrocarbons substituted with nitrogen, oxygen, and sulfur heteroatoms are likely to pose a major threat to aquatic life based on the indications of persistence and bioaccumulation from screening-level hazard evaluation using *in silico* approaches. Although heterocyclic PAHs are theoretically likely to enter aquatic food web (given the emissions and physicochemical characteristics of these chemicals) and accumulate in higher trophic levels, few laboratory data are available to draw concrete conclusions about bioaccumulation of this chemical class. There are also challenges in testing such hydrophobic and poorly water-soluble chemicals with the current methods, i.e., limitations arise from loss of compounds during testing as well as the lack of standard testing protocols with ethically more acceptable animal alternatives, e.g., crustaceans like *Daphnia magna*. Therefore, we studied the bioaccumulation of several heterocyclic PAHs with *Daphnia magna* using passive dosing method for maintaining a controlled and defined exposure concentration for chemical uptake. We argue that measuring bioaccumulation in daphnids is ethically more acceptable and easier to perform, especially for so-called “difficult compounds”. We also generated data that can be used as proxies of hydrophobicity – octanol-water (log K_{OW}) and membrane lipid-water (log $K_{lip/w}$) partition coefficients – which are predictors of bioaccumulation potential. Subsequently, we correlated the bioaccumulation factor (BAF) with log $K_{OW}$and log $K_{lip/w}$ to build Quantitative Structure-Activity Relationship (QSAR)models to predict the bioaccumulation potential of heterocyclic PAHs in *Daphnia magna*. Lastly, the relevance of using $K_{lip/w}$ over log K_{OW} for estimating bioaccumulation/bioconcentration of heterocyclic PAHs was discussed.

3.01.P-Th149 Effects of Dietary Selenium on the Freshwater Amphipod, Hyalella azteca

*David Harper, John Besser, Rebecca Dorman, Danielle Cleveland and **Aida Farag**, U.S. Geological Survey*

Fish are the most sensitive group of aquatic organisms to chronic toxic effects of selenium (Se), based on reproduction and early life stages of numerous fish species. The US Environmental Protection Agency (USEPA 2016) concluded that Chronic Se toxicity data available for freshwater invertebrates indicate that invertebrates are less sensitive to chronic Se toxicity than fish, but the number of suitable toxicity studies with invertebrates was limited (3 species), and not all these studies included reproductive endpoints. USEPA was interested in development of additional invertebrate toxicity data to confirm that invertebrates are protected by the selenium criterion. We conducted a 28 day feeding study to compare the sensitivity of *Hyalella Azteca* and *Chironimus dilutes*, which indicated that H. Azteca were more sensitive. A 42 day chronic feeding study further evaluated the toxicity of Se to the amphipod *H. azteca*. *Hyalella* were fed a combination of selenized yeast and diatoms. Endpoints for the exposures were survival, reproductive success, and Se tissue concentrations. Chro c 42-day exposures with *H. azteca* produced an EC_{20} for growth and biomass of 22 ug/g. Effect on reproduction were found as low as 3 μg/g, but these results are preliminary and data are being studied further because the novel approach resulted in less control reproduction than is standard.

3.01.P-Th150 Lipid Normalisation in the OECD 305 Dietary Test

*Michael Crookes[1], Claire Gibson[1], Steph Jones[2], **Emma Jack**[3] and Pippa Kate Curtis-Jackson[4], (1)Vitis Regulatory Ltd, United Kingdom, (2)Chemicals Assessment Unit, Environment Agency (England), Bristol, United Kingdom, (3)Ecotoxicology, Vitis Regulatory, Belgium, (4)Environment Agency (England and Wales), United Kingdom*

One of the main environmental priorities under the UK and EU REACH Regulations is the assessment and identification of persistent, bioaccumulative and toxic (PBT) or very persistent and very bioaccumulative (vPvB) substances. A key test method used to investigate bioaccumulation is the OECD 305 Test Guideline (Bioaccumulation in Fish: Aqueous and Dietary Exposure). This test guideline was updated in 2012 to include dietary exposure. To support the update to the test guideline, the OECD together with three lead countries (UK, Germany and the Netherlands) prepared guidance on specific aspects of the dietary accumulation test. This guidance was published by the OECD in July 2017; amongst other aspects, it recommends performing lipid normalisation of the dietary biomagnification factor (BMF) to both the lipid content of the fish and the lipid content of the food for the interpretation of results.

During the latter stages of development of the guidance in 2017, the Chemicals Evaluation and Research Institute, Japan (CERI) presented new research of the effect of different spiked foods in the dietary test. CERI suggested that the dietary BMF should only be standardised for the fish lipid content, not the food lipid content. CERI also suggested that the BMF should be standardised to 5% fish lipid content. The work by CERI is acknowledged in the published OECD guidance, but further analysis of the research in relation to other experimental and theoretical evidence was warranted.

We have reviewed the available experimental and theoretical evidence for lipid normalisation in the dietary accumulation test and this suggests strongly that the growth-corrected and lipid-normalised kinetic BMF value (BMF_{kgL}, as defined in the OECD 305 Test Guideline) varies depending on the lipid content of the diet/food used. This can be explained by examining both the differences in the fugacity capacity between the diets of different lipid contents, and differences in the apparent feeding rate, when expressed on a lipid basis. As a result, the lipid normalisation method currently recommended in the OECD 305 test guidance will lead to differences in the growth-corrected and lipid-normalised kinetic BMF obtained when different diets are used. We present recommendations for how the results of dietary accumulation results are best interpreted, with the aim of informing a future update to the OECD guidance document for the OECD 305 test guideline.

3.01.P-Th151 Lateral Transport of Pharmaceuticals and Endocrine Disruptors in Riparian Zone Through Food Webs

***Marina Veseli**[1], Iva Kokotović[2], Marko Rozman[3], Andreja Brigić[1], Mira Petrovic[4] and Ana Previsic[1], (1)University of Zagreb, Faculty of Science, Department of Biology, Croatia, (2)Department of Biology, University of Zagreb, Croatia, (3)Ruder Boskovic Institute, Croatia, (4)Catalan Institute for Water Research (ICRA), Spain*

Sewage pollution causes the presence of pharmaceuticals (PhAC) and endocrine disrupting compounds (EDCs) in freshwaters worldwide. Like many other emerging contaminants (ECs), PhACs and EDCs can be bioaccumulated in various aquatic organisms. Emergence of aquatic insects connects aquatic and terrestrial food webs in riparian zones causing transfer of pollutants from aquatic to terrestrial food webs. Data on such contaminant flux are very scarce for PhACs and EDCs; for instance, lateral transport through food webs in the riparian zone is still unexplored. With the aim of exploring how food web linkages impact transfer from aquatic to terrestrial ecosystem of PhACs and EDCs we conducted an *in situ* study at a river stretch impacted by the WWTP effluents. More specifically, to study transport of the ECs laterally into the riparian zone, sampling sites on one riverbank were split into three transects – aquatic and two in riparian zone (0-1 m and 1-3 m distance from the waterline, respectively). Sampling involved invertebrates belonging to various levels of food webs, as well as soil, water, biofilm and macrophytes samples. All samples were screened for 123 compounds using ultra-performance liquid chromatography (UPLC) system coupled to a quadrupole time-of-flight mass spectrometer. First results show that 65% of ECs were detected across all samples; however, presence and concentrations of individual compounds vary among sample types. For instance, bisphenol-A (BPA), a chemical widely used in plastics manufacturing, was present in majority of sample types; however, in low concentrations (e.g., up to 0.4 ng/g dry weight in biofilm, up to 1.64 and 2.96 ng/g dry weight in soil and macrophytes, respectively). Furthermore, BPA concentrations in riparian spiders declined with distance from the waterline in the riparian zone, highlighting the importance of trophic transfer of waterborne pollutants into terrestrial habitats, as emerging aquatic insects are known to represent the major food source of riparian spiders. Through providing new insights on food web flux and related lateral extent of the subsidy in the riparian zone, this study will contribute to understanding of the cross-ecosystem flux of PhACs and EDCs.

3.01.P-Th152 Quantitative Weight-of-Evidence Approach for Bioaccumulation Assessment of Volatile Methylsiloxanes in Aquatic and Terrestrial Species Using the Bioaccumulation Assessment Tool

Jaeshin Kim[1]*, Debra McNett*[1]*, Sami Belkhiria*[2] *and Kathleen Plotzke*[1]*, (1)Dow Chemical Company, Midland, (2)Dow Silicones Belgium srl, Belgium*

Bioaccumulation of a chemical is predicted or assessed using different metrics such as bioconcentration factor (BCF), bioaccumulation factor (BAF), biomagnification factor (BMF), and trophic magnification factor (TMF). The metrics have different criteria for bioaccumulation according to the design of the endpoint. It is not uncommon to obtain conflicting results using the different metrics. We have previously reported an evaluation of the bioaccumulation potential for cyclic and linear volatile methylsiloxanes (VMS: D4, D5, D6, L2, L3, L4, and L5) in aquatic and terrestrial species using the Bioaccumulation Assessment Tool (BAT, ver2.02) that facilitates the evaluation of multiple kinds of bioaccumulation data in a quantitative weight-of-evidence (QWoE) approach. The model assesses bioaccumulation potential with consideration of the relevance and reliability of each available data point. VMS are used as chemical intermediates and some can be found as ingredients in consumer products. As a result, their environmental concentrations are in a wide range in different media including biota, surface water, air, and sediment. Thus, there have been multiple laboratory- and field-based data available such as BCF, BMF and TMFs which as previously reported, were utilized in the tool along with QSAR predicted biotransformation rates and BCFs from the EAS-E Suite (QSARINS, IFS, and OPERA) and the EPA CompTox Chemicals Dashboard. We have now incorporated additional terrestrial data for rats utilizing available pharmacokinetic (PK) and adsorption, distribution, metabolism, elimination (ADME) studies with VMS to assess bioaccumulation potential. The metabolism and elimination rates were determined from these PK/ADME studies and BMF values were calculated utilizing the IVIVE-B model (Lee et al. 2017). BMF values in rats indicated no bioaccumulation for VMS due to relatively fast removal via metabolism and elimination through expired air. When these data were incorporated into BAT, the QWoE conclusion is that dietary uptake of VMS cannot result in bioaccumulation of VMS in both aquatic and terrestrial species.

3.01.V Advances in Bioaccumulation Science and Assessment

3.01.V-01 Bioaccumulation Factor Relationship Analysis with Heavy Metal Concentrations in River Sediments and Dominant Benthic Macroinvertebrates

Kiyun Park[1]*, Cheol Hong*[2]*, Ji-hoon Kim*[3]*, Won-Seok Kim*[3] *and Ihn-Sil Kwak*[3]*, (1)Fisheries Science Institute, Chonnam National University, Yeosu, Korea, Republic of (South), (2)Chonnam National University, Yeosu, Korea, Republic of (South), (3)Department of Ocean Integrated Science, Chonnam National University, Yeosu, Korea, Republic of (South)*

Environmental contaminants have been continuously sink in the aquatic sediments, having detrimental impacts on life of the resident biota, finally disturbed aquatic ecosystems. Heavy metals, one of environmental pollutions from growing population and urbanization, are natural and anthropogenic occurring elements. In the study, we investigated heavy metal distributions in sediments and benthic macroinvertebrate communities to compare heavy metal bioaccumulation by potential contamination sites. To do this, heavy metal concentrations in the body and trace metal concentrations in the sediments of the dominant species at each site were analyzed using an inductively coupled plasma mass spectrometer, and mercury was measured using an atomic absorption spectrometer. As a result of evaluating the degree of heavy metal contamination based on the contamination load index and the geochemical enrichment coefficient, it was found that the lower part of the Suyeong River had the most heavy metal contamination, and in particular, the accumulation of mercury was the most severe. Among the 15 sites, 11 sites satisfied the biomass (Decapod 4 sites, Gastropod 5 sites, Insect class 1 sites, Hairy class 1 sites), the species with the highest concentration of heavy metals in the body was *Chironomus* sp. collected from the main stream of the Yeongsan River. Among the heavy metals, the most frequent accumulations in benthic macroinvertebrates were copper (8 sites) and mercury (8 sites). The copper and arsenic enrichment coefficients showed opposite trends to those representing the health of benthic macroinvertebrate communities. These results suggest that it is necessary to comprehensively assess the degree of contamination of the sediment itself, the degree of accumulation in the organism, and the stability of the community to manage heavy metal pollution in the river ecosystem.

3.02 Advances in Exposure Modelling Toward Data-Driven Decision-Making

3.02.T-01 Plastics in the Environment Using Mass Flow Analysis, Including Degradation, Accumulation, and Environmental Dispersion

Anna Schwarz*, Sietske Lensen, Jan Harm Urbanus, Luke Parker and Eline Langeveld, TNO, Netherlands*

Plastics are rapidly accumulating in the environment. To assess mitigation strategies, insight in sources and fate of plastics has to be obtained. Plastic products are used and lost among all sectors, in numerous applications, during multiple uses and along different lifetimes. To assess the complex value chain of plastics, a Mass Flow Analysis (MFA) can be used to track plastics in the economy but also to explore losses to the environment. Except for yearly losses, also degradation of plastics in the environment and dispersion of the plastics in the environment are important to assess the plastics' impacts and risks. In this study, a yearly MFA approach was developed for plastics to assess yearly losses of plastics to the environment. The MFA is extended to an Accumulation and Dispersion model (ADM) to simulate global accumulation of plastics in the environment until 2050. Additionally, environmental parameters were developed to assess fate and dispersion in the environment with higher accuracy. The basis of the yearly MFA is based on existing literature and includes potential losses from the full life cycle of the plastic product. Product lifetimes were included in the model to correct for stocks for specific sectors. In both the MFA and ADM, eight polymer types, seven sectors, 12 environment types, two plastic size classes, and 190 countries were distinguished. The yearly MFA gives interesting insights among multiple dimensions. For microplastics, rubber microplastics from car tyres contribute over 60% of total microplastics lost. Most macroplastics in the environment originate from the packaging sector. According to the ADM, most of the macro- and microplastics will accumulate in terrestrial environments. Only limited micro- and macroplastics lost on land will reach oceanic environments. Quick degradation of specific polymers in environments with UV access will significantly increase the number of microplastics formed. Potential human and biota exposure was assessed, where increased intake depends mostly on microplastic access in indoor air and surface waters. To conclude, the MFA and ADM give insight in quantities of micro- and macroplastic losses to the environment with multiple dimensions. Future scenarios can be modelled for potential impacts on the environment, on biota and human exposure. Also the effect of mitigations, such as material replacements, alternative policies, and clean-up efforts, can be assessed.

3.02.T-02 Country-Wide Prediction of (Micro-) Plastics in Freshwaters
David Mennekes *and Bernd Nowack, Empa – Swiss Federal Laboratories for Material Science and Technology, St. Gallen, Switzerland*
Over the last years, more and more approaches have been introduced to not only model plastic movement in oceans but also in freshwaters. Most microplastics models for freshwaters are based to certain extents on sedimentation modelling or are extracted from sedimentation experiments. The drawback for this model design is the complexity and data requirements which so far restrict the models in their scale of application. Especially, for policymakers relevant national scales are insufficiently covered by existing modelling approaches.

The aim of our work was therefore to develop a microplastic fate model for freshwaters that is able to predict microplastic fate at the scale of whole watersheds or countries. The model was parameterized for Switzerland considering a network of 600,000 river segments and over 200 lakes. Coupling this model to an existing spatially resolved plastic emission model allowed to predict microplastic flows in all river segments and lakes for seven specific polymers (LDPE, HDPE, PP, PVC, PS, EPS, PET). We base our model on existing mechanistic transport models for microplastic but simplified the parameter input in order to create a country-wide model.
Through our work, we are able to predict the contamination of freshwaters by microplastics on the scale of each river section for an entire country. Compared with available catchment scale models, this will provide an even closer look at local sources and sinks of plastics. As one result, we clearly see the influence of lakes which retain microplastics through sedimentation. However, for Switzerland many lakes are located upstream of the major cities which are considered hotspots of microplastic emissions through their waste water treatment plants. Thus, the effect of plastic retention in lakes is lower than expected. Additionally, we differentiate between removed and accumulated plastics as well as plastics in the sediment or water column. Through this, we are able to predict exposure masses on spatial high resolution.
We believe that our work can help to better understand the sources of the global plastic pollution but rises the need for experimental data on plastic transport in the environment. The large-scale understanding of plastic transport processes will provide policy makers with options were to tackle the spread of plastic pollution in the most efficient way.

3.02.T-03 Application of Real World Data to Refine Runoff Exposure - Australian Situation
Christopher I. Lee-Steere*, Australian Environment Agency Pty Ltd, Australia*
Australia has a wide range of environmental conditions in agricultural areas including temperate, subtropical, and tropical. A "one size fits all" approach to exposure modelling does not work and such an approach results in a high failure rate for substances assessed for risk from runoff. The primary reason is that the screening step provides no context in terms of space or time, and runoff risk is therefore assumed to be equal regardless of where in the country application occurs, or at what time of the year.

Real world data are available to address this problem. The data are not held by a single entity and significant data extraction from information held by different organizations has allowed development of necessary real world data sets in the areas of soil types, cropping contribution and slopes in growing regions. Climatic data sets have been developed based on long term rainfall (daily rainfall and intensity) and hydrology characteristics in catchments. This data mining has allowed relationships to be developed and described mathematically for different regions and times of the year.

The climatic data sets are analyzed on a temporal scale (seasonal for temperate regions and monthly for tropical and subtropical regions) and at the highest tier of assessment, cumulative frequency curves for theoretical receiving water concentrations are developed. These curves are developed for each region and at two stream flow levels (25th and 75th percentiles). The methodology allows risk to be described in terms of probability of exceeding allowable concentrations and can result in targeted controls to better address identified risk areas.
The problem facing regulators with the use of such real world data is the size of data sets and the complex relationships that require development. The time required for such refined assessments is a limiting factor, and the scope for human error is large given the high number of different runoff curve numbers, slopes, rainfall values and stream flow rates that need to be included. However, all the algorithms for runoff curves based on soil specific profiles and stream concentration distributions have been successfully coded into a software tool making it possible to undertake such complex assessments rapidly and compare scenarios quickly and consistently. The approach has successfully been applied in Australian regulatory decisions and relied on by industry in preparing submissions.

3.02.T-04 Deconstructing Sources of Aquatic Toxicity for the Hundreds of Pesticides in Use, Irrigation Impacts, and Exposure at Scale

Nicol Parker *and Arturo Keller, University of California, Santa Barbara*

Pesticides remain a leading environmental hazard, imperiling aquatic and terrestrial ecosystems. The mitigation of pesticide impacts is hampered by the ability to evaluate their exposure over large extents, the spatiotemporal resolution of use data, the ability to assess cumulative toxicity, and the identification of unique inter and intra-crop irrigation practices on aquatic pesticide exposure. We introduce the Pesticide Mitigation Prioritization Model to advance these four areas within the United States. We describe tool development and apply the tool to evaluate aquatic exposures in California, whose agricultural applicators must provide daily-time step pesticide use reports and whose pesticide use database is recognized as the most comprehensive globally. Additionally, many growers in California must report irrigation methods used; these data are combined with crop-specific evapotranspiration rates, crop rotations, and soil hydrologic properties to predict the effects of irrigation on aquatic exposures of pesticides at scale. California is a valuable study site representing over 400 agricultural application site types. The state's mass of applied pesticides is also 20% of the total used in the United States and 3% of applications worldwide. We apply the tool to address the following questions: 1) How is toxicity distributed among the numerous pesticides in use for diverse aquatic taxa? 2) Are current efforts reducing pesticide toxicity? 3) Does quantifying cumulative toxicity improve our understanding of aquatic exposure at the monthly and annual time steps? 4) Can low water volume irrigation methods render higher acute pesticide concentrations in rainfall-runoff events due to pesticide buildup?

3.02.T-05 How Confidently Can Current Computational Models Evaluate Ecological and Human Exposure to the Myriad of Chemicals in Commerce?

Zhizhen Zhang[1]*, Alessandro Sangion*[2]*, Shenghong Wang*[1]*, Trevor N Brown*[2]*, Jon A. Arnot*[2] *and Li Li*[1]*, (1)School of Public Health, University of Nevada, Reno, (2)Arnot Research and Consulting Inc. (ARC), Canada*

More than 350 000 chemicals and mixtures registered in national and regional chemical inventories are awaiting exposure and risk assessments. Generic mechanistic exposure models are cost-effective and user-friendly tools for this goal. Excellent examples of these models, e.g., EUSES, PROTEX, USEtox, and RAIDAR(ICE), have been used to track ecological and human exposure to thousands of chemicals through multiple routes from multiple sources. In general, the applicability of these models is constrained by (i) the applicability domain of tools used for parameterization of fundamental properties, e.g., quantitative structure-activity relationships (QSARs), (ii) built-in empirical relationships generalized from experimental measurements for parameterization of the rest parameters, and (iii) assumptions adopted by model algorithms, e.g., well-mixing homogenous environmental compartments and steady state. In this presentation, we evaluate the extent to which existing generic mechanistic exposure models apply to 112 000+ chemicals registered in five comprehensive chemical inventories. In brief, using the state-of-the-art QSAR tools, we parameterize the selected models with partitioning and reaction properties to predict exposures of ecological receptors and humans to this myriad of chemicals. We systematically analyze the applicability domains of QSARs, built-in empirical relationships, and model assumptions for these chemicals, whereby we determine the chemicals in these inventories for which these models can make predictions with the highest confidence. Preliminary results indicate that we can be confident in evaluations of exposure for only a small fraction of commercial chemicals using the current computational models. Specifically, violating the assumption of well-mixing in outdoor compartments (notably large water bodies) limits the application of generic, mechanistic exposure models to most chemicals. The applicability domain of empirical relationships limits the application of generic, mechanistic exposure models to more than half of chemicals. The combination of multiple QSAR models greatly expands the applicability domain. Reliably predicting the biodegradation half-life is the current bottleneck of QSAR applications. This presentation, for the first time, systematically informs academia and regulatory agencies on the applicability and uncertainty of the generic, mechanistic exposure models.

3.02.P Advances in Exposure Modelling Toward Data-Driven Decision-Making

3.02.P-Tu136 Modelling the Friction of Vehicle Tyres to Estimate Emission of Microplastics

Johannes Meesters, Jaap Slootweg and ***Joris T.K. Quik****, National Institute for Public Health and the Environment (RIVM), Netherlands*

Understanding the source of microplastics from tyre wear is key for implementing effective mitigation measures and monitoring microplastic emissions. Current country specific procedures to estimate the emission of microplastics from tyre wear are based on outdated measurement data and assume same levels of wear per distance for different car models. Any development in vehicle and tyre design or traffic regulations and road track are as such not accounted for in calculated tyre wear particle (TWP) emissions after the year 2000. A new microplastic emission model for TWPs is presented here that calculates the friction between tyre and track for different vehicles performing different manoeuvres. Model sensitivity analyses indicate vehicle velocity and landscape slope are most determinant in simulating friction work. The abrasion coefficient of tyres that represents the amount of mass abraded per unit of friction work performed (mg/J) is both an important and difficult to collect input parameter. The emission model however can estimate such abrasion coefficients from field data sources that express the level of tyre wear as the amount of mass abraded per driven kilometre (mg/km). As such, the model is used to estimate abrasion coefficients (mg/J) by dividing given wear rates (mg/km) in available data sources with the model outcome for the friction work performed on the respective road track divided by the track's distance (J/km).

Additionally, lab and field measurements are planned in the near future to estimate abrasion coefficients from measured tyre wear and conditions that control the level of friction work. Furthermore, field measurements in which tyre wear abrasion is measured for vehicles performing specific manoeuvres over an outdoor track circuit are used to validate the model script.

It is also planned to set up a database that comprises the relevant vehicle specifications, tyre quality indexes, country traffic regulations and road infrastructures for the period of 2000-2021. The content of the database will serve as input for the TWP emission model routines to calculate the amount of TWPs released per driven kilometre of the vehicles per year.

As such, the model can be used to update country emission factors, quantify the impact of developments in vehicle and tyre design as well as the impact of future policy measures to reduce microplastic emissions from tyre wear. In particularly relevant as tyre wear is included in new EURO7 emission criteria.

3.02.P-Tu137 Introducing µBETR Global, a Global-Scale, Geographically Explicit, Multimedia Microparticle Transport and Fate Model

***Marianne Seijo*[1]*, Michael John Whelan*[2]*, Todd Gouin*[3] *and Antonia Praetorius*[1]*, (1)University of Amsterdam, Institute for Biodiversity and Ecosystem Dynamics, Netherlands, (2)Centre for Sustainable Resource Extraction, University of Leicester, United Kingdom, (3)TG Environmental Research, United Kingdom*

Owing to the broad spectrum of current and innovative applications and low cost, the production of plastics has drastically increased over the last decades and is still on the rise: Since the 1950s, 8.3 billion tons of plastics have been produced. But the reverse of the medal is that 79% accumulated in landfills and the natural environment. A particular issue is the fragmentation of larger plastic waste into microplastics (MPs), ranging from 5 mm down to 1 µm (and < 1µm nanoplastics). The MP (and nanoplastic) size range encompasses different dynamics processes from Newton to Brownian and makes them readily available for ingestion and/or inhalation for a plethora of organisms. Moreover, MPs have been found in all environmental compartments, from soils to air, from freshwaters to oceans. Still, limited mechanistic understanding is available on specific transport pathways and the complex interaction and transformation processes that MPs can undergo in different environmental media over time.

Models play an important role in understanding the emissions, transport, and complex transformation processes of MPs in air, freshwater, soils, sediments, and the oceans, and adequate modelling tools are needed to support exposure and risk assessment. In addition, the particulate nature of MPs and their huge heterogeneity in terms of sources and physicochemical properties require data-intensive modeling approaches, accounting for MP-specific transport and fate processes.

Here we introduce a recently developed global-scale multimedia transport and fate model for MPs. Our µBETR Global model implements the latest developments in MPs mobility and fate on a global scale with a 3D high resolution of 0.5° grid cells (equivalent to 55.0 km) and a real-time scale. µBETR Global is a mechanistic multimedia mass-balance model developed to evaluate short- and long-range transport of MPs and their transformation processes (e.g., weathering, fragmentation, biofouling, and aggregation). The model includes both the role of MPs' physicochemical properties (size, shape, density/composition) and the influence of environmental system parameters on the overall fate. Environmental system parameters are obtained from the Copernicus observation program, the European Centre for Medium-Range Weather Forecasts' (ECMWF's), and Era5 reanalysis data. The focus of this presentation will be a demonstration of the atmospheric transport of MPs within µBETR Global under selected emission scenarios.

3.02.P-Tu138 Engagement from the Environmental Chemistry Community is Needed to Protect the Martian Environment

***John Daniel Hader** and Matthew MacLeod, Stockholm University, Sweden*

The production, use, and disposal of anthropogenic chemicals and materials has led to the contamination of the Earth environment, such that a 'planetary boundary' for their safe use is currently exceeded. The introduction of novel entities into natural environments has not stopped at the top of Earth's atmosphere, as an estimated 9979 kg of spacecraft materials from Earth have been transported to the Martian environment. International agreements on the safe and sustainable exploration and exploitation of celestial bodies are limited in scope and legal enforceability. Furthermore, several government and private entities have plans to transport humans to the surface of Mars. Against this backdrop, several frameworks have been proposed for environmental impact assessments of human activities on celestial bodies. Missing from these proposed frameworks, however, is recognition of many of the hard-learned lessons from humans' contamination of the Earth with novel entities, particularly regarding their emissions at the point of material use and subsequent transport to remote regions. We argue that the expertise of the environmental chemistry community should be leveraged to investigate the potential for anthropogenic chemicals to be emitted into the Martian environment, transported regionally and planet-wide, and accumulate into regions with a relatively higher likelihood of harbouring extant life. A logical entry point for the environmental chemistry community into the assessment of novel entities on Mars is the use of chemical fate models. Simple box-models could be used as a starting point to explore the potential for known chemical fate and transport pathways to result in accumulation of chemicals in high-value environmental media (e.g., subsurface water), with further model refinement as workflows develop. Such exercises would likely elucidate knowledge and data gaps related to chemical processes in the Martian environment that could be further explored via experimental work. The environmental toxicology and chemistry community has an immense amount of knowledge regarding local and planetary contamination by anthropogenic chemicals that could aid research focused on protecting the Martian environment. As more governments and other entities set their sights on exploration or exploitation of the Red Planet, it is imperative that sound interplanetary chemical management is established far in advance of any human expansion deeper into the solar system.

3.02.P-Tu139 Application of a Spatially Resolved Model to Refine Exposure Assessment of Down-the-Drain Chemicals in European Rivers

Chiara Maria Vitale[1]*, Susan A Csiszar*[2]*, Raghu Vamshi*[3]*, Brenna Kent*[3]*, Michaela Koopmans*[2]*, Diederik Schowanek*[1]*, Ping Sun*[2] *and Kathleen McDonough*[2]*, (1)Procter & Gamble, Belgium, (2)Procter & Gamble, (3)Waterborne Environmental, Inc.*

A spatially resolved model was developed for Europe that predicts the fate and transport of chemicals disposed down-the-drain and estimates aquatic concentration distributions (i.e., percentiles) in receiving waters. The model uses chemical specific information (per-capita emissions, wastewater treatment plant (WWTP) removal, in-river decay) and spatially explicit data on WWTP infrastructure, population served and river basin hydrology, to simulate water and chemical routing and predict in-stream concentrations. This modelling framework, built upon the iSTREEM® framework, which contains geographic datasets for USA, China, and Japan, was implemented for European countries, using spatially refined publicly available datasets. The USDA Curve Number method was used to generate spatially resolved mean river flows for use in the model. Chemical case studies were run for common surfactants used in cleaning products with down-the-drain emissions (i.e., linear alkyl benzene sulphonates (LAS); alcohol ethoxysulphates (AES); alcohol sulfates (AS)) to evaluate model performance. Predicted environmental concentrations (PECs) in rivers were compared to monitoring data, as well as simulations performed by EUSES predictions, as a comparison. Results suggest that the spatially resolved Europe modeled PECs were predictive while being conservative when compared to monitoring data. The modeled PECs also reproduced the spatial variability of monitored concentrations with agreements generally greater than an R^2 of 0.9. Additionally, EUSES estimates were also conservative when compared to the monitoring data and the spatially resolved model can be used to further understand differences between these results and to perform refined exposure assessments for down-the-drain chemicals.

3.02.P-Tu140 Automated Classification of the German Soil Map (BUEK 200) into FOOTPRINT Soil Types and Parameterization in MACRO

Stefan Reichenberger[1]*, Thorsten Pohlert*[2]*,* ***Qianwen He***[3]*, Sebastian Gebler*[3]*, Sebastian Multsch*[4] *and Beate Erzgraeber*[3]*, (1)knoell France SAS, France, (2)knoell Germany GmbH, Germany, (3)BASF SE, Germany, (4)APD/EFM, BASF SE, Germany*

The FOOTPRINT Soil Type (FST) system has been derived during the FOOTPRINT project (2006-2009) to facilitate spatially distributed pesticide fate modelling at national or EU scale. The basic idea of this approach is to classify the soil typological units (STUs) of a national or European soil database into a limited number of soil types (FSTs) in order to reduce the number of unique soil-climate combinations for the later numerically expensive simulations with a pesticide fate model. The FST code consists of a hydrological class (the FOOTPRINT Hydrologic Group), a topsoil and a subsoil texture code, and an organic matter profile code. The FST system is model-independent, but complete parameterization methodologies for MACRO and PRZM were established during FOOTPRINT. In this study we i) translated the latest version of the German soil map 1:200,000 (BUEK200) into FSTs, ii) derived representative profiles for all FSTs with arable land use, and iii) parameterized these representative profiles in MACRO. The 3648 STUs with arable land use in the BUEK200 were classified into 226 FSTs. Area proportions covered by the different FSTs are highly skewed: The 13 FSTs with the largest areas already cover 50% of the total arable land. The hydrological class of each FST indicates whether artificial drainage is needed to allow arable landuse and a map of potential drained arable land was derived for Germany accordingly. A representative soil profile was established for every FST by depth-based averaging over all soil profiles belonging to the same FST. The plausibility of the representative FST profiles and their MACRO parameterization was checked with water balance simulations. The present case study for the BUEK200 soil database demonstrates the potential of the FST system for spatially distributed fate modelling at large scale based on national soil databases.

3.02.P-Tu141 Using Remote Sensing Methods to Characterize Grassland Landscapes for Scenario Development and Biodiversity Assessment

Jillian LaRoe[1]*,* ***Christopher M Holmes***[1] *and Thorsten Schad*[2]*, (1)Applied Analysis Solutions, LLC, (2)Bayer AG - Crop Science Division, Germany*

Grasslands support essential biodiversity and ecosystem services, and their resilience is threatened by climate change and degradation through anthropogenic land use changes. Remotely sensed satellite imagery has previously been utilized to characterize the intensity and usage of grasslands over time and broad geographic areas. We used synthetic aperture radar and optical multispectral imagery with repeat images captured every six and five days (respectively) to identify grassland changes at a high temporal resolution, as highly managed grasslands may be cut multiple times per season (March – October). Time series images were used to characterize grassland type, cutting frequency, and use intensity for over 6000 grassland parcels in Germany between 2018 and 2021. Training data were collected for grassland types including; silage, meadow (hay), pasture, and natural grassland. Spectral indices related to vegetation were derived across grassland parcels to create annual metrics. Thresholding methods were applied to annual time series of Sentinel-1 and Sentinel-2 to detect cutting events within each grassland patch. Results from the two methods were combined to improve cut detection confidence. A random forest modeling approach was used to classify the grassland type and use intensity. The case study area studied was dominated by silage grassland type, and results estimated that 88% of all grassland parcels were cut three or more times per year. The final statistics provide a suite of metrics that may be useful for assessing the quality of insect habitat (e.g., first grassland cutting of the year), habitat connectivity, and investigating which grassland management practices best support biodiversity. Comparable remote sensing approaches have been used to develop landscape scenarios for honey bee (*Apis mellifera*) risk assessment, selection, and characterization of habitat for wood mouse (*Apodemus sylvaticus*) population models supporting regulatory pesticide risk assessment, and within other studies to characterize insect habitat and biodiversity. Outlook of future activities incorporating these technologies includes fusion of multiscale data sources (e.g., UAVs, satellites, *in-situ* field observations), and diverse sensor platforms applied to a wide variety of ecological investigations.

3.02.P-Tu142 Comparing the Sensitivity of Predicted Environmental Concentrations of Pharmaceuticals Using Empirical and Quantitative Structure-Activity Relationship (QSAR)-Derived Physicochemical Parameters

***Jeff Rominger**, Tim Verslycke and Wasfia Hoque, Gradient, Boston, Massachusetts*

Environmental exposure assessments of active pharmaceutical ingredients (APIs) require information about API behavior in environmental media. Upon release into the environment, APIs can be present in wastewater, biosolids, surface water, groundwater, sediment, and soil, differentially partitioning among these media according to their physicochemical properties. APIs also degrade following release through various abiotic and biotic processes, thereby reducing their environmental concentrations over time. Environmental exposure assessments often estimate predicted environmental concentrations (PECs) in an environmental medium to assess potential human or ecological exposures. However, information on API partitioning and degradation is often not available for many APIs, presenting an important obstacle in environmental exposure assessments.

In the absence of empirical data, quantitative structure-activity relationship (QSAR) data are often used as alternatives to support environmental exposure assessments. QSARs rely on predictive relationships between a chemical structure and its physicochemical or environmental properties. QSARs have wide use in chemistry, biology, toxicology, and environmental applications. However, there is uncertainty associated with the use of nonempirical data to inform exposure assessments and the magnitude of this uncertainty is often unknown.

In this study, we calculated the sensitivity of exposure estimates to the use of QSARs by comparing the difference between PECs calculated using QSARs versus those calculated using empirical API parameters. To perform this study, we employed a recently developed environmental fate tool that incorporates existing exposure assumptions from applicable regulatory guidance (e.g., EMA, ECHA, USEPA) and can be adjusted to account for local hydrogeology as well as exposure pathway (e.g., land application of wastewater biosolids). The results for a suite of APIs show that PECs can be sensitive to physicochemical parameters in certain settings, and that, in the absence of empirical data, using a range of QSAR-derived parameters in a sensitivity analysis framework in environmental exposure assessments can help in evaluating uncertainties of the results.

3.02.P-Tu143 Tracking a Chemical's Journey from Production Line to Body Burden Using the PROduction-To-EXposure (PROTEX) Model

***Li Li**[1], Dingsheng Li[1], Alessandro Sangion[2], Zhizhen Zhang[1], Christopher Hoang[3], Jon A. Arnot[2] and Frank Wania[3], (1)School of Public Health, University of Nevada, Reno, (2)Arnot Research and Consulting Inc. (ARC), Canada, (3)Department of Physical and Environmental Sciences, University of Toronto, Canada*

Human and ecological exposures to synthetic chemicals involve chemical emissions from multiple lifecycle sources, multimedia environments at multiple scales, multiple sources of exposure, and multiple pathways of intake and elimination. These components are governed by the complicated interactions between chemical properties, environmental conditions, and human and ecological characteristics. Such multidimensionality and complexity warrant a systematic, mechanistic perspective in exposure modeling and necessitate a holistic approach to track a chemical's journey from the production line to body burden. In this presentation, we introduce a state-of-the-science model named PROduction-To-EXposure (PROTEX), which supports characterizing the entire continuum from chemical production, lifecycle multisource emissions, multiscale multimedia environmental fate and transport, and multipathway exposure, to the presence in humans and other organisms. PROTEX builds on theories of substance flow analysis, multimedia fate and transport, bioaccumulation, and exposure and toxicokinetics, and it integrates mechanistic descriptions of various physical, chemical, biological, and socioeconomic processes. Its mechanistic nature allows PROTEX to be parameterized for a wide range of chemical substances (both neutral and ionizable chemicals) in a wide range of regional environments (e.g., the subtropical US, the Canadian side of the Lake Ontario basin, central China, and the western Baltic drainage basin) for a wide range of populations (Whites, Blacks, Asians, etc.). When supplied with time-variant production or use data, PROTEX provides dynamic time-dependent estimates, allowing users to reconstruct the long-term history of chemical contamination. By considering interindividual variabilities in human anthropometrics, behavior, and physiology, PROTEX additionally supports predicting the distribution of chemical exposure within a population. Outputs from PROTEX support science-based risk assessment and decision-making. The presentation serves as a knowledge hub for PROTEX's rationale and mechanism, applications and case studies, and user tips.

3.02.P-Tu144 Modelling the Effects of Microplastic on the Fate of Persistent Organic Pollutants and Their Entry into the Base of Aquatic Food Webs

***Brendan Eoin Hickie**, Trent University, Canada*

Concerns about microplastic pollutants in aquatic ecosystems have been increasing exponentially over the last 15 years. One of the leading concerns with microplastics is that they absorb hydrophobic persistent organic pollutants (POPs) from the environment and, upon ingestion, may enhance the bioaccumulation of these pollutants. This however has yet to be demonstrated in either field or laboratory studies using environmentally relevant concentrations of microplastic particles and particulate organic matter (POM) including algae. To explore this, microplastics were added into the well-established fugacity-based Quantitative Water, Air, Sediment Interaction (QWASI) Model to examine whether their presence would affect the overall fate of POPs in aquatic ecosystems. We also added a bioenergetics and kinetics-based submodel for herbivorous zooplankton to estimate microplastic ingestion rates and any associated POPs accumulation at environmentally realistic concentrations of microplastics, algae, and other POM. The model shows that even the highest current environmental microplastic concentrations have virtually no effect on the overall aquatic fate of POPs spanning a wide range of hydrophobicity, nor do they contribute to POPs accumulation by zooplankton. Our results show that POPs accumulation by zooplankton is dominated by direct partitioning from water, while any accumulation from ingested particles would be mainly from algae rather than microplastics owing to their much greater abundance, and higher bioavailability of algae-associated POPs. The model also provides estimates of density-dependent microplastic ingestion rates which may be useful for addressing other concerns about microplastics. Our research also highlights the need for greater consistency in sampling of microplastic abundance and characterization of their particle size distribution, especially for particles <100 µm.

3.02.P-Tu145 Radon Exposure in Indoor and Outdoor Environments for Subpopulation Groups Using Monte-Carlo Simulations

*Soo yong Lee, Sang hun Im and **Hee Seok Kim**, Department of Nano, Chemical and Biological Engineering, Seo Kyeong University, Korea, Republic of (South)*

Although monitoring of radon has been extensively implemented throughout South Korea, the risk assessment was mainly limited to indoor environments such as schools, workplaces, and multiuse facilities, and was evaluated separately. In this study, the differences in radon exposure according to the life cycle (0, 1-6, 7-13, 14-18, 19-24, 25-39, 40-64, and 65 years age or older) were evaluated using Monte-Carlo simulation, comprehensively considering various indoor and outdoor environments, time-activity patterns, variations in radon concentrations, and dwelling type. The distribution and representative values of radon concentration by microenvironments were confirmed through the Anders-Darling test, and a uniform distribution was applied in case of uncertainty. The effective dose (DT) ranged from 2.35 ± 2.14 to 2.81 ± 3.03 mSv/y in single-detached houses, and the DT in apartment houses ranged from 1.45 ± 9.78 to 2.15 ± 1.27 mSv/y. Comparing the levels recommended by EPA, WHO, and ICRP with the top 5% values of this study, the results of the population groups aged 0, 1-6, 7-13, and 14-18 in the type of detached houses were exceeded. The populations that spend a lot of time in homes and/or schools (elementary, middle, and high schools) with relatively high levels of concentration are assessed to be relatively more vulnerable to radon exposure.

3.02.P-Tu146 Great Britain-Specific Environmental Exposure Scenarios for Chemicals in EUSES

*Michael Crookes[1], **Wouter Gebbink**[2], Oliver Warwick[1], Charlotte Collins[3] and Stacey Bowskill[3], (1)Vitis Regulatory Ltd, United Kingdom, (2)Vitis Regulatory, Belgium, (3)Environment Agency (England), Bristol, United Kingdom*

The primary environmental exposure model used in UK REACH is EUSES, which was developed more than 20 years ago to serve the purposes of the European Union (EU). A previous scoping study for the Environment Agency in 2018 identified several potential changes and updates to EUSES, including targeted parameterisation to make the outputs more useful and relevant to UK REACH stakeholders, particularly regulatory agencies.

Within this current project, key environmental parameters within EUSES were identified which could be altered to be more specific to Great Britain (GB). Key parameters that are altered included temperature, rainfall, wind speed, soil parameters, sewage sludge spreading assumptions, dilution factors to rivers and coastal areas, size of the regional scale, and food intake for humans exposed via the environment. Parameters that may require amendment to reflect future projected climate change scenarios in GB were identified. The impact of these parameters will be assessed for several time periods.

GB-specific data have been collected for temperature, wind speed, and rainfall with average values over the last 20 years as selected values. The impact of future climate change predictions on these values has also been considered. Data on GB-specific soil parameters and sewage sludge application on soil have also been collected. A catchment area containing an industrial area and a large population was selected as the regional scale. The continental scale was altered to GB dimensions.
A sensitivity analysis has been conducted to identify GB-specific parameters which have the most impact on the predicted environmental concentrations (PECs) derived in the exposure model compared to the standard EUSES model. This was illustrated using a small number of example substances with variable physicochemical and environmental fate properties. The differences between the standard and GB-parameters are discussed and the potential for use of a GB-adapted EUSES model under UK REACH is considered.

3.02.P-Tu147 SimpleBox in R

*Jaap Slootweg, **Joris T.K. Quik** and Johannes Meesters, National Institute for Public Health and the Environment (RIVM), Netherlands*

SimpleBox is a well-known "fate model" that supports (European) chemical regulation (e.g., REACH). The model comprises of boxes, which are combinations of compartments at nested geographical scales. The original version is implemented in excel, which allows easy adaptation for specific use, for instance a version for nanomaterials. But this implementation has several disadvantages, most importantly version control of both the data and the model and limiting the use to steady state. We present a novel implementation of SimpleBox in R that overcomes the mentioned disadvantages and has other advantages as a bonus.

The design of the R version is object-oriented, using the R6 package, with methods disclosing and extending the data, enabling a single codebase for general and specific use, and easy integration with R-shiny as user-interface for users not specialized in programming. The basis of SimpleBox in R is the easy and transparent way the process algorithms are assembled in the R6 object oriented classes: Core, State, Emission, and CalcGraph.

The “Core” class is the most prominent object and handles the internal data, others are "injected" in it. The State class generates the scenario (boxes of a compartment in a scale and their coherence). The Emission class defines the interface for emissions. Other classes inherit from the so-called CalcGraph class. Instances of these subclasses are initiated with a (simple) function as argument. These functions have atomic arguments, are automatically called whenever needed, and are provided with the arguments corresponding to the data in the Core. Subclasses are for (1) defining the velocity of the transfer processes, (2) calculating intermediate variables for boxes stored in the Core for future use, (3) calculating fluxes associated with a transfer process, and (4) solving the set of first-order differential equations; either for steady state, dynamic responses, or sensitivity analyses. Functions for the CalcGraph classes to reproduce the current version are available but can be changed easily. The steps to define a scenario, calculate results and plot them in graphs are kept in R scripts which are concise and clear due to the use of the R6 classes. The logic of your SimpleBox application can thus easily be defined, documented, shared and archived. In this script you can initiate a Core with a State object and an Emission object both extended for your scenario.
SimpleBox in R will be made available on github

3.02.P-Tu148 Evaluation of Models Coupled with Measured Data for Determining Organic Carbon-Water Partition Coefficients

Jaeshin Kim*, Gary Kozerski and Jeremy Durham, Dow Chemical Company, Midland*

The organic carbon-water partition coefficient (K_{OC}) plays an important role in determining the fate and distribution of chemicals using environmental multimedia models. The sorption process into particulate organic matter in soils and sediments can compete with other fate processes such as volatilization, degradation, advection, sedimentation, etc. Especially for volatile methylsiloxanes (VMS), many published studies suggested selecting accurate values to predict the environmental behaviors at environmentally relevant conditions. Thus, K_{OC} values at different temperatures relevant to real world conditions are needed although most K_{OC} values have been measured at 25 °C or at room temperature. Various methods have been employed to measure or predict equilibrium concentrations of target chemicals in both phases of particulate organic carbon and water. It would be preferable to measure equilibrium concentrations in both phases at different temperatures (i.e., a batch equilibrium method), but more resources are required for the method than other indirect methods that may be used to predict equilibrium concentrations. In the latter indirect methods, only water concentrations are measured over a testing period of desorption from the chemical-laden organic phase. In this case, chemical concentrations in organic carbon phase are predicted. In another case, chemical concentrations in both water and organic phases are predicted by measuring gas-phase concentrations via volatilization from water, similar to a purge-and-trap method. The prediction can be done using a form of modeling with assumptions. We have developed a model to predict equilibrium concentrations for lab experimental conditions and performed sensitivity analysis for input parameters at different temperatures. The model suggested that desorption rate from VMS-laden organic carbon phase, mass transfer coefficient at the air-water interface, and the fraction of loss via degradation and irreversible sorption must be well characterized to predict K_{OC} values. It is also noted that the methods that predict an equilibrium concentration(s) are less precise and more variable that a batch equilibrium method. When measured data from an indirect method were optimized with model parameters, model equifinality was possible where different K_{OC} values with distinct model parameters would be obtained.

3.02.P-Tu149 Environmental Fate Modeling of Volatile Methylsiloxanes and Degradation Products

Jaeshin Kim*, Gary Kozerski and Debra McNett, Dow Chemical Company, Midland*

Various environmental multimedia models have been developed and applied for volatile methylsiloxanes (VMS). The models have been crucial in understanding the behavior of VMS in the environment and developing tools to determine persistence, long-range transport, and bioaccumulation. Among many input parameters for the models, degradation rates are key parameters for the prediction of the fate of VMS as parent compounds. The main degradation pathways are atmospheric oxidation by hydroxyl radicals, hydrolysis in water, and surface-catalyzed hydrolysis in soil. As a result of degradation process, VMS can be transformed into a series of degradation products at different rates of formation. Since degradation products have different physicochemical properties from VMS, their formation (or emission) and distribution in the environmental media would also be different. Since degradation can be reversible as in the case of aqueous hydrolysis, it is reasonable to model a parent compound and its degradation products simultaneously so that we may develop a holistic understanding of environmental fate of VMS. In this study, we focused on the fate of VMS and degradation products in aquatic systems. Hydrolysis kinetics were evaluated for several degradation products (i.e., dimethylsiloxane-α,ω-diols and silanols) and their hydrolysis rate constants. In addition, main partition coefficients (such as K_{OW}, K_{AW}, and K_{OA}) of VMS and degradation products were estimated using reliable quantitative structure-property relationships. We developed a fugacity-based multimedia model where mass balance equations for the multiple chemical species were solved simultaneously. We will discuss model results of mass distribution and transport as well as environmental concentrations for VMS and degradation products.

3.02.P-Tu150 Go-Phytodron Project. Validation and Safety of Unmanned Aerial Spraying Systems (UASS) in Forest and Crops. Preliminary Drift Results

Elena Alonso Prados[1]*, José Alonso-Prados*[2]*, Amaya Ortiz Barredo*[3]*, Luis Asín Jones*[4] *and Santiago Planas-Martí*[5]*, (1)INIA-CSIC - Spanish National Institute for Agricultural and Food Research and Technology, Spain, (2)National Institute for Agricultural and Food Research and Technology (INIA), Spain, (3)NEIKER Instituto Vasco de Investigación y Desarrollo Agrario, Spain, (4)Fruitcentre, Intitute of Agrifood and Technology, IRTA, Spain, (5)Research Group on Crop Protection, Agrotecnio CERCA Center - UdL, Spain*

The European Commission’s Farm to Fork strategy aims to reduce the use of chemical plant protection products (PPPs) in the EU by 50% over the next decade. This initiative pursues facilitating the adoption of new technologies of application able to improve effectiveness and competitiveness to ensure the sustainability of agricultural systems under the principles of precision agriculture.

Over the last years, many research institutes, chemical companies, and other entities have been looking for development of practical and novel solutions to spray applications problems and integration of new technologies into spray processes for application of plant protection products (PPPs). Among these technologies, UASS (Unmanned Aerial Spraying Systems) provide an opportunity to introduce precision agriculture techniques, such as spot spraying, becoming a promising tool with potential to increase spatial resolution and, consequently, to optimize the amount of product applied, towards a friendly environmental agriculture.

GO_PhytoDron project (https://gophytodron.es/), co-funded by Spanish Ministry of Agriculture and European Agricultural Fund for Rural Development (EAFRD), aims to promote the use of UASS as a precise and safe tool for the application of PPPs seeking to advance in its regulatory framework and establishing scenarios of use.
The project includes field trials to assess potential drift (ISO 22866:2005) on target depostions (ISO 22522:2007), product efficacy, and humans' health exposure to chemicals of UASS in comparison to conventional ground spraying.

The selected crops, olive trees, citrus, and vineyards, are representative of the diversity of three-dimensional crops cultivated in Spain. Pine trees were also chosen to validate the use of this technology in plant health management in cultivated forest. Trials took place across the Spanish territory, covering different climates and conditions representative of the heterogeneity of agricultural systems.

In this work we compare the preliminary results of drift potential (airborne and sedimenting) an from UASS and conventional ground sprayers, together with drift values used currently in the aquatic and terrestrial risk assessment in the EU framework of approval of active substances of PPP, with the aim of developing of specific scenarios for UASS treatments in the future.

3.02.P-Tu151 Dissipation of 11 Micropollutants in Soils
Miroslav Fér[1]*, Radka Kodesova*[2]*, Ganna Fedorova*[3]*, Martin Kočárek*[1]*, Vit Kodes*[4]*, Ales Klement*[1]*, Antonín Nikodem*[1] *and Roman Grabic*[5]*, (1)Czech University of Life Sciences Prague, Prague, Czech Republic, (2)Soil Science and Soil Protection, Czech University of Life Sciences Prague, Prague, Czech Republic, (3)University of South Bohemia in Ceske Budejovice, Faculty of Fisheries and Protection of Waters, Czech Republic, (4)Czech Hydrometeorological Institute, Prague, Czech Republic, (5)University of South Bohemia in České Budějovice, Czech Republic*
Various micropollutants may enter soils due to the application of treated wastewater or biosolids from wastewater treatment plants. Their leakage from soils and their uptake by plants is controlled mainly by sorption and degradation in soils. Standard laboratory batch degradation experiments were performed using soil samples from the top horizons of three different soil types (Arenosol, Cambisol, and Chernozem) and eleven micropollutants. The wet soil was preincubated in the dark at a constant temperature of 20 °C to guarantee optimal microbial conditions. Next, a solution of one compound was added to achieve similar compound loads per dry soil unit (1 $\mu g\ g^{-1}$), and incubation continued. Three samples for each soil with each compound were analyzed immediately, 1, 2, 5, 12, 23, 40, 61, and 90 days after the compound's application to find concentrations of the remaining compound in soils. The first-order and second-order kinetic expressions were next used to fit experimental data points. The first-order equation correctly described the dissipation trends, but the second-order equation was more suitable in a few cases. The highest dissipation half-lives were observed for memantine (212±78 days), followed by venlafaxine (203±8 days), atorvastatin (14±5 days), telmisartan (98±72 days), sertraline (50±26 days), lamotrigine (48±15 days), 2-phenyl benzimidazole-5-sulfonic acid (44±26 days), 1-methyl-1H-benzotriazole (38±13 days), valsartan (10±7 days), triclosan (8±0.4 days), and bisphenol S (4±1 days). However, for different micropollutants, the same trends of their dissipation with respect to the tested soils were not observed. Data from this study will be coupled with the maps of the Freundlich sorption coefficients, which were derived for agricultural soils in the Czech Republic, to assess the potential threat associated with using treated wastewater for irrigation or the application of sewage sludge onto soils as a source of nutrients. This information will be used to improve the monitoring of groundwater quality within the Czech Republic, to identify areas unsuitable for broader utilization of these two resources, or to propose their safe application onto agricultural soils.

3.02.V Advances in Exposure Modelling Toward Data-Driven Decision-Making

3.02.V-01 Automated Tracking of Changes in Agricultural Land Use by Means of Deep Learning
*Su Yeong Park and **Magnus Wang**, WSC Scientific GmbH, Germany*
Field margins play a crucial role in sustaining biodiversity in intensively managed agricultural lands. In Germany, agricultural land use areas are reported to be continuously decreasing since reunification, changing the structure of arable landscapes including the field margin. However, while the land use changes are monitored over a long period of time through survey and remote sensing technologies, tracking structural changes or field margin changes was rare.

The contribution aims to examine the impact of land use changes on field margins and agricultural landscape structures (e.g., heterogeneity) in Germany for the last decade. For the analysis, the deep-learning based image processing method ALDiS is applied to historical and current high-resolution aerial photographs and quantified structural differences, especially in field edge areas. The selection of landscapes was based on the agricultural area statistics from the German state office, by choosing the districts with relatively high agricultural land use changes both for the increase and decrease. This contribution will provide examples of how field margin and structure are driven by land use changes, addressing its role as one of the stressors in the future pesticide risk assessment and management.

3.03.P Analysis and Evaluation of Efficacy, Stability, Degradation, Release of Biocides From Building Materials and Their Effect on Terrestrial Ecosystems

3.03.P-Th153 Point and Nonpoint Sources of Urban Biocides in Sediments from Stormwater Infiltration Facilities
Felicia Linke[1,2]*, Omoyemi Edun*[3]*, Tobias Junginger*[4]*, Sylvain Payraudeau*[4]*, Gwenaël Imfeld*[4]*, Frank Preusser*[2] *and Jens Lange*[3]*, (1)Chair of Hydrology, Faculty of Environment and Natural Resources, University of Freiburg, Freiburg, Germany, (2)Institute of Earth and Environmental Sciences, Faculty of Environment and Natural Resources, University of Freiburg, Germany, (3)Chair of Hydrology, Faculty of Environment and Natural Resources, University of Freiburg, Germany, (4)Institut Terre et Environnement de Strasbourg (ITEST), University of Strasbourg, France*
Stormwater infiltration facilities (SIF) are part of sustainable stormwater management which helps infiltrate stormwater locally and reduce urbanization impacts on groundwater recharge. SIF collect urban runoff containing contaminants such as biocides, which are frequently used as film preservatives on building facades and washed off during wind-driven rain. Previous studies found biocides in stormwater, wastewater, standing water in SIF, and groundwater. However, only a few studies investigated biocide occurrence, distribution, and behaviour in SIF sediments. While input types of biocides have not been characterized yet, we distinguish between point sources of biocides with high emissions from single locations and nonpoint sources from diffuse entry of biocides. Here we quantified three widely used biocides (diuron, octylisothiazolinone - OIT, terbutryn) in paints and renders and selected transformation products in sediments of 46 SIF in two cities of Germany and France. SIF ages varied from 2 to 19 years. Biocide occurrence in SIF sediments differed for the respective substances. Terbutryn was detected and/or quantified at low concentrations (max. 1.7ng g^{-1}) in 36 out of 46 SIF. This suggests that terbutryn, which is relatively stable ($t_{1/2}$ 90d in soil), may be used as a marker for nonpoint urban biocide emission. Furthermore, recently built SIF showed higher terbutryn concentrations in their sediments than older SIF. This is likely due to a higher biocide load from connected buildings with recently painted facades. Worthy of note, soil characteristics of SIF sediments, such as organic carbon content and clay content, did not correlate with terbutryn concentrations. Diuron and OIT were only found in one SIF, but in very high concentrations (168 and 58 ng g^{-1}, respectively), which suggests recent point source emission from, e.g., repair works or construction site. Five occasional detections of acetochlor (max. 3.2 ng g^{-1}), an herbicide whose use is banned in agriculture, supported the occurrence of point source emission. Detection of diuron, OIT, and acetochlor confirmed rare but high biocide inputs in urban SIF. Overall, low biocide accumulation in SIF soils in both cities but punctual inputs in specific SIS invite future studies to extend our approach to other micropollutants and across the facade-soil-groundwater continuum.

3.03.P-Th154 Simulation and Experimental Validation of Distribution of Biocides in Soil Considering a Realistic Emission from Building Façades
Nadine Kiefer[1]*, Judith Klein*[2]*, Michael Klein*[2]*, Mirko Rohr*[3]*, Michael Burkhardt*[4] *and Stefan Kalkhof*[5]*, (1)Department for Bioanalysis, Coburg University of Applied Sciences and Arts, Coburg, Germany, (2)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany, (3)Insitute of Environmental and Process Engineering (UMEC), Eastern Switzerland University of Applied Sciences (OST), Rapperswil, Switzerland, (4)Eastern Switzerland University of Applied Sciences (OST), Rapperswil, Switzerland, (5)Institute for Bioanalysis, HAW Coburg, Germany*
Biocides are used in building materials to protect the building from microbial colonisation and resulting discoloration or even decomposition. However, these biocides are gradually washed out and are emitted into the soil near the building. To obtain a realistic estimate of the toxicity of façade runoff to the soil environment, a predictive tool for risk assessment is definitely required. Thus, the aim of our study is on the one hand to realistically simulate the resulting concentration of various biocides in different soil depths over the lifetime of the building and on the other hand to verify this simulation experimentally.

For the simulation using PELMO three different scenarios for the generation of the biocide emission data were used: (i) experimentally determined in a natural weathering experiment, (ii) based on this natural weathering experiment the emission curve has been modelled in smaller time steps with the software COMELAM and (iii) the same paint/render formulations were tested in the lab using the DIN EN 16105 immersion test and were utilized as emission curve for the simulation. All emission curves were normalized concerning the soil/façade ratio based on the model house described in the OECD Guideline for product type 10. For the experimental validation a set-up has been developed and applied to investigate ten sampling time points at six different soil depths within three months. During the experiment, 3 months of the modelled intake scenario was used experimentally to compare the predicted concentrations with experimental data. Both experimental assessments of biocide leaching and of biocide distribution in soil require time-consuming and costly studies. Therefore, there is an urgent need for reliable simulation software for risk assessment of biocides from building materials. Due to the many material combinations, house geometries, different local weather influences and material and substance related leaching behaviour, estimating application concentrations for further simulations with tools like PELMO is difficult. COMELAM is a solution that provides values comparable to natural weathering experiments even for an artificial immersion test and is able to capture the entire weathering parameters in their complexity. The combination of these two tools with experimentally determined adsorption and degradation values were experimentally valuated for could thus may can reduce or even replace the number of required free weathering tests.

3.03.P-Th155 Simulations with PELMO (PEsticide Leaching MOdel) Describing Biocide Leaching in Urban Soils

***Dimitrios Alexander Skodras**, Judith Klein and Michael Klein, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany*

The original FOCUS (FOrum for Co-ordination of pesticide fate models and their USe) models describe agricultural areas that represent realistic worse case scenarios and take into account all relevant target crops, topography, soil, and climate. The locations are geographically distributed throughout the EU (European Union) and show a wide range of temperatures and precipitation. In this study, the FOCUS models shall be used for biocides leaching from buildings. In this case, the application pattern is described by façade leaching data and to adequately reflect the dynamics of façade leaching, an hourly resolution is used. Compared to the classic FOCUS soil profiles, urban soils contain high stone contents (coarse soil). It is necessary to adapt the soil profiles to account for the higher stone content in the soil profile. Due to the stone content, urban soils have an extremely low ability to store water. This affects the infiltration behaviour. The transport of water (and possibly of biocides) is accelerated. Furthermore, there is evidence for fast transport (preferential flow) in urban soil.

3.03.P-Th156 Determination of Fumagillin Residue in Honey by Liquid Chromatography Coupled with Tandem Mass Spectrometry

***Min-Chul Shin**[1], Ji-Young An[1], Wenting Wang[1], Jong-Su Seo[2] and Jong-Hwan Kim[1], (1)Environmental Safety-Assessment Center, Korea Institute of Toxicology (KIT), Korea, Republic of (South), (2)Ecological Risk Assessment Center, Korea Institute of Toxicology (KIT), Korea, Republic of (South)*

Fumagillin is used as an antibiotic in apiculture to control nosema disease. To investigate the fumagillin residue in honey after feeding the bees with sugar syrup, analytical methods for fumagillin in feeding sugar syrup and honey were both developed. The analytical method validation of fumagillin in sugar syrup was conducted to assess the specificity, system suitability, linearity, accuracy, precision, carryover effect, and various stabilities using liquid chromatography. Meanwhile, the analytical method validation of fumagillin in honey was also conducted to assess the selectivity, linearity, accuracy, and precision using the liquid chromatography coupled with triple quadrupole tandem mass spectrometry.

The concentrations of calibration standards ranged from 1 to 10 µg/mL for sugar syrup and ranged from 5 to 250 ng/mL for honey. The correlation coefficients (R^2) of the calibration curves were all higher than 0.999. The accuracy of the analytical method was checked by recovery results, and the precision was estimated by the relative standard deviations (RSDs) of three replicate samples. As the results, the mean accuracies ranged from 100.4–102.7% for sugar syrup and ranged from 99.4–107.0% for honey, while the precisions were within 1.1% for sugar syrup and ranged from 3.6–13.8% for honey. In both analytical conditions, there was no interference peak to affect the quantification of fumagillin.

Especially, fumagillin in sugar syrup was confirmed to be stable at room temperature (7 days) and refrigeration (14 days), but it could be photolysis in one day. Thus, all the samples were stored and analyzed without light to avoid the photolysis of fumagillin. Consequently, these results are within the acceptable ranges specified in the guidelines for analytical method validation. Therefore, both developed analytical methods could be applied to determine fumagillin residue in sugar syrup and honey.

3.03.P-Th157 Method Validation Comparison of Liquid-Liquid Extraction and QuEChERS Methods to Quantify Clopidol in Chicken Tissues

***Min-Chul Shin**[1], Wenting Wang[1], Ji-Young An[1], Jong-Su Seo[2] and Jong-Hwan Kim[1], (1)Environmental Safety-Assessment Center, Korea Institute of Toxicology (KIT), Korea, Republic of (South), (2)Ecological Risk Assessment Center, Korea Institute of Toxicology (KIT), Korea, Republic of (South)*

Clopidol is a feed additive that is used worldwide to control coccidiosis in chickens. To investigate the clopidol residue in chicken tissues, analytical methods for clopidol in chicken tissues were developed. So far, liquid-liquid extraction (LLE) and QuEChERS methods were mainly used pretreatment methods to determine clopidol in various biota samples. Thus, in order to establish an optimized method for clopidol analysis, both pretreatment methods were conducted and compared. The analytical method was validated with respect to parameters such as selectivity, linearity, accuracy, and precision. The accuracy and precision were also evaluated based on three replicate samples at four different spiking concentrations.

As the results, the concentrations of calibration standards ranged from 0.5 to 50 ng/mL, and the correlation coefficients (R^2) of the calibration curves were all higher than 0.99 in both compared methods. The accuracy of the pretreatment method was evaluated by recovery results, and the precision was estimated by the relative standard deviations (RSDs). The mean accuracies were 84.0–90.8% for LLE and 86.5–89.0 % for QuEChERS, while the RSDs ranged from 1.8 to 12.6% for LLE and ranged from 0.9 to 3.2% for QuEChERS, respectively. Additionally, there was no interference peak to affect the quantification of clopidol in both pretreatment methods. Consequently, these results are within the acceptable ranges specified in the guidelines for analytical method validation.

Both LLE and QuEChERS methods showed similar and satisfied accuracy and precision results in our current study. However, besides QuEChERS having the advantage of a faster and easier pretreatment process than LLE, both methods were suitable for quantifying clopidol in chicken tissues. Therefore, both pretreatment methods could be applied to determine clopidol residue in chicken tissues.

3.03.P-Th158 Degradation, Leaching, and Ecotoxicological Behavior of Encapsulated and Nonencapsulated Biocides from Building Façades

Moritz Nichterlein[1]*, Nadine Kiefer*[2]*, Dominik Markus Müller*[2]*, Michal Ciok*[2]*, Matthias Noll*[3] *and Stefan Kalkhof*[4]*, (1)Institute of Bioanalysis, Coburg University of Applied Sciences and Arts, Coburg, Germany, (2)Department for Bioanalysis, Coburg University of Applied Sciences and Arts, Coburg, Germany, (3)Coburg University of Applied Sciences and Arts, Coburg, Germany, (4)Department for Bioanalysis, HAW Coburg - Institute for Bioanalysis, Germany*
Moritz Nichterlein[1], Nadine Kiefer[1], Dominik Müller[1], Michal Ciok[1], Matthias Noll[1], Stefan Kalkhof[1,2]

To preventively protect building materials from microbial infestation, the product formulations are provided with biocides. Environmental influences lead partly to UV-induced and hydrolytic degradation and transformation of the biocides already within the façade. Furthermore, rain events lead to the leaching of the biocides and their degradation products and thus to their release into the environment.

The aim of this study is to characterize the formation of biocide degradation products and to evaluate the effects on constitution and ecotoxicity of façade runoffs. Thus, render- and paint-based test façades were exposed to artificial weathering. Specimens containing the in-can preservatives MIT, CMIT, and BIT (nonencapsulated only) and the film preservatives TER, OIT and DCOIT (encapsulated or non-encapsulated) were irradiated in a weathering chamber using artificial sunlight and/or were treated according to the leaching test DIN EN 16105. Biocides and their degradation products were analyzed in the leachates and in the exposed façade matrix using HPLC-UV/VIS and HPLC-MS/MS. Ecotoxicological effects of the leachates were tested on luminescent bacteria and green algae.

For both irradiated and nonirradiated samples, it could be shown that nonencapsulated (ne) biocides are washed out to a higher extent than encapsulated (e) biocides (nonirradiated: TER (ne) up to 4 x higher, OIT (ne) up to 8 x higher; irradiated: TER (ne) up to 3 x higher, OIT (ne) up to 4 x higher). Consequently, samples with nonencapsulated biocides exhibit a higher toxicological behavior to green algae (nonirradiated: G_a (ne): 32, G_a (e): 16-24; irradiated: G_a (ne): 16-32, G_a (e): 12-16). Regardless of irradiation and encapsulation, all leaches showed a high toxicological effect to luminescent bacteria (G_l: 96). Furthermore, it could be shown that less biocides are leached from irradiated test façade, resulted by the UV-induced degradation of the biocides, which is in line with the increased detection of degradation products of nonencapsulated biocides in the leachate and in the façade matrix.

3.03.P-Th159 Release of Organic Contaminants from Geosynthetics in Dynamic Surface Leaching Test - Nontarget Screening, Target Analytic, and Effect-Based Identification

Christian Brüggemann[1]*, Peter Schweyen*[2]*, Anna Maria Bell*[3]*, Arne Wick*[2] *and Thomas A Ternes*[4]*, (1)G2 - Aquatic Chemistry, Federal Institute of Hydrology (BfG), Koblenz, Germany, (2)G2-Aquatic Chemistry, German Federal Institute of Hydrology, Germany, (3)G3-Biochemistry, Ecotoxicology, German Federal Institute of Hydrology, Germany, (4)G Qualitative Hydrology, German Federal Institute of Hydrology, Germany*

Geosynthetics are often used for traffic route construction, where they are in contact with water and soil. In this study, we investigated geotextiles which were used for waterway construction. This material consists mainly of synthetic needle-punched polymer fibers (e.g., polypropylene or PET) which allows the material to be suitable for bank stabilization and filtration. Avivage agents are used in large quantities to optimize the manufacturing process and to improve the material properties (e.g., light and oxidation stability). The material is laid in stitched lanes along riverbanks and is covered with armoring stones or sand. The tensile strength and flexibility of the material ensures its durability, prevents erosion of the substructure material, and ensures its stability over several decades. For this purpose, two typical nonwoven geotextiles with different polymer compositions were characterized and investigated in a laboratory release study which focuses the dynamic surface leaching (DSLT: DIN CEN/TS 16637-2:2014). The test consists of eight elution steps over a total period of 64d (days). The intervals for the water changes increases from initial step for each step, so that the first step lasts 6h and the following ones 18h, 1d 6h, 1d 18h, 5d, 7d, 20d, and 28d. Our study consists of the quantification of the total dissolved organic carbon (DOC), several target compounds as well a nontarget screening approach to identify relevant organic substances which were released from the material in the leachate. The number of components and the overall intensity decreases over the elution steps. The detected components were sorted to different levels of identification and prioritized compounds were quantified with target analytics. The identified substances can be assigned to the groups of sulfates, (benzene)sulfonates, polyethylene glycols (PEG), phosphates, and PET oligomers. One of the identified compounds, which leaches out of just one of the geomaterials, showed effects via bacteria luminescence inhibition tests and can be classified as ecotoxicological relevant. The DOC content in the leachates of the geotextile from which the ecotoxicologically relevant substance leaches out is significantly lower than in the leachates of the geotextile which show no effects. As a result, (eco)toxicity cannot be predicted by the DOC alone, but needs to be addressed on the ecotoxicological effects measured.

3.03.P-Th160 Toxicology of Eluates from an Early Stage façade Lifetime and the Impact of UV Irradiation and Encapsulation

Nadine Kiefer[1]*, Moritz Nichterlein*[2]*, Fabienne Reiß*[3]*, Madeleine Runge*[4]*, Ulf Biermann*[5]*, Matthias Noll*[6] *and* ***Stefan Kalkhof***[7]*, (1)Department for Bioanalysis, Coburg University of Applied Sciences and Arts, Coburg, Germany, (2)Institute of Bioanalysis, Coburg University of Applied Sciences and Arts, Coburg, Germany, (3)Microbiology, Coburg University of Applied Sciences and Arts, Coburg, Germany, (4)SGS Analytics Germany GmbH, Germany, (5)Limbach Analytics GmbH, Germany, (6)Coburg University of Applied Sciences and Arts, Coburg, Germany, (7)Institute for Bioanalysis, HAW Coburg, Germany*

Biocides are used as film and in-can preservatives are applied in paint and render formulations to protect building facades from microbial colonisation and biological decomposition. In-can preservatives leach out at the beginning of a façade lifetime, whereas film preservatives leach out over a long period in small concentrations. Consequently, these biocides were reported to be found in rivers and sewage systems.

The goal of this study was to chemically characterize façade runoffs obtained from free weathering experiments as well as from lab experiments after defined treatment and to evaluate the ecotoxicological effect of the resulting eluates on soil, sediment and water organisms.
Therefore paint/render systems were prepared as test samples being either biocide free, containing film and in-can preservatives or only containing in-can preservatives. The samples were collected after every rain event and immersion cycle, diluted with a dilution factor of 5.19 to reflect additional rain caused dilution and analyzed via HPLC-DAD or MS. The toxicity of the generated leachables were evaluated for several aquatic and sediment organisms, namely luminescent bacteria, green algae, umu-test, fish-egg test, *Chironomus riparius*, and *Lumbriculus variegatus*. The general leaching trend for both tests was the same, the free in-can preservatives with higher water solubility (especially BIT) leach out at the beginning of a façade lifetime in high concentrations and were not found after the first rain events / immersion cycles. Even considering high dilution, BIT shows toxic effect on various aquatic and sediment organisms. The more hydrophobic film preservatives, which were additionally encapsulated, leach out in low concentration over the complete period. In-can preservatives related effects could be observed for luminescent bacteria. Film preservatives mostly affect the toxicity for organisms like green algae. Even for more complex organisms like *Chironomus riparius* and *Lumbriculus variegatus* toxic effects for the natural weathering eluates could be observed. In the risk assessment of complex building materials, previous studies have mainly considered film preservatives, as those have a long service life and continuous leaching behavior. Therefore, despite their short-term toxic effects, these substances can be a stress factor for the environment and should not be neglected in the risk assessment of facades even if they degrade rapidly.

3.03.P-Th161 Removal and Biodegradation of Quaternary Ammonium Biocides in Wastewater Treatment

*Andrea Mongelli[1], **Yrsa Larsson**[2] and Kai Bester[3], (1)Environmental Chemistry and Toxiology, Aarhus University, Denmark, (2)ENvironmental Sciences, Aarhus University, Denmark, (3)Environmental Science, Aarhus University, Denmark*

Quaternary ammonium compounds (QUATs), are the most commonly sold biocides in Europe and several thousand tons are marketed every year for use in human and veterinary hygiene, wood protection, as well as other applications. However due to their surfactant nature it is not easy to determine basic physicochemical data and thus predictions for the behaviour in wastewater treatment are difficult to make.
Thus we studied mass balances and metabolism of QUATs in municipal wastewater treatment. Inflow and effluent concentrations were determined by means of HPLC-MS/MS from 24 h composite samples from three smaller WWTPs in Denmark. Especially Benzalkonium chlorides (BAC) and Dimethyl-Diakyl Ammonium chlorides (DDAC) were determined. Especially BAC-12, -14, and -16 as well as DDAC-12 were detected in all WWTPs. The highest concentrations in WWTP influents were measured for DDAC-12 (1000-4900 ng/L) followed by those for BAC-12 (900-2200 ng/L), BAC-16 (88-217 ng/L) and BAC-14 (25-100 ng/L). As the effluent concentrations were very small, the removal in the tested WWTPs was high (exceeding 99%). According to the sorption studies, this could completely be due to sorption, as sorption alone could result in 99% removal. However, also biodegradation contributes to the removal: for some compounds this is significant.

Biodegradation rate constants for a large variety of QUATs in sludge were determined in incubation experiments. The resulting half-lives ranging from 1.5-60 h. Concerning the congeners found in Danish WWTPs the spread was on average: 13 h (BAC-16) and 14 h (BAC-14), 31 h DDAC-12 and 49 h (BAC-12). Considering the relative rapid biodegradation of BAC-16, it can be assessed that biodegradation is also contributing the high removal of BAC-16. Thus there are two issues concerning the emissions of WWWTPs: the parent compounds as sorbed to sludge pose a risk for terrestrial ecosystems. The formed metabolites are probably more water soluble than the parent compounds and might well be discharged with the effluent water to a relative high extent.

3.04.A Application of Biomonitoring Approaches to Support Surveillance of Chemical Exposure in the Environment

3.04.A.T-01 Complementing Active Biomonitoring with Proteomics in an Aquatic Invertebrate Sentinel Species, *Gammarus Fossarum*

***Davide Degli Esposti**[1], Maxime Lepretre[2], Anabelle Espeyte[2], Nicolas Delorme[3], Sophie Ayciriex[4], Arnaud Salvador[4], Arnaud Chaumot[5] and Olivier Geffard Pr[6], (1)Laboratoire d'écotoxicologie INRAE, France, (2)INRAE, France, (3)UR RiverLy - ECOTOX, Laboratoire d'écotoxicologie INRAE, France, (4)University of Lyon, France, (5)INRAE (Institut National de la Recherche Agronomique), France, (6)UR RiverLy, Institut national de recherche pour l'agriculture, l'alimentation et l'environnement (INRAE), France*

Environmental risk assessment of chemical mixtures is challenging because of the multitude of possible combinations that may occur. Biological approaches, such as active biomonitoring to measure both bioavailable contamination and the biological responses of exposed organisms, may provide valid complementary tools to chemical monitoring. The freshwater amphipod *Gammarus fossarum* has been established to assess the contamination levels of a great variety of aquatic systems and the measurement of some specific molecular biomarkers is currently available in this species. In order to identify biomarkers or pathways of exposure and effect, it is necessary to screen and determine the most environmentally responsive molecular features

(e.g., proteins, metabolites). Multiple reaction monitoring (MRM) mass spectrometry is emerging as a relevant tool for measuring customized molecular markers in freshwater sentinel species. However, it is typically used for the validation of a limited number of molecular markers preselected from shotgun experiments at a whole-individual level in small invertebrates. This limits the physiological interpretation of these markers due to a lack of organ specificity. In this study, we used highly multiplexed MRM mass spectrometry to conduct large-scale screening of organ-specific proteomes in the sentinel species *Gammarus fossarum*. By combining laboratory and active biomonitoring (*in situ* caging) approaches, and MRM technologies, this study proposes a new strategy for the discovery of candidate molecular markers in the caeca, one of the main detoxification and metabolically active organs in amphipods. Seven hundred and sixty-five peptides representing 450 distinct proteins were monitored in MRM, resulting in a comprehensive coverage of biological functions. This MRM method was then successfully applied to analyse the caeca of gammarids either exposed in the laboratory to several environmental concentrations of cadmium (Cd), silver (Ag) and zinc (Zn) or caged in river sites across French with various types and levels of metal contamination.
Differential proteomics and functional analyses indicate that the proteome of *Gammarus fossarum* caeca show metal specific responses to different metal exposures, although the transfer of protein biomarkers to field biomonitoring still represents many challenges.

3.04.A.T-02 Temporal Suspect Screening of the Aquatic Invertebrate *G. pulex*

Lucy Birkitt[1], *Alexandra Kate Richardson*[2], *Thomas Miller*[3], *Stewart Owen*[4] *and Leon Barron*[5], *(1)Imperial College London, United Kingdom, (2)Analytical, Environmental & Forensic Sciences, King's College London, United Kingdom, (3)Brunel University, United Kingdom, (4)Astrazeneca UK Ltd, United Kingdom, (5)School of Public Health, Imperial College London, United Kingdom*

There are over 350 000 chemicals licensed for manufacture and sale globally, including pharmaceuticals, pesticides, and personal care products. Through various routes, these chemicals are regularly detected in waterways. Where a chemical is detected in water, the biota that reside therein are exposed. To understand the effects on aquatic invertebrates, analytical methods must be developed to detect the contaminants that they are exposed to. However, the huge range of chemical pollutants means that developing targeted techniques to monitor the vast numbers of potential pollutants is a mammoth task. High-resolution mass spectrometry has made it possible to perform "suspect screening" – using a large library to tentatively identify analytes present in full-scan data. This is useful when it is impractical to obtain the number of reference standards required. Using the results of suspect screening means that the development of targeted techniques can be prioritised.

The aim of this study was to use suspect screening to monitor *G. pulex* to understand where prioritisation of techniques should be focussed.

G. pulex and river water samples were taken over the course of six months. Suspect screening was performed using a Shimadzu LC-QTOF-MS system, and a suspect screening was performed using a library of 1,195 compounds.

A total of 55 analytes were detected in *G. pulex*, predominantly pharmaceuticals, but also pesticides, illicit drugs, and metabolites. These results may be explained by the nearby wastewater treatment plant, which contributes to the high proportion of pharmaceutical pollution. Quantification was only possible for the antidepressant drug citalopram, whose concentration in *G. pulex* ranged from 52 to 107 ng/g. This concentration was plotted against the water temperature over the six month period and there was a moderate correlation, suggesting that there may be a connection between temperature and extent of contamination.

Although suspect screening has successfully been used in river water, using this method to screen aquatic invertebrates is novel and valuable because it highlights the contaminants that the biota absorb, which can be selected for further investigation to determine behavioural or biochemical changes. The results of this study also revealed an implication for a relationship between temperature and concentration of pharmaceuticals, which may be vital to understand an additional detail in the impact of climate change on chemical pollution.

3.04.A.T-03 First Evidence of Widespread Anticoagulant Rodenticide Exposure of the Eurasian Otter (*Lutra lutra*) in Germany

Julia Regnery[1], *Simon Rohner*[2], *Julia Bachtin*[1], *Christel Möhlenkamp*[1], *Olaf Zinke*[3], *Stefanie Jacob*[4], *Ursula Siebert*[2], *Georg Reifferscheid*[5] *and Anton Friesen*[4], *(1)Federal Institute of Hydrology (BfG), Koblenz, Germany, (2)University of Veterinary Medicine Hannover, Germany, (3)Museum of the Westlausitz Kamenz, Germany, (4)German Environment Agency (UBA), Dessau-Rosslau, Germany, (5)Biochemistry and Ecotoxicology, Federal Institute of Hydrology (BfG), Koblenz, Germany*

Exposure of wildlife to anticoagulant rodenticides (ARs) has been extensively monitored and documented worldwide for a variety of terrestrial species that are directly or indirectly linked to pest rodents (the supposed target organisms and vectors of these biocides) via the terrestrial food web. Over time, more pieces have been added to the puzzle, unraveling the widespread AR contamination of other terrestrial nontarget organisms, including primarily exposed invertebrates and tertiarily exposed predators. In recent years, the scientific focus of environmental AR monitoring extended to a former blind spot, namely AR emissions to the aquatic environment, and provided clear evidence of hepatic rodenticide residues in various freshwater fish species. As second-generation ARs are likely to be transferred along the aquatic food chain, this study investigated a total of 122 Eurasian otter (*Lutra lutra*) individuals found dead in Germany between 2005 and 2021 regarding hepatic residues of anticoagulants to shed more light on aquatic exposure pathways of ARs and involved environmental risks. Target analytes comprised one pharmaceutical and 8 biocidal anticoagulants as well as one suspected environmental metabolite. Notably, all target compounds were detected in the analyzed livers of otters, a fish-eating top predator and sentinel species for the aquatic environment that is strictly protected by conservation laws. In regions with pronounced rodent control measures, otters were frequently exposed to biocidal ARs in spite of strict regulations regarding the sale, supply, and use of ARs. The elevated levels of second-generation ARs measured in several otters, compared to freshwater fish, confirmed their transfer along the aquatic food chain. Our monitoring data corroborate the predicted unacceptable risks of secondary poisoning for fish-eating mammals and birds during environmental risk assessment of second-generation ARs and their high potential for bioaccumulation and biomagnification. Thus, risk mitigation measures and restrictions of use that were implemented in Germany within the biocidal product authorization may not be protecting aquatic nontarget wildlife as intended. Improvements of stipulated measures are required to minimize the almost ubiquitous occurrence of hepatic second-generation AR residues in nontarget wildlife as the potential ecotoxicological consequences thereof are yet unknown.

3.04.A.T-04 Using the Northern Gannet (Morus bassanus**) to Monitor Environmental Changes of PFAS Prior and After Restrictions**

***M. Gloria Pereira**[1], Lee Walker[1] and Silvia Lacorte[2], (1)UK Centre for Ecology & Hydrology (UKCEH), United Kingdom, (2)Spanish Research Council (CSIC), Institute of Environmental Assessment and Water Research (IDAEA), Spain*

Perfluoroalkyl substances (PFAS) are a large group of manmade compounds, produced since the 1950's, with chemical and thermal stability. Because of their persistence, ubiquity in the environment, bioaccumulation potential, and toxicity they are considered compounds of concern: PFOS (perfluorooctanesulfonic acid) and its related compounds are listed in the in the Stockholm Convention (2009).

We analysed long term trends of eight Perfluorinated Carboxylic Acids (PFCAs) and three perfluorinated sulfonates (PFSAs) in a marine sentinel species, the Northern gannet, in two UK colonies (Ailsa Craig, and Bass Rock) between 1977 and 2014.

We found no significant differences in the ∑PFAS between both colonies also that they were dominated by the ∑PFSAs which accounted for >80% of the total load measured in the eggs. By contrast, the ∑PFCAs was slightly, but significantly higher in Ailsa Craig (2-34.5 ng/g w.w.) than in Bass Rock (1.6- 26.4 ng/g w.w). This group of compounds was dominated by perfluorotridecanoate (PFTriDA), perfluoroundecanoate (PFUnA) and perfluorooctanoic acid (PFOA), with these compounds comprising 90% and 82% of the total in Ailsa Craig and Bass Rock, respectively. No significant difference in the ∑PFSAs (16.5 - 165 ng/g w.w.) were found between the colonies. PFOS dominated the PFSAs, accounting for 99% of the total concentration of sulfonates.

The ∑PFSAs and ∑PFCAs had very different temporal trends. The ∑PFSAs increased significantly in eggs of both colonies in the earlier part of the study. However, from the 1990s onwards there was a significant declined, possibly as a result of the phasing out of PFOS production in 2000. By contrast, in the 1970s and 1980s the concentrations of PFCAs were low and remained low, suggesting not much usage of these compounds. Then, their levels increased significantly in both colonies until the end of the study. The increase in ∑PFCAs was linked to the rise in large chain, namely odd, perfluorinated carboxylic acids. PFOA, the best known of the PFCAs, had a different temporal trend from the other predominant acids, showing a slow decline in the last 15 years of the study. In the first 20 years, PFSAs accounted for >90% ΣPFAS in eggs but from 1994 onwards, this proportion decreased to 62% - 73%, suggesting a temporal decline of PFSAs combined with increase of PFCAs.

3.04.A.T-05 Legacy and Emerging PFAS in Cetacean and Seal Species Stranded Around the UK: Using UPLC-HRMS to Characterise Chemical Burdens Between Species

***Imogen Bailes**[1], Jonathan Barber[2], Sara Losada[2], Rob Deaville[3], Andrew Brownlow[4] and Andrew Sweetman[5], (1)Lancaster Environment Centre, Lancaster University, United Kingdom, (2)Centre for Environment Fisheries and Aquaculture Sciences (Cefas), United Kingdom, (3)Institute of Zoology, Zoological Society of London, United Kingdom, (4)University of Glasgow, United Kingdom, (5)Lancaster University, United Kingdom*

Poly- and perfluoroalkyl substances (PFAS) are a large group of chemicals that are characterised by a hydrophilic moiety (e.g., SO_3^- or COO^-) and a hydrophobic perfluorocarbon chain that varies in length. PFAS display unique properties due to combined oil and water repellence, extreme stability, and hence are used in a wide range of industrial processes and consumer products. These chemicals can be problematic in the environment due to their potential to undergo long-range transport, persistence, and toxicity. However, only some of these substances, particularly the longer-chain PFAS, have been regulated by the Stockholm Convention and other international regulations. As a result, shorter-chain alternatives are being increasingly used in industry and, therefore, there is a growing need to document evidence of these emerging chemicals of concern in the environment. Liver samples can be used to determine the body burden of PFAS chemicals in marine mammals. Here, we employ an ultra-performance liquid chromatograph coupled to a high resolution mass spectrometer (Orbitrap) to analyse a range of both legacy and emerging PFAS including 11 PFCAs (C4-C14), 9 PFSAs (C4-C10), 3 FASAs, 3 PFPiAs and 6 fluorotelomer acids, among others. We have analysed the liver tissue of 130 individuals from a variety of species including bottlenose dolphins, humpback whales, and harbour seals stranded between 2012 and 2022. We report high total PFAS concentrations in a range of species of marine mammals collected around the UK. Concentrations of different compounds vary highly within species, but most species tend to be dominated by PFOS and long chain PFCAs. Contamination profiles reveal a potentially important route of exposure through the atmospheric transport of precursor compounds and a varying bodily response to *in vivo* PFOSA degradation between species. By quantifying and identifying PFAS in marine mammals, not only can we estimate bioaccumulation factors for specific chemicals, but we can also provide evidence for emerging chemicals that are not yet regulated. Our research addresses the need to understand exposure levels in wildlife to PFAS compounds and also how PFAS fingerprints vary between different species over time.

3.04.B Application of Biomonitoring Approaches to Support Surveillance of Chemical Exposure in the Environment

3.04.B.T-01 Characterization of Stream Communities Affected by Pesticides
Alina Koch[1]*, Jes Rasmussen*[2]*, Ove Jonsson*[1] *and Mikaela Gönczi*[1]*, (1)Department of Aquatic Sciences and Assessment, Swedish University of Agricultural Sciences (SLU), Sweden, (2)Norwegian Institute for Water Research (NIVA), Norway*
Pesticides biomonitoring is important to evaluate the effects of pesticides on nontarget organisms for sustainable management of aquatic ecosystems in agricultural landscapes. However, it remains a challenge to evaluate pesticide specific stress. This study gives a comprehensive characterization of two streams of the Swedish pesticide monitoring programme as well as a reference stream to elucidate pesticide-specific effects on the stream ecosystem. Besides the pesticide monitoring, i.e., weekly time-integrated surface water sampling and biomonitoring of benthic invertebrates and diatoms each fall, two sampling campaigns were conducted in early summer and fall 2022. Among other samples, benthic invertebrates and biofilm samples were collected for chemical analysis (110 pesticides and metabolites) and ecological analysis (species identification and fatty acid analysis).

The concentrations of 110 pesticides in benthic invertebrates, biofilms, water, and sediment were quantified and the benthic invertebrate and biofilm samples identified to species. Results between the two sampling seasons will be compared and put into relation with agricultural use data (i.e., amount of active substances sprayed in the catchment, crops grown, etc.). Taxonomy data and pesticide concentrations are used to calculate biological indices (SPEcies At Risk (SPEAR) index, TUmax, Average Score Per Taxon (ASPT), EPT). Distribution, occurrence, and correlations between measured concentrations in all matrices and biological indices will be evaluated with a follow up discussion about the expressive power of the indices to assess ecological effects of pesticides in agricultural streams.

3.04.B.T-02 An Integrated Biological Effects Assessment of an Offshore Oil and Gas Installation in the North Sea
Steven Brooks[1]*, Shaw Bamber*[2]*, Bjørn Einar Grøsvik*[3] *and Daniela Maria Pampanin*[4]*, (1)Norwegian Institute for Water Research (NIVA), Norway, (2)NORCE Norwegian Research Centre, Norway, (3)Havforskningsinstituttet/Institute of Marine Research, Norway, (4)University of Stavanger, Norway*
The following study was part of the Norwegian Water Column Monitoring (WCM) programme, which performs investigations into the potential effects of offshore oil and gas activities on the marine environment. An integrated biological effects monitoring programme was designed to determine the potential effects of Ekofisk and Eldfisk oil and gas installations. Produced water (PW) impacts were assessed in the water column by deploying monitoring stations containing mussels, passive samplers (PSDs), and scientific equipment downstream of the Ekofisk and Eldfisk installations for 6 weeks at 2 depths between March and May 2023 and compared to two reference stations and a day zero group. Chemical and biological effects were measured and a clear relationship between PAH concentration in mussels and proximity to the Ekofisk installation was shown in the 20 m mussels reaching background concentrations in mussels 4000 m downstream. Only low concentrations were found in the Eldfisk mussels and 40 m mussels showing low exposure to the PW plume. Biological responses in relation to proximity to the Ekofisk installation were only found for some biological effects representing a weak response to low PW exposure. In addition, demersal fish were collected from within the Ekofisk safety zone and three regions of the North Sea (Ekofisk region, Egersundbank, Vikingbank).The fish species sampled included: cod (*Gadus morhua*), dab (*Limanda limanda*), haddock (*Melanogrammus aeglefinus*), and whiting (*Merlangius merlangus).* Integrated chemical and biological effects were measured and a clear relationship was found between PAH exposure (liver /metabolites) in dab and CYP1A activity (EROD and CYP1A protein), with higher levels in dab populations living in areas of oil and gas activity. Genotoxicity was also observed in cod and dab from the Ekofisk, however, higher level orders of biological response such as histological changes were absent.

3.04.B.T-03 MALDI-Mass Spectrometry Imaging Applied to Environmental Problems
Ana Maria Herruzo-Ruiz[1]*, Chiara Trombini*[2]*, Julian Blasco*[2]*,* ***Carmen Michan***[1]*, Jose Alhama*[1]*, Berta Cillero-Pastor*[3,4] *and Eduardo Chicano-Galvez*[5]*, (1)Dpt. Biochemistry and Molecular Biology, ceiA3, Universidad de Córdoba, Spain, (2)Dpt. Ecology and Coastal Management, Instituto de Ciencias Marinas de Andalucía, Spain, (3)The Maastricht MultiModal Molecular Imaging Institute (M4I), Division of Imaging Mass Spectrometry, Maastricht University, Netherlands, (4)Dpt. Cell Biology-Inspired Tissue Engineering, MERLN, Institute for Technology-Inspired Regenerative Medicine, Netherlands, (5)Mass Spectrometry and Molecular Imaging Unit (IMSMI), University of Cordoba, Maimonides Biomedical Research Institute of Cordoba (IMIBIC), Spain*
MALDI-Mass Spectrometry Imaging (MSI) is a multiomic technique that can record the mass spectrum of multiple analytes in a 2D matrix, usually sections of tissues or of a complete organism. MSI can be applied to locate the spatial distribution of biomolecules (e.g.: proteins, peptides, lipids, metabolites, etc.) in biological samples, and this information can be later combined with histological information from classical staining techniques to get molecular morphological maps. Here, we have used this approach to evaluate pollution effects in aquatic environments by analysing *Scrobicularia plana* clams. This bivalve mollusk is widely distributed in European intertidal mudflats and is considered a good bioindicator of exposure and bioavailability to metallic/organic contamination. A complete peptide and lipid maps from *S. plana* were generated, allowing the spatial definition of the different organs of the bivalve (i.e.: digestive gland, stomach, siphons, and foot) at a molecular level. Also, we have compared the peptidome and the lipidome of clams from different areas of the southwestern Andalusian coast and changes are being correlated with metal contents. The peptide analysis showed significant changes in animals from the Guadalquivir estuary,

specifically in their siphons. Furthermore, in the lipidomic analysis specific *m/z* values were associated to the different organs of the clam, and some of them presented altered patterns at different locations of the Huelva estuary. To our knowledge this work is the first molecular imaging mapping of clams and the first application of this technique for biomonitoring the effects of pollution in the environment.

3.04.B.T-04 Plastic in the Air?! – Spider Webs as Spatial Mirrors for Microplastics and Tire Wear in Urban Air
*Isabel Goßmann[1], Rebecca Süßmuth[2] and **Barbara Scholz-Boettcher**[3], (1)University of Oldenburg, Institute for Chemistry and Biology of the Marine Environment, Germany, (2)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany, (3)University of Oldenburg, Institute for Chemistry and Biology of the Marine Environment (ICBM), Germany*
Urban air is highly imprinted by anthropogenic activities resulting in microsized particulate matter release. Besides dust, soot, brake, and tire wear particle abrasion (TWP) the content of common microplastics (MP) in air, their composition, distribution, and transport potential have come into the focus of investigations recently. However, available quantitative data sets are highly limited.

Spider webs act as nonselective, climate-, and season-independent particle traps, which occur worldwide. They are costless and renewable. Successfully applied as passive samplers for inorganic contaminants 30 years ago, we investigate spider webs as a cheap and easily accessible biomonitor for evaluation of MP and TWP composition, spatial distribution, and relative concentrations in urban air.

Samples were collected in covered bus stops at different trajectories and times in a mid-sized German city. The spider webs were processed with an advanced oxidation process (Fentons reagent) and analysed with PY-GC/MS. Polymers were quantified as backbone-related clusters (indicated by prefix “C”) as introduced earlier. Various soot samples were analyzed to evaluate potential interferences with the C-PVC indicator naphthalene; subsequently a factor was introduced to correct the C-PVC data (indicated by *). TWP and “traditional” MP were present in all samples representing 1 to 10% of the web’s total mass. Most dominant was car tire wear (Ø 41%), followed by C-PET (Ø 36%) and *C-PVC (Ø 12%). C-PET is most likely derived from textile fibers. *C-PVC is assumed to originate notably from road markings. Although frequently found, truck tire wear, C-PE, C-PP, C-PS, C-PMMA, and C-PC were present in much lower concentrations (Ø <6.4%). TWP prevails in highly traffic-influenced sampling areas, while “traditional” MP dominated in residential areas. Spider webs are suggested as a globally applicable “pollution mirror” to get an overview of spatial (horizontal/vertical) as well as temporal MP contamination trends and to identify hotspots in (urban) air (outdoor/indoor).

3.04.B.T-05 Identification of Unmonitored Aryl Hydrocarbon Receptor Agonists in Marine Biological Samples in South Korea Using Advanced Effect-Directed Analysis
***Jihyun Cha**[1], Jiyun Gwak[1], Junghyun Lee[2], Sang Hee Hong[3], Hyo-Bang Moon[4], Jong Seong Khim[2] and Seongjin Hong[1], (1)Department of Marine Environmental Science, Chungnam National University, Daejeon, Korea, Republic of (South), (2)School of Earth and Environmental Sciences & Research Institute of Oceanography, Seoul National University of Science and Technology, Korea, Republic of (South), (3)Oil and POPs Research Group, Risk Assessment Research Center, Korea Institute of Ocean Science and Technology, Korea, Republic of (South), (4)Department of Marine Science and Convergence Engineering, Hanyang University, Ansan, Korea, Republic of (South)*
In the present study, we investigated major aryl hydrocarbon receptor (AhR) agonists in marine biota samples using effect-directed analysis (EDA) combined with full-scan screening analysis (FSA). The specific objectives were to: i) investigate major AhR-active compounds in organic extracts of eggs and livers of black-tailed gulls and blubber, liver, and muscle of common dolphins and a fin whale using H4IIE-*luc* bioassay, ii) measure concentrations of known AhR-active compounds, including traditional and emerging polycyclic aromatic hydrocarbons (PAHs) and polar AhR agonists in biota extracts using GC-MSD and HPLC-MSMS, respectively, iii) identify tentative AhR agonists in highly potent fractions using high-resolution mass spectrometry, and finally iv) evaluate relative contributions of each AhR agonist to overall potencies. Significant AhR-mediated activities were observed in the mid-polar fraction of egg extracts of black-tailed gulls and the polar fraction of liver extracts of black-tailed gulls and blubber and liver extracts of fin whale. Known AhR agonists had limitations in explaining the total biological effects. FSA was conducted on mid-polar fractions of egg extracts using GC-QTOFMS and on polar fractions of liver extracts of black-tailed gulls and blubber and liver extracts of a fin whale using LC-QTOFMS. AhR agonist candidates were selected through the application of selection criteria. Of these, ethylbenzoate (6.0×10^{-5}), 3-phenylpropanal (2.0×10^{-4}), and 1,4-dicyclohexylbenzene (7.0×10^{-4}) of egg extracts were identified as novel mid-polar AhR agonists. Polar AhR agonists such as [10]-gingerol (4.0×10^{-3}), angelicin (3.0×10^{-3}), corticosterone (2.0×10^{-2}), eupatilin (3.0×10^{-3}), etofenprox (2.0×10^{-3}), oxadixyl (5.0×10^{-4}), tretinoin (5.0×10^{-4}) in liver extracts of black-tailed gulls, and raloxifene (2.0×10^{-3}) and fluphenazine (3.0×10^{-4}) in blubber extracts, peimisine (6.0×10^{-3}) and alantolactone (3.0×10^{-3}) in liver extracts, and hydroxygenkwanin (2.0×10^{-4}) in blubber and liver extracts of a fin whale were newly identified. With the addition of novel AhR agonists, the contribution increased by 0.001–86% in egg extracts, 27–52% in liver extracts of black-tailed gulls, 2.6%–16% in blubber extracts of common dolphins and a fin whale, and 49% in liver extracts of a fin whale. Further studies are needed to evaluate the quantitative ecological risk that can be expressed by the AhR-mediated activities in biological samples.

3.04.P Application of Biomonitoring Approaches to Support Surveillance of Chemical Exposure in the Environment

3.04.P-Mo157 Complementing the Assessment of the Chemical Status of Transitional and Coastal Water Bodies, Considering Both Waters and Biota

Joana Larreta[1]*, Oihana Solaun*[2]*, Izaskun Zorita*[2]*, Germán Rodríguez*[2]*, Ángel Borja*[2] *and Jesus Alberto Manzanos*[3]*, (1)FUNDACION AZTI, SUKARRIETA, Spain, (2)AZTI, Spain, (3)Basque Water Agency (URA), Spain*

The Water Framework Directive, through its Directive 2013/39/EU, establishes how to carry out the assessment of the chemical status of water bodies, defining the quality standards for priority and preferential substances. The directive encourages the study of pollutants in water, irrespective of water type: river, groundwater, reservoir, transitional, or coastal water. In certain types of water or pollutant, this could be adequate, but when the variability of the water body is large, the characterisation of water pollutants becomes more complicated. Thus, the directive recommends periodic point sampling of such water bodies.

Biota is considered as an integrative, cumulative system over time, which, thanks to toxicity studies that validate the quality standards established for it, could indicate the degree of contamination of an area.

This directive establishes fish as the biota to be considered, except in the case of polycyclic aromatic hydrocarbons (PAHs), for which crustaceans or mollusks are indicated for monitoring.

In water bodies such as transitional water bodies interacting with the coastal zone and coastal water bodies, the assessment of chemical status with fish could be somewhat complicated, as fish do not distinguish humans established boundaries between water bodies.

Given that the variability of water in point sampling is very high, sediment and biota (i.e., fish), due to their integrative characteristic, could be considered as more suitable matrices for the assessment of the chemical status of transitional and coastal water bodies. Sediment could be used to study the temporal evolution of the status of a water body within the WFD. However, considering the mobility of fish, it is difficult to use them to evaluate, with any degree of confidence, the status for each water body.

Therefore, the Basque Water Agency (URA) takes into account punctual water samples throughout the year and molluscs in estuaries to monitor the chemical status in the Basque coast. Mollusc data is used to confirm the evaluation of those substances for which the level of confidence of the data in water is not high enough to make the evaluation, as is the case of PAHs, specifically Benzo(*a*)pyrene.

3.04.P-Mo158 Making Use of Long-Term Monitoring Data Sets: Factors Affecting Biomarkers Commonly Used in Environmental Monitoring Programmes

Marta G.L. Assuncao[1]*, Aldina M. Franco*[2] *and Shannon Dalessandri*[3]*, (1)Centre for Environment Fisheries and Aquaculture Sciences (Cefas), United Kingdom, (2)University of East Anglia, United Kingdom, (3)University of Alabama*

Anthropogenic chemical pollutants in the marine environment have the potential to accumulate in the tissues of organisms leading to biological disruption and disease which can adversely affect ecosystems. Long-term monitoring programmes like the UK Clean Seas Environmental Monitoring Programme (CSEMP) rely on biological effects techniques to assess if such chemicals are affecting sentinel species. We have applied mixed and fixed effect linear models to the long-term CSEMP dataset to evaluate if factors such as region (location), sex, age, condition factor (CF), and gonadosomatic index (GSI) contribute to the variability observed in the levels of 3 well established biomarkers (inhibition of acetylcholinesterase in muscle-AChE, induction of hepatic ethoxyresorufin-O-deethylase-EROD, and presence of biliary 1-hydroxypyrene-1-OH pyrene) used to monitor biological effects of contaminants in dab (*Limanda limanda*) in England. Regional differences (location) were a significant explanatory variable for the 3 biomarkers. We report for the first time that, while accounting for region, sex and gonadosomatic index are significant predictors of muscle Acetylcholinesterase isoform in dab. Dab condition factor is also a significant predictor for both enzymatic markers (AChE and EROD) but not for 1-OH pyrene. We observed a significant age and sex interaction for hepatic EROD, with male dab, above 2 years, having higher values when compared to females. While the results from this study confirm the adequacy of the current CSEMP biomarkers protocol they also highlight the factors to account for when analysing/assessing if environmental contamination is contributing to the responses of these 3 biomarkers in dab around UK waters.

3.04.P-Mo159 Whole Slide Imaging, Digitalization, and Automation of Histopathological Lesion Evaluation in Marine Organisms for the Purpose of Environmental Monitoring

Daniela Maria Pampanin[1]*, Philip Tanabe*[2]*, Kristy Forsgren*[3]*, Aleksandra Szwedo*[1] *and Daniel Schlenk*[4]*, (1)University of Stavanger, Norway, (2)NCCOS, NOAA National Centers for Coastal Ocean Science, (3)California State University Fullerton, (4)Environmental Sciences, University of California, Riverside*

Use of histopathology to identify changes in marine species in response to contaminants is a long-known practice. The suitability of histopathological biological markers in the assessment of marine environment quality is derived from its high ecological relevance, as alterations on the tissue level are often irreversible. Also, affecting the physiology of an individual could impose a potential effect on the whole population. Visual assessment, traditionally used in the scoring of histological parameters, is a tedious procedure, which requires highly trained personnel and it is often prone to bias. The advances in image acquisition and digital image analysis over the last decades has created a suitable, dynamically evolving environment for analysis of high-content histological images.

Herein, the use of digital pathology, taking advantage of computer vision and the high potential for automation, was utilized to analyse various tissues of both mussels (*Mytilus edulis*) and fish collected in the vicinity of an offshore oil and gas exploration platform in the North Sea.
The application of digital image analysis in performing analysis of histological parameters was implemented in the evaluation of gonads. Using QuPath, an open-source digital analysis software, specifically designed to handle whole slide images, we developed a method for gender recognition in Hematoxylin & Eosin (H&E) colored slides with >97% success rate. We performed a comprehensive analysis of other lesions and are working on developing scripts to analyse a selected set of lesions particularly relevant for the purpose of environmental monitoring. Obtained results were compared with the available scores from the manual assessment, in addition QAQC aspects (using independent and blind experts) were carried out to secure high quality data. Data regarding the liver tissue, center of the metabolic activity of the organisms are also presented.

3.04.P-Mo160 NORMAN Workshop: Improving the Use of (Semi-)Field Data for the Risk Assessment of Chemicals

Paul van den Brink[1], *Alina Koch*[2], *Anne Bado-Nilles*[3], *Beate Escher*[4], *Belen Gonzalez-Gaya*[5], *Enya Cody*[6], *Francisco Sylvester*[7], *Gabriele Treu*[8], *Roque Gastón Alurralde*[9], *Helen Wilkinson*[10], *Henner Hollert*[11], *Iker Alvarez*[12], *Jannicke Moe*[13], *Joanne de Jonge*[14], *Kelsey Ng*[15], *Manuel Soto*[16], *Matthias Liess*[17], *Melis Muz*[18], *Mirco Bundschuh*[19], *Naroa Lopez*[20], *Nicolas Pucheux*[21], *Nikiforos A Alygizakis*[15], *Peter Von der Ohe*[8], *Rémy Beaudouin*[22], *Saskia Finckh*[23], *Tobias Schulze*[23], *Udo Hommen*[24], *Yves Verhaegen*[25] *and Andreu Rico*[26], *(1)Wageningen University & Research, Netherlands, (2)Department of Aquatic Sciences and Assessment, Swedish University of Agricultural Sciences (SLU), Sweden, (3)Umr-I 02 Sebio, Institut National de l'Environnement Industriel et des Risques (INERIS), France, (4)Department of Cell Toxicology, Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany, (5)ESTACION MARINA DE PLENTZIA. As part of the NORMAN network (https://www.norman-network.net/) Working Group 2: Bioassays, the Expert Group (EG) on "Ecosystem level effects of chemicals of emerging concern (CECs) on aquatic ecosystems" organised the workshop: ´Improving the use of (semi-)field data for the risk assessment of chemicals´ on the 21st and 22nd of November, 2023. The aim of the workshop was to create a framework for the field-based calibration of the different (new) tools that can be used to assess the effects of chemical mixtures on ecosystems, with focus on the integration of higher tiers of biological complexity/organization. We propose a framework that integrates (i) analytical data of individual chemicals, (ii) effect-based monitoring data obtained by *in vitro* and *in vivo* bioassays with multiple endpoints accompanied by chemical measurements, (iii) PNEC values based on laboratory toxicity data for standard test species (i.e., from the NORMAN ecotox database) to assess risks of single substances, (iv) multisubstance potentially affected fraction (msPAF) calculations to predict the toxic pressure of mixtures, (v) mesocosm effect data (e.g., NOECs) into predictive mixture assessment tools like the PERPEST model, and (vi) biomonitoring data based on ecological (e.g., diversity indices) and biological effects assessment (e.g., biochemical, physiological and molecular markers) to evaluate mixture effects of contaminants in the environment, and explored how these can be integrated or compared for validation/calibration. As a proof of concept, we used a lowland stream monitoring dataset collected in Germany, which covered the majority of these data types (https://doi.org/10.1594/PANGAEA.931673) and focussed on pesticides. We added PNECs from the NORMAN ecotox database, msPAF values and effect data from mesocosm studies to this dataset to enable a linkage and comparison. A specific proof-of-concept study has been created which demonstrates how the validation and calibration of the different parts can be performed, and/or where the main uncertainties and data gaps are. The results of the workshop and regulatory implications will be discussed further and summarised for the SETAC meeting aiming to establish an applied framework for the integration of all these available resouces for risk assessment.

3.04.P-Mo161 Contamination of Marine Biota and MSFD Environmental Status

Tiphaine Mille[1], ***Nathalie Wessel***[2], *Melanie Brun*[2], *Paco Bustamante*[3], *Tiphaine Chouvelon*[2,4], *Paula Mendez*[4], *Gauthier Poiriez*[3], *Jérôme Spitz*[4] *and Aourell Mauffret*[2], *(1)CCEM, IFREMER, France, (2)IFREMER, France, (3)LIENSs CNRS & Université de la Rochelle UMR 7266, France, (4)Observatoire Pelagis Université de La Rochelle/CNRS, France*

Under the European Marine Strategy Framework Directive, spatiotemporal trends of contaminants should be assessed on the entire exclusive economic zone. In the present study, the approach implemented to monitor and assess the chemical contamination of marine ecosystems in France, is described. Criteria have been identified i) to select sentinel species with different habitats, trophic levels/diets, and covering different dimensions of the marine environment, and ii) to limit the effect of confounding factors on bioaccumulation of contaminants. Then, two assessment approaches were employed; absolute assessments based on distance of contamination indices to thresholds, and relative assessments based on temporal trends. Among chemical contaminants, mercury (Hg) is used in the present communication as a "model" contaminant to illustrate our approach.

In bivalves from 36 coastal stations, Hg concentration indices ranged from 0.013 to 0.129 µg/g wet weight (ww). On the continental shelf, Hg indices ranged from 0.023 to 0.677 µg/g ww in fish (7 species), from 0.038 to 0.686 µg/g ww in birds (6 species) and from 6.8 to 15.4 µg/g ww in mammals (2 species). Increase in Hg concentrations with trophic position (bivalves<fish<birds<mammals) illustrates its biomagnification in trophic food webs. Absolute assessments showed that Hg concentrations were 0.7 to 6.5 times higher than their thresholds (0.02 µg/g ww) in bivalves and 1.1 to 33.9 times higher in fish, depending on the species and region. Though concentrations in birds and mammals were higher than in bivalves and fish, they were 0.02 to 0.69 times the selected thresholds (1 and 61 µg/g ww, respectively), depending on the species and region. This emphasizes that threshold selection and use are not trivial as absolute assessments depend on it. In bivalves and mammals, the two groups of species with sufficient temporal coverage for relative assessments, mercury concentrations increased over the last 20 years. The source of this increase is still to be characterized (e.g., increase in global emission, change in diet), but it indicates that individuals should continuously allocate energy for detoxification and adapt to this pressure (cost for adaptation). Overall, Hg is giving rise to pollution effect in French Atlantic marine ecosystems according to several lines of evidence. The present approach is ambitious and enables to assess environmental quality based on a comprehensive observation of the marine ecosystems.

3.04.P-Mo162 Assessment of Polycyclic Aromatic Hydrocarbons and Phenolic Endocrine-Disrupting Compounds in Seawater, Sediment, and *Posidonia oceanica* in Giglio Island (Arcipelago Toscano National Park, Italy)

***Jasmin Rauseo*[1]**, *Francesca Spataro[1], Edoardo Casoli[2], Anna Barra Caracciolo[3], Daniele Ventura[2], Gianluca Mancini[2], Paola Grenni[4], Andrea Visca[5], Tanita Pescatore[6], Livia Mariani[4], Gian Luigi Garbini[5], Ludovica Rolando[5] and Luisa Patrolecco[1], (1)National Research Council-Institute of Polar Science (ISP-CNR), Italy, (2)Sapienza University of Rome, Italy, (3)Water Research Institute - Italian National Research Council IRSA-CNR, Italy, (4)Italian National Research Council - Water Research Institute (CNR-IRSA), Italy, (5)CNR-IRSA Rome, Italy, (6)National Research Council (CNR), Institute of Polar Science (ISP), Italy*

The Mediterranean coastal areas are characterised by different anthropogenic activities including tourism, shipping, and industrial activities, which are responsible for chemical contaminations. Unfortunately, there are evidences that also marine protected areas are not free from contamination. Many contaminants have mutagenic and/or carcinogenic properties, representing a risk for ecosystem health. The evaluation of chemical contamination in both biotic and abiotic matrices in environmental monitoring programs makes it possible to better assess chemical risk for ecosystems than those solely based on abiotic compartments. In this context, the Mediterranean endemic seagrass *Posidonia oceanica* (L.) Delile 1813 is currently used in several monitoring programs associated to metal contamination, but it has been recently proposed as a suitable bioindicator of organic contamination, due to its potential bioaccumulation capacity. Among contaminants, polycyclic aromatic hydrocarbons (PAHs) and phenolic endocrine-disrupting compounds (PEDCs), including bisphenol A (BPA), 4-nonylphenol (4-NP), and its ethoxylated precursors, have gained considerable attention for their potential toxic effects on humans and wildlife. PAHs are priority pollutants, to be monitored as tracers of anthropogenic impacts. BPA has been recognized as a ‘possible future priority substance’ in the Water Framework Directive and its use has been banned from infant plastic feeding bottles, toys, varnishes, coatings, and plastic food contact materials. 4-NP has been included in different EU regulations and in the list of priority hazardous substances to be eliminated in surface waters. In this context, the present study aims to evaluate the occurrence of PAHs and PEDCs in seawater, sediment, and *P. oceanica* samples collected at 4 stations located at increasing distance from the sewage pipeline of the small touristic town of Giglio Porto (Tyrrhenian Sea, Italy). The abundance of the autochthonous microbial communities in seawater and sediments, as well as in *P. oceanica* leaves and rhizomes was also investigated. Samplings were performed in early spring and late summer 2021, during the minimum and maximum level of tourist presence on the island, respectively. Target contaminants were detected in all matrices investigated suggesting their ubiquitous presence in this marine ecosystem. As expected, higher average concentrations of PAHs and PEDCs were observed in summer.

3.04.P-Mo163 The First Assessment of Halogenated Organic Compounds in the Blubber of Short-Finned Pilot Whales (*Globicephala macrorhynchus*) Stranded Along the Coast of Savu Island, Indonesia

***Dede Falahudin*[1,2,3]**, *Sekar M.C. Herandarudewi[4], Frensly Demianus Hukom[4], Zainal Arifin[4], Ita Wulandari[4], Agus Sudaryanto[5], Anh Quoc Hoang[6], Isao Watanabe[7], Hazuki Mizukawa[7] and Shin Takahashi[7], (1)Ehime University, Ehime University, Ehime, Japan, (2)Ehime University, Ehime University, Center of Advanced Technology for the Environment (CATE), Ehime, Japan, (3)Research Center for Oceanography, Indonesia, (4)Research Center for Oceanography, National Research and Innovation Agency, Indonesia, (5)Research Center for Environment and Clean Technology, National Research and Innovation Agency, Indonesia, (6)Faculty of Chemistry, University of Science, Vietnam National University, Hanoi, Viet Nam, (7)Ehime University, Center of Advanced Technology for the Environment (CATE), Ehime, Japan*

Short-finned pilot whales (SFPW) are frequently stranded cetaceans, although the cause of their stranding is unknown. Toxic, persistent, bioaccumulative, and endocrine disruptor substances, such as polychlorinated biphenyls (PCBs) and brominated flame retardants (BFRs), may threaten these cetaceans' existence. In this study, the contamination status, congener profiles, and ecological risks of PCBs, PBDEs, and other brominated flame retardants (BFRs), including decabromodiphenyl ethane (DBDPE), 1,2-bis(2,4,6-tribromophenoxy)ethane (BTBPE), pentabromoethylbenzene (PBEB), and 2,2,4,4,5,5-hexabromobiphenyl (BB-153), were investigated. Blubber samples were analyzed from 20 of the 46 dead-stranded short-finned pilot whales (SFPW) on Haingahu Beach, Savu Island, Indonesia, in October 2012. PCBs and BFRs were extracted using a high-performance dispersion homogenizer and purified using a multilayer silica gel column (44% H_2SO_4-silica, 22% H_2SO_4-silica, and anhydrous Na_2SO_4) and activated silica column. PCBs and BFRs were quantified using GC-HRMS (EI-SIM) and GC-qMS (NCI-SIM). Our results show

that concentrations of ∑209PCBs, Σ7in-PCBs, Σ12dl-PCBs, and Σ21u-PCBs were between 48−490 (mean:240±140), 22−230 (110±60), 2.6−38 (17±10), and 1.0−13 (6.3±3.7) ng g^{-1} lipid weight (lw), respectively. As for BFRs, concentrations of Σ41PBDEs, PBEB, BB-153, and BTBPE were between 3.7−32 (13±8), <0.01−1.8 (0.73±0.49), <0.04−0.22 (0.16±0.045), and 0.14−2.2 (1.3±0.50) ng g^{-1} lw, respectively. Although not significant, concentrations of Σ209PCBs and Σ41PBDEs in juveniles were relatively higher than those in subadult females and males. Congener-specific profiles of PCBs among sex and estimated age groups were observed; sub-adult females accumulated high proportions of hepta- to deca-CBs and recalcitrant structure-activity groups congeners compared to sub-adult male and juvenile groups. The estimated toxic equivalency (TEQs) value for dl-PCBs ranged from 2.2 to 60 TEQWHO pg g^{-1} lw, with juveniles containing high TEQ values than sub-adults and adults. For BFRs, the most abundant congener detected was BDE 47, with a proportion of approximately 47%. Although the concentrations of PCBs and BFRs in SFPW stranded along the Indonesian coasts were lower than those reported for similar whale species from other North Pacific regions, further research is needed to assess the long-term impact of halogenated organic pollutants on their survival and health.

3.04.P-Mo164 A Biological Effects Assessment Tool: An Integrated Approach to Evaluate Mixture Effects of Contaminants on the Baltic Sea Biota

***Roque Gastón Alurralde*[1,2]*, Kari K. Lehtonen*[3]*, Owen Rowe*[2] *and Elena Gorokhova*[4]*, (1)Environmental Science, Stockholm University, Sweden, (2)Baltic Marine Environment Protection Commission HELCOM, Finland, (3)Finnish Environmental Institute (SYKE), Helsinki, Finland, (4)Department of Environmental Science, Stockholm University, Sweden*

Biological effect monitoring detects and assesses early biochemical or physiological changes caused by exposure to contaminants, most commonly in complex mixtures and under various environmental factors. To achieve Good Environmental Status (GES), the regulatory efforts, including Marine Strategy Framework Directive (MSFD), rely on ecological (based on the community status) and chemical (based on the contaminant levels) assessments. However, the essential link between those assessments is the ecotoxicological effect assessment of contaminants, which is currently missing. In this context, the challenge is in integrating monitoring data on the effects of contaminants across the different levels of biological organisation and species into a functional framework, which could then be linked to the contaminant levels in the environment.

Biological effects in biota exposed to diverse contaminant mixtures are often related to different mechanisms and modes of action. We propose a new approach for integrating these effects by defining operational sets of physiological traits, bioindicator species, and biomarkers that respond in concert. The strength of this integration could be used to detect and quantify responses to the entire array of stressors present in the study area. As a tool for assessing the co-variation across the response components, we will use multivariate ordination and geometrical properties (i.e., sphericity) of the response profile in the multidimensional space. The rationale is that the scatter of multivariate data consisting of various responses (i.e., biomarkers, physiological and population-level responses) measured in biological effect monitoring would exhibit a directional organisation appearing as an ellipsoid shape of the data cloud when multiple mechanisms are in action to overcome stress. By contrast, a circular or random pattern would suggest a non-stressful and healthy environment indicative of GES.

We will develop and explore this approach, including appropriate statistical properties, using data from the biological effect monitoring and studies applying various ecotoxicological methods to assess the ecological consequences of chemical pollution in the Baltic Sea. The work will be conducted as a part of the INTERREG Baltic Sea Region BEACON project aiming to develop environmental assessment tools. The outcome of the project will be instrumental for MSFD implementation by assessing the impacts of pollution in the Baltic Sea.

3.04.P-Mo165 Sharks as Biomonitors of Plastic Pollution in Benthic and Pelagic Marine Ecosystems

Roger B. Casado[1]*, Luis Alves*[1]*, Marco F.L. Lemos*[1]*, Filipe R. Ceia*[2]*, Filipa Bessa*[3] *and* ***Sara Novais***[4]*, (1)Polytechnic of Leiria & MARE, Portugal, (2)MARE - Marine and Environmental Sciences Centre, University of Coimbra, Portugal, (3)MARE - Marine and Environmental Sciences Centre / ARNET – Aquatic Research Network, University of Coimbra, Portugal, (4)Instituto Politécnico de Leiria, Portugal*

Plastic waste has increased markedly in the last decades and the aggravated effect of this super-production and inefficient waste management is that millions of untreated plastic tones end up in the ocean. The different types of plastics can have distinct behaviours on marine environments, sinking and accumulating in marine sediments or remaining in the water column, potentially affecting both benthonic and pelagic ecosystems. Long-lived top predators are prone to accumulate large quantities of plastic debris due to bioaccumulation and biomagnification processes. For that reason, and given the diversity of habitats they can occupy (i.e., from benthic to pelagic and from coastal to oceanic environments), carnivorous sharks can be considered good sentinels of microplastic contamination. The main objective of this study was to assess microplastic incidence in two carnivorous shark species inhabiting different environments within the Northeast Atlantic Ocean: the benthic small-spotted catshark (*Scyliorhinus canicula*) and the pelagic blue shark (*Prionace glauca)*. Sharks were opportunistically captured aboard commercial fishing vessels operating in the North Atlantic (37 *P. glauca* and 44 *S. canicula*) and their stomachs stored for the analyses of microplastic ingestion. Stomach contents (*P. glauca*) and the entire stomachs (*S. canicula*) were digested with 10% potassium hydroxide (KOH) at room temperature, added in a 1:3 proportion (m:v), and filtrated in order to identify, count, and characterize microplastic particles. The results showed a prevalence of 100% in the frequency of occurrence of microplastics in the stomachs of the sampled sharks. Notwithstanding, the abundance and type of plastics present in each species was substantially different. The benthic *S. canicula* accumulated mostly microfibers (88% fibers, 9% fragments, and 3% filaments) but in relatively low numbers (around 7-8 microplastics per individual), while the pelagic *P. glauca* accumulated uncountable numbers of microfragments (i.e., hundreds). These results are in accordance with previous studies of microplastic contamination in marine ecosystems, being fibres more associated with benthic environments, and fragments with pelagic individuals. Our study highlights the high susceptibility of larger sharks to the contamination by microplastics, raising concerns on their potential negative effects.

3.04.P-Mo166 Monitoring the Co-Occurrence of Microplastics and Chemical Contaminants in Freshwater Invasive Mussels

*Timothy Hoellein[1], Catherine Rovegno[1], **Amy V. Uhrin**[2], Ed Johnson[3] and Carlie E. Herring[4], (1)Loyola University, (2)Marine Debris Program, NOAA National Centers for Coastal Ocean Science, (3)NOAA National Centers for Coastal Ocean Science, (4)NOAA Marine Debris Program*

Because bivalves are sessile, relatively tolerant to toxic compounds, and abundant in aquatic ecosystems globally, they are often used to monitor chemical contaminants. Since 1992, NOAA's Great Lakes Mussel Watch Program has used invasive zebra and quagga mussels (*Dreissena* spp.) as biomonitors for chemical contaminants. Microplastic concentrations in the Great Lakes are similar and sometimes higher than in the ocean, suggesting dreissenid exposure. Although dreissenids ingest microplastics in the lab, no studies have examined spatial and temporal patterns of microplastics *in situ* for Great Lakes dreissenids. We compared microplastics in dreissenids among sites, mussel size classes, and sampling dates and examined the relationship between microplastics and contaminants, while considering if these mussels could be valuable for monitoring both contaminants and microplastics in the Great Lakes. Mussels were harvested from reference sites and sites influenced by wastewater effluent and urban river discharge in Milwaukee Harbor (Lake Michigan, USA). Caged mussels were deployed in summer for 30 and 60 days, sorted by size, and analyzed for microplastics and body burden of three contaminant classes: alkylphenols, polyaromatic hydrocarbons, and petroleum biomarkers. The number of microplastics in dreissenid mussels was similar to published values for other bivalve species globally. Microplastics in dreissenids were highly variable with no clear link to pathways of introduction (wastewater discharge, river confluence) or a consistent site trend. At the wastewater site, microplastics were higher in the largest mussels after 30 days. However, for smaller mussels, no distinction among sites was apparent with no differences among sites after 60 days. Out of 93 contaminant comparisons, the only positive correlation was between microplastics and three PAHs (decalin, methylnaphthalene, 1-methylfluorene). Our initial conclusion is that dreissenid mussels in the Great Lakes are not reliable biomonitors for microplastics because variation in microplastics among individuals, size classes, and time periods was higher or equal to the variation among sites. It is clear that intrinsic and extrinsic factors influencing mussel-microplastic interactions require further examination. Even so, our data contribute to the understanding of microplastic spatial distributions in urban freshwaters, the role of dreissenid mussels in plastic budgets, and models for the fate of microplastics.

3.04.P-Mo167 Egg Yolk and Albumen as Biomonitoring Tissues for Organic Pollution in Maternal Foraging Grounds

***Cynthia C. Munoz** and Peter Vermeiren, Radboud University, Netherlands*
