The composition and concentration of chemical cocktails are often poorly established in marine environments particularly beyond the coastal zone. Marine migratory species could act as biomonitors to represent the exposure of associated communities, provided that suitable tissues for biomonitoring are available. Sea turtles could present suitable biomonitors because they integrate pollution across their long lifespan and wide migrations. They also do not feed during their nesting migrations, making their eggs potentially suitable biomonitoring tissues to reflect pollution in maternal foraging grounds. We investigated maternal transfer among 56 PCB, 12 OCP, and 34 PBDE compounds from coupled samples of loggerhead turtle maternal plasma and replicate egg yolk and albumen. We applied robust Regression on Order Statistics to calculate summary statistics among samples with measured concentrations below detection limit. Wet weight concentrations of compounds were lower and more variable among replicate samples in albumen than yolk. Additionally, the correlation with plasma concentrations was lower for albumen than yolk, which discourages the use of albumen as a model tissue for maternal burdens at the current moment. By contrast, lipid-normalized concentrations of PCB and OCP were positively correlated between plasma and yolk, and overlapped with previous observations between whole blood and whole egg for leatherback and green turtles. The maternal transfer rate between yolk and plasma indicated that lipid normalized concentrations in yolk were on average 6.6 times lower than those in plasma. Nevertheless, this maternal transfer rate varied between compounds suggesting compound-specific transfer, and negatively related with compound lipophilicity as estimated by the octanol-water partitioning coefficient, K_{ow}. Dioxin-like PCB 118 was among the three PCB with highest concentrations in yolk, and obtained a high $\log_{10}$ maternal transfer ratio of -0.30. Regarding OCP, p,p`DDE was the most prevalent compounds in yolk, albumen, and plasma, and obtained a near-equilibrium $\log_{10}$ maternal transfer ratio of 0.01. Our results indicate that yolk could offer a suitable biomonitoring tissue which relates to maternal body burdens. Nevertheless, compound-specific maternal transfer rates need to be considered when translating yolk levels back to maternal pollution burdens, and when assessing the risk to the subsequent generations of turtle embryos.

3.04.P-Mo168 Seasonal Variation in Size, Stable Isotopes (Carbon and Nitrogen), and Fatty Acids in Riparian Sentential Spiders (Tetragnathidae)

*Jessica L. Landaverde[1] and **Ryan R Otter**[2], (1)Molecular BioSciences, Middle Tennessee State University, (2)Data Science Institute, Middle Tennessee State University*

Riparian spiders are used in ecotoxicology as bioindicators of aquatic to terrestrial transfer of energy and bioaccumulative contaminants through the insect mediated contaminant pathway. Spiders in the family *Tetragnthidae* are particularly of interest because of the high amount of emergent aquatic insects in their diet. These spiders have become more well studied in recent years; however, the changes in their diet and size throughout a year have not been investigated. In this study, our objective was to determine if variation in size, carbon and nitrogen stable isotopes, and the fatty acid biomarker eicosapentaenoic acid (EPA) occurs in tetragnathid spiders throughout a year. Spiders were sampled within a 100m reach of the East Fork Stones River in

Cannon County, TN twice a month between April and November 2021. It was found that spider total mass and body measurements steadily increased from April to September, then decreased in October. It was also found that carbon and nitrogen stable isotopes were consistent over time and that the %EPA of total fatty acids in spiders varied greatly, with spikes in May and August. This work adds to the growing literature on the use of tetragnathid spiders as bioindicators. The implications of this research show that seasonality may not be a significant factor when considering stable isotope or EPA as food web tracers.

3.04.P-Mo169 Biomonitoring of Maritime Traffic and Tourism Recovery Post-COVID-19 lockdown in the MPA of Ischia Island (Italy) Using *Mytilus galloprovincialis*
*Camilla Della Torre[1], Sara Villa[2], Antonio Cannavacciuolo[3], Antonia Chiarore[3], Cristiana Rizzi[4], Lisa Piccinelli[4], Luigi Musco[5], Andrea Binelli[1] and **Marco Munari**[6], (1)Dipartimento di Bioscienze, Università degli Studi di Milano, Italy, (2)Dept Earth and Environmental Sciences, University of Milano-Bicocca, Italy, (3)Integrated Marine Ecology, Stazione Zoologica Anton Dohrn (SZN), Italy, (4)University of Milano-Bicocca, Italy, (5)Dipartimento di Scienze e Tecnologie Biologiche ed Ambientali, Università del Salento, Italy, (6)Integrated Marine Ecology, Università di Padova, Italy*
Ischia is the biggest island in the Gulf of Naples, and constitutes the most important part of the Regno di Nettuno's marine protected area (MPA). This island is historically characterized by a high number of tourists, a fact that leads to a high anthropic impact on coastal seawaters due to intense maritime traffic and mass tourism. During the first Sars-CoV-19 pandemic lockdown that occurred between March and June 2020, the island was almost completely isolated by the land for 3 months. This event represented a unique opportunity to understand the temporal and quantitative trend of the release of human-discharged chemicals in seawater and their potentially deleterious effects on coastal seawater biota. Therefore, an active biomonitoring was carried out transplanting adult mussels of the species *Mytilus galloprovincialis* in three coastal sites of the island (Ischia Harbour, San Pietro shore, and Castello Aragonese). The accumulation in soft tissues of chemicals that are suitable marker of domestic waste such as caffeine, carbamazepine, and N,N-diethyl-meta-toluamide was measured through UPLC/MS. A suite of biomarkers related to energetic metabolism, detoxification, oxidative stress, and oxidative damage was also applied. The results showed that pollutants related to day-life activities are significantly released at sea and bioavailable for filter feeders and can represent an actual risk for local benthic communities. Indeed, the metabolic functions and biochemical performances resulted significantly modulated in translocated organisms and remarkable level of lipid peroxidation was observed. The application of a biomarkers Response Index allowed distinguishing impacts of pollution, showing mussels from Castello Aragonese as the most threatened. The approach adopted in this study emerged as a useful tool to point out the potential vulnerability of coastal areas with high natural values, contributing to their management and conservation.

3.04.P-Mo170 Monitoring of Contaminants in the Northern Baltic Sea: Toward an Integrated Approach
***Raisa Turja**, Emmi Sofia Vähä, Anu Lastumäki, Heidi Ahkola and Kari K. Lehtonen, Finnish Environmental Institute (SYKE), Helsinki, Finland*
The Baltic Sea is heavily polluted by a large variety of chemicals. While the relatively small number of "legacy" contaminants have been addressed in the monitoring programs, there is a wide array of emerging substances present in the marine environment that bioaccumulate and cause harmful effects in organisms. Therefore, there is an urgent need for the development and implementation of modern integrated monitoring approaches.

Biomarkers can be used as early warning signals to measure stress caused by environmental conditions, including contaminants, to biota. In the Finnish monitoring programme, lysosomal membrane stability (LMS) has been regularly analysed in perch (*Perca fluviatilis*) and herring (*Clupea harengus membras*) since 2014 from coastal and open sea areas. The caging of mussels (*Mytilus trossulus*) was used to study pollution at different coastal sites by analysing tissue concentrations of selected contaminants in combination with various biological effects methods including biomarkers of oxidative stress, neurotoxicity, biotransformation, and the condition index. In addition, polydimethyl siloxane (PDMS)-passive samplers attached in the cages detected the presence of PAHs, PCBs and organotins in water. To gain a deeper understanding of the chemical compounds present in these areas, target and nontarget screening methods were applied in mussel and fish samples. The targeted analysis included more than 2000 different chemicals and the nontarget screening around 90 000 substances. The sampling sites included both heavily polluted sites (e.g., near a wastewater treatment plant outlet) and areas away from point pollution sources.

The results showed significant differences in the accumulation of contaminants and the measured biological effects between the study sites. Moreover, different groups of contaminants were detected in different species; e.g., PFASs and PCBs were commonly detected in fish, but less in mussels while PAHs and organotins were typically detected only in mussels. Passive samplers mimic accumulation of chemicals to biota and passive sampling has proven to be an efficient technique to study,, e.g. organotin compounds in aquatic environment as also shown in the present study. Using different chemical-biological methods in the environmental monitoring enables to estimate the exposure and effects of emerging contaminants in the aquatic environments to gain a more holistic view of the contamination status of the Baltic Sea.

3.04.P-Mo172 Flame Retardants in Eggs of Black-Tailed Gull from its Breeding Sites Along the Korean Coast
***Gi Myung Han**[1], Sang Hee Hong[2], Mi Jang[3], Sung Yong Ha[4] and Won Joon Shim[5], (1)Risk Assessment Research Center, Korea Institute of Ocean Science and Technology (KIOST), Korea, Republic of (South), (2)Oil and POPs Research Group, Risk Assessment Research Center, Korea Institute of Ocean Science and Technology, Korea, Republic of (South), (3)Risk Assessment Research Center, Korea Institute of Ocean Science and Technology (KIOST), Korea, Republic of (South), (4)1Risk Assessment Research Center, Korea Institute of Ocean Science and Technology (KIOST), Korea, Republic of (South), (5)Korea Institute of*

Ocean Science and Technology (KIOST), Korea, Republic of (South)
Seabird has long been used as a biomonitor for long-term monitoring of environmental contaminants in the Europe and North America. This study was performed to identify the levels and profiles of flame retardants (FRs), emerging persistent organic pollutants (POPs), in seabird eggs inhabiting along the Korean coasts. Black-tailed gull eggs were collected from breeding places located in the southern (Hong-do), eastern (Dok-do), and western (Seoman-do) coasts from 2015 to 2020, and egg content was used for chemical analysis. FRs were widely detected in seagull eggs. The overall concentration of FRs in the egg were in the range of 19-1280(median value: 74) ng/g lipid wt. for polybrominated diphenyl ethers (PBDEs), 28-1141(136) ng/g lipid wt. for hexabromocyclododecanes (HBCDs), and 0.8-131(11) ng/g lipid wt. for novel brominated flame retardants (NBFRs) including PBT, PBEB, DPTE, HBBz, HCDBCD, BTBPE, OBIND, and DBDPE. Among the target analytes, HBCDs showed the highest concentration and followed by PBDEs and NBFRs. NBFRs were detected at concentrations 5-19 times lower than PBDEs and 8-14 times lower than HBCDs. The levels of PBDEs and HBCDs were relatively high in the western coast (Seoman-do), while NBFRs showed no significant regional differences. No differences in NBFRs were observed while an increasing and decreasing trends for PBDEs and HBCDs were observed during 2015 to 2020.

3.04.P-Mo173 Determination of Atmospheric Microplastics in Moss with TED-GC-MS and µRaman by Using a Combination of Exfoliation and Flotation for Sample Pretreatment

***Mike Wenzel**[1], Björn Fischer[2], Justus Schöttl[1], Carmen Wolf[1], Christine Kube[3], Stefan Nickel[4], Annekatrin Dreyer[5], Barbara Völksen[4], Winfried Schröder[4], Gerrit Renner[6], Jürgen Schram[7], Torsten C. Schmidt[8] and Jochen Tuerk[3], (1)Institut für Energie- und Umwelttechnik e. V. (IUTA), Germany, (2)Fischer GmbH, Germany, (3)Institute of Energy and Environmental Technology e.V. (IUTA), Germany, (4)Planwerk, Germany, (5)ANECO, Germany, (6)University of Duisburg-Essen, Instrumental Analytical Chemistry (IAC), Germany, (7)Hochschule Niederrhein, Germany, (8)Instrumental Analytical Chemistry, University of Duisburg-Essen, Germany*

Moss can be used as a biomonitor for the determination of atmospheric pollutants such as heavy metals, nitrogen, and persistent organic components. As a result, local and time-dependent trends of these pollutions can be investigated. Up to now, it is unclear if moss can also serve as a biomonitor for atmospheric microplastic deposition. This study demonstrates the development of a method for identifying and quantifying microplastics in moss using Raman microscopy (µRaman) and thermal extraction-desorption gas chromatography mass spectrometry (TED-GC-MS). For sample preparation, microplastics on the moss surface were exfoliated with glass beads (d = 0.5 mm). Furthermore, the exfoliated sample was sieved (< 1 mm) and a flotation was performed using the recently published microplastics separator µSEP. The TED-GC-MS investigations showed the robustness and reproducibility of this kind of sample preparation procedure by performing microplastics recovery experiments. Also, chromatograms of high quality can be observed, which reduce the impact of matrix interferences on the identification and quantification of microplastics in a sample. The µRaman analysis indicated a high separation quality because of the possibility to perform a contrast-based particle identification on gold-coated filters. In addition, this method was applied to moss specimens collected from different sampling sites in Germany, which were part of the German moss survey 2020/2021. The moss survey is supported by the German Environment Agency (Research code: 3720632010). Within first investigations of these samples, different polymers, such as polyethylene terephthalate (PET) and polyethylene (PE) could be identified and quantified.

3.04.P-Mo174 Laboratory Testing of Hexachlorocyclohexane Retention in Moss as a Potential Biomonitor for the Surveillance of Water and Air Pollution

***María Zoe Chaos Carballo**[1], Aldara Méndez[1], Pablo Pérez-Alonso[1], María Balseiro-Romero[1,2], María Celeiro[3], J. Ángel Fernández Prof[4], Jesús R. Aboal[5], Carmen García-Jares Prof[3] and Carmela Monterroso[1], (1)Department of Soil Science and Agricultural Chemistry, University of Santiago de Compostela, Cross-Research in Environmental Technologies (CRETUS), Spain, (2)Instituto de Recursos Naturales y Agrobiologia, Spain, (3)Department of Analytical Chemistry, University of Santiago de Compostela, Cross-Research in Environmental Technologies (CRETUS), Spain, (4)University of Santiago de Compostela, Cross-Research in Environmental Technologies (CRETUS), Spain, (5)Department of Functional Biology, Ecology Unit, University of Santiago de Compostela, Cross-Research in Environmental Technologies (CRETUS), Spain*

Passive biomonitoring with mosses has emerged as a useful tool for the study of environmental pollutants, but its application in persistent organic pollutants (POPs) monitoring is limited and mainly focused on PAHs. This work aims to evaluate the capacity of two moss species to retain hexachlorocyclohexane isomers (α-, β-, γ-, and δ-HCH) from aqueous and aerial media to determine their potential use as biomonitors in HCH-contaminated environments. *Fontinalis antipyretica* Hedw. and *Sphagnum palustre* L. were selected because of their widespread use in aquatic and atmospheric pollution monitoring, respectively. Moss clones grown in photobioreactors and devitalised (oven-drying with a temperature ramp) were used. The biosorption of HCH from aqueous media was evaluated by a batch experiment of successive additions of a solution of HCH isomers (total concentration of 10.2 mg L^{-1}, above solubility limit). Spiked moss suspensions (n = 5) were left under agitation until equilibrium (24 h) and the analytes were determined in the liquid phase by ultrasound-assisted extraction (UAE) followed by gas chromatography-mass spectrometry analysis. Free-moss solution was used as control. The biosorption was calculated by the difference of the equilibrium concentration with the added concentration of HCH and sorption isotherm models were used for quantitative description of sorption processes. The adsorption of HCH from air was assessed by active indoor air sampling based on a solid phase extraction (SPE) system. The air was fortified with HCH isomers to obtain the spike level of 0.5 mg kg^{-1} and then pumped through two serial samplers with sorbent: the first with moss tissues (or Florisil® as control) and the second, with Florisil®. Sampling was carried out in triplicate. HCH isomers in sorbent samples was quantified by UAE and gas chromatography-tandem mass spectrometry analysis. The biosorption was determined according to the recoveries achieved.

Data obtained from sorption experiment in aqueous media showed that *F. antipyretica* bioaccumulated up to 4792 mg HCH per kg moss and a good fit to the Freundlich and Lineal models was achieved. Very low bioaccumulation from water was observed using *S. palustre.* In the data obtained from sorption experiment in air, recoveries ranged 89 – 129 % using *F. antipyretica* and less than 70 % using *S. palustre*. *F. antipyretica* had a higher retention capacity in both media, probably due to different cell wall composition.

3.04.P-Mo175 Biological and Practical Implications of Trace Metal Accumulation in Devitalized Seaweeds
Antón Vázquez-Arias[1]*, Jesús R. Aboal*[2] *and J. Ángel Fernández*[2]*, (1)CRETUS, Ecology Area, Functional Biology Department, Universidade de Santiago de Compostela, Spain, (2)University of Santiago de Compostela, Cross-Research in Environmental Technologies (CRETUS), Spain*
The biomonitoring of coastal waters with seaweeds is a method with potential to be a key tool to control trace metal pollution. However, further standardization and a better understanding of the uptake mechanisms of seaweeds are necessary to use this technique at a global scale. The objective of our study is to test the use of devitalized transplants of the brown algae *Fucus vesiculosus* to control trace element pollution, and to compare their accumulation patterns with those of fresh transplants to better understand the uptake pathways involved. To do this, we exposed material of *F. vesiculosus* picked up from an unpolluted site in six stations, five polluted and the collection site itself. In each place, four differently treated types of transplants were exposed: three treatments consisted of the three most apical dichotomies in mesh bags, the material was fresh in one of the types, dried in another, and boiled in the last. The fourth treatment consisted of whole thalli attached to stones by the basal part, as a control. Then we collected five transplants of each type after 4, 8, and 20, in addition to the day 0, and analyzed their concentration of ten trace elements. We found that devitalized transplants (dried and boiled) lost most of the material during the exposure period, in many cases being completely lost after 8 days, while the amount of material in fresh transplants (in bags and on stones) did not decrease. The concentrations of most elements (Al, V, Fe, Ni, Cu, Hg, and Pb) increased over time for all four types of transplants, but the increase was much more pronounced in devitalized transplants over fresh ones. Thus, the use of devitalized transplants for biomonitoring is limited to short exposition periods, but their quick uptake of most elements would make it possible. On the other hand, fresh transplants are more useful to get temporal representativity on a longer period, or insight on the impact of trace elements on organisms, as metal uptake in devitalized transplants is not comparable. Different factors can be the cause of the accumulation differences between live and devitalized seaweed, such us the exposure or modification of binding sites during the devitalization process, the inactivation of metal regulation mechanisms, or dilution by growth in live transplants. This experiment also indicates that elemental accumulation by seaweed is not mostly caused by active internalization of trace elements, but rather chemical adsorption.

3.04.P-Mo176 Evaluating the Presence of Heavy Metals on Commercial Fish and Limpet Species in the Azores Region: First Approach Toward the Assessment of Seafood Safety for Human Consumption
Ana Sofia Oliveira*, Joana Goulart and Ines Martins, University of the Azores, Institute of Marine Sciences - Okeanos, Portugal*
The benefit of seafood consumption for human health worldwide is consensual. Nevertheless, the volcanic origin of the Azorean Region and the constant anthropogenic activities raise concerns regarding the quality status of fish and shellfish products consumed in the Region. Therefore, the academy and the government set out a monitoring programme to evaluate the contaminant levels in seafood species with high economic value. Besides ensuring the efficient protection of public health this programme aims to evaluate the "*Good Environmental State"* (Commission Decision 2010/477/UE) of the Azorean marine environment through the quantification of contaminants levels in demersal fish and mollusk species for human consumption.

The concentration of 4 heavy metals (Cd, Hg, As, and Pb) was determined in the muscle of 10 commercial species (*Phycis phycis, Phycis blennoides, Beryx splendens, Helicolenus dactylopterus, Conger conger, Pagellus bogaraveo, Beryx decadactylus, Mora moro, Sparisoma cretense, Patella aspera*) captured on the Azorean archipelago. Analysis of methylmercury is in progress in species that present the highest Hg content. The evaluation of this element is crucial for the measurement of consumers exposure levels to the most toxic fraction of Hg (Commission Regulation (UE) 2022/617).

Analysis was performed in dorsal muscle samples of each fish species and in all tissues of the limpets (*Patella aspera*). Metal analysis followed standard analytical methodologies, specific for each element: ICP-MS, GC, GC-MS, GC-ECD. Results were compared with the maximum levels set by the European Union legislation ((EC) No 1881/2006;(UE) 2022/617)).
Results so far revealed high concentration levels of As and low concentrations of Cd and Pb in all demersal fish species. High Hg levels were found in splendid alfonsino and common mora. The common mora presented Hg levels above the maximum set by the EU legislation. Analysis are still in progress for european conger, blackbelly rosefish, greater forkbeard, parrotfish, and rough azorean limpet.

With this study, we will fill the gap of knowledge regarding the metal accumulation levels in demersal fish species and limpets, captured in the Azores Archipelago EEZ and also support policy decisions regarding the safe and conscious consumption of seafood.

3.04.P-Mo177 Determination of Perfluoroalkyl Substances, Parabens, Bisphenols, and Metabolites of Phthalate Esters in Serum and Urine with APGC-MS/MS and UPLC-MS/MS
Chia-Yang Chen*, Shih-Hsiang Liao, Sheng-Che Tseng and Pau-Chung Chen, Institute of Environmental and Occupational Health Sciences, National Taiwan University, Taiwan*

Perfluoroalkyl substances (PFASs), phthalate esters (PAEs), parabens, and bisphenols (BPs) are potential endocrine-disrupting chemicals. Biomonitoring of themselves or metabolites can provide crucial information for exposure and health risk assessment. This study developed and validated a method for determining 22 PFASs, eight PAE metabolites, six BPs, and four parabens in serum and urine. Serum samples were mixed with 1% formic acid in acetonitrile and passed through Waters Ostro plates. Urine samples were incubated at 37°C for enzyme deconjugation, then were mixed with acetonitrile and filtrated with Waters Sirocco plates.
Four fluorotelomer alcohols (FTOHs) and *N*-methyl perfluorooctane sulfonamide (*N*-MeFOSA) were separated on a J&W DB-5ms column and were analyzed with an atmospheric pressure gas chromatography coupled with a tandem mass spectrometer (APGC-MS/MS). The rest 35 analytes were determined with Waters ultra-performance liquid chromatography-MS/MS (UPLC-MS/MS) using UniSpray ionization; a Waters BEH C18 column and a Waters CORTECS column were used for the chromatographic separation. The method was applied to analyze 265 serum samples and 298 urine samples collected from 7- to 11-year-old children in 2018 in Taiwan.

The intra- and interday recoveries at three tested levels were higher than 80%, and the %RSD was lower than 20%; the limits of detection (LODs) were 0.12–1.12 ng/mL and 0.5–521 pg/mL for the assays of APGC-MS/MS and UPLC-MS/MS, respectively.

OA, PFNA, PFHxS, and PFOS were all detectable in serum samples at average concentrations of 2.20-5.14 ng/mL; 8:2 diPAP was also observed in all the samples with a mean of 89.8 ng/mL; the averages of FTOHs ranged from 0.51–1.19 ng/mL.

The average concentrations of PFBA, PFBS, and 6:2 PAP for urine samples were 29.4, 15.1, and 36.1 ng/mL, respectively; most average concentrations of PAE metabolites ranged from 23.0 to 104 ng/mL. The average BPA, BPF, and BPS concentrations were between 3.89 and 4.66 ng/mL. The positive rates of parabens were 92.6–100%, with the highest average concentration of methyl paraben at 419 ng/mL.

Levels of PFASs and BPs in samples positively associated with using plastic tableware and consumption of sea fish, oysters, and kelp. Concentrations of PAE metabolites and parabens in samples positively associated with using plastic tableware and lotion.

3.04.P-Mo178 A Human Biomonitoring-Based Study of Brazilian Lactating Women, Infants, and Children Exposed to Polycyclic Aromatic Hydrocarbons

Marilia Souza *and Fernando Barbosa Junior, University of São Paulo (USP), Brazil*

Polycyclic aromatic hydrocarbons (PAHs) are highly lipophilic organic compounds formed during the incomplete combustion of organic matter from natural processes or by anthropogenic activities. PAHs are widely spread pollutants of public health concern, classified as endocrine disruptors, and have been listed as priority pollutants by the United States Environmental Protection Agency. Exposure to pollutants is even more critical during pregnancy, postnatal periods, and childhood. In these stages, some chemicals might induce genetic damage early in life and delay the epigenetic maturation of metabolic, endocrine, and neural pathways. Therefore, quantitatively determining these pollutants and their metabolites in biological matrices is essential for assessing human exposure; however, these biomonitoring approaches are limited in Brazil. Given the context, this study aimed to measure the levels of seven PAH metabolites (OH-PAHs) in urine (n = 400) from Brazilian lactating women, infants, and children. The methodology used for quantification employed solid phase extraction and gas chromatography-mass spectrometry. Our results show that PAH metabolites were quantified in all samples. Besides, naphthalene was the major contributor to Brazilian exposure to PAHs, with a detection rate of 100%. 2-hydroxy-naphthalene (2OH-NAP) showed the highest concentration in lactating women and their infants, with a median of 0.97 ng/mL and 0.78 ng/mL, respectively. Whereas 1-hydroxy-naphthalene (1OH-NAP) presented higher levels (1.33 ng/mL) in Brazilian children, which may suggest exposure to the carbaryl insecticide since it is based on the high concentrations of 1OH-NAP. In this study, the ratio of 1OH-NAP/2OH-NAP in children was 1.78. 3-hydroxy-benzo[a]pyrene was the least detected metabolite, probably because this compound is primarily eliminated through feces. The Spearman correlation test showed high scores between the sum of OH-PAHs levels in lactating women and infants (0.62). In addition, it is possible to assess co-exposure between PAH classes in children. However, it is important to conduct studies that assess human exposure to multiple classes of environmental pollutants. This research should be a valuable tool to guide future regulatory actions that require a groundbreaking approach. Besides, future trials should be conducted to provide more generalizable results to other at-risk populations over time.

3.04.P-Mo179 Biomonitoring of Blood and Hair Samples to Assess Metals and Metalloids Exposure in Mother-Child Pairs from Delivery to 18 Month Old in a Cohort from the Population of Sevilla (Spain)

Bouchra Dahiri[1], P. Carbonero-Aguilar[2], Lucas Cerrillos[3], Rosa Ostos[4], Anabel Garrido[5], Marta González[5], Antonio Millán[6], Laura Acosta[6], Ángela Periañez[6], Ana Fernández-Placín[7], J. Bautista[2] and ***Isabel Maria MORENO Navarro****[1], (1)Universidad de Sevilla, Spain, (2)University of Sevilla, Spain, (3)Unidad de Medicina Maternofetal Genética y Reproducción, Hospital de la Mujer. Hospital Universitario Virgen del Rocío, Sevilla, Spain, (4)Unidad de Ginecología y Obstetricia. Hospital Universitario Virgen de Valme, Sevilla, Spain, (5)Unidad de Pediatría y Áreas Específicas. Hospital Universitario Virgen del Rocío, Sevilla, Spain, (6)Unidad de Gestión Clínica de Pediatría. Hospital Universitario Virgen de Valme, Sevilla, Spain, (7)Área de Medicina Preventiva y Salud Pública, Universidad de Sevilla, Spain*

There is an increasing concern about the exposition during prenatal and early postnatal stages to environmental pollutants such as heavy metals and metalloids. Metals and metalloid are ubiquitous in the environment and pregnant women are exposed to them through their diet, lifestyle factors, or occupational and environmental sources. Among all population groups, pregnant women and newborns are two of the most vulnerable groups since these substances can cross the placental barrier and access the fetus, even from the earliest times of gestation. After birth, the newborn continues to be exposed not only through the environment but also through their diet, including breast milk, having consequences on the health of the newborn. Numerous studies have shown associations between the prenatal exposition to some metals and an impact on cognitive, motor, and intellectual development of the child. Biomonitoring allows us to identify and eliminate possible sources of exposure, studying possible relationships between these pollutants and health problems.

The aim of this work was biomonitoring the levels of metals (As, Cd, Cr, Cu, Fe, Hg, Ni, Pb, Se, and Zn) in a cohort of mother-child pairs in Seville (Spain). Samples of maternal and cord blood have been taken at the time of delivery, previous signing of the informed consent, and filling the epidemiological questionnaire. Hair samples from the newborns have been collected at 6, 12, and 18 months, being an ideal sample to determine metals, as these accumulate throughout human life, and because it is a noninvasive sample for infants. Samples were submitted to a microwave digestion process optimized to minimize the loss of volatile elements and ICP-MS was used to determine the content of metals.
Results showed a correlation between most metals on blood samples of maternal and cord blood. A multivariate analysis of variance (*MANOVA*) was used to study the correlation between all hair samples on the newborn from month 6 to month 18. All values were inside normal ranges for the study population.

3.04.P-Mo180 Monitoring of Heavy Metals Levels from Blood in a Rural Population of Sevilla
J. R. Aguilera-Velazquez[1], Maria Gracia Hinojosa[2], J. Martin-Reina[1], P. Carbonero-Aguilar[1], J. Bautista[1] and ***Isabel Maria MORENO Navarro***[3]*, (1)University of Sevilla, Spain, (2)Stockholm University, Spain, (3)Universidad de Sevilla, Spain*
Environmental pollution is a global problem today. The "One Health" concept, promoted by the EU, focuses on the interrelationship between environmental health and the health of humans and other animals. Uncontrolled industrial activity, aggressive fertilisation programmes, and even natural events such as fires or volcanoes release toxic substances into the environment. Among these toxic substances are heavy metals. The accumulation and transfer of these metals from soils, aquifers, or air to organisms cause serious damage to human and animal health. Metals such as Lead (Pb), Cadmium (Cd), Aluminium (Al), and Chromium (Cr) cause serious health problems such as neurological disorders, liver problems, cardiovascular diseases, and even kidney complications. Very high concentrations of these metals are being detected in rural areas, which were considered "clean areas."

The aim of this study was monitoring the concentration of Pb, Cd, Al, and Cr in the blood of a cohort of agricultural and nonagricultural workers in the region of Estepa in the province of Seville, southern Andalusia. The selection of participants was nonprobabilistic in a snowball sampling. A final sample of 100 men (age between 18 and 45 years) were asked to be part of this longitudinal study. In this case, 50 of them were classified as farmers group and the other 50 participants who work and live in the same rural environment were classified as nonfarmer group.

Samples were collected once a year during the harvest time in the Occupational Medicine Unit (Preventiam). Collected blood was refrigerated at 4 °C during transportation and immediately stored at−80 °C before analysis. Samples were submitted to a microwave digestion process optimized to minimize the loss of volatile elements. ICP-MS was used to determine the content of Cu. IBM SPSS software was used to perform the data analysis.

Preliminary data show that exposition prolonged of residents (agricultural worker or not) to heavy metals (Pb, Cd, Al, and Cr) leads to an increase in the blood level of these metals. Slightly lower levels were found in residents who did not work in the fields. These data should be carefully analysed, since the study has not yet been completed.

3.04.P-Mo181 Monitoring of Copper Levels from Blood in a Population of Olive Farmers from Seville (Spain).
J. R. Aguilera-Velazquez[1], C Chamorro-López[1], J. Martin-Reina[1], Rocio Sanchez-Ruiz[2], J. Bautista[1] and ***Isabel Maria MORENO Navarro***[2]*, (1)University of Sevilla, Spain, (2)Universidad de Sevilla, Spain*
Copper derivates such as sulphate of copper have been commonly used in agriculture for disease control. In the case of olive, copper is the main pesticide authorized for the control of “Repilo,” a fungal infection which causes great economic losses to the olive sector. Its long-term application leads to a copper accumulation in olive soils, together with the remaining traces accumulated in leaves, posing a risk to worker health. Although copper is an essential trace element, its prolonged indirect exposition is associated with serious health problems such as neurodegenerative diseases, hepatic disorders, atherosclerosis, cardiovascular diseases, or even renal disorders. Due to high temperatures in southern Andalusia, olive farmers are unable to wear personal protective equipment. In addition, these suspended particles containing copper could travel to nearby urban areas.

The main objective of this study was to monitor levels of copper in blood from a cohort of olive farmers from Seville (Spain). The selection of participants was nonprobabilistic in a snowball sampling. A final sample of 80 men (age between 18 and 45 years) was asked to be part of this longitudinal study. In this case, 60 of them, directly involved in collection of olives in the field, were classified as farmers and the 20 remaining participants who work and live in the same rural environment were classified as nonoccupational exposed (NOE) group.

Samples were collected during the olive harvest time in the Occupational Medicine Unit (Preventiam). Collected blood was refrigerated at 4 °C during transportation and immediately stored at−80 °C before analysis. Samples were submitted to a microwave digestion process optimized to minimize the loss of volatile elements. ICP-MS was used to determine the content of Cu. IBM SPSS software was used to perform the data analysis.

Preliminary data indicate that exposition prolonged to copper affects not only farmers but also, to a lesser extent, people living in the same rural environment. These data should be carefully analysed, since the study has not yet been completed.

3.04.P-Mo182 Maternal Urine and Amniotic Fluid Biomonitoring Using Electromembrane Microextraction (EME) to Assess Paraben Exposure in a Cohort from the Population of Sevilla (Spain)

*Eduardo Leo-Martos, Rocio Sanchez-Ruiz, Bouchra Dahiri, **Rut Fernandez-Torres**, Noemí Aranda-Merino, Isabel Maria MORENO Navarro and Maria Ramos-Payán, Universidad de Sevilla, Spain*

Among all population groups, pregnant women are considered one of the most vulnerable due to many factors, including the increasing concern about exposition during prenatal stages to environmental pollutants such as parabens. These contaminants are a widespread group of endocrine disrupting compounds (EDCs), with confirmed transplacental passage. The usage of cosmetics, pharmaceuticals, and consumer products during pregnancy that may contain parabens has led to the need for monitoring surveys. To date, some works have demonstrated fetal exposure to parabens affects their development and subsequently adult health.

In this study, maternal urine and amniotic fluid samples were obtained at delivery from Spanish pregnant women after signing the informed consent to determine simultaneously their possible exposure to 7 parabens (methyl, ethyl, propyl, isopropyl, butyl, isobutyl, and benzyl) and their main hydroxybenzoic acids metabolites (4-hydroxy, 3,4-dihydroxy, and 3,4,5-trihydroxy). Sample treatment was performed by EME, a simple liquid-liquid microextraction technique based on the use of an electric potential to achieve a selective extraction across an organic solvent known as supported liquid membrane (SLM). Polypropylene hollow fibers were used as support for the organic solvent. Analytes were extracted using a three-phase configuration applying the following conditions: donor phase pH 4 (10 mL), acceptor phase pH 13 (50 µL), stirring rate 400 rpm, applied voltage 30V, extraction time 40 minutes and 1-octanol as SLM.
Samples were analyzed by ultra-high performance liquid chromatography coupled to quadrupole time of flight (UHPLC-QTOF) on a Zorbax XDB C18 column (150 mm × 3.0 mm i.d., 3.5 µm particle size) at 30 ºC using 5mM ammonium acetate and methanol as mobile phase at a flow rate of 0.4 mL/min for 10 min under gradient elution. The detection was performed with negative ionization in an electrospray source at 1.5 kV capillary voltage, 120 ºC for source temperature and 350 ºC for desolvation temperature. The analyzed samples showed positive results for most of the selected parabens and their metabolites.

3.04.P-Mo183 Human and Environmental Lead Exposure from Abandoned Lead Acid Battery Recycling Sites in Bangladesh

***Md. Mahbubur Rahman**, Shaikh Sharif Hasan, Rehnuma Haque, , Sarker Masud Parvez and Jesmin Sultana, Environmental Intervention Unit, Infectious Diseases Division, icddr,b, Bangladesh*

Lead is a potent neurotoxin and cases of lead poisoning evolving globally. About 800 million children worldwide have blood lead levels (BLL) at or above 5 micrograms per deciliter (µg/dL); half of them live in South Asia. Among many possible sources of lead poisoning, Used Lead Acid Battery (ULAB) recycling is one of the significant contributors to elevated BLLs. Here we explored the baseline data of a quasi-experimental study with a control group to assess the extent of environmental lead contamination within 700 meters radius of abandoned ULAB sites and the BLL status of children aged 0 to 12 years. Two hundred one children (151 from ULAB-exposed and 50 from ULAB-nonexposed sites) were surveyed and blood and environmental samples were collected with proper consent and precaution. Blood samples were analyzed using graphite furnace atomic absorption spectroscopy and environmental samples were analyzed using a handheld XRF (X-ray fluorescence) machine at icddr,b. The average BLL of the children living in the ULAB exposed area was 10.4 µg/dL (SD: 6), where male children had higher BLL than females (11.3 vs. 9.2 µg/dL). Ninety-nine percent of the children in the ULAB-exposed area had BLL more than 3.5 µg/dL, compared to 78% children of ULAB-nonexposed children. According to WHO, BLL more than 5 µg/dL requires medical attention, and we found an alarming 91% of ULAB-exposed children's BLL exceeded this value. Nevertheless, the ULAB-nonexposed group had 38% children whose BLL was more than 5 µg/dL. The lead level of the ULAB exposed area's environmental samples was consistently higher than nonexposed area samples. The lead concentration of the most contaminated child play area soil sample was 4249 ppm (median 36 ppm). Height amount of lead detected in other environmental samples like floor dust, courtyard soil, and roadside dust are 389, 1088, and 773 ppm lead, respectively. Out of 147 turmeric powder samples tested, 11 were lead-contaminated. People living close to ULAB sites are at higher risk of lead poisoning due to the high contamination of surrounding soil and dust with lead compared to the ULAB-nonexposed group. However, the ULAB nonexposed group's BLL was higher than the US and other children of developed countries, which urges the further exploration of significant sources contributing to higher BLL among the general population of Bangladesh.

3.04.V Application of Biomonitoring Approaches to Support Surveillance of Chemical Exposure in the Environment

3.04.V-01 Time Trends in PCB and PBDE Congeners and in ΣPCBs and ΣPBDEs Residue Concentrations in the Common Buzzard *Buteo buteo* in the Netherlands 1994-2020 in Relation to Restrictions on Chemicals Use.

***Paola Movalli**[1], Alessandra Cincinelli[2], Shinji Ozaki[3], Nikiforos A Alygizakis[4,5], Andreas Androulakakis[5], Alexander Badry[6], Rene Dekker[1], Guy Duke[3], Georgios Gkotsis[7], Natalia Glowacka[4], Hugh Jansman[8], Jan Koschorreck[6], Maria-Christina Nika[7], Saul Santini[9], Chiara Sarti[9], Jaroslav Slobodnik[4], Nikolaos Thomaidis[5], Gabriele Treu[6], Nico van den Brink[10] and Lee Walker[3], (1)Naturalis Biodiversity Center, Netherlands, (2)Department of Chemistry "Ugo Schiff", University of Florence, Italy, (3)UK*

Centre for Ecology & Hydrology (UKCEH), United Kingdom, (4)Environmental Institute, Koš, Slovakia, (5)National and Kapodistrian University of Athens, Greece, (6)German Environment Agency (UBA), Dessau-Rosslau, Germany, (7)National and Kapodistrian University of Athens, Greece, (8)Wageningen Environmental Research (WUR), Netherlands, (9)University of Florence, Italy, (10)Division of Toxicology, Wageningen University & Research, Netherlands
EU chemicals regulation has introduced restrictions (bans and other risk management measures) to reduce the threats posed by the presence of persistent, bioaccumulative and toxic substances to human and wildlife health. In particular, restrictions have been introduced over recent decades on the use of many persistent organic pesticides (POPs).

Top predators such as raptors can be used as sentinels to assess the effectiveness of such restrictions on reducing residue concentrations in the environment. The common buzzard *Buteo buteo* is widely distributed in Europe and has been suggested as a suitable species to systematically monitor trends in terrestrial wildlife exposure to contaminants in the environment at national and pan-European scales. To date, limited use has been made of such systematic biomonitoring to assess the efficacy of restrictions in reducing wildlife exposure to chemicals at these scales.

We carried out biomonitoring of 31 PCBs and 23 PBDEs (including decaBDE) in buzzard livers at country and pan-European scales to examine whether restrictions have led to reduced exposures over time. In this poster, we report on the country scale study for the Netherlands.
We used 64 buzzard livers from birds found dead in ten Dutch provinces over the period 1994-2020. We analysed these livers for PCBs and PBDEs using GC-MS. Time trends for the numbers of PCB congeners and of PBDE congeners, and for sum of PCBs residues (ΣPCBs) and sum of PBDE residues (ΣPBDEs) were modelled using linear models, integrating year of sampling, age, sex and location (province) as variables. Significant effects of these variables on the compositions of PCBs and PBDEs in livers were assessed by redundancy analysis.

Our initial findings show a significant difference in PCB composition and ΣPCBs, but not in PBDEs, between the province of Drenthe and other provinces. Age was not found to be a significant factor in either ΣPCBs or ΣPBDEs. We observed a declining trend over time in the number of PCB congeners, ΣPCBs and ΣPBDEs in males, but not in females. These findings suggest that the effectiveness of regulatory restrictions in the buzzard might vary with sex and location, but not age. Interpretation of these findings should take into account any data bias arising from opportunistic sampling and sample size.

We discuss the implications of our findings for the further application of biomonitoring in Europe to assess the effectiveness of regulatory restrictions.

3.04.V-02 Comparison of the Accumulation of Atmospherically Deposited Metals and Nitrogen in Mosses Collected Throughout Germany with Data from Emission Inventories and Deposition Models

Winfried Schröder[1]*, Stefan Nickel*[2]*, Annekatrin Dreyer*[3]*, Barbara Völksen*[2]*, Ilia Ilyin*[4] *and Oleg Travnikov*[4]*, (1)University of Vechta, Germany, (2)Planwerk, Germany, (3)ANECO, Germany, (4)Meteorological Synthesizing Centre - East, Russian Federation*
Emission inventory data are used for modelling and mapping atmospheric deposition, and mosses are used for recording the bio-accumulation of atmospheric deposition. Crucial questions are, whether emission, exposure and modelled deposition data are correlated. To answer them, we used data from the German national emission register, latest data derived by deposition modelling and data derived by moss surveys. The comparison of the moss data determined between 1990 and 2020 showed a significant decrease of metal bio-accumulation. Nevertheless, contrary to emission data, intermediate increases of metal accumulation compared to the preceding moss survey was observed between 2000 and 2005 and from 2015 until 2020. Trends in nitrogen medians over the last three campaigns, 2005 to 2020, show that nitrogen medians decreased by -2% between 2005 and 2015, and increased by +8% between 2015 and 2020. The differences are all nonsignificant and not consistent with emission trends. Results of most recent modelling of atmospheric concentration and deposition of the metal elements Cd, Hg and Pb were compared with the results of technical measurements and moss surveys. The modelling results with status 2020 have a higher spatial resolution of 0.1° x 0.1° than the modelling results valid up to then (50 km x 50 km). This is associated with partly slightly higher correlations between the findings of the modelling and those of the moss monitoring. For a statistically adequately deepened analysis and evaluation of the high-resolution modelling results it is particularly important to link the exposure data derived by deposition modelling, by technical deposition sampling and by moss surveys with information on the receptors in terms of ecosystem types. This would be a step forwards to a more differentiated risk assessment of impacts on ecosystems due to atmospheric metal deposition.

3.04.V-03 Pollution Induced Alterations in the Motility of Mussel Hemocytes: An In Field Study

Gayatri Udayan, Maria Elena Giordano and ***Maria Giulia Lionetto****, Biological and Environmental Sciences and Technologies, University of Salento, Italy*
In the last decades, effect-based methodologies such as exposure/effect biomarkers in sentinel organisms have known an increasing interest in environmental biomonitoring and assessment. The present work aimed to study pollutant-induced alterations in the motility of hemocytes in the bioindicator organisms *Mytilus galloprovincialis* in view of ecotoxicological biomonitoring and assessment application. Hemocytes are motile, phagocytic cells that represent the key elements of innate immunity in bivalves. Motility is an intrinsic characteristic of these cells since the first phase of their immune response is represented by their recruitment and migration to the site of infection.

The study was carried out on native *M. galloprovincialis* collected from 6 sites along the coast of the Salento Peninsula (Italy), two control sites, and four impacted sites characterized by the presence of an industrial plant close to Brindisi town (Apulia, Italy) and a thermoelectric central. Hemolymph was withdrawn from the posterior adductor muscle sinus of mussels, it was diluted in the sampling syringe 1:1 with filtered seawater (0.2µm filters) and then added in the wells of a 96-well flat bottom polystyrene TC-treated microplates. Hemocytes were allowed to adhere for 30 min at 15 °C. Then, the cells were imaged by time-lapse microscopy, at a rate of 1 image every 2min for 20 min using Cytation 5 cell imaging multimode reader. Cell tracking was performed on single cells; velocity, migrated distance, and directionality of migration were quantified.

Results showed a statistically significant decrease in the velocity and migrated distance of hemocytes of mussels sampled in all the impacted sites with respect to control sites; moreover, alterations in the directionality of migration were also detected. The use of the neutral red retention assay on the same hemolymph sample allowed the detection of lysosomal membrane stability destabilization and in turn the presence of a stress syndrome in the specimens coming from the impacted sites.

In conclusion, obtained results provide a novel approach to analyzing hemocyte activity and open the perspective for the use of cell motility as a cellular function sensitive to exposure to chemical pollution in the environment.

3.05 (Bio)Degradation and Persistence of Chemicals - New Perspectives and Developments

3.05.P-Th162 Development of a High Throughput Method for Screening of Readily Biodegradable Chemicals

Aina Charlotte Charlotte Wennberg, *Merete Grung and Adam Lillicrap, Norwegian Institute for Water Research (NIVA), Norway*

Substitution of hazardous chemicals with safer and greener chemicals is part of the EU strategy for a nontoxic environment and a circular economy. Part of the definition of being safe and sustainable is that the chemical is not persistent, meaning that it will biodegrade in the environment. However, current standard test methods are laborious and not suited for high throughput screening of chemicals because of both the required volume of the test systems, and the limited possibility of automation of the analytical methods. A high throughput method should preferably be in a miniaturized system to minimize footprint in the laboratory, be based on an analytical method suitable for automation, and based on a generic parameter.

The aim of this study was to develop a high throughput biodegradation test for nonvolatile and water-soluble organic chemicals based on growth of bacteria as an indicator of biodegradation, measured by flow cytometry (FCM). A set of eight reference chemicals were included in the test method development and four sources of environmental bacterial communities. To allow for high throughput and automation, incubation of environmental inoculum with test chemicals were performed in deep 96-well plates which could be sampled directly by a multipipette to 96-well plates that were compatible with FCM.

In most cases, the positive controls aniline and sodium benzoate gave significant increased bacterial concentrations in some or all concentrations of added test chemical. However, the rest of the reference chemicals did not, or only to a very limited extent, induce significantly increased growth of bacteria. This is likely due to the stringent test conditions of this set up with only one ml volume of test medium, low bacterial number, and these chemicals being only moderately biodegradable. However, since both positive controls induced significant growth compared to the blank control in most experiments, the method showed potential for being used to identify readily biodegradable chemicals.

A total of 24 96-well plates with different inoculum variations were included in the experiment, with each well plate containing eight test chemicals at three different concentrations in experimental triplicates. Thus, a total of 576 experiments were run in triplicates on one instrument by one person over a six-week period. This demonstrated the high throughput potential for this method that should be included in the toolbox for developing new green chemicals.

3.05.P-Th163 Investigation into the OECD 309 Surface Water Mineralisation Test – Exploring Impacts of Sample Collection and Storage, Experimental Factors, and Reference Compounds

Sigrid Hakvåg[1], *Christopher Hughes*[2], *Katharina Giray*[3], *Deni Ribicic*[1], *Odd Gunnar Brakstad*[1], *Roman Netzer*[1], *David Brown*[2], *Udo Noack*[3], *Dirk Scheerbaum*[3] *and Silke Fiebig*[4], *(1)SINTEF, Norway, (2)Ricardo Energy & Environment, United Kingdom, (3)Noack Laboratorien GmbH, Germany, (4)Vitis Regulatory GmbH, Germany*

Biodegradation is an important process for the removal of several environmental organic contaminants and is a major determinant of both chemical persistence and chemical exposure. Guidelines for chemical hazard assessment in certain regional and global regulations, such as the European chemicals regulation REACH, set thresholds for persistence in environmental compartments (e.g., degradation half-life in water) that need to be evaluated quantitatively. Furthermore, to assess chemical exposure, quantitative estimates of degradation half-lives are required for environmental media that influence the exposure of target organisms.

In this ongoing work, the OECD 309 Surface Water Mineralisation Test is investigated in detail by providing an in-depth assessment of inoculum quality and viability; identifying and validating more relevant reference substances that better reflect the vital status and composition of the inoculum and providing a data-based evaluation of the test robustness and applicability at the new mandated test temperature (12°C in freshwater/9°C in seawater). The data obtained will form a basis for providing improved guidance on surface water sample collection, storage, and treatment. A suite of quantitative and qualitative tests (as MPN/CFU, respirometric analysis, 16S rDNA microbiome analyses) that further demonstrate inoculum status and guidance on the test validity criteria will incorporate detailed information on selected reference chemical biodegradation rates at different temperatures. Besides the well-known reference substances sodium benzoate and aniline as a fast-degrading substance, there is also a need for reference substances with a slower degradation.

These improvements will be based on the principal theme of characterising the relationship between inoculum diversity, viability, and performance of biodegradation with more appropriate new reference substances. Characterization of the bio-physio-chemical water sample diversity may be important to resolve inoculum variations between seasons and changes during storage, and to secure the chance of competent cells in a biodegradation process. Studies of microbial community structure and succession analyses have also proven to be important for a more comprehensive understanding of biodegradation processes.

3.05.P-Th182 Biodegradation Testing of Constituents of Natural Complex Substances

Georg Kreutzer[1]*, Arturo Mendoza*[2]*, Karen Jenner*[3] *and Thomas Dutriez*[4]*, (1)Raps, Givaudan Suisse SA, Vernier, Switzerland, (2)Environmental, RAPS Analytical, Givaudan Suisse SA, Vernier, Switzerland, (3)Givaudan UK Ltd, United Kingdom, (4)Givaudan International SA, Vernier, Switzerland*

The use of Naturals as ingredients in perfumery has a long history. In the pursuit of environmental sustainability, using renewable materials rather than synthetic ingredients derived from petrochemical feedstock, is of increasing interest. At the same time the question of the environmental impact of fragrances is central – namely the biodegradability of ingredients.
Some of the Naturals used in perfumery are complex in chemical composition, consist of a high number of different chemical constituents, and are therefore commonly designated as Natural Complex Substances (NCS). OECD screening tests for ready biodegradability are not generally applicable for complex mixtures containing different types of chemicals. A case-by-case evaluation has to take place on whether a biodegradability test on such a complex mixture would give conclusive information regarding the biodegradability of the mixture as such or whether instead an investigation of the biodegradability of individual components of the mixture is required.

While composition information is available on a number of NCS, this information may not be sufficiently detailed. In such cases gathering additional information on the composition of the NCS is the first step of the biodegradability assessment. Ideally all constituents ≥1wt%, and at least 80wt% of the NCS are identified - it is impractical (even impossible) to identify all minor components in NCS. However, the minor constituents in the remaining unknowns of a given NCS are generally related to the identified constituents and hence expected to have similar biodegradation profiles.

The next step is gathering information on the biodegradability of the known individual constituents. If data on constituents are not available, data need to be generated for these “missing” constituents. This may in some cases include the isolation of the individual constituents to be tested from the NCS or involve the testing of more readily available representative molecules.

In this presentation, new biodegradation results for key constituents of fragrance NCSs will be presented. Case studies will also be used to show how this new data has allowed the completion of the biodegradation assessment of NCSs using the constituent approach where before crucial information was missing. For some Naturals specific constituents / or the Natural as such were tested to complete the assessment, demonstrating that the two approaches (constituent and whole substance) are complementary.

3.05.T-01 Regulatory Landscape for Persistence Assessment in PBT/vPvB and PMT/vPvM Identification Under REACH and CLP

*Anu Kapanen, **Romanas Cesnaitis**, Kostas Androu, Konstantinos Prevedouros and Marta Sobanska, European Chemicals Agency (ECHA), Helsinki, Finland*

Many actions have been taken to clarify, improve, and harmonise hazard assessment of substances in EU. “One substance, one assessment” is one of the key elements in the Chemical Strategy for Sustainability (CSS) adopted by the European Commission on 14th October 2020. EU Commission considers CLP Regulation (EC) No 1272/2008 as one of the key regulatory “tools” to centralise the “One substance, one assessment”. Identifying substances as PBT (persistent, bioaccumulative, toxic), vPvB (very persistent, very bioaccumulative), PMT (persistent, mobile, toxic), or vPvM (very persistent, very mobile), was considered necessary to be introduced as new hazard classes and criteria into CLP Regulation. Furthermore, the REACH ((EC) No 1907/2006) Annexes VII-XI on standard information requirements were revised to clarify the obligations of registrants regarding the submission of information. To inform and integrate on the scientific and technical advances in the assessment of PBT/vPvB substances, ECHA has launched revision and subsequent consultation of the respective ECHA Guidances on IR&CSA, Chapters R.11, R.7b and R.7c. Persistence is a fundamental property of a substance to be considered in environmental hazard, fate, exposure, and risk assessments across different regulatory frameworks. Persistence assessment is also the first step in the assessment of PBT/vPvM and PMT/vPvM properties. This presentation will provide an overview of the regulatory actions taken to improve identification and regulation of persistent substances and recent scientific advances in PBT/vPvB and PMT/vPvM assessments.

3.05.T-02 Impact of Different Sterilisation Techniques on Sorption and NER Formation of Test Chemicals in Soil

Rebecca Süßmuth[1]*, Prasit Shrestha*[2]*, Cecilia Andrea Diaz Navarrete*[1]*, Christine Achten*[3] *and Dieter Hennecke*[1]*, (1)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany, (2)Ecological Chemistry, Fraunhofer IME*

- *Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany, (3)University of Münster, Institute of Geology and Palaeontology, Germany*
Standard OECD tests are used to generate data on the degradation (OECD 307) and sorption (OECD 106) of test chemicals in soil. In degradation testing, data on abiotic degradation using sterile samples is utilised to investigate any losses due to abiotic processes. In the context of sorption and nonextractable residues (NER) formation, data from sterile samples are often used to interpret results and findings of nonsterile samples. Generally, sterile samples are prepared by sterilisation techniques using autoclaving, gamma-radiation, and soil poisoning (adding sodium azide). To ensure the comparability of the results obtained from sterile and nonsterile samples, the influence of the sterilisation should be minimal. However, studies have shown that sterilisation techniques can influence physical and chemical properties of soil and can result in different sterilisation efficiencies. In this study, we aim to further investigate 1) the impact of different sterilisation techniques on sorption and NER formation behaviour of chemicals in soil and 2) cross compare the results obtained on sterilisation efficiencies using traditional viable plate count (VPC) methods with the RNA (cDNA) molecular approaches. For this study, two different reference soils were used: I) 01-A with low organic carbon (OC) (0.93%) and II) 03-G with high OC content (3.01%). Soil samples were sterilised by autoclaving, gamma-radiation and soil poisoning with 1% (W/W) sodium azide. Two sets of tests were performed using the sterilised soil samples: 1) OECD 106 (tier 1-2), where sorption behaviour of test items was compared by calculating adsorption kinetics and K_d-values in sterile and non-sterile soils and 2) OECD 307 (only sterile sample), where impact of sterilisation techniques on sterilisation efficiencies and NER formation was studied. For OECD 307 test, ^{14}C-labelled phenanthrene and bromoxynil were used, whereas for OECD 106 test nonlabelled phenanthrene and atrazine were used. The results from VPC and molecular approaches suggest autoclaving to be the most effective sterilisation technique. OECD 307 (only sterile sample) results showed differences in NER formation of the test chemicals, which could be due to inefficient sterilisation and/or change in soil phys.-chem. properties. OECD 106 (tier 1-2) results suggest that autoclaving of soil did not considerably affects the sorption behaviour of the test chemicals. The study is still ongoing.

3.05.T-03 The Relationship Between Composition and Environmental Degradation of Poly(Isosorbide Oxalate) (PISOX) Copolyesters

Yue Wang[1]*, John Parsons*[2]*, Albert Tietema*[1]*, Robert-Jan van Putten*[3] *and Gert-Jan Gruter Prof*[1]*, (1)University of Amsterdam, Netherlands, (2)Ibed, University of Amsterdam, Netherlands, (3)Avantium Support BV, Netherlands*

To reduce the global CO_2 footprint of plastics, bio- and CO_2-based feedstock is considered the most important design feature for plastics. Although reuse and recycling are the most desired end-of-life options for plastics, biodegradability will become very important when waste collection is not available/viable or to avoid endless accumulation of waste plastics into the environment. Oxalic acid from CO_2 and isosorbide from biomass are interesting rigid building blocks for high Tg polyesters. A family of novel fully renewable (bio- and CO_2-based feedstock) poly(isosorbide-*co*-diol) oxalate (PISOX-diol) copolyesters was recently developed. We systematically investigated the effects of the composition on biodegradation at ambient temperature (25 °C) in soil for PISOX copolyesters by measuring CO_2 evolution. All copolyesters mineralised completely within 180 days (>80%; faster than cellulose as reference) except one composition with the cyclic diol CHDM (1,4-cyclohexanedimethanol) as second diol. Oxalate esters were shown to favour fast biodegradation independent of the type of the noncyclic co-diol. Moreover, their relatively fast degradability results from facile nonenzymatic hydrolysis of oxalate ester bonds (hydrolyse completely within 180 days). Thus, partially replacing oxalate by terephthalate units increased the resistance of the polymer to hydrolysis as well as to biodegradation. We demonstrated the variation in biodegradability of PISOX copolyesters by their lag phase, ranging from 1 to 10 weeks and by the time to reach complete biodegradation, typically all in a matter of months for compositions with noncyclic second diol comonomers. This work shows the potential for tuning the composition of PISOX copolyesters, for optimizing the resulting properties (thermal-, mechanical-, barrier-, hydrolysis- and biodegradability) to target certain applications, such as controlled release for fertilizers, films and rigids for packaging, 3D printing, etc.

3.05.T-04 Influence of Season on Biodegradation Rates in Rivers

Run Tian[1]*, Malte Posselt*[1]*, Kathrin Fenner*[2] *and Michael McLachlan*[3]*, (1)Stockholm University, Sweden, (2)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Dübendorf, Switzerland, (3)Department of Environmental Science, Stockholm University, Sweden*

There is evidence that biodegradation rates in the environment have considerable temporal variability, which can have a major impact on overall chemical fate. However, our quantitative knowledge of the rate of biodegradation during different seasons remains limited. Existing data are fragmented and often derived from tests with questionable environmental relevance. The present study therefore had two main objectives: (i) To obtain insights into the influence of season on biodegradation rates of a broad range of contaminants in surface water through a modified OECD 309 test with better environmental relevance; (ii) to explore whether the temporal variability of the biodegradation rates can be described using proxies for microbial biomass. We performed a modified OECD 309 test with water and sediments from up- and downstream of wastewater treatment plants in 2 Swedish rivers (Hågaån, Knivstaån) during 4 seasons (winter: early March, 4 °C; spring: May, 17 °C; summer: August, 19 °C; autumn: October, 11 °C). An aqueous mixture of 129 compounds was spiked to a concentration of 1 $\mu g\ L^{-1}$ each and their dissipation was followed over a 10-day incubation. The total organic carbon content of the sediment and the cell density in the water and sediment will be measured for both field samples and samples collected at the beginning and the end of each experiment. These measures will be used as viable microbial biomass proxies to test whether they can explain the variability of biodegradation rates across seasons. Initial results show high seasonal variability of k for some chemicals in both rivers. We expect the evaluation of the full dataset will further our understanding of the seasonal variability of biodegradation rates.

3.05.P (Bio)Degradation and Persistence of Chemicals - New Perspectives and Developments

3.05.P-Th164 Dealing with Scarce or Ambiguous Information in Persistence Assessment – Two Perspectives

Marlies Bergheim[1], *Andreas Schaeffer*[2], *Leonie Mueller*[3] *and Johannes Tolls*[1], *(1)Henkel AG & Co, KGaA, Germany, (2)Institute Environmental Research, RWTH Aachen University, Germany, (3)RWTH Aachen University, Germany*

Characterizing the environmental degradation behavior of chemicals is a pivotal element of chemical hazard and risk assessment. The EU Chemicals Strategy for Sustainability will further reinforce this because many thousands of chemicals will have to undergo a persistence assessment in this context. Two situations may frequently be encountered in evaluating the degradation behavior. First, existing information is ambiguous and, hence difficult to interpret. Second, information from simulation tests is inavailable (as is the case for thousands of substances). Weight-of-evidence approaches have been proposed for decision-making for those cases. Using the current guidance on persistence assessment of the European Chemicals Agency as a starting point the present contribution evaluates the usefulness of the weight of evidence approach and explores options for refinement. These options are discussed in the light of ease of application, range of substance covered, degree of precaution, and scientific soundness. An academic and an industry perspective are given.

3.05.P-Th165 Biodegradation Assessment of Data Poor Substances: Case Studies Exploring a Weight of Evidence Approach

Marlies Bergheim, *Thorsten Wind, Sven Langhans and Johannes Tolls, Henkel AG & Co, KGaA, Germany*

The introduction of the EU Chemicals Strategy for Sustainability will further increase the regulatory relevance of the persistence characterization of chemicals. It is foreseen that chemicals will have to be classified into two new hazard classes in the EU, 'persistent, mobile, and toxic' and 'very persistent, very mobile'. Persistence characterizations may be needed for some 7000 to 8000 chemicals (out of 12 500 chemicals) that are registered under the EU chemicals legislation REACH. Based on the currently available information these chemicals cannot be regarded as biodegradable based on results from ready or inherent biodegradation tests. Neither has their persistence been assessed based on simulation tests. These are highly costly and have a long duration. Hence, there are practical issues that may impede a rapid persistence characterization for thousands of chemicals. Those may be overcome by evidence, which can be considered sufficient to qualify a substance as 'principally degradable'. In this contribution we present the development of such evidence in several case studies. The evidence considered includes kinetics information from biodegradation screening tests, the expected formation of stable metabolites, structural similarities with chemicals with well-established degradation behavior, etc. The case studies demonstrate the integration of pieces of evidence into a 'principally biodegradable' evaluation.

3.05.P-Th166 An Integrated Tool for the Screening of Fate, Persistence, and Long-Range Transport of Organic Chemicals

Alessandro Sangion[1,2], *Knut Breivik*[3], *Liisa Toose*[1], *James M Armitage*[4], *Frank Wania*[5] *and Jon A. Arnot*[1], *(1)Arnot Research and Consulting Inc. (ARC), Canada, (2)University of Toronto, Canada, (3)Norwegian Institute for Air Research (NILU), Norway, (4)AES Armitage Environmental Sciences, Inc, Canada, (5)Department of Physical and Environmental Sciences, University of Toronto, Canada*

Potential risks to human or environmental health caused by chemicals that are very persistent in the environment are poorly reversible. For chemicals with the potential to undergo long range transport (LRTP) such harm is not spatially contained. Prioritizing chemicals with respect to persistence (P) and LRTP is therefore often an important consideration in chemical assessment. P assessment is typically accomplished by comparing kinetic (bio)degradation data to bright-line pass/fail criteria while LRTP is often quantified by metrics such as characteristic travel distances (CTDs) or a transfer efficiency (TE). Other metrics to estimate P and LRTP (e.g., Overall Persistence (P_{OV}) or the emissions fractions) exist and should be integrated in a Weight of Evidence (WoE) assessment framework. With the aim to establish a multimedia framework for the screening for P and LRTP, we designed the Fate and Persistence Estimation & Simulation Tool (F-PEST) and implemented it in the Exposure And Safety Estimation (EAS-E) Suite platform (www.eas-e-suite.com). F-PEST assembles information on chemical partitioning, emission, degradation, and environmental fate and transport for the prioritization and screening-level assessment of neutral and ionizable organic chemicals (IOCs). F-PEST input parameters such as chemical partitioning and distribution ratios and degradation half-lives in different environmental compartments are auto-parameterized from the EAS-E Suite database or predicted by built-in Quantitative Structure Activity Relationships (QSARs). These properties are then used in a mass balance model of fate in a multimedia environment that calculates the relative chemical mass distribution between, and the chemical activities in, the environmental compartments to identify media of concern. In addition to P_{OV}, CTDs and TE, F-PEST estimates the three emissions fractions (i.e., dispersion, transfer and accumulation), thereby enabling a comprehensive P and LRTP assessment. A set of libraries reflecting different regional-scale environmental conditions is available to easily parameterize the system. Specifically, simulations can be run with the default conditions of the "OECD Pov and LRTP Screening Tool" or with sets of conditions adopted from other models (e.g., EQC, RAIDAR, EUSES) that are representative of different geographical areas (e.g., temperate North America, Europe). A case study with selected chemicals is presented to demonstrate the integrated framework.

3.05.P-Th167 The Persistence Assessment Tool (PAT): Implementing a Methodology for Data Quality Evaluation and Weight of Evidence in Persistence Assessments

Christopher Hughes[1], *Megan Griffiths*[1], *Simon Cook*[1], *Dik van de Meent*[2], *John Parsons*[2], *Delina Lyon*[3] *and Amelie Ott*[4,5], *(1)Ricardo Energy & Environment, United Kingdom, (2)Association of Retired Environmental Scientists ARES, Netherlands, (3)Concawe, Brussels, Belgium, (4)Cosmetics Europe, Belgium, (5)International Collaboration on Cosmetics Safety*

Chemical persistence plays a key role in determining environmental exposure making it an important component in risk assessment and regulation. Recently, interest in chemical persistence has increased significantly. Persistence assessment in the regulatory context involves comparing chemical degradation half-lives to set criteria for different environmental compartments (water, sediment, and soil). Other information is also relevant for assessments (e.g., biodegradation screening tests, non-standard experiments, QSARs, field data, etc.), and should be considered following a weight of evidence approach. Implementation challenges remain in persistence assessments, particularly relating to guidance around the evaluation of data quality, and the weight-of-evidence determination. In addition, there are issues for substances whose properties render them difficult to evaluate using standard methods.

To address these challenges, a software tool – the Persistence Assessment Tool (PAT) – has been developed to support the evaluation of persistence under regulatory frameworks such as EU REACH. This tool provides clear guidance and structure to evaluate data quality, and a quantitative weight-of-evidence (qWoE) methodology to process the information input and calculate persistence conclusions in line with regulatory guidance. The PAT is applicable to all substance types and provides specific features to account for difficult and complex substances. Various options for customisation of the methodology are included to adapt assessments to specific regulatory frameworks and purposes. In addition a multimedia fate model, SimpleRisk4PAT, is included to optionally calculate overall persistence (P_{OV}), allowing for additional potentially important environmental fate processes to be taken into account. The PAT aims to support robust, consistent and transparent decision-making for persistence assessment. There is a need for stakeholder input to support further validation, consensus-building and uptake of the methodology.

3.05.P-Th168 Persistence Revisited – Do Substances of Equal Degradation Half Life in Water Have Equal Lifetimes in the Environment?

*Dik van de Meent[1], **John Parsons**[2], Emiel Rorije[3] and Eric Verbruggen[4], (1)Association of Retired Environmental Scientists ARES, Netherlands, (2)Ibed, University of Amsterdam, Netherlands, (3)Centre for Safety of Products and Substances, Dutch National Institute for Public Health and the Environment (RIVM), Bilthoven, Netherlands, (4)National Institute for Public Health and the Environment (RIVM), Netherlands*

In Europe, under the REACH regulation, chemical substances with unacceptably long lifetimes in the environment cannot be used without restriction. Criteria to assess whether chemicals are “P” are, like in most international regulatory frameworks, based on comparison of single-media half lives with chosen cut-off criteria, silently assuming that chemicals with half lives that exceed the chosen criteria have lifetimes in the environment that are unacceptably long. However, criteria for (un)acceptability of lifetimes of chemicals in the environment. What is more, it has not even been decided how “lifetime in the environment” is to be measured. Environmental scientists in Europe and North America have proposed multimedia fate model based overall half life at steady state (Pov) as a useful measure of lifetime in the environment. Stroebe (2004) has warned against this on theoretical grounds, because Pov and single-media half lives tend to measure different things, so that exceedance of single-media half lives cannot be taken as evidence of unacceptability of lifetime in the environment.

We have tested whether QSAR-derived half life in water can be used as predictor of calculated Pov. To this end we have used EUSES to calculate overall persistences in the environment of 1977 REACH-registered organic substances, and compared these with QSAR-estimated degradation half lives in water of the same 1977 substances. A plot of the results will be presented at the poster. It clearly shows that substances with equal half lives in water may have greatly different Pov. This result confirms the theoretical work of Stroebe (2004): substances with short half lives in water may have long environmental lifetimes.

3.05.P-Th169 The Importance of Accurate Measurements of Nitrification in Biodegradation Tests

***Arturo Mendoza**[1], Georg Kreutzer[2], Yannick Favre[3], Karen Jenner[4] and Thomas Dutriez[5], (1)Environmental, RAPS Analytical, Givaudan Suisse SA, Vernier, Switzerland, (2)Raps, Givaudan Suisse SA, Vernier, Switzerland, (3)Givaudan Suisse SA, Vernier, Switzerland, (4)Givaudan UK Ltd, United Kingdom, (5)Givaudan International SA, Vernier, Switzerland*

Nitrification is an important process in soils, wastewater treatment plants, and in general in the ecosystem because it completes the mineralization of organic nitrogen. The conversion of nitrogen into nitrate is done in two steps by two different groups of microorganisms, the first step is the conversion of ammonium into nitrite ($NH_4^+ \rightarrow NO_2^-$) and the second is the rapid oxidation of nitrite into nitrate ($NO_2^- \rightarrow NO_3^-$). These biochemical reactions are of high importance in biodegradation testing of organic nitrogen compounds. Those that are susceptible to biodegradation will release nitrogen atoms as ammonium and, if nitrification subsequently occurs, ultimately in the form of nitrite and/or nitrate. Accurate measurement of nitrification is essential in biodegradation testing because serious errors can arise in the determination of the percentage of biodegradation by oxygen uptake (i.e., in respirometric OECD methods 301F, 301D, 302C, etc.) if the observed oxygen uptake is not appropriately corrected by the amount used in oxidizing ammonium to nitrite and ultimately nitrate. Simple methods for the measurement of nitrite and nitrate in solution may include coloured test stripes, which are fast but of low accuracy, and/or colorimetric methods, which are more accurate but require a previous derivatization of nitrogen into an UV absorbent species before analysis. In this poster, we propose the use of a simple and optimized method for the measurement of nitrate at the end of respirometric biodegradation tests by using a highly sensitive Ion Selective Electrode (ISE). After an initial calibration, the use of an ISE allows a fast and accurate determination of nitrate in a complex matrix (salt medium + activated sludge). An optimization of the method was also made to determine the right ionic strength needed in solution when measuring low levels of nitrate (< 2ppm). Quantifying the exact values of nitrate in the solution allows us to calculate a weighted theoretical oxygen demand of the substance by using the proportions of nitrate and ammonium. This calculation yields a more accurate determination of the overall percentage biodegradation of the test substance and avoids over- or underestimations. Some examples of calculation of biodegradability with this approach will be presented.

3.05.P-Th170 Evidence of Nitrogen Limitation in Manometric Respirometry Tests for Ready Biodegradability

Don Bealing*, TSG Consulting, United Kingdom*

Standard methods for ready biodegradability assessment employ stringent 'fail-safe negative' conditions (unadapted inoculum, test item is the sole source of C for microbial energy and growth needs, high substance:biomass ratio). All use an aqueous medium containing inorganic salts intended to support microbial growth requirements for the duration of the test. The current manometric respirometry test guideline of the Organization for Economic Cooperation and Development (OECD TG 301F) has its origins in a 1983/4 EC ring-test that *i.a*. gave rise to a proposal to lower the medium N content – not to ensure test stringency and minimize the potential for false-positive test outcomes, but as a technical fix to limit the potential for nitrification to confound oxygen uptake measurements. The fix was adopted without further validation or assessment of impact on test outcomes.
We present evidence of Nlimitation in tests performed with a multiconstituent derivative of *Eucalyptus citriodora* oil. Rate and extent of mineralisation under OECD 301F conditions were reproducibly influenced by the inorganic N content of the test medium. There are implications for the rate constant for removal in STP and consideration of persistence in the EU regulatory framework.

3.05.P-Th171 TheImportance of Data Relevance Criteria for Regulatory Use of Nonstandard Test Data for Persistence and Bioaccumulation Assessments

Leslie J. Saunders[1]*, Delina Lyon*[1]*, David Saunders*[2]*, Louise Camenzuli*[3]*, Sandrine Sourisseau*[4]*, Christopher Hughes*[5] *and Emma Pemberton*[5]*, (1)Concawe, Brussels, Belgium, (2)Shell Global Solutions, Netherlands, (3)ExxonMobil, Belgium, (4)TotalEnergies, France, (5)Ricardo Energy & Environment, United Kingdom*

Regulatory assessments of persistence, bioaccumulation, and toxicity (PBT) rely on available data, either generated directly by registrants or from other scientific sources. Following evaluation, substances meeting PBT criteria are identified as Substances of Very High Concern (SVHC), which can have far-reaching repercussions (see Borchert et al., 2022). While standardized test methods (e.g. OECD/ISO) may be used to generate data for such assessments, these data may be unreliable as these methods are not suitable for all types of substances with varying physicochemical properties. In such cases, modified or nonstandard test methods are often used to accommodate substance-specific issues (e.g., hydrophobicity, volatility, UVCBs). Additionally, as per the Chemical Strategy for Sustainability under the EU Green Deal, it is expected that use of non-standard data including NAMs will become more common in regulatory decision making. However, data generated in nonstandard tests may be variable and their analysis complex which can inevitably pose challenges to determine which studies will achieve regulatory acceptance. Hence, more systematic approaches to data quality assessment are needed to support greater consistency and transparency in PBT assessments (Pemberton et al. 2022. SETAC Copenhagen [We125]). The quality of standard and nonstandard data is typically assessed for relevance and reliability. Approaches for reliability evaluation have evolved over time, becoming more systematic with available scoring criteria (e.g., Klimisch). However, there is currently much less consensus on data relevance scoring, which may introduce bias and inconsistencies in the assessments. This is particularly true for P&B evaluations, where there are currently no agreed upon relevance criteria. In the present study we reviewed multiple studies used in previous evaluations and the wider scientific literature to determine the types of P&B data used in regulatory decision making. We targeted studies performed with difficult-to-test substances (i.e., UVCBs), since evaluations of these substances often rely on nonstandard data. Using this information, we identified relevance criteria that are being used in practice for P&B data with the goal of informing future study methodologies that would result in more acceptable data for regulatory evaluation.

3.05.P-Th172 OECD 309 Study – What is the Role, Purpose, and Relevance in EU Risk Assessment?

Derek Wallace*, ERM Regulatory Services Limited, United Kingdom*

The evaluation of the fate and metabolism of active substances applied in the environment are prescribed by Commission Regulation (EU) No 283/2013, which outlines the requirement to define behaviour in water/sediment systems (OECD 308) and open-water bodies (OECD 309). Using the information generated whilst conducting the key OECD guideline studies, the exposure of active substances in surface water can be modelled using FOCUS Steps 1-4. However, in the FOCUS Surface Water Generic Guidance, the characteristics of typical edge-of-field water bodies are defined and broadly grouped as "Pond", "Stream" and "Ditch" scenarios and there is no assessment or parameterisation of an "open lake" scenario.

In order to mimic exposure to "open water bodies", which denotes degradation with a very low sediment component, the OECD 309 study is required. Typically, results in the OECD 309 study are variable, characterised by slow degradation with evident lag phases, plus the potential for identification of novel metabolites not typically observed in the OECD 308 study. This creates the potential requirement to identify, synthesise and characterise these metabolites in order to perform a risk assessment; in particular driven by the lack of an exposure scenario and the tendency to assume extremely conservative ecotox endpoints. Given that the nature of exposure to an OECD 309 study explicitly describes a significant volume of water and that FOCUS SW Step 1-4 describe edge-of-field exposure scenarios of water bodies not fitting this description, the requirement to conduct an assessment for unique OECD 309 metabolites against FOCUS PECSW is overly conservative.

In conclusion, the role and application of the OECD 309 study in EU Crop protection risk assessment is reviewed against the original definitions of edge of field water bodies in FOCUS Surface Water. Considering the definitions of the water bodies, the relevance and appropriateness of applying observations from the OECD 309 study requires discussion.

3.05.P-Th173 Pitfalls and Potential of the OECD 309 Test

Michael McLachlan[1], *Run Tian*[2], *Malte Posselt*[2] *and Kathrin Fenner*[3], *(1)Department of Environmental Science, Stockholm University, Sweden, (2)Stockholm University, Sweden, (3)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Dübendorf, Switzerland*

The assessment of persistence is of growing importance in chemical regulation. With the introduction of a persistent, mobile and toxic (PMT) hazard class, many more chemicals will be subject to persistence evaluation under REACH. The prioritized test for assessing persistence under REACH is OECD 309, a simulation test for chemical persistence in surface water. In this contribution, we first explore the pitfalls of the OECD 309 test, which include limited sensitivity, poor reproducibility, and lack of representativeness for biodegradation in the water body being simulated. This leads to the conclusion that most chemicals that pass the persistence screening assessment under REACH will be classified as persistent, which would seriously impact the ability of REACH to prioritize chemicals. We then explore several possible modifications to OECD 309, including adding larger quantities of sediment, focusing on the biodegradation kinetics during the first few days of the test, and spiking test chemicals at very low concentrations. We conclude that with these changes a sensitive, reproducible and much more representative test of persistence in aquatic systems is possible. Finally, we note that the dependence of the test result on the sediment : water ratio raises questions about lab-to-field extrapolation of half-lives and how the measured half-life can be compared with regulatory thresholds for persistence in water alone.

3.05.P-Th174 Integration-Optimization of Bioavailability Measurements and OECD 307 Test to Evaluate Persistence of Organic Pollutants During Incomplete Biodegradation Processes in Soil

Rosa Posada[1], *Carmen Fernandez-Lopez*[2], *Dieter Hennecke*[3] *and Jose Julio Ortega-Calvo*[1], *(1)Instituto de Recursos Naturales y Agrobiologia, Spain, (2)University Center of Defence (CUD), Spanish Air Force Academy, MDE-UPCT, Spain, (3)Ecological Chemistry, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany*

The incomplete biodegradation of organic pollutants in soil can rise the environmental risks if the transformation products are more toxic and mobile than the parent compounds. Alternately, the biodegradation products may remain as nonextractable residues, or as slowly desorbing but still extractable chemicals, which may be less risky than the parent, fast desorbing pollutants. The biodegradation process is itself influenced by the bioavailability of contaminants to the soil microbial populations, so bioavailability and risk assessment should be integrated and persistence studies combining these are limited. The significance of evaluating bioavailability during a biodegradation process has been examined in our previous studies on soil bioremediation, explaining that integrating bioavailability assessment gives a more realistic risk information than using the total contaminant concentrations only. Here, we studied the biodegradation by organic compounds in a prospective risk assessment scenario, with the OECD 307 simulation test incorporating bioavailability assessments. To assess bioavailability, the standardized ISO method (16751:2020) was used, which is based on a single-step desorption extraction with Tenax at 20 h. Two different organic pollutants (^{14}C-pyrene and ^{14}C-carbamazepine (CBZ)) and different scenarios (soils with different content in organic matter, incubation periods and inoculation) were examined to follow the evolution of bioavailability of the parent compound and the transformation products from cometabolic reactions. The ISO method was adapted with CBZ, given its relatively low K_{ow} (= 2.7) by changing the soil/water/Tenax ratio. For both compounds, the bioavailability decreased and its phase-distribution changed during the transformation. At the end of the incubation, the fraction of transformation products present in Tenax were 48 % and 10 % of the initial concentration (4 mg/kg) for pyrene and carbamazepine, respectively. The products not trapped by Tenax but partitioned into the water were 3 % and 30 % of the initial pyrene and carbamazepine concentrations, respectively. The rest of the compounds remained as nonbioavailable residues.

3.05.P-Th175 Influence of Soil-Treatment on the Release of NER I

Nico Anton Josef Balzer[1] *and Andreas Irmer*[2], *(1)Environmental Fate, Eurofins Agroscience Services EcoChem GmbH, Niefern-Öschelbronn, Germany, (2)Eurofins Agroscience Services EcoChem GmbH, Niefern-Öschelbronn, Germany*

Several guidelines define the experimental conduct, evaluation of data and, therefore, the criteria for the assessment of (physico-) chemical properties or toxicological and environmental behavior of chemicals. However, in environmental fate studies, the handling of nonextractable residues (NERs) remains vague and no standardized procedure is defined. Consequently, the risk assessment of NERs varies from potentially hazardous to “safe sink”. It is therefore of ubiquitous interest to be able to further characterize the nature of nonextractable residues and possibly subdivide them into further groups such as sequestered and entrapped residues (NER I), strongly bound residues (NER II) and biogenic residues (NER III). While NER II and NER III are of low or no environmental concern, NER I should be considered as potentially remobilizable.
To quantify the amount of NER I experimentally, several techniques are in discussion. These experiments aim to change the surface structure of the soil resulting in the release of entrapped molecules.

In this work, the influence of soil-treatment on the release of NER I using two different approaches is shown and discussed. Firstly, the feasibility of using EDTA to facilitate the release of NER I is presented. For this purpose, different types of soil (variation in organic matter, texture and cationic exchange capacity [CEC]) are treated with EDTA solution and the subsequent release of radiolabeled compounds is evaluated. Secondly, the influence of various silylation agents on different types of soil is shown. The correlation between bulkiness/rigidity of silylation agent as well as the influence of the CEC on the subsequent structural change and release of radiolabeled compounds is evaluated.

This contribution discusses feasibility, the conduct and the subsequent evaluation of postextraction soil treatments in order to differentiate between different types of nonextractable residues.

3.05.P-Th176 Integration of Quantification and Characterisation of Nonextractable Residues (NER) in Regulatory Persistence Assessment

Ulrich Jöhncke[1], *Astrid Wiemann*[1], *Anu Kapanen*[2] *and Kostas Androu*[2], *(1)German Environment Agency (UBA), Dessau-Rosslau, Germany, (2)European Chemicals Agency (ECHA), Helsinki, Finland*

Knowledge of the characteristics of nonextractable residues formed in degradation studies plays an important role in regulatory persistence assessment by providing further elucidation of the fate and behaviour of the chemicals in the environment. Characterisation of NER in reversible and irreversible bound fractions improves the confidence in interpretability of simulation degradation tests. There has been a long debate on the acceptability of the available NER characterisation methodologies. Therefore, a research project was initiated by UBA and carried out by a consortium of academia with the aim to test the practicability of different approaches for capturing NER in simulation degradation studies. Based on the extensive discussion and collaboration among regulators, academia, and industry, a stepwise approach for quantification and charaterisation of NER has been developed. Step 1 of the approach specifies extraction methods for quantification of total NER and Step 2 describes NER characterisation by silylation or EDTA extraction to remobilisable and irreversibly bound fractions. Differentiation of NER types will improve interpretability of degradation study results and provides more robust information for assessment of persistence of substances. The updated ECHA Guidance on IR&CSA, Chapters R.11, R.7b and R. 7c takes into account the outcome of these scientific advances in quantification and characterisation of NER and integrates this in the regulatory persistence assessment. This presentation will provide an overview of the scientific discussions leading to the integration of the quantification and characterisation of NERs in the regulatory persistence assessment.

3.05.P-Th178 The Performance of Aged Sorption Laboratory Studies: Considerations and Experience

Victoria Rose Peck, *Fera Science Ltd., York, United Kingdom*

Adsorption of chemicals to soil significantly influences their potential to move to groundwater and/or surface waters. Within the regulatory risk assessment procedure for pesticides, first tier assessments currently assume that pesticide sorption is instantaneous and fully reversible, and that the strength of adsorption is therefore constant with time. However, adsorption has frequently been observed to increase as the time of interaction between substances and soil also increases, i.e., ‘aged sorption’.

As a result of these observations, it is becoming more common for experimental studies that demonstrate and quantify the increase in pesticide sorption with time to be submitted to regulatory authorities as part of the regulatory data package. The results of these studies are then used to revise estimates of predicted environmental concentrations in groundwater using FOCUS modelling. However, such studies are complex and difficult to standardise, and the results are often difficult to interpret.

A guidance document on the performance of aged sorption studies has been developed over many years and was originally approved and published on the EU Commission website in January 2021, with a revised version published in the following October. This guidance includes the design of the appropriate experimental protocol, standardisation of deriving the required parameters from the experimental data and how the parameters are subsequently used during exposure modelling.
While the guidance is comprehensive, further knowledge and experience in the performance of aged sorption studies has been recently developed and will be communicated in this poster. Areas that will be explained more fully and need to be further considered when performing an aged sorption study include dealing with fast degrading substances, addressing the strict requirements regarding outliers and considering the value of preliminary investigations.

3.05.P-Th179 Degradation of Polyethylene by *Penicillium brevicompactum*

Ana Maria Paço[1], *Joao Pinto da Costa*[1], *Artur Alves*[2], *Armando C Duarte*[1] *and Teresa Rocha-Santos*[1], *(1)Chemistry, University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Aveiro, Portugal, (2)University of Aveiro, Aveiro, Portugal*

The massive presence of plastics in the environment, and, specifically, in the marine environment, has become a topic of great concern in recent years.

Plastics have deleterious effects on marine fauna, and studies indicate that small plastics, dubbed microplastics, may have greater pervasiveness and impact.

Polyethylene (PE) is the most commonly found plastic in the environment, as it is also the most used polymer in our daily lives.

Biodegradation, the ability of some microorganisms to use a contaminant as source of nutrient, has been presented as a promising solution to reduce plastics already present in the environment and different microorganisms, including bacteria and fungi, have already been demonstrated to have the ability to biodegrade different microplastics. Within the Fungi kingdom, species of the *Penicillium* genus have been widely studied regarding this skill due to their large presence across the globe and their great ability to adapt and survive in different conditions.

Penicillium brevicompactum is commonly used to produce mycophenolic acid, an immuno-suppressant, and amenable to be grown and kept at industrial scale, and, as such, was chosen to assess its viability in the biodegradation of PE.

To test this hypothesis, three different experimental conditions were considered, with a one-month experiment, with four time points, one per week. We studied fungal growth in reduced medium with PE microplastics and fungal growth in a reduced medium without PE microplastics, and these two conditions were used to compare how fungal growth was influenced by the microplastics. The last condition was PE microplastics in a reduced medium, to see if any alteration present in the microplastics would be caused by the medium.

Our experiment showed that, in under 30 days, *P. brevicompactum* was able to reduce 50% of the microplastics present in the medium. In addition, it also showed that the fungus grew less when in contact with the microplastics. This may indicate that some nutrients required for fungal growth may be missing, so a possible next step would be to optimize the medium, with the objective of maximizing the removal of microplastics.

3.05.P-Th180 Biodegradation of a Range of Nonpolymeric and Polymeric Surfactants in Seawater
*Odd Gunnar Brakstad[1], James Dawick[2], Roy Geerts[3], Philipp Hopp[4], **Bruno Campos**[5] and Abel Machado[6], (1)SINTEF, Norway, (2)Innospec Limited, United Kingdom, (3)Nouryon, (4)BASF Personal Care and Nutrition GmbH, Germany, (5)Unilever, United Kingdom, (6)Procter & Gamble*
Surfactants are a major class of chemicals commonly used in a wide range of domestic and industrial products. Despite efficient wastewater treatments, small fractions of surfactants may reach aquatic and eventually marine environments. Although many surfactants have been tested for ready biodegradability by standard freshwater OECD screening test guidelines, there is still a lack of systematic biodegradation data across various types of surfactants in the marine environment. In addition, little is known about seawater (SW) biodegradability of polymeric surfactants, such as the nonionic ethoxylated and/or propoxylated aliphatic alcohols. In this study, ultimate biodegradation of 18 surfactants representing different classes (including several polymeric alcohol ethoxylates), was determined in SW at 20°C by the OECD306 Closed Bottle test method. After 28 days of incubation, 12 surfactants reached 60% biodegradation and were considered to be readily biodegradable in SW. The results for the 6 additional surfactants indicated that the 60% threshold level may be reached by extended incubation time, or that reduced biodegradation could be associated with toxicity of the chemicals. All these 6 surfactants were biodegraded >20% after 28 days, indicative of primary biodegradation in SW. Polymeric ethoxylates with high numbers of ethylene oxide (EO) groups (40-50 EO groups) were more slowly biodegraded than polyethoxylates with 4 to 23 EO groups. A biodegradation experiment of the alcohol ethoxylate (AE) C12-EO9 (3 to 18 EO groups) was performed in a carousel system at 20°C with natural SW and a surfactant concentration of 500 µg/L. Rapid primary biodegradation was determined by targeted analyses (LC-MS) of the AE, with >99% primary biodegradation after 2 days of incubation. The surfactant depletion coincided with temporary formation of polyethylene glycols, suggesting that central fission is an important degradation step in SW. A primary biodegradation experiment in the carousel system with C12-EO9 was conducted in the presence of suspended particulate materials (SPMs; marine phytoplankton and clay particles, showing that the presence of SPMs did not hamper the primary biodegradation of the surfactant. Separation of fractions in 20 µm steel filters indicated some particle association of the surfactant.

3.05.P-Th181 Assessing Effects of Cationic Charge on the Biodegradation Profile of Cationic Guars Following OECD 302B with Concurrent GPC Analysis
***Nigel Crabtree**[1], Carrie E. Jantzen[2], Alan Fernyhough[3], Ryan Hamilton[2], Saiful Ahmed[3] and Andrea Burron[3], (1)Measurement Science, Ashland, United Kingdom, (2)Ashland, (3)Ashland, United Kingdom*
Hydroxypropyl guar hydroxyproplytrimonium chloride polymer (Common name: cationic guar, CAS number 71329-50-5) is a commonly used ingredient in personal care products, particularly hair care products, due to the cationic charge making the material a good thickener and conditioning agent. Additional benefits of using this material include a favorable human toxicity profile and a high ISO naturality index score. However, highly charged materials may have the potential to be inhibitory to microbes and persistent in the environment. In this study, four cationic guars with various cationic degree of substitutions (cat DS) ranging from 0.08 – 0.22, including a low, medium, charge, and very high charge, were assessed following an extended (60 day) OECD Testing Guideline 302B (Zahn-Wellens/EMPA Test). In addition to biodegradation measurements, GPC analysis was performed at the following timepoints (days 0, 7, 14, 21, 28, 42, and 60) to measure changes in average molecular weight and molecular weight distribution of the polymers after such exposure. A general trend between increase in cationic charge and decrease in biodegradation percentage to day 28 was observed, with a threshold that a cationic guar could be classified as inherently biodegradable at approximately cat DS 0.20. Significant decreases in molecular weight and peak area were observed regardless of cat DS, however there was not a significant alteration in the pattern of reduction between differently charged guars. These results indicate that increasing cationic charge may negatively affect the biodegradation of cationic guars, as well as indicate the potential limits of OECD 302B with regards to charged materials. The additional GPC data provides evidence that it does not affect the method of degradation or the mineralization potential.

3.05.P-Th183 Fate of the Azole Fungicide Fluconazole in Sunlit Waters: Kinetics, Transformation Products, and Reaction Mechanisms
***William D. Fahy** and Scott A. Mabury, Chemistry, University of Toronto, Canada*
The common antifungal pharmaceutical fluconazole is a persistent organic pollutant regularly found contaminating bodies of water around the world. Fluconazole can cause adverse health effects to at environmentally relevant concentrations and has been shown to inhibit the human cytochrome P450 system, which could slow metabolism of other xenobiotics and lead to synergistic toxic effects. Little is known about the environmental fate and transformations of fluconazole, although existing work on biodegradation and advanced oxidation processing indicates it is recalcitrant to many natural transformation pathways, often

requiring forcing conditions to degrade. Here we used the PhotoFate system to investigate the indirect photolysis of fluconazole in simulated sunlit freshwater environments. We estimate a half-life with respect to indirect photolysis in natural waterways ranging from around 5 to 25 days, with faster degradation observed with high concentrations of dissolved organic matter and/or nitrates. Transformation products have been identified and semiquantified using liquid chromatography coupled to (high resolution) mass spectrometry (LC-MS), with major products observed including multiple OH addition isomers, fragmentations of the bridging alkyl chain, and fragmentation of the aromatic ring. Tentative structures and reaction mechanisms to produce those structures are proposed based on exact mass analysis, retention time analysis, and previous observations of hydroxyl and carbonate radical reactivities in aqueous solutions. Notably, the electron-rich triazole azole rings do not appear to be as prone to oxidation as we predicted, as stable OH addition products do not dominate the product profile indirect photolysis of fluconazole or 1,2,4-triazole, even when exposed to high OH radical concentrations by addition of hydrogen peroxide. We propose that either the hydroxyl radical causes slow fragmentation of the azole ring, resulting in volatile transformation products or OH addition products are formed, but they are very unstable and fragment in the electrospray ionization source, and are unlikely to be long-lived in the environment. Finally, the proposed transformation products will be tested for their binding energies to the cytochrome p450 isozyme CYP2C19 using a molecular dynamics approach to quantify the change in human cytochrome P450 enzyme inhibition following indirect photolysis of fluconazole.

3.05.P-Th184 Analysing the Biodegradation of Acesulfame in Lysates from Enriched Bacterial Cultures via Application of Enzyme Assays and Shotgun Metaproteomics

***Sandro Castronovo*[1]**, *Lissa Helmholz[2], Jan Struckmann Poulsen[3], Jeppe Lund Nielsen[3], Thomas A Ternes[4], Torsten C. Schmidt[5] and Arne Wick[1], (1)G2-Aquatic Chemistry, German Federal Institute of Hydrology, Germany, (2)Aquatic Chemistry, Federal Institute of Hydrology (BfG), Koblenz, Germany, (3)Department of Chemistry and Bioscience, Aalborg University, Denmark, (4)G Qualitative Hydrology, German Federal Institute of Hydrology, Germany, (5)Instrumental Analytical Chemistry, University of Duisburg-Essen, Germany*

The biodegradability of anthropogenic organic substances in wastewater treatment has been extensively studied, but information about the enzymes catalyzing the degradation reactions is scarce. In this context, we analyzed the enzymatic degradation of the artificial sweetener acesulfame (ACE), which is frequently detected in waters impacted by municipal wastewater. Biodegradation of ACE has already been proven and sulfamic acid (SA) was identified as quantitatively formed transformation product (TP). Genomes of ACE-degrading bacteria have been published lately, but the crucial proteins are still unknown and the degradation pathway has not yet been unequivocally clarified. To address this, we expanded the range of analytical methods used so far by combining i) enzyme assays with ii) protein fractionation and iii) proteomics analysis. We enriched ACE-degrading bacteria by incubating activated sludge in an artificial medium, using ACE as sole carbon source. A so far unknown *Chelatococcus* species and *Ensifer adhaerens* were identified as most abundant taxa after enrichment. Lysates were extracted next and fractionated via two-dimensional fast protein liquid chromatography. ACE was spiked to all fractions and enzyme activity was monitored by measuring the ACE degradation. Protein composition and abundances in all fractions were analysed using shotgun proteomics and label-free protein quantification. The protein fractionation succeeded in separating the enzyme(s) catalyzing the first degradation reaction of ACE from the enzyme(s) catalyzing the second reaction step sufficiently to detect an accumulation of the intermediate TP acetoacetamide-n-sulfonic acid (ANSA). ANSA has been previously identified in ACE-degrading cultures, but up till now was quantified only in trace amounts, leaving open the possibility of being solely the product of a sidechain reaction. The quantitative detection of ANSA observed here indicated that the initial step in the biodegradation of ACE is a hydrolytic ring cleavage at the sulfuric ester moiety, catalyzed by sulfatases or hydratases. Subsequently, ANSA must be degraded through cleavage of its amide bond catalyzed by amidases to form SA. A highly abundant metallo-β-lactamase fold metallo-hydrolase was identified as most probable enzyme candidate for the catalytic cleavage of ACE by comparing protein abundances with the corresponding ACE degradation rates. Moreover, an amidase possibly catalyzing the degradation of ANSA was detected.

3.05.P-Th185 Microbial Degradation Potential of Emerging Contaminants by Isolated Bacterial Strains

***Hatice Turan*[1]**, *Bahia Khalfaoui-Hassani[1], Alisson Godino Sanchez[1], Zulfatun Naimah[1], Mathieu Sebilo[2], Rémy Guyoneaud[1] and Mathilde Monperrus[1], (1)Université de Pau et des Pays de l'Adour, France, (2)Sorbonne University, CNRS, INRAE, IRD, UPD, UPEC, Institute of Ecology and Environmental Sciences, France*

Emerging contaminants (CECs) are defined as unregulated or inadequately regulated chemicals. Many of them are used and released continuously into the environment, and may cause chronic toxicity, endocrine disruption in humans and aquatic wildlife. Bacterial degradation is an effective way in removing CECs either through metabolic or enzymatic pathways. High concentrations of CECs (musks; galaxolide (HHCB) and tonalide (AHTN)), UV-filters (Octocrylene (OC) and padimate-O(OD-PABA)) have been previously reported in sediments of a submarine canyon (Capbreton canyon). The bacterial strains belonging to the genus *Bacillus* sp. (S-1, S-2, S-3, S-5 and S-6) and the genus *Rhodococcus* sp. (S-4) have been then isolated from the marine sediments enriched with a single CEC and have been tested for their degradation potential against the CEC used for isolation. The aim of this study is to assess the biodegradation of CECs such musks (HHCB and AHTN); UV-Filters (OC and OD PABA); pharmaceuticals (ketoprofen and oxazepam) and pesticide (atrazine) by pure isolated strains related to different genus. The degradation potentials of these compounds were also discussed considering to chemical structure of CECs, phylogeny, and resistance of the strains.

The strains were cultivated in MM_{20} medium and were spiked with a single CEC at 1 mg L^{-1} for 24 hours incubation for *Bacillus* sp. and 48 hours for *Rhodococcus* sp. HHCB, AHTN, OD PABA, OC and Atrazine. The results show that some strains have high degradation potentials against CECs (S-3, S-4 and S-5 strains) whereas others are only able to degrade OC (S-1 and S-2). S-6 was not able to degrade any CEC. For those with high degradation potentials, 5 CECs (HHCB, AHTN, OD-PABA, OC, and ketoprofen) were degraded with different potentials meaning that the degradation extent is CEC-dependent. The results also reveal that atrazine and oxazepam are highly persistent CECs as no degradation by any strain was observed. Moreover, the resistance of the selected two strains belonging to *Rhodococcus* sp.(S-4) and *Bacillus* sp.(S-5) was investigated by exposing HHCB, AHTN, OC, OD-PABA, and ketoprofen up to 500 mg L^{-1}. The results showed no toxicity effect for musks and UV-Filters. However, the growth was inhibited when more than 30 and 60 mg L^{-1} of ketoprofen of S-4 and S-5 were used, respectively. Overall, the experimental results demonstrate that degradation ability of the strains is not linked to toxicity or resistance to CEC.

3.05.P-Th186 Determining Marine Biodegradation Kinetics of Chemical Mixtures Discharged from Offshore Oil Platforms – Mixture Toxicity Inhibited Biodegradation at Low Dilutions

***Mette Moller**, Heidi Birch and Philipp Mayer, Department of Environmental and Resource Engineering, Technical University of Denmark (DTU), Lyngby, Denmark*

Enormous volumes of produced water carrying complex chemical mixtures are discharged to the marine environment from offshore oil platforms. Environmental Impact Assessments (EIAs) focus generally on the (eco)toxicological effects of these discharges in the near field, but it is equally important to avoid large discharges of chemicals that are persistent which can build up in the environment. This asks for new approaches to determine marine biodegradation kinetics of discharged chemicals at low environmentally relevant concentrations.

This study aimed to (1) determine biodegradation kinetics of chemicals in produced water (discharged chemical mixture) diluted in seawater (inoculum microorganism at discharge) and (2) determine how the dilution factor affects biodegradation kinetics. Produced water and seawater samples were received from an offshore oil platform in the North Sea and biodegradation experiments started within 32 hours. Parallel experiments were conducted with produced water diluted in seawater by factors of 20, 60, and 200, and with a gasoline calibration standard (23 reference substances) spiked in seawater. The test systems were prepared in 20 mL gastight autosampler vials and incubated up to 60 days at ambient seawater temperature (10°C). At predetermined time points, automated Solid Phase Microextraction coupled to GC-MS was applied directly on test systems to determine constituent specific biodegradation based on biotic to abiotic peak area ratios (i.e., primary biodegradation). The gasoline calibration standard was used to identify constituents in the produced water. Biodegradation kinetics of 15 reference substances were determined at all tested dilutions and generally showed faster biodegradation with increasing dilution factor. Toxicity tests of the produced water using marine algae and luminescent bacteria yielded EC_{50} values in the same range as the highest concentration in the biodegradation experiments, which suggests mixture toxicity inhibiting microbial degraders at low dilutions. These results emphasize the linkage between mixture toxicity and biodegradation kinetics and underline the importance of conducting biodegradation tests at low environmentally relevant concentrations. Biodegradation kinetic data are highly valuable for assessing the environmental risk of discharged chemicals and can focus management efforts on persistent and slowly degradable chemicals where substitution or treatment before discharge might be necessary.

3.05.P-Th187 Emerging Polychlorinated Biphenyl Dechlorination Congener Profiles in Five Environmental Compartments In and Near the Mohawk Community at Akwesasne

***Mark H. Hermanson**[1], Anthony David[2] and David Carpenter[3], (1)Hermanson & Associates LLC, Netherlands, (2)Environmental Div, St. Regis Mohawk Tribe, Akwesasne, (3)University at Albany-State University of New York*

The industrial area west of the St. Regis Mohawk Tribe (SRMT) in Akwesasne, NY, USA, along the St. Lawrence River, has been heavily impacted by polychlorinated biphenyl (PCB) contamination since at least the 1950s, with three Superfund PCB sites located within 18 km of the reservation's western border. Sampling of five environmental compartments in the area (air, ground water, soils, sediments, tree bark) since 2020, and analysis of 209 PCB congeners, show evidence of PCB dechlorination: In all but the soil samples neurotoxic dechlorination end-point congener 2,2'-dichlorobiphenyl (PCB-4) dominates the congener profile in at least one sample, or is among the four most abundant congeners in some soil samples. The neurotoxic activity of 2,2'-dichlorobiphenyl is inhibition of dopamine synthesis. While this congener is not considered to be bioaccumulative (log $K_{ow} < 5$), its production in the environment is apparently continuous because of the results from air samples. Intermediate dechlorination PCB congeners include 2,3,2',5'-tetrachlorobiphenyl (TetraCB), 2,4,2',4'-TetraCB, 2,3,2'3'-TetraCB, which are also found in many Akwesasne samples. Dominance of PCB congener profiles by 2,2'-dichlorobiphenyl is not found in Aroclor products, and it is not more than 0.32% of the Aroclor 1248 used at the Superfund sites, so there is no significant historic source. Among these five compartments, one (tree bark) comes from near drainage of the western Superfund site, while the others were from the eastern Superfund site where total PCB contamination amounts are high. The effect of dechlorination on these five environmental compartments at and near Akwesasne is apparently active throughout the area. We hypothesize that the observed dechlorination process involves organisms in contaminated ground water or landfill leachate, with some of the 2,2'-dichlorobiphenyl volatilizing to the atmosphere, and then is found in what is considered to be a passive air sampler – tree bark. This is a recent discovery because PCB congener analysis in environmental samples has previously been limited at the site. PCB dechlorination was not suspected in congener-specific PCB air analysis from this site in 1993 because no evidence was observed in results at the time. The recent appearance of 2,2'-dichlorobiphenyl to these five environmental compartments presents a previously unrecognized health compromise to residents in and near Akwesasne.

3.06 Climate Change in Arctic and Antarctica and Its Effect on Legacy and Emerging Micropollutants in Abiotic and Biotic Environmental Compartments

3.06.P-Tu152 Pharmaceuticals and Personal Care Products in the Kongsfjorden Ecosystem (Svalbard, Norway)
Francesca Spataro[1], *Jasmin Rauseo*[2], *Tanita Pescatore*[3], *Ida Beathe Overjordet*[4] *and Luisa Patrolecco*[2], *(1)National Reasearch Council Institute of Polar Sciences, Montelibretti, Italy, (2)National Research Council- Institute of Polar Science (ISP-CNR), Italy, (3)National Research Council (CNR), Institute of Polar Science (ISP), Italy, (4)SINTEF, Norway*
Climate warning (CC) is occurring faster and with greater magnitude in the Arctic compared to other parts of the world, causing significant effects on the environment (faster sea ice retreat, melting glaciers, thawing permafrost, extreme weather events and alterations of atmospheric and oceanic circulation and biogeochemical cycles). On one side, these processes alter the contaminant fate, transport and distribution into ecosystems, on the other hand, the Arctic warming has favoured the development of anthropogenic activities (e.g., fisheries, tourism and resource extraction), which are additive local sources of pollutants, also considering the low technologies of wastewater treatment plants currently used.

Among chemicals of emerging Arctic concern, pharmaceuticals and personal care products (PPCPs) have recently attracted increased attention, due to their bioactive nature and potential effects on natural microbial communities and, thus, on the structure and functioning of the ecosystem. PPCPs are considered “pseudo-persistent contaminants” because they are daily-use products continuously released into the environment. Depending on their chemical-physical properties, some PPCPs have a relatively high lifetime and can be long-range transported from mid-latitudes.

The current knowledge on the distribution of PPCPs in the Arctic ecosystems is still limited, even though the global consumption of many PPCPs has increased since 2020 due to the COVID-19 pandemic.

In this context, the present work aims at evaluating the occurrence, distribution, and sources of selected PPCPs in the Kongsfjorden marine ecosystem (KF, Svalbard Norway). Seawater and sediment samples were collected in a grid of points along KF, from the Ny- Alesund (NA) Village, where research scientific bases are settled, to the main glaciers.

Target PPCPs were detected in seawater and sediment samples, suggesting their ubiquitous occurrence. In particular, concentrations of pharmaceuticals, caffeine and insect repellents ranged between n.d. and 100 ng/L in seawater samples. PPCPs occurred also in sediment samples with a concentration range between n.d. and 200 ng/g d.w. Higher concentrations were found in the sampling points close to the NA village, suggesting an important role of local sources of contamination, even if a contribution from atmospheric and sea current transport cannot be excluded.

3.06.P-Tu153 Are Ingredients of Personal Care Products Likely to Undergo Long Range Transport to Remote Regions?
Marianna D'Amico[1], *Frank Wania*[2], *Knut Breivik*[3], *Andrea Gambaro*[1] *and Marco Vecchiato*[4], *(1)Department of Environmental Sciences, Informatics, and Statistics, Ca' Foscari University of Venice, Italy, (2)Department of Physical and Environmental Sciences, University of Toronto, Canada, (3)Norwegian Institute for Air Research (NILU), Norway, (4)National Research Council (CNR), Institute of Polar Science (ISP), Italy*
Personal Care Products (PCPs) contain contaminants of emerging concern (CECs). Whereas their occurrence in environmental matrices in polar regions has been reported, little is still known about their behaviour under cold environmental conditions. A selected group of PCPs was studied to understand their potential for atmospheric and oceanic transport to remote regions and their environmental fate in cold environments. In this study, we (I) estimated the key chemical properties of the PCPs and their temperature dependence, (II) calculated the equilibrium phase distribution in the atmosphere and the dominant deposition processes at temperatures above and below freezing, and (III) simulated their potential for long-range transport (LRTP). The chemical properties were estimated using a variety of methods and databases. We predicted the atmospheric behaviour by superimposing the predicted properties onto chemical space plots that display the equilibrium phase distribution in the atmosphere and the dominant deposition mechanisms at 25° and -6.8°C. The LRTP of the selected PCPs, when emitted to air, water, and soil, was estimated using the emissions fractions approach as implemented in a modified version of the OECD Screening Tool. Most of the selected PCPs, especially the fragrance materials, are expected to be partitioning mostly into the atmospheric gas phase but are also sufficiently water soluble to be subject to precipitation scavenging. Especially at lower atmospheric temperatures (-6.8°C), scavenging with snow is predicted to be the dominant atmospheric deposition process for all investigated PCPs. The dispersal is highest if the chemical is emitted into the air, while, for most PCPs, transfer, and accumulation in surface media of remote regions are more pronounced when emitted into water. The relatively low LRTP estimated for the selected PCPs is at odds with the detection of those PCPs in surface media of remote polar regions. Future work should seek to reconcile this discrepancy. Potential hypotheses include: (i) the presence of PCPs in remote regions is a result of local sources and/or (ii) the degradation half-lives of the PCPs are greatly underestimated with the prediction methods used in this work.

3.06.P-Tu160 Contaminants of Emerging Concern in the Arctic Fjord Kongsfjorden: from Glaciers to Marine Ecosystem
Jasmin Rauseo[1], *Francesca Spataro*[2], *Ilaria Baneschi*[3], *Marco Doveri*[3], *Federico Giglio*[4], *Stefano Miserocchi*[4], *Leonardo Langone*[4], *Tanita Pescatore*[5] *and Luisa Patrolecco*[1], *(1)National Research Council- Institute of Polar Science (ISP-CNR), Italy, (2)National Reasearch Council Institute of Polar Sciences, Montelibretti, Italy, (3)CNR IGG, Italy, (4)CNR-ISP, Italy, (5)National Research Council (CNR), Institute of Polar Science (ISP), Italy*
Climate warming, which is occurring most rapidly in the Arctic, is leading to strong alterations in atmospheric and oceanic circulation and hydro-biogeochemical cycles as well as has favoured a major human presence in this area. All these aspects affect directly or indirectly fate, transport and distribution of contaminants within the Arctic environment. Due to the presence of international scientific stations, Kongsfjorden (KF- Svalbard, Norway) has been extensively investigated for many years. This

small Arctic fjord is directly influenced by the inflow of warm Atlantic water and various land and tidal glaciers. The anthropic impact (cruise tourism, Ny-Ålesund research stations etc.) is also increasing in this area. It is, therefore, a highly sensitive marine system to climate change (CC) and constitutes a representative environmental monitoring area to evaluate the impacts induced by CC on new emission sources, remobilization, transport and circulation of contaminants.
Among them, the chemicals of emerging Arctic concern (CEACs) have gained considerable attention for their potential toxic effects on humans and wildlife. Studies on the environmental dynamics of CEACs in the Arctic ecosystems, as well as on the better-known POPs (Persistent Organic Pollutants), are of strategic relevance because the impact of CC on the spread of contamination in the Arctic can provide early warning signals for similar repercussions on a global scale.

In this context, the present study aims at investigating the occurrence and distribution of selected CEACs and POPs, such as old and new-generation pesticides, bisphenol A and nonylphenols (NPs) in the KF ecosystem. The study area includes sampling sites strongly affected by tidal and land glacier runoff and sites locally impacted by human settlements. The Bayelva catchment including the two land terminating glaciers, and their periglacial/proglacial area until the river mouth, was also investigated both before and during the melting period. Contaminants were determined in floor sediment and seawater of KF, as well as in snow and drainage waters by high sensitive chromatographic determinations.

Target compounds were found in all environmental samples analysed, suggesting their ubiquitous presence in the Arctic ecosystem. Higher concentrations were found for NPs in all matrices. The overall results indicate that both local sources and glacier runoff, can contribute to the contaminant load in the KF marine ecosystem.

3.06.T-01 Stable Isotope Values (d13C, d15N) Reveal Long-Term Bioaccumulation of Perfluoroalkyl Substances (PFASs) in Icelandic Seabirds

Rui Shen[1], Daniel Vassao[2], Ralf Ebinghaus[3], Norman Ratcliffe[4] and ***Thomas Larsen****[5], (1)Helmholtz Center Hereon, Germany, (2)GEA-MPG, Germany, (3)Helmholtz Center Geesthacht, Germany, (4)British Antarctic Survey, United Kingdom, (5)Max Planck Institute for the Science of Human History, Germany*

Exposure to the environmentally persistent perfluoroalkyl substances (PFASs) has been linked to harmful health impacts in humans and fauna. The ability of PFASs to biomagnify through food webs make high trophic level consumers particularly vulnerable to exposure. Although PFASs have produced on an industrial scale since the 1950s, our understanding of their sourcing, exposure and bioaccumulation in the environment is limited, especially for Arctic consumers.
This study seeks to fill this knowledge gap by characterizing PFASs patterns and levels in two congeneric seabird species in Iceland, the true Arctic Brünnich's guillemot (*Uria lomvia*) and the temperate Common guillemot (*Uria aalge*). Iceland is a key region for understanding anthropogenic impacts in Arctic regions because it hosts both temperate and arctic species, and the waters around Iceland are fed by warm Atlantic currents introducing contaminants into the Arctic Ocean, but also from cold Arctic Overflow. In addition, global warming is causing a decline in Arctic species on the island.

By combing analyses of commonly observed perfluorooctane sulfonic acids (ΣPFOS, linear and its isomers), perfluoroalkyl carboxylic acids (PFCAs), and bulk stable isotope of blood plasma samples retrieved from five geographically distinct bird colonies during their breeding season in 2018, we test species differences and whether PFASs levels in blood plasma reflect current or past season diets. Linear PFOS is particularly interesting because of its high bioaccumulative potential and wide occurrence in Arctic wildlife.

Across all birds, we observed a generic PFCA profile with high proportion of odd and long carbon-chain length homologues, i.e. ,PFNA, PFUnDA and PFTrA. We found significantly higher PFCA concentrations in *U. aalge* than *U. lomvia*. Since the correlation between PFCA exposure and recent diets (as inferred from the stable isotopes) is very weak, we posit that the birds incorporated most PFASs prior to the breeding season. ΣPFOS concentrations were generally not linked to species but rather to the geographical location of the breeding colonies: Birds sampled in southern Iceland almost had twice the exposure than birds from northern Iceland. In summary, our PFAS results suggest that the high exposure levels of *U. aalge* are linked to winter migration in proximity to densely populated regions. More studies are needed to characterize the linkages between PFAS concentrations and the birds' wintering habitats

3.06.T-02 Organophosphorus Esters in a Firn Core from Austfonna, Svalbard

Mark H. Hermanson*[1], Richard Hann[2], Elisabeth Isaksson[3] and Geir Gabrielsen[3], (1)Hermanson & Associates LLC, Netherlands, (2)Norwegian University of Science & Technology (NTNU), Norway, (3)Norwegian Polar Institute, Norway*

In spring 2015 we drilled a 13.2 m deep firn core representing dates mid-2001 to early-2015 from Austfonna, the largest ice cap on Svalbard. The core was separated into 18 samples for analysis of 13 organophosphorus esters (OPEs). Six OPEs were detected in at least 18 samples: The two OPEs with highest flux in most samples were tris(2-chloroisopropyl) phosphate (TCIPP) and tri-*n*-butyl phosphate (TNBP), each reaching maximum values of nearly 3500 pg cm^{-2} yr^{-1} in the surface sample. Correlation of these values among all 18 samples was 0.775, significance <<0.05, suggesting a similar environmental source over time. These two OPEs have different uses, suggesting that they have been used consistently at the source sites. These maximum flux values are nearly four times greater than maximum brominated flame retardant (hexabromocyclododecane, 910 pg cm^{-2} yr^{-1}) or for a current-use pesticide (chlorpyrifos, 809 pg cm^{-2} yr^{-1}) both measured in the Svalbard ice core at Holtedahlfonna (2005) showing both that OPEs have greater input and high amounts of transport and deposition to Austfonna. The second-most abundant OPEs included tris(2-chloroethyl) phosphate (TCEP) and triphenyl phosphate (TPHP), but not varying consistently with a correlation of 0.325

and significance 0.19, showing that there is no relationship with these OPEs and apparent different sources over time. Two other OPEs detected are tricresyl phosphate (TMPP) and tris(2-ethylhexyl) phosphate (TEHP). Both are detected in all samples but both with fluxes about 100 times less than TCIPP and TNBP, typically not greater than 30 pg cm^{-2} yr^{-1}. The fraction of each of these six OPEs when summed showed high variability in principal components analysis when the input values were comparatively low. Air particle samples collected in Longyearbyen, a town 230 km southwest from the Austfonna drill site, showed maximum OPE values for TNBP and 2-ethylhexyl-diphenyl phosphate (EHDPP), the latter not detected in any sample at Austfonna. At Longyearbyen, the TCIPP amount was about three times greater than TCEP, similar to the ratio at Austfonna. TCIPP, the most concentrated at Austfonna, was fourth most-concentrated at Longyearbyen. The non-chlorinated OPEs comprised ~75% of all OPEs in Longyearbyen air in contrast to ~50% in Austfonna firn. These contrasts show that Longyearbyen is not a likely OPE source to Austfonna, if transport and deposition are equal among OPEs.

3.06.T-03 First Detailed Assessment of Organic Contaminants in Killer Whales Across the North Atlantic Ocean and the Influence of Diet Composition

Anais Remili[1]*, Rune Dietz*[2]*, Chistian Sonne*[3]*, Filipa Samarra*[4]*, Robert J. Letcher*[5]*, Audun Rikardsen*[6]*, Lisa E. Kettemer*[6]*, Steve Ferguson*[7]*, Cortney A Watt*[7]*, Cory J.D. Matthews*[7]*, Jeremy J. Kiszka*[8]*, Aqqalu Rosing-Asvid*[9] *and Melissa A. McKinney*[1]*, (1)McGill University, Canada, (2)Aarhus University, Denmark, (3)Department of Ecoscience, Aarhus University, Arctic Research Centre (ARC), Denmark, (4)Marine and Freshwater Research Institute, Iceland, (5)Science and Technology Branch, Environment and Climate Change Canada, Canada, (6)Faculty of Biosciences, Fisheries and Economics, UiT The Arctic University of Norway, Tromsø, Norway, (7)Fisheries and Oceans Canada, Winnipeg, Canada, (8)Department of Biological Sciences, Florida International University, Miami, Florida, (9)Greenland Institute of Natural Resources, Greenland*

Recent studies have highlighted the critical threat posed by ongoing, high concentrations of persistent organic pollutants (POPs) in cetaceans and particularly in killer whales due to their high trophic position and limited biotransformation and elimination capacity. Although tissue concentrations of legacy POPs are reasonably well documented for Northeast Pacific killer whales, considerably less is known for North Atlantic (NA) conspecifics and for new or emerging POPs. Although POP concentrations are influenced by feeding habits, precise estimates of killer whale diet composition, especially in remote areas of the NA Ocean, were not available until recently. Here, we use our newly developed quantitative fatty acid signature analysis (QFASA) approach to estimate the diet composition of ~200 NA killer whales from 2008 to 2022. Then, we quantify POP concentrations in these same individuals and assess the relationship between diet composition and POP concentrations. Diet estimates showed that killer whales mainly consume other whales in the western NA, seals in the mid-NA, and fish in the eastern NA. Nonetheless, diet estimates also varied widely among individuals within most regions. Concentrations of PCBs ranged from a high of ~ 100 mg/kg lw in the western NA, to about 50 mg/kg in the mid NA, to safer levels in the eastern NA. Generally similar patterns were observed for DDTs and CHLs. Based on a threshold for health risk at 10 mg/kg lw and high risk at 100 mg/kg lw, killer whales in the western NA face high risks of health effects due to PCBs alone. The diet of killer whales in the NA explained up to 60% of the variation in PCB concentrations. These results indicate how critical this feeding variation among NA killer whale groups is for their resulting contaminant loads. Nonetheless, intrapopulation differences were also found and detailed analysis including other biological variables (e.g., sex) will serve to further clarify the drivers of these substantial differences in contaminant concentrations and associated health risks.

3.06.T-04 Small Microplastics, and Microlitter Components in Superficial Water and Sediments of Krossfjorden, Svalbard Archipelago

Giulia Vitale[1]*, Massimiliano Vardé*[2]*, Federico Giglio*[3]*, Beatrice Rosso*[1]*, Sara Giansiracusa*[4]*, Stefano Miserocchi*[3]*, Ingeborg Hallanger*[5]*, Fabiana Corami*[2] *and Mathia Sabino*[2]*, (1)Department of Environmental Sciences, Informatics, and Statistics, Ca' Foscari University of Venice, Italy, (2)National Research Council (CNR), Institute of Polar Science (ISP), Italy, (3)CNR-ISP, Italy, (4)Ca' Foscari University of Venice, Italy, (5)Norwegian Polar Institute, Norway*

Small microplastics (SMPs, <100 µm), part of the microlitter, can reach high latitudes through long-range transport, but they can also be released locally by human settlements and commercial/tourist activities. In the same way, other microlitter components (MLCs), i.e., plastic additives, plasticizers, and natural and nonplastic synthetic fibres, can be carried from mid- to high latitudes or released into the environment. Microplastics > 100 µm were studied at high latitudes, while small microplastics, which can easily enter the food web due to the ingestion by invertebrates, have been overlooked. So far, the occurrence and distribution of plastic additives and plasticizers have never been investigated. Additives and plasticizers are generally included in plastic objects and can therefore be proxies for the presence of specific plastic polymers.

In the summer of 2022, samples of surface seawater and marine sediments were collected in different sites of the Krossfjorden in the Svalbard Archipelago. Sampling activities were performed on board of MS-Teisten (Kings Bay vessel), using Niskin bottles and Van Veen Grabs. Field blanks were collected as well. At the "Dirigible Italia" base, sediment samples were divided into decontaminated glass jars, while seawater samples were filtered on glass fibre filters. All the samples were stored at 4°C before being shipped to Italy. Laboratory blanks were collected to check the contamination. At the CNR-ISP in Venice, samples were pretreated to extract simultaneously small microplastics and the microliter components, employing an oleo-extraction procedure which does not further degrade plastic particles and MCLs. Reagent and procedural blanks, together with those collected at Svalbard's, were pretreated and analyzed as samples. The analytical phase was performed with the Micro-Fourier-transform Infrared spectroscopy.

The results of this study provide us with information (i) on the identification and quantification, via microscopic counting, of SMPs and MLCs in surface seawater and sediments samples, (ii) on the sources, transport and fate of these pollutants. This study will be a starting point for increasing knowledge about plastic additives and plasticizers in the Arctic environment.

3.06.P Climate Change in Arctic and Antarctica and Its Effect on Legacy and Emerging Micropollutants in Abiotic and Biotic Environmental Compartments

3.06.P-Tu155 Quantification of Water Discharge From the Bayelva Glacial River and Water-Driven Pollutant and Microbe Fluxes into Kongsfjorden (Western Svalbard-Norway)
*Marco Doveri[1], Ilaria Baneschi[1], Gabriella Caruso[2], Marianna D'Amico[3], Linda Franceschi[1], Matteo Lelli[1], Angelina Lo Giudice[2], Matia Menichini[1], Giovanna Maimone[2], Luisa Patrolecco[4], Francesco Norelli[1], **Tanita Pescatore**[5], Jasmin Rauseo[4], Alessandro Ciro Rappazzo[3], Francesca Spataro[6], Sandra Trifirò[1] and Marco Vecchiato[5], (1)CNR IGG, Italy, (2)CNR ISP, Italy, (3)University Ca' Foscari of Venice, Italy, (4)National Research Council- Institute of Polar Science (ISP-CNR), Italy, (5)National Research Council (CNR), Institute of Polar Science (ISP), Italy, (6)National Reasearch Council Institute of Polar Sciences, Montelibretti, Italy*
Climate change heavily affects Arctic hydrologic dynamics, generating significant environmental modifications and potentially leading to climatic feedback and further warming amplification. In formerly glacierized watersheds, hydrologic processes are evolving, with new storage mechanisms and distribution of water resources, as more persistent rivers and developed groundwater systems. However, water balance still cannot be considered good enough to assess the individual components of the hydrological cycle with sufficient accuracy, including groundwater, which can play a key role for ecosystems and human communities in Arctic regions. Changes in river flows will alter fluxes of freshwater, sediments, and nutrients with implications for biodiversity in both freshwater and marine ecosystems. The rapid glacier melting affects weathering processes, resulting in the mobilization-transport of different inorganic and organic molecules (i.e., pollutants), microorganisms stored for a long time, and turbid meltwaters. Thanks to its geographical characteristics, the retreating glaciers, the research stations and infrastructures, and the studies carried out in the past and present, the Bayelva catchment near Ny-Ålesund (Western Svalbard-Norway) is an ideal site for surveys aimed at increasing knowledge on hydrology dynamics and associated effects, in the continuum from glaciers to the fjord.
In this framework, within the ICEtoFLUX project (MUR/PRA2021 project-0027) a field campaign was conducted both in the spring and summer of 2022 in the Bayelva River catchment, from its glaciers and periglacial/proglacial systems up to the Kongsfjorden zone significantly affected by the river. The activities were aimed to quantify hydrologic processes and related transport of inorganic-organic chemical compounds (counting pollutants) and microbial biomass and activities. Chemical results from snow, drainage water, and seawater samples are presented here, together with discharge measurements. The first results suggest that, in general, electrical conductivity and total suspended solids increase from the glacier to the Bayelva monitoring station, which is located less than 1 km far from the coast. Seasonal evolution of physical-chemical features was also observed. The marine samples collected near Bayelva mouth show the influence of freshwater input and changes in turbidity. First evidence on organic pollutant and microbe transport is also discussed.

3.06.P-Tu156 Using Passive Air Samplers to Sniff Out Local Sources of Persistent Organic Pollutants (POPs) at Remote Sites
***Tom Harner**[1], Karla Pozo[2] and Hayley Hung[3], (1)Environment and Climate Change Canada, Canada, (2)Universidad San Sebastián, Chile, (3)Environment and Climate Change Canada, Toronto, Canada*
Local sources of POPs and related chemicals at remote sampling locations (e.g., land-based stations, polar stations, ship-based sampling) can lead to challenges for the integrity of air monitoring studies. Potential emissions associated with current or past human activity or infrastructure can generate a "halo" of elevated concentrations that will depend on the magnitude of the emission.   ssive air samplers are proposed as a simple and effective tool for identifying local sources of POPs.

A mapping study was conducted at the Alert, high Arctic air monitoring station to assess homogeneity and potential hots spots / local sources of selected POPs in air. Samples were deployed using polyurethane foam disk passive air samplers (PUF-PAS) at approximately 10 sites during October 2004 to March 2005 (Period 1) and March 2005 to October 2005 (Period 2) with replicate samples collected at some sites. Period 1 samples were analyzed for organochlorine pesticides (OCPs), including (hexachlorocyclohexanes (HCHs; a-, b-, g- and d- isomers); heptachlor, heptachlor epoxide (HepX), aldrin, dieldrin; sum of chlordanes i.e., trans-chlordane (TC), cis-chlordane (CC), trans-nonachlor (TN); o,p'-DDE, p,p'-DDE, o,p'-DDD, p,p'-DDD, o,p'-DDT, p,p'-DDT; and sum of endosulfans i.e., endosulfan I, endosulfan II, and endosulfan sulfate.   riod 2 samples were analyzed for polychlorinated biphenyls (PCBs) (sum of 56 congeners) and polybromodiphenyl ethers (PBDEs) (sum of 17 congeners).

Results show that none of the OCPs or the PCBs exhibited "halos" of concentrations that would indicate a significant local source. However, PBDEs were elevated at a site in the southwest corner of the base, where newly installed infrastructure was suspected of being the local source. The "halo" of PBDEs was very localized and diminished beyond approximately one hundred meters and only impacted a few nearby adjacent sites. PUF-PAS are recommended as a simple approach for investigating potential local sources of gas- and particle-associated POPs that may impact monitoring at remote sampling platforms.

3.06.P-Tu157 Small Microplastics (<100 µm) and Microlitter Components in Antarctic Snow

Fabiana Corami[1,2]*, Beatrice Rosso*[1,3]*, Giulia Vitale*[4,5]*, Elena Gregoris*[1,2]*, Nicoletta Ademollo*[6]*, Alessandra Cincinelli*[7]*, Francisco Ardini*[8]*, Andrea Gambaro*[1,4]*, Marco Grotti*[8]*, Carlo Barbante*[1,2] *and Marco Vecchiato*[1]*, (1)National Research Council (CNR), Institute of Polar Science (ISP), Italy, (2)Department of Environmental Sciences, Informatics, and Statistics, Department of Environmental Sciences, Informatics, and Statistics, Ca' Foscari University, Venice, Italy, (3)Ca' Foscari University of Venice, Italy, (4)Department of Environmental Sciences, Informatics, and Statistics, Ca' Foscari University of Venice, Italy, (5)Department of Environmental Sciences, Informatics and Statistics, Ca' Foscari University of Venice, Italy, (6)Insititute of Polar Sciences, CNR-ISP, Italy, (7)Department of Chemistry "Ugo Schiff", University of Florence, Italy, (8)Department of Chemistry and Industrial Chemistry, University of Genova, Genova, Italy*

Despite their versatility and long-lasting quality, plastics can degrade, producing particles with different shapes and sizes; those particles < 5 mm are called microplastics and have been observed in seawater, sediments, and soil. There is scientific evidence that organisms ingested microplastics (MPs); in particular, invertebrates at the bottom of the food web can ingest MPs < 100 µm (small microplastics, SMPs), according to the size of their mouthparts. Once entering the trophic web, SMPs may be bioaccumulated and even biomagnified, posing a threat to human beings as well. By their definition, plastics may contain plastic additives, i.e., plasticizers, antioxidation agents, lubricants, antistatic agents, pigments, etc. When plastics are degraded into the environment, plastic additives may be exposed in different shapes and released into the environment, becoming part of the microlitter together with natural and non-plastic synthetic fibers (microlitter components, MLCs). While MPs > 100 µm were investigated in the mountain and polar snow, SMPs and especially MLCs are still overlooked.

In this study, surface snow was sampled at different sites in Antarctica. Field blanks were collected during the sampling, and snow samples were stored in decontaminated glass bottles; after sampling, they were stored at 4 °C before being shipped to CNR-ISP, Venice, Italy. Quality assurance and quality control (QA/QC) were strict to check the contamination at any step, from sampling to analysis. Once in Italy, all the samples were pretreated (via oleo-extraction previously developed at CNR-ISP, Venice); field blanks, reagent and procedural blanks were pretreated as samples. All the operations were performed in a plastic-free ISO 7 clean room. Oleo-extractions were then filtered on aluminum oxide filters (porosity 0.2 µm, 47 mm) and purified. Filters were dried in the clean room at room temperature in decontaminated Petri dishes covered with decontaminated aluminum foil, and then they were analyzed via Micro-FTIR. Identification and quantification via microscopic counting of SMPs and MLCs were performed simultaneously in semiautomated mode; only spectra with a similarity match percentage equal to or greater than 65% were regarded as identified and thus were quantified. Preliminary data are presented regarding the abundance, size distribution, and weight of SMPs and MLCs.

3.06.P-Tu158 Small Microplastics (<100 µm), Plastic Additives, and Other Microlitter Components in Snow from Different Glaciers in Svalbard Islands

Beatrice Rosso[1]*, Andrea Spolaor*[2]*, Federico Scoto*[3]*, Ingeborg Hallanger*[4]*, Catherine Larose*[5]*, Jean-Charles Gallet*[4]*, Carlo Barbante*[2]*, Andrea Gambaro*[1] *and Fabiana Corami*[2]*, (1)Department of Environmental Sciences, Informatics, and Statistics, Ca' Foscari University of Venice, Italy, (2)National Research Council (CNR), Institute of Polar Science (ISP), Italy, (3)Institute of Atmospheric Sciences and Climate, National Research Council, CNR-ISAC, (4)Norwegian Polar Institute, Norway, (5)Environmental Microbial Genomics, Laboratoire Ampère, École Centrale de Lyon, Université de Lyon, Écully, France*

Most of the recent studies have focused on microplastics (MPs) presence and transport in aquatic and terrestrial ecosystem, while airborne MPs are very limited investigated. The smallest and lighter microplastics (e.g., SMPs small microplastics < 100 µm) can easily be transported over long distances to receptor and pristine regions, such as Arctic. Besides the presence of SMPs, there is a fundamental research gap in understanding long-range transport of microliter components (MLCs), such as plastic additives, to the remote areas via atmospheric deposition. Further, there is a significant lack of standardized methods on these contaminants regarding their sampling, quality assurance and quality control (QA/QC) protocols, the pretreatment, quantification, and chemical identification. In this research different snow samples from snow pits were collected from April 2021 at the Gruvebadet site located in the proximity of the Ny-Ålesund settlement (78.918 N, 11.895 E) and at the summit of different glaciers: the Midtre Lovénbreen (MDL; 78.871N, 11.984E), the Austre Brøggerbreen (ABG; 78.872N, 11.915E) and the Holtedahlfonna (HDL; 79.140N, 13.393E). Specifically, the annual snowpack was sampled separating the upper layer (superficial fresh snow deposition) and the lower layer to the ground. A detailed QA/QC was designed to avoid/minimize potential plastic contamination of samples during all the operations until the analysis. All samples were pre-treated using an oleo extraction-method previously development from CNR-ISP. The quantification and chemical identification of SMPs and MLCs were carried out via Micro-FTIR. The superficial layers were evaluated to study the temporal variability of SMPs and MLCs; while the bulk layers were investigated for the spatial distribution, since these layers are more conservative. Weight, polymer typology and size of SMPs and MLCs were calculated for each glacier. Nylon was one of the most abundant typologies analyzed as SMPs; while rayon and different plastic additives (e.g., vulcanizing agents, cosmetic additives...) were identified. The total load (µg SMPs/m2 /d) between Gruvebadet site, near Ny Alesund scientific urban settlement, and the summit of the glaciers, confirmed that SMPs could be influenced by long-range transport even in remote sites. Further, the presence of MLCs, at the summit of the glaciers confirming their role as SMPs proxy in environmental matrices and a potential threat for biota in polar ecosystems.

3.06.P-Tu159 Personal Care Products in Northern Greenland: First Results in Snow Samples from Station Nord

Marianna D'Amico[1]*, Andreas Massling*[2]*, Henrik Skov*[2]*, Andrea Spolaor*[3]*, Christel Christoffersen*[2]*, Andrea Gambaro*[1] *and Marco Vecchiato*[3]*, (1)Department of Environmental Sciences, Informatics, and Statistics, Ca' Foscari University of Venice, Italy, (2)Department of Environmental Science, Aarhus University, Denmark, (3)National Research Council (CNR), Institute of Polar*

Science (ISP), Italy
Human activities have both direct and indirect impacts on the delicate arctic environment. For years, in the Arctic the attention was mainly focused on legacy contaminants, still, the Arctic Monitoring Assessment Program recently stressed the importance of monitoring a new set of compounds defined as Chemicals of Emerging Arctic Concern (CEACs). These chemicals are present as ingredients in Personal Care Products (PCPs) such as shampoos, perfumes, detergents, and sunscreens. A limited number of studies show the occurrence of PCPs in environmental matrices in polar regions and, to date, the general monitoring of CEACs in Greenland is limited. Most of the available studies focused on sewage sludge, freshwater sediments, air, and marine biota. To the best of our knowledge, no studies have yet investigated the occurrence of PCPs in the snow of Greenland.
In this study, we investigate the occurrence and the temporal trends of a selected group of PCPs in snow: seven fragrance materials (Amyl Salicylate 1 and 2, Oranger Crystals, Hexyl Salicylate, Peonile, Ambrofix, and Benzyl Salicylate), four UV-filters (EHMC, BP3, EHS, and Octocrylene), BHT, and BPA. The snow samples were collected once every two weeks in the area surrounding the Villum Research Station (VRS) in Station Nord (81°36' N, 16°40' W; 30 m a.s.l.), between December 2018 and June 2019. All the samples were prepared in a stainless clean-room for organics (class 10000) and analysed with GC-MS/MS at the Ca' Foscari University laboratories in Venice.

The preliminary results show the presence of most of the selected chemicals. Particularly, the UV-filters and BPA are the most occurring compounds. The cumulative concentrations of PCPs increase in Spring, and they reach the maximum in May. The VRS operates all year round and it can host up to fourteen scientists. The period with high cumulative concentrations of PCPs coincides with the all-day long-lasting sunlight season in the Arctic. During these months the need for sunscreen becomes important for people operating in the area, and this can explain the increasing concentrations of UV-filters. However, concentrations of the selected PCPs are found throughout the whole sampling period so we cannot exclude they also underwent regional or long-range transport.

3.06.P-Tu161 Assessment of Polycyclic Aromatic Hydrocarbons and Polychlorobiphenyls in Arctic Marine Sediments (Svalbard Islands, Norway)
***Francesca Spataro**[1], Jasmin Rauseo[2], Tanita Pescatore[3] and Luisa Patrolecco[2], (1)National Reasearch Council Institute of Polar Sciences, Montelibretti, Italy, (2)National Research Council- Institute of Polar Science (ISP-CNR), Italy, (3)National Research Council (CNR), Institute of Polar Science (ISP), Italy*
The Arctic is characterized by extreme seasonal light variations, low temperatures, short growing seasons, and limited availability of nutrients, making this ecosystem one of the least productive and species-poor in the world. For these reasons, this cold area is ecologically sensitive to global and local impacts, including climate change (CC) and pollution.
Anthropogenic contaminants can be transported from lower latitudes into Arctic regions through sea and atmospheric currents, rivers, and migratory animals. Global warming is affecting atmospheric and oceanic circulation processes, leading to sea ice reduction, increased seawater temperatures, and a higher influx of Atlantic water masses, altering, in turn, the contaminant transport, distribution and fate in the Arctic. In addition, the increase in glacier melting and permafrost thawing can remobilize pollutants previously trapped, representing a secondary source of local pollution. An increase in "old" contaminants in Arctic seawaters, including some persistent organic pollutants (POPs), banned many years ago, has been found, triggering a possible mechanism to promote the transformation of the Polar Regions from sink to a source of pollutants. The development of fisheries, cruise tourism, and resource extraction, favoured by the increasing inflow of warmer Atlantic and Pacific waters and reduced sea-ice cover, has increased economic benefit for the coastal Arctic communities as well as the anthropogenic contamination on a regional scale (www.amap.no).
The present study investigates the occurrence of polycyclic aromatic hydrocarbons (PAHs) and polychlorobiphenyls (PCBs) in marine sediments collected in Kongsfjord (Svalbard, Norway) during the summer of 2018 and 2022. The contribution of different local contamination sources as well as the risk assessment for the marine environment were also evaluated.
The results indicate that the combination of long-range transport, glaciers melting, as well as local anthropic activities, contributes to the contaminant load in the Kongsfjorden ecosystem. A comparison between the concentrations of target compounds measured in Kongsfjorden sediment and empirical and mechanistic indices derived from sediment quality guidelines, suggests that the occurrence of PAHs and PCBs in the study area does not currently pose a risk for this Arctic ecosystem, but further investigation on the spread of hazardous contaminants and their effects on these fragile environments is needed.

3.06.P-Tu162 Diffusive Fluxes of Persistent Organic Pollutants Between Arctic Atmosphere, Surface Waters, and Sediments
***Ian Moran**[1], Lane Tidwell[1], Michael Barton[1], Molly Kile[1], Pamela Miller[2], Diana Rohlman[1], Samarys Seguinot Medina[2], Bobby Ungwiluk[2], Viola Waghiyi[2] and Kim Anderson[1], (1)Oregon State University, (2)Alaska Community Action on Toxics*
Arctic communities are disproportionately exposed to persistent organic pollutants from sources including global atmospheric transport and formerly used defense sites (FUDS). The effects of global climate change and increasing development in the Arctic have the potential to exacerbate this problem. Yupik residents of Sivuqaq (also known as St Lawrence Island), Alaska are one such community with documented exposures to pollutants from FUDS, and traditional foods like blubber and rendered oils of marine mammals. Troutman Lake, adjacent to the Yupik village of Gambell, Alaska, was used as a disposal site during the decommission of the adjacent FUDS, leading to community concern about exposure to legacy military pollution. In collaboration with a local community group, this study utilized passive sampling devices deployed at eight locations in Troutman Lake. Air, water and sediment pore-water deployed samplers were analyzed for 41 unsubstituted and 22 alkylated polycyclic aromatic hydrocarbons (PAHs), 43 brominated and organophosphate flame retardants and 52 polychlorinated biphenyls (PCBs). Sum PAH

concentrations ranged from 20 – 55 ng/m^3 in air, 1.4 – 3.2 ng/L in surface water and 0.46 – 1.4 ng/L in sediment pore-water. Naphthalene was the most abundant PAH in the air and water, constituting more than 70% of total PAHs. In the sediment pore-water, PAHs were primarily three ring compounds, in particular, phenanthrene and sulfur heterocycle dibenzothiophene. The majority of PAHs were in deposition from the overlying atmosphere into Troutman Lake. Brominated diphenyl ether 47 was detected in all surface water samplers (0.0018 – 0.0156 ng/L). Organophosphate flame retardant, triphenyl phosphate was detected in all environmental compartments at concentrations less than 0.004 ng/m^3, 0.07 ng/L and 0.07ng/L in air, water and sediment porewater, respectively. Of particular interest, we measured higher vapor phase concentrations of tris(2-chloroethyl) phosphate (TCEP) (0.75 - 2.8 ng/m^3) than previously reported in the literature for similar remote Arctic sites (0.017 – 0.56 ng/m^3). TCEP was found to be in deposition to Troutman Lake at magnitudes ranging from 290 ng/m^2/day to 1300 ng/m^2/day. No PCBs were detected in this study. These findings can help us to understand the fate of anthropogenic contaminants in dynamic Arctic systems with both global and local sources of modern and legacy pollutants.

3.06.P-Tu163 Persistent Organic Pollutants (POPs) in Pygoscelis adeliae **from the Ross Sea (Antarctica): Evaluation of their Temporal Trends in a Climate Change Context**

Nicolas Pala[1]*, Katrin Vorkamp*[2]*, Rossana Bossi*[2]*, Nicoletta Ademollo*[3]*, Tania Martellini*[4]*, Alessandra Cincinelli*[4]*, Leonardo Checchini*[4]*, Davide Baroni*[1] *and Simonetta Corsolini*[1]*, (1)Department of Physical, Earth and Environmental Sciences, University of Siena, Italy, (2)Department of Environmental Science, Aarhus University, Denmark, (3)Insititute of Polar Sciences, CNR-ISP, Italy, (4)Department of Chemistry "Ugo Schiff", University of Florence, Italy*

Antarctica is rapidly undergoing the most pronounced effects of climate change worldwide. Events like ice melting, iceberg calving, and changes in oceanic and atmospheric currents are affecting the lifecycle and health of endemic species, in some cases posing their survival at risk. Among the major acknowledged threats for organism health are Persistent Organic Pollutants (POPs) which are transported to Antarctica by long-range transport mechanisms and which can also be released in local anthropogenic activities. Legacy pollutants that were decreasing in recent years could be remobilised from melting ice and become available for uptake and biomagnification in the trophic webs. Transport patterns of emerging POPs to Antarctica could be changed. Adèlie penguin (*Pygoscelis adeliae*) being an intermediate predator and a resident with a circumpolar distribution represents a good sentinel species for monitoring POPs in Antarctica. Continuous monitoring of the presence, distribution and levels of pollutants is fundamental to make predictions about potential consequences of climate change and to evaluate if the implemented protection measures are having the expected effect. That is even more important considering the increasing human impacts connected with scientific research, industrial fishing and tourism activities that could also release contaminants and contribute to contaminant exposure of the penguins. The main aim of this work was to analyse legacy and emerging compounds in penguin eggs from the Ross Sea coast (East Antarctica). Fifty-one unhatched eggs were collected in seven years between 1997 and 2022, during Italian expeditions conducted in the framework of the National Programme of Research in Antarctica (PNRA), and analysed for polychlorinated biphenyls (PCBs), polybrominated diphenyl ethers (PBDEs) and per-/polyfluoroalkyl substances (PFAS). The temporal trends of target compounds will be evaluated and, when feasible, correlations to available climatic and/or biological parameters will be assessed. We hypothesize decreasing trend for legacy pollutants such as PCBs still prevailing on the reduced emissions and increasing trends for emerging POPs such as PFAS due to new environmental inputs or, focusing on specific congeners/isomers, connected with recent human activities.

3.06.P-Tu164 Using Faeces as a Noninvasive Biomonitoring of Mercury in Svalbard Reindeer (*Rangifer tarandus platyrhynchus*)

Bjørg Marie Pollestad[1]*, Malin Andersson Stavridis*[2]*, Bjørn Munro Jenssen*[3]*, Tomasz Maciej Ciesielski*[4] *and Valentina Araya Piqué*[5]*, (1)Biology, Norwegian University of Science & Technology (NTNU), Norway, (2)Department of Arctic Technology, University Centre in Svalbard (UNIS), Svalbard and Jan Mayen, (3)Department of Biology, Norwegian University of Science & Technology (NTNU), Norway, (4)Norwegian University of Science & Technology (NTNU), Norway, (5)Chemistry, Norwegian University of Science & Technology (NTNU), Norway*

Anthropogenic activities have increased mercury (Hg) atmospheric emissions, resulting in higher concentrations in the environment. The methylated form of Hg (MeHg) is of high ecological concern, as it bioaccumulates in organisms and biomagnifies in food chains. Even though there are few local sources of Hg in the Arctic, the majority of the Hg detected in the Svalbard biosphere derives from the atmospheric and ocean currents transport.

The study aims to monitor total Hg (THg) and MeHg levels in the faeces of the Svalbard reindeer (*Rangifer tarandusplatyrhynchus*) as a non-invasive matrix. *R. tarandus* faeces were collected in Colesdalen, Bjørndalen and Hollendarbukta, Svalbard, during the summer of 2022. The THg content was analysed using a direct mercury analyser (DMA-80), and MeHg levels using MerX-M. The results showed faecal THg levels ranging from 36 – 421 mg/kg dry weight (d.w), depending on location and sampling week. Generally, higher levels of THg were found later in the summer. Faeces samples from Hollendarbukta in the late summer had particularly high levels, ranging from 139 – 421 mg/kg d.w, which is an increase of about 20% compared to the same location at previous sampling weeks. The THg levels in the faeces samples reflect the diet of the reindeer and contribute to the monitoring of Hg levels in the environment and the health of *R. tarandus.* The samples are currently analysed for MeHg levels to evaluate MeHg concentrations and calculate the THg:MeHg ratio. These data provide more information about MeHg distribution in terrestrial ecosystems in Svalbard and its potential for bioaccumulation in *R. tarandus*.

3.06.P-Tu165 Mercury Uptake, Distribution and Excretion in Svalbard Reindeer

Malin Andersson Stavridis[1]*, Bjørg Marie Pollestad*[2]*, Valentina Araya Piqué*[3] *and Bjørn Munro Jenssen*[4]*, (1)Department of*

Arctic Technology, University Centre in Svalbard (UNIS), Svalbard and Jan Mayen, (2)Biology, Norwegian University of Science & Technology (NTNU), Norway, (3)Chemistry, Norwegian University of Science & Technology (NTNU), Norway, (4)Department of Biology, Norwegian University of Science & Technology (NTNU), Norway
Frozen soils of the Arctic have been found to store large amounts of legacy mercury (Hg). Due to climate change and increasing soil temperatures, permafrost is thawing, which could remobilise the accumulated Hg and make it bioavailable for uptake in biota. The Svalbard reindeer (*Rangifer tarandus platyrhynchus*) is an important primary consumer, and therefore a key species in the local Arctic terrestrial ecosystem. This study aimed to determine the levels of total Hg (THg, which includes both inorganic and organic Hg) in a range of both tissues and faeces from the Svalbard reindeer, as well as in *Salix polaris*, a major constituent of their diet. These data will contribute to assessing the uptake, distribution and excretion of Hg in an Arctic terrestrial herbivore and form the basis for the potential development of a toxicokinetic model that predicts internal tissue Hg concentrations based on the levels found in faeces.
THg was analysed in *Salix polaris* (n = 15), and fur, faeces, muscle, brain, liver and kidney from twenty reindeer, culled in central Spitsbergen in 2021 (n = 20). All samples were analysed using a direct mercury analyser (Milestone DMA-80 evo). The highest Hg levels were found in kidney (226.55-58.69 µg/kg ww), followed by liver (32.33-120.21 µg/kg ww), faeces (7.33-25.71 µg/kg ww), muscle (0.94-7.64 µg/kg ww), brain (0.04-1.46 µg/kg ww) and fur (0.86-17.65 µg/kg ww). The levels of Hg in *Salix polaris* ranged from 1.95-17.93 µg/kg (ww). Hg levels correlated well between kidney and liver samples and between muscle and brain samples ($p<0.001$, $R^2=0.77$ and 0.95, respectively). While faecal Hg levels represent local dietary intake and short-term exposure, internal tissues such as kidney and liver are known to store Hg, and concentrations in these organs would rather represent chronic exposure. The lack of significant correlation between the faecal Hg levels and the levels in any of the other analysed reindeer tissues is therefore not surprising. The relatively high faecal Hg levels however suggest that while the Svalbard reindeer is exposed to Hg through their diet, they are also efficient in excreting it.

3.06.P-Tu166 Legacy and Emerging PFAS in Three Seabird Species in the Sub-Antarctic Using UPLC-HRMS to Evaluate Long-Range Transport and Emerging Chemicals
Imogen Bailes[1]*, Jonathan Barber*[2]*, Sara Losada*[2]*, Richard Phillips*[3]*, Lloyd Peck*[3] *and Andrew Sweetman*[4]*, (1)Lancaster Environment Centre, Lancaster University, United Kingdom, (2)Centre for Environment Fisheries and Aquaculture Sciences (Cefas), United Kingdom, (3)British Antarctic Survey, United Kingdom, (4)Lancaster University, United Kingdom*
Poly- and perfluoroalkyl substances (PFAS) are a large group of chemicals that are characterised by a hydrophilic moiety (e.g. SO_3^- or COO^-) and a hydrophobic perfluorocarbon chain that varies in length. PFAS display unique properties due to combined oil and water repellence, extreme stability, and hence are used in a wide range of industrial processes and consumer products. These chemicals can be problematic in the environment due to their potential to undergo long-range transport, persistence and toxicity. However, only some of these substances have been regulated by the Stockholm Convention; therefore, there is a growing need to document evidence of these emerging chemicals of concern in the environment. Here, we employ an ultra-performance liquid chromatograph coupled to a high resolution mass spectrometer (Orbitrap) to analyse a range of both legacy and emerging PFAS including 11 PFCAs (C4-C14), 9 PFSAs (C4-C10), 3 FASAs, 3 PFPiAs and 6 fluorotelomer acids, among others. We have analysed liver tissues of black-browed albatrosses, white-chinned petrels and common diving petrels collected from the Falkland islands and South Georgia from the early 2000s to the mid 2010s. The data show varying spatial and temporal trends between different species and compounds; in particular we draw comparisons between trophic levels by employing stable isotope analysis. We have also conducted nontarget analysis to horizon scan for related chemicals that are being released into the environment, and are accumulating at detectable concentrations in biota, but are not on regulatory agendas as of yet. Our research addresses the need to understand exposure levels in wildlife to PFAS compounds in areas close to and remote from sources, and also how PFAS fingerprints vary between different species over time.

3.06.P-Tu167 Sources and Levels of Mercury in Terrestrial and Fresh Water Resources Related to Feeding Areas for Reindeer at Svalbard (TERRA)
Valentina Araya Piqué[1]*, Malin Andersson Stavridis*[2] *and Øyvind Mikkelsen*[1]*, (1)Chemistry, Norwegian University of Science & Technology (NTNU), Norway, (2)Department of Arctic Technology, University Centre in Svalbard (UNIS), Svalbard and Jan Mayen*
Recent studies indicate that permafrost, the permanently frozen topsoil layer, might be the largest reservoir of Hg globally. As a result of Arctic amplification, the circumpolar permafrost soils have started to thaw, and the stored Hg could remobilize into the environment again. Hg is a known toxic pollutant that can cause adverse effects in biological systems, even at low doses. Due to the potential release of Hg from the permafrost, terrestrial species such as *Rangifer tarandus platyrhynchus*, the Svalbard Reindeer, could thus be exposed to Hg through their diet. This study aims to determine the levels of Hg released from permafrost in the Arctic and to compare the sources of Hg uptake for terrestrial species. To assess whether Hg remobilizes from permafrost, gold traps were set at the start of the thawing season and retrieved after summer. Additionally, soil and moss samples were collected to determine the atmospherically deposited Hg. Water and vegetation (*Salix polaris*) samples were also collected. All samples were analyzed using the Direct Hg Analysis (DMA80) for Hg content and ICP-MS for elemental composition. The preliminary results from the gold traps show no significant differences between with the blanks, suggesting that this technique might not have been able to determine the Hg released from the soil during the summer, or that no Hg was remobilized in the studied period. Soil samples from the end of summer show significant location differences, with higher levels of Hg in Colesdalen (178-427 µg/kg), compared to both Foxdalen (53-179 µg/kg) and Bjørndalen (29-64 µg/kg) samples. *Salix polaris* samples show values ranging from 30-172 µg/kg in dry weight. Water levels are still being analyzed. The ongoing hypothesis is that values from both soil and water from the beginning of summer will have lower Hg values than those at the end of summer. This study will

provide an overview of the remobilisation of Hg in terrestrial ecosystems in Svalbard, emphasizing the risk for the Svalbard Reindeer.

3.06.P-Tu168 Determination of Organochlorine Pesticides in Biota Using Gas Chromatography Atmospheric Pressure Chemical Ionization (GC-APCI) MS/MS

Janitha De Alwis[1] *and Douglas Michael Stevens*[2]*, (1)Food and Environment, Waters Corporation, United Kingdom, (2)Waters Corporation*

Despite the fact that many organochlorine pesticides (OCPs) have been banned or limited in their production and application for decades, their recalcitrance to degradation in the environment and their global transport potential still make them an important class of compounds to monitor today. Furthermore, these compounds bioaccumulate and are associated with a range of negative health effects for many different organisms. So while water and soil samples play an important role in determining the occurrence, fate and transport of OCPs, biota samples from sentinel species more directly connect with the need to determine the incorporation of OCPs into the food web and the potential for human exposure presented by their presence.

Across recent years tandem quadrupole GC/MS/MS with atmospheric pressure ionization has begun to replace electron ionization (EI) on magnetic sectors for challenging environmental analyses such as OCPs. The shift to GC-APCI MS/MS in particular also facilitates the conversion of methods relying on He carrier gas to more sustainable, reliable and less expensive alternative of nitrogen. The atmospheric pressure source adapts to the use of nitrogen carrier gas without loss of sensitivity or chromatographic separation.

This work compares the analysis of whale and seal blubber samples for the presence of OCPs using EI HRMS with He carrier gas to GC-APCI MS/MS using He carrier gas and nitrogen carrier gas. Preliminary data shows agreement between the EI HRMS data and GC-APCI MS/MS within 1ppb and within 10% in the range of 1 to 200ppb.

A calibration curve from 1 - 200ppb was analyzed along with 3 biota samples, 2 interlab study samples, 2 standard reference materials, 2 spiked matrix samples, and 3 blanks. Following the analysis of this batch of samples the system using He and GC-APCI MS/MS the system was converted to nitrogen carrier gas. Across the 49 peaks monitored the agreement between the He 60m column and nitrogen 40m column data averaged +/- 1.1s. Sensitivity between the two data sets showed all analytes within a factor of +/- 2X of the same values as measured using signal to noise. Critical pair separations were the same between the two data sets and all allowed accurate and precise quantitation with good agreement to the EI HRMS data. An alternative method to traditional EI GC HRMS based on GC-APCI MS/MS demonstrated the ability to generate comparable data for the monitoring of OCPs in biota using either He or nitrogen carrier gas.

3.06.P-Tu169 Considerations for Designing an Antarctica Monitoring Program for Cyclic Volatile Methylsiloxanes (cVMS)

Jeremy Durham[1]*, Debra McNett*[1]*, Pernilla Bohlin-Nizzetto*[2]*, Shihe Xu*[3] *and Kathleen Plotzke*[1]*, (1)Dow Chemical Company, Midland, (2)Norwegian Institute for Air Research (NILU), Norway, (3)Tridge Environmental Consulting LLC*

Environmental monitoring in the Arctic and Antarctic remote locations brings several challenges compared to monitoring in metropolitan and major source regions in general. This presentation will highlight important considerations for the design and implementation of a remote monitoring program for cVMS. In particular, the main goal is to be able to obtain accurate cVMS concentrations in air and surface media with a more thorough understanding of impact from local emission sources often found in polar regions and potential bias from collection. In 2021, the Silicone industry partnered with the Norwegian Institute NILU, and launched an Antarctica air monitoring project with a strict quality control protocol and sampling locations that allowed for an assessment of impacts from the local station compared to a sampling location upwind and isolated from the local station. These types of comparison site selections are critical for understanding the impact of these local point sources within the Arctic and Antarctic regions. Impact of local wastewater release or solid waste disposal is equally important.

The types of matrices available also lead to challenges. For example, the concentration in air is much lower than in the Arctic; this requires highly sensitive methods. In addition, soils in Antarctica are often frozen and rocky with low organic carbon (OC); this brings challenges in sample collection and processing. The low OC can lead to difficulty with storage and collections due to high potential for analyte loss.

Use of matrix (soil, vegetation, biota) matched quality control and the use of target analyte spike addition to collected samples and following the exact sample transport, storage, processing, and analytical procedures would be essential to understand loss and contamination during collections, transport, and analysis.

With these considerations a program is being planned in Antarctica for cVMS materials with three main objectives.

- First, to determine the presence of airborne cVMS including fractions both in gas phase and bounded by atmospheric particulates to check if the airborne cVMS concentrations in the remote Antarctica sites are high enough to contribute to exposure in the surface media.
- Second, to determine the cVMS concentrations in soil, vegetation, and aquatic biota in locations free of local source influence.
- Third, to understand the potential of local sources or sample artefacts to impact reported concentrations in this region.

3.06.V Climate Change in Arctic and Antarctica and Its Effect on Legacy and Emerging Micropollutants in Abiotic and Biotic Environmental Compartments

3.06.V-01 Brominated and Chlorinated Flame Retardants in the Air and Snowpack of Northern Norway

Crispin Halsall[1]*, Olivier Bertrand*[2]*, Axel Moller*[3]*, Zhiyong Xie*[3]*, Ralf Ebinghaus*[4]*, Dorte Herzke*[5]*, Eldbjørg Sofie Heimstad*[5] *and Sandra Huber*[5]*, (1)Lancaster University, United Kingdom, (2)Lancaster Environment Centre, Lancaster University, United Kingdom, (3)Helmholtz Center Hereon, Germany, (4)Helmholtz Center Geesthacht, Germany, (5)Norwegian Institute for Air Research (NILU), Norway*

Halogenated flame retardants (HFRs) undergo long-range environmental transport with growing evidence of their occurrence in remote oceanic and Polar Regions. In regions of high latitude/altitude snowmelt often represents the dominant hydrological feature, accounting for the majority of surface water flow and a route by which atmospherically-derived pollution can affect freshwater systems. In this study, we examined polybrominated diphenyl ethers (PBDEs) and a selection of current-use HFRs in the winter snowpack in the remote far north of mainland Norway (~69°N). Compounds detected and quantified included BDE-47, -99, -100, -153, -209, allyl-2,4,6-tribromophenylether (ATE), α- and β-tetrabromoethylcyclohexane (TBECH), pentabromobenzene (PBBz), pentabromotoluene (PBT), *syn*- and *anti*-Dechlorane Plus (DP), and decabromodiphenyl ethane (DBDPE). Concentrations of these chemicals in snow ranged from <1 to >200 pg L^{-1} (meltwater), with the highest median concentrations in the order of α- and β-TBECH>PBBz>PBT>BDE-209>DBDPE>ATE>*anti*-/*syn*-DP>other BDE congeners. Concentrations were considerably lower than those reported from earlier studies conducted in the Canadian High Arctic and on Svalbard (firn/ice core, 2005-2008) indicating rapidly changing sources with time and/or variations in seasonal input. Snowfall scavenging ratios (generated from air samples collected at the same time as the snow sampling) were found in some cases to be high (e.g. $\sim 2.1 \times 10^7$ for ATE for a fresh snow fall event and $\sim 10^5$ for other HFRs) indicating the efficiency by which snowfall events can strip these chemicals from the air. Particle-bound fractions (Φ) were significant for the higher MW compounds (e.g., $\Phi = \sim 0.5\text{-}0.8$ for DP, BDE-209, DBDPE). Differences in HFR concentrations between the upper and deeper snowpack were observed indicating the propensity of these chemicals to migrate to deeper layers with the onset of melt.

3.07.A Coastal Ecosystems are Critical Areas for the Assessment of Pollutant Exposure

3.07.A.T-02 The Role of Plastics in the Bioaccessibility of Trace Elements in New Zealand Near-Shore Coastal Zones

Hayden Masterton[1]*, Sally Gaw*[2]*, Grant Northcott*[3]*, James Hadley Bridson*[4]*, Beatrix Theobald*[4]*, Maxime Barbier*[4]*, Francois Audrezet*[5]*, Dawn Smith*[4]*, Stefan Maday*[6]*, Jessica Wallbank*[6]*, Anastasija Zaiko*[5]*, Xavier Pochon*[5]*, Gavin Lear*[6]*, Joanne Kingsbury*[1]*, Louise Weaver*[1] *and* ***Olga Pantos***[1]*, (1)ESR, Christchurch, New Zealand, (2)University of Canterbury, (3)Northcott Research Consultants Ltd, New Zealand, (4)Scion, New Zealand, (5)Cawthron Institute, New Zealand, (6)University of Auckland, New Zealand*

Plastics represent a diverse range of materials, containing complex chemical mixtures consisting of additives, processing aids, and nonintentionally added substances (NAIS). Chemicals may also be acquired from the environment. The potential risk to the environment that plastics pose, in-part, depends upon these associated chemicals, and how they behave under different conditions, as well as the ecosystem they are present in. A lack of knowledge exists around the levels and behaviour of the trace elements associated with marine plastics in New Zealand, and their bioaccessibility is under-studied worldwide. This study aims to fill this knowledge gap.

In situ experiments examined trace elements associated with 5 polymers, of both virgin and artificially aged to represent the type and degree of weathering found in the ocean. Bespoke plastics, with known additives, were attached to marine grade steel frames affixed to pontoons at three distinct locations. Plastics and associated biofilms were sampled over 9 months. Beached debris was collected from across New Zealand. Trace elements were determined for all plastics by ICP-MS. The proportion of each trace element present in the plastic that was bioaccessible to marine invertebrates and vertebrates was determined using two commonly collected items.

Trace elements were detected in the virgin and aged experimental plastics. Cobalt and antimony are used as catalysts in the production of PET, Mn as a degradation accelerant in oxo-LLDPE, and Zn as a colourant in LLDPE and oxo-LLDPE. Antimony was the only element that demonstrated loss over time, with greater loss from aged PET. Sb was not seen to accummulate in the biofilm. A total of 957 plastic items were collected from 21 sites. Trace elements demonstrated a wide range of concentrations. A varying proportion of trace elements were bioaccessible to both vertebrates and invertebrates. Vertebrate gastric simulants leached a greater number of trace elements as well as a higher percentage from the debris.

This study of plastics in the New Zealand marine environments confirms that toxic trace elements are present, and their ability to disassociate from the plastic on ingestion poses a significant threat to New Zealand's unique marine ecosystems. In addition, it highlights that the state of aging is a significant factor influencing the associated trace elements and therefore can affect the behaviour and fate of associated trace metals in the marine environment.

3.07.A.T-03 Searching for Evidences of Seasonal Variation and Plant Effects in the Production of Methylmercury in Saltmarsh Sediments Using Mercury Stable Isotope Techniques

Rute Cesário[1]*, Henrique Zilhão*[2]*, Holger Hintelmann*[3]*, Patrícia Pereira*[4]*, Joana Pereira*[4]*, Mário Pacheco*[4] *and Joao Canario*[5]*, (1)IST, Portugal, (2)University of Lisbon, Centro de Química Estrutural, Instituto Superior Técnico, Portugal, (3)Trent University, Canada, (4)University of Aveiro, Aveiro, Portugal, (5)Instituto Superior Técnico, Portugal*

Mercury (Hg) is a recognized global pollutant and its impact in ecosystems can have dramatic effects. Previous studies have

reported highly Hg contaminated areas in Ria de Aveiro, which makes of extreme importance to understand Hg biogeochemical cycle at a local scale. In saltmarshes, recent studies have suggested that the rhizosphere of halophyte plants play an important role in Hg speciation, more specifically in the Hg methylation.
Throughout the seasons, we evaluated Hg and monomethylmercury (MMHg) natural concentrations and used stable isotope techniques to determine methylation (K_M) and demethylation rates (K_D). Our aim was to evaluate the impact of plants on the MMHg budget in saltmarshes, understand the impact of seasonal change, and compare two saltmarshes in Ria de Aveiro, a Portuguese contaminated coastal Lagoon.

For this study, one saltmarsh was selected in a contaminated area (Laranjo-LAR) and another used as a reference site (Chegado-CHE). Hg concentrations varied between 0.05 and 6.20 µg g^{-1} in CHE and between 0.07 and 58.53 µg g^{-1} in LAR. These environments also presented significant MMHg concentrations, varied between 2.6 and 334 ng g^{-1} in CHE and between 2.3 and 260 ng g^{-1} in LAR. The highest MMHg contents were always recorded in vegetated sediments, which indicates the influence of plant activity in the Hg methylation. Also, in both saltmarshes, the highest MMHg concentrations were recorded during summer, implying that higher temperatures favour MMHg production likely due to higher microbial activity in warmer months. This was also corroborated by the significant increase of K_M during summer with values up to 0.452 day^{-1} and 0.312 day^{-1} respectively in CHE and LAR. Additionally, the elevated K_D (between 0.48 – 15 in CHE and 1.4 – 32 day^{-1} in LAR) with significant changes between seasons and highly affected by the presence of plants, indicates that demethylation process happens faster than the methylation process. Higher K_D values combined with measured half-life of less than 2 days for MMHg (mostly in unvegetated sediments) is surprisingly short. In these particular cases, it indicates that MMHg is not persistent in aquatic systems and a constant supply of MMHg is necessary to maintain a steady level of MMHg in sediments, making the formation process important.

These results showed that the use of stable isotope techniques allowed us to understand the importance of the balance between $K_M$and K_D in the MMHg pool in saltmarsh environments.

3.07.A.T-04 Effects of Individual and Binary Mixtures of Aquaculture Pesticides on Nontarget Marine Invertebrates
Davide Asnicar *and Benjamin Patrick de Jourdan, Huntsman Marine Science Centre, Canada*
Around 40% percent of global aquatic products derive from aquaculture, showing an increasing trend of production. Salmon aquaculture sites create a particular environment for the aggregation and reproduction of sea lice (marine ectoparasites) which cause severe skin and tissue damage with consequent fish stress, mortality, and economical loss. Chemical solutions involving the usage of drugs and pesticides are commonly used as part of an integrated management plan to maintain fish health and limit loss.

To this end, nearly 75% of the active marine finfish aquaculture sites in Canada use at least one drug or pesticide each year. Chemicals that enter the marine environment are expected to disperse following release.

Despite their wide usage, there are still unknowns and concerns regarding the environmental effects of these compounds, as well as the influence of formulation vs active ingredient (AI) and the impact of mixtures. The formulation ingredients enhance factors such as solubility; therefore the physical-chemical data derived from the AI may not be appropriate when predicting environmental fate and effects. With multiple aquaculture sites using multiple products of differing fates and modes of action, it is important to understand the synergistic, antagonistic, and additive effects of these multiple stressors.

In this study, we performed a series of toxicity tests using the early-life stages of American lobster and green sea urchin with the active ingredient and formulated products of 2 commonly used pesticides, SALMOSAN 50WP (AI: Azamethiphos; recommended dosage: 100µg/L) and Paramove 50 (AI: Hydrogen peroxide; 1.2-1.8 mg/L).

Immobilization and mortality presented in a concentration-dependent manner within 24-hrs of exposure, with no difference between the formulated product or the active ingredient. The Salmosan:H_2O_2 mixture trial highlighted possible antagonistic effects between the two compounds.

Significant differences in percent fertilized were observed in the urchin, with a more detrimental effect in the case of the formulation Salmosan, in particular, at the highest concentration. On the other hand, the percentage of normal larvae has not shown differences between the two treatments.

The data generated in this project will provide greater context and understanding of these compounds in coastal environments to define environmental quality standards or monitoring thresholds.

3.07.A.T-05 Presence of Microplastics in the Delaware River Estuary in Northeast USA
*Gangadhar Andaluri[1] and **Rominder PS Suri**[2], (1)Civil & Environmental Engineering, Temple University, Philadelphia, Pennsylvania, (2)Temple University, Philadelphia, Pennsylvania,*
Plastics in the aquatic environment are of increasing concern because of their persistence and effect on the environment, wildlife, and human health. To date, little is known about microplastics in the upper Delaware estuary, USA and their effects on fish and wildlife. The first step in understanding these potential effects is to understand the distribution and concentration of microplastics within the estuary.

This research is aimed to increase the understanding of the distribution of microplastics in the Delaware estuary, USA (a major river in northeast USA) through monitoring and modeling and to increase public awareness of the issues associated with microplastics. Grab and net samples were collected at nine tributary locations and five mainstem locations throughout the basin. Sample analysis was performed using FTIR spectroscopy. Data collected for the samples included total particle count, particle size, color, and composition. A 3-Dimensional hydrodynamics model was applied for the Delaware Estuary using the USEPA supported Environmental Fluid Dynamics Code (EFDC). The 3-D hydrodynamics model simulates hydrodynamic and transport information (e.g., tides, water depth, current velocity, salinity, water temperature) over a range of hydrologic and meteorological conditions.
Microplastics were detected in every sample. Concentration ranged from 8.5 – 250 particles/ft^3 with the highest concentrations occurring in Rancocas Creek. Mainstem Delaware River grab samples generally showed mid-high concentrations of microplastics with similar concentrations being found at both surface and bottom collections. Microplastics were found in a variety of colors in samples including clear, pink, purple, red, orange, yellow, green, black, brown, gray, silver, and white. Apart from this, microplastics were found in sizes ranging from 50 µm to 2000 µm. Grab samples generally had smaller particles with 75% of the particles being less than 500 µm. Net samples had larger particles with 53% of the particles being greater than 500 µm. Samples were composed of a variety of plastics. Polyester, Rayon, and manmade cellulosic fibers were the most common types seen in samples. Microplastic composition was found to be similar between both net and grab samples, however a higher proportion of polyethylene particles were observed in the net samples. Data on microplastic concentrations can be used to target cleanup efforts in high plastic loading watersheds.

3.07.B Coastal Ecosystems are Critical Areas for the Assessment of Pollutant Exposure

3.07.B.T-01 Emerging Trace Metal Contamination in Representative Urbanized Estuarine Systems
Melina Abdou[1]*, Carlos Eduardo Monteiro*[2]*, Pedro Aboim de Brito*[3]*, Teresa Neuparth*[4]*, Bárbara Marlene Pinheiro*[5]*, Miguel M. Santos*[4] *and Miguel Caetano*[6]*, (1)Center of Marine and Environmental Research CIIMAR, Portugal, (2)Environmental Biogeochemistry, Centro de Química Estrutural, Institute of Molecular Sciences, IST-UL, Lisbon, Portugal, (3)Portuguese Institute of the Sea and Atmosphere, Portugal, (4)University of Porto, Interdisciplinary Centre of Marine and Environmental Research, Portugal, (5)Department of Biology, Faculty of Sciences of the University of Porto (FCUP), Portugal, (6)Portuguese Institute for Sea and Atmosphere (IPMA), Portugal*
Continuously increasing mining, use, and subsequent release of Technology Critical Elements (TCEs) pose growing environmental concerns regarding their dispersion, fate, and ecotoxicological impact in aquatic systems. Platinum Group Elements (PGEs) belong to this group and represent contaminants of emerging environmental concern for which gaps in knowledge remain for their behavior and reactivity in recipient waters, especially in estuarine/coastal systems that are impacted by human activities. Among the variety of specific applications, PGEs are especially used in car catalytic converters (vehicle emission control) as well as anti-cancer drugs (for platinum: Pt), and other industrial processes. While recent studies provided PGE levels in seawater, scarce knowledge still exists regarding PGE contamination in marine organisms, especially for rhodium (Rh) element. Analytical challenges in terms of sensitivity and interference control required for Rh and Pt ultra-trace detection in marine matrices may explain such general lack of information.

In this study, water, macroalgae (various species) and mussels (*Mytilus galloprovincialis*) were sampled in several sites from two estuarine systems and adjacent coastal areas reported to be under anthropogenic pressure, i.e., the Douro and the Ave estuaries (North Portugal). Together with master physicochemical parameters and nutrient levels determined in seawater, Rh and Pt concentrations were quantified through both Adsorptive Cathodic Stripping Voltammetry (AdCSV) and Inductively Coupled PlasmaMass Spectrometry (ICP-MS) in the dissolved phase (< 0.2 µm) and biological samples.

Spatial monitoring of selected PGEs, together with proxies of sewage inputs revealed the presence of Rh and Pt in the dissolved phase as well as in marine biota. The determination of Pt/Rh ratios in the various samples reflected the influence of different PGE sources that include traffic emissions, hospital/domestic effluents, and industrial activities. The higher range of Pt/Rh ratio in the dissolved phase in the Ave Estuary suggested the importance of other Pt-dominated sources that may include specific Pt-based industrial processes. Our study confirmed that urbanized estuaries represent important pathways to transfer PGE from the coastal zone to the open ocean. Further studies are therefore required to evaluate the extent of those emissions and to collect more data on Rh as an emerging coastal contaminant.

3.07.B.T-02 Seals in a Changing Sea: A Multitracer Approach
Krishna Das[1]*, Ursula Siebert*[2]*, France Damseaux*[1]*, Marianna Pinzone*[3]*, Gilles Lepoint*[1]*, Anita Gilles*[2]*, Joseph Schnitzler*[2]*, Thierry Jauniaux*[1] *and Patrick Pomeroy*[4]*, (1)University of Liege, Belgium, (2)University of Veterinary Medicine Hannover, Germany, (3)FOCUS RU, University of Liege, Belgium, (4)Sea Mammal Research Unit, University of St Andrews, United Kingdom*
We present here an innovative use of stable isotopes ratios of carbon ($\delta^{13}C$), nitrogen ($\delta^{15}N$), and sulphur ($\delta^{34}S$) combined with total mercury (THg) and selenium (Se) concentrations in seal body tissues as ecological tracers of harbour and grey seal foraging activities and exposure to Hg. SIBER (Stable Isotope Bayesian Ellipes in R) allows the use of stable isotope ratios, [Se] and [Hg] to build geometric spaces (or “isospaces”). These can be used as proxies of species ecological niches commonly referred to “isotopic niches.” Our objectives are (1) to evaluate potential temporal changes in foraging patterns and exposure of grey seals and harbour seals, (2) to highlight the trophic plasticity of these two seal species in a changing environment.

A multitracer approach ([THg] and [Se]; $\delta^{13}C$, $\delta^{15}N$, $\delta^{34}S$ values) was applied to harbour seals and grey seals (blood; German and Scottish coasts, n = 174 and n = 80, respectively) during different time periods (from 1900 to 2017). Additionally, the same tracers were analysed in harbour seals (hair; from 1930 to 2017) from the Natural History Museum of Stockholm (n = 10), free-ranging and stranded harbour seals from the North Sea (German and Belgian coasts, n = 40 and n =6, respectively). SIBER package in R was used to explore the variation in the isotopic niche ($\delta^{13}C$ vs. $\delta^{15}N$ and $\delta^{15}N$ vs. $\delta^{34}S$) and the ecological niches ($\delta^{13}C$ vs. T-Hg, T-Hg vs. $\delta^{15}N$, $\delta^{34}S$ vs. T-Hg, $\delta^{13}C$ vs. Se, Se vs. $\delta^{15}N$ and $\delta^{34}S$ vs Se).

Our multi-tracer approach revealed:
(1) An increase of the size isotopic and ecological niche size in agreement with a more offshore foraging distribution, and an increase of benthic resources (more flatfish and less sandeels) for Scottish grey seals over time. In contrast, we calculated a smaller isotopic niche size for harbour seals over time likely linked to an increase of phytoplankton biomass, supporting zooplankton for planktivorous fish species such as clupeids.

(2) Long-term changes having affected the North Sea are reflected in hair collected from harbour seals (1930-2017). We found [THg] and $\delta^{13}C$ values increased linearly with time. Higher $\delta^{13}C$ values may be related to local higher primary productivity that may explain the possible increase of prey species abundance. Such increases may be related to changes in habitat use, particularly as tracking studies have shown that some foraging now occurs around wind farm installations.

3.07.B.T-03 Micro-Estuaries as Bio-Filters: Attenuation of Organic Pollutants and the Effects of Salinity and Seasonality
***Tom Topaz**, The Faculty of Marine Science, Ruppin Academic Center, Israel*
Micro-estuaries are small ubiquitous transitional water bodies that mediates surface water to seas and oceans. Unlike the vastly studied large estuaries, micro-estuaries lack the ability to dilute and contain pollution from point and nonpoint sources due to low natural water discharges. Therefore, these diverse ecological systems are susceptible to pollutant loads due to prolonged water residence time and complex geochemical dynamics. Although this elevated anthropogenic stress limits their potential to provide ecological and recreational services, micro-estuaries have some traits similar to those found in constructed wetlands. These traits provide a natural potential to retain and mitigate organic pollutants. A two consecutive years field study conducted at the Alexander micro-estuary tracked the influx and outflux of a large organic pollutant mixture (46 pesticides and 19 pharmaceuticals) during base-flow and flood events. Throughout the research period, 165 kg of active ingredients entered the micro-estuary and 160 kg flowed out to the coastal zone of the Mediterranean Sea, suggesting negligible net attenuation. However, this broad picture conceals seasonal shifts in pollutant mixture loads, and only a handful of pollutants were actually balanced. The majority of compounds were either removed or added to the flow, with no observed correlation to chemical properties. A prominent observation was the load increase along the flow for some pollutants during base-flow conditions. This trend was correlated with salinity elevation and was verified in sorption-desorption lab experiments conducted at different levels of water salinity. These results imply that seawater intrusion to the bottom of the estuary may increase desorption rates of pollutants from the estuary bed, creating an estuarine desorption magnification effect which may increase chronic exposure of the coastal system. The combination of strong anthropogenic stress with increased desorption rates severely limits the estuary's potential to mitigate pollutants, frequently transforming it into a pollution source rather than a sink.

3.07.B.T-04 Global and Regional Decrease in Metal Concentrations in Brown Algae
***Carme Pacin**[1], Jesús R. Aboal[1], Rita García-Seoane[2], Zulema Varela[1], J. Ángel Fernández Prof[1] and Aridane González[3], (1)University of Santiago de Compostela, Cross-Research in Environmental Technologies (CRETUS), Spain, (2)Instituto Español de Oceanografía, IEO-CSIC, Centro Oceanográfico de A Coruña, (3)Instituto de Oceanografía y Cambio Global, IOCAG. Universidad de Las Palmas de Gran Canaria, ULPGC*
Metal pollution is of major concern because of its associated toxic effects and the persistence of these pollutants in the environment. In this study, we evaluated the temporal changes in metal concentrations of coastal brown algae using two complementary approaches: i) A metanalysis of >15,700 metal concentration data across the globe reported from studies for the period 1933-2020; ii) The analysis of >450 samples of *Fucus vesiculosus, F. spiralis,* and *F. ceranoides* collected in Galicia (NW Spain, North Atlantic coast) from 1990 to 2021 in the same sampling stations. Both approaches provide different information: large spatial-temporal scale data but with low resolution because of the use of nonstandardized methodologies vs. smaller spatial-temporal scale data but higher resolution given the use of standard methods, respectively. Globally, the study findings revealed significant decreases in the concentrations of Cd, Co, Cr, Cu, Fe, Hg, Mn, Pb and Zn of around 60-84% (ca. 2% annual) in brown algae tissues. The decreases were consistent across the different families considered (Dictyotaceae, Fucaceae, Laminariaceae, Sargassaceae, and Others), and began between 1970 and 1990. Regionally, the concentrations of the metals tended to decrease from 1990 to 2021, although these declines showed oscillations over time. The observed declines could be explained to a large extent by the reduction in metal concentrations in oceans, although global change drivers such as decreasing pH and increasing sea surface temperature and heat content could also explain them partially. In any case, this study shows a reduction in metal concentrations in brown algae over time, which is important in itself given their key role in the trophic transfer of these contaminants. This data can be used as a starting point for future emission scenarios and to inform management decisions.

3.07.B.T-05 Sediment Surface Distribution of Organic Pollutants and Ecological Risk Assessment in the South of the Southern California Bight (SCB), Mexico
*Jose Vinicio Macias-Zamora[1], Nancy Ramírez-Álvarez[1], Felix Hernandez-Guzman[1], Cristina Quezada-Hernández[1], **Juan Munoz-Arnanz**[2] and Begona Jimenez[3], (1)Instituto de Investigaciones Oceanológicas, Universidad Autónoma de Baja California,*

Mexico, (2)Institute of Organic Chemistry - Spanish Research Council (IQOG-CSIC), Spain, (3)Institute of Organic Chemistry - Spanish National Research Council (IQOG-CSIC), Spain
The Southern California Bight (SCB) is a complex ecoregion shared by the US and México on the Pacific Ocean, extending from Point Conception in USA to Cabo Colonett in Mexico. In this work we investigate the presence and distribution of organic pollutants such as PBDEs, PAHs, PCDDs, and PCDFs in surface sediments of this marine environment. We expect that coastal development and economic growth will continue, thereby, increasing the input of these and other pollutants via wastewater into marine sediments threatening the local benthic fauna and food chains.

The sampling design was based on a randomly stratified design using that usually followed in SCB projects. Twenty-six surface sediment samples were collected in 2018 with a Van Veen dredge.

We present data for PAHs, PBDEs and, for the first time, PCDDs and PCDFs in the south end of the SCB. The range of concentrations were from non-detected to a maximum of 9.74 ng/g d.w. and from 3.1 to 312 ng/g for ∑14PBDEs and total PAHs, respectively. For PCDFs and PCDDs, the concentrations ranged from 0.8 to 9.5 pg/g and from 3.8 to 55 pg/g, respectively. Generally, largest concentrations were found in the samples collected at deeper sites and located to the north and central sampling areas.

All study pollutants were generally found in the sampled places. Except for PBDEs, the other two families of compounds occurred in such low concentrations that they did not appear to represent a large risk to benthic organisms. Nevertheless, since these substances can bioaccumulate and biomagnify, it becomes advisable to investigate on marine food webs if they represent a threat to humans via food consumption.

3.07.P Coastal Ecosystems are Critical Areas for the Assessment of Pollutant Exposure

3.07.P-Mo184 Quantifying Temporal Changes in Mercury Speciation and Photochemistry in a Tidal River: Effects of Salinity and Total Suspended Solids

Rachel G. Clarke[1], Sara Klapstein[1], Robert Keenan[2] and ***Nelson J. O'Driscoll**[1]*, *(1)Acadia University, Canada, (2)Environment and Climate Change Canada, Dartmouth, Canada*
Daytime volatilization of gaseous elemental mercury ($Hg(0)_{aq}$) is an important mechanism for mercury removal from aquatic systems and may potentially limit the formation and bioaccumulation of methylmercury. Changes in incoming solar radiation, dissolved organic matter, salinity, and suspended particles were investigated concurrently with several mercury species ($Hg(0)_{aq}$, dissolved total mercury (THg), easily reducible mercury (ERM), and mercury associated with total suspended solids (THg_{TSS})) during daylight hours near the mouth of a hypertidal river, Jijuktu'kwejk (Cornwallis River). An empirical predictive model for $Hg(0)_{aq}$ concentrations was also derived based on experimental lab data for mercury photoreduction in the absence of total suspended solids and assuming negligible photooxidation. There were no consistent temporal changes observed for $Hg(0)_{aq}$ in unfiltered surface water. $Hg(0)_{aq}$ ranged from 0–12 pg L^{-1}, THg ranged from 0–492 pg L^{-1}, ERM ranged from 13–381 pg L^{-1}, and THg_{TSS} ranged from nondetectable–261.32 ng g^{-1}. The range of $Hg(0)_{aq}$ predicted by the empirical model was similar to measured THg and ERM concentrations, however it was also shown that ERM was not an ideal predictor of photoreducible $Hg(II)_{aq}$ ($Hg(II)_{RED}$). Production of $Hg(0)_{aq}$ appears to largely be suppressed by suspended solids, which limits ultraviolet radiation transmission through surface water. This research demonstrates the importance of complementary field measurements in association with controlled lab experiments, and the need for further research to better understand $Hg(II)_{RED}$.

3.07.P-Mo185 Examining Export and Bioaccumulation of Methylmercury in a Wetland Impacted by Avian Guano and Water Table Restoration

***Nelson J. O'Driscoll**, Mia Doncaster, Sara Klapstein and N. Hillier, Acadia University, Canada*
Big Meadow Bog (Brier Island, NS) underwent water table restoration which was completed in the summer of 2018. The bog is also host to 4000-6000 herring gulls clustered in a small area in the Northern Bog that feed at nearby mink farming and aquaculture sites. Previous research in our group has shown that bird biomass and waste products are increasing the trace metals and nutrients measured in groundwater. Gull guano analysis results have shown that gull guano is very high in water soluble PO_4^{3-} and that total mercury (THg) and methylmercury (MeHg) are low in guano. Research from various studies examining terrestrial freshwater catchment flooding indicated that export of methylmercury (MeHg) increases over a multiyear time span in otherwise undisturbed catchments. An examination of water quality and lower trophic level biota was initiated to set a baseline for methylmercury concentrations in the base of the food web.
Outflow water samples showed a seasonal trend between 2018-2022 with highest concentrations and % MeHg occurring during the summer period for 2019 and remaining lower for 2020-2022 data. The % MeHg increases to >60% in July of 2019 and reduces to <40% in the following years. Similar patterns were observed in DOC (mid summer highs of 40-60 ppm DOC) and total phosphorus (0.5-2 mg/L) with a large portion present as orthophosphate. A survey of invertebrate bioindicators of mercury bioaccumulation in the food web indicated a wide range in concentrations. Highest median MeHg concentrations were observed in water striders, water boatmen, milky backswimmers. An examination of MeHg versus THg results for a subset of samples shows 4% to ~100% of the THg is present in a MeHg form. The top 3 families for MeHg content (Corixidae, Gerridae, Notonectidae) have >90% MeHg likely due to feeding ecology and specific habitat chemistry.

3.07.P-Mo186 Geochemical and Ecological Controls on Mercury Speciation and Bioaccumulation in Coastal Invertebrates
Molly Bradford[1], Mark Mallory[2] and ***Nelson J. O'Driscoll**[3]*, (1)Earth and Environmental Science, Acadia University, Canada, (2)Biology, Acadia University, Canada, (3)Acadia University, Canada*
Estuaries are ecologically sensitive areas that are vulnerable to bioaccumulation of methylmercury (MeHg), a neurotoxin that readily bioaccumulates in ecosystems resulting in negative impacts on organism health. The Minas Basin, Bay of Fundy, is an important stopover site for fish spawning and for foraging birds during migration and determining uptake of MeHg by invertebrates at the base of the coastal food web is essential for determining MeHg exposure in these higher trophic level organisms. Fourteen species of invertebrate were collected from five intertidal sites in the Minas Basin during summer 2021 and analysed for concentrations of MeHg and total mercury (THg), and stable isotopes of $d^{13}C$ and $d^{15}N$. The mean concentration of MeHg of all individuals (12.78 ± 11.23 ng/g dry weight (dw)) was approximately an order of magnitude below the Canadian tissue residue guideline for the protection of wildlife consumers like fish and birds of 157.20 ng/g dw. Trophic position ($d^{15}N$) of all 14 species was strongly positively correlated with bioaccumulation of Hg (THg: $r_{208} = 0.14$, $p = 0.04$ and MeHg: $r_{208} = 0.34$, $p < 0.0001$). Additionally, stable isotopes of sulfur ($d^{34}S$) (measured in tissues of *Corophium volutator*, *Ilyanassa obsoleta*, and *Littorina littorea*) were positively related to MeHg in invertebrates, and when used in combination with $d^{15}N$ values improved predictions of Hg concentrations in biota. Trophic Magnification Factors (TMF) for MeHg and THg (1.59 and 1.21, respectively) were similar to others reported in studies of food webs containing higher trophic level organisms. To assess the effects of environmental geochemistry on MeHg bioavailability to invertebrates, organism MeHg concentrations were compared to sediment THg, %LOI (carbon), and $d^{34}S$, and porewater concentrations of MeHg, TOC, sulfate, and sulfide. MeHg in porewater was the best predictor of invertebrate MeHg, but sediment $d^{34}S$, which can be used as an indicator of sulfate reduction and thus Hg methylation, was also a relatively strong predictor and should be included in studies on Hg bioaccumulation moving forward to improve predictive models. This research provides quantitative data on Hg bioavailability in the Minas Basin which is important for Hg modelling in the region, and can be used to protect both ecosystem and human health.

3.07.P-Mo187 Toxicodynamics of Methylmercury in the Saltmarsh Plant *Halimione portulacoides* in Hydroponic Culture
Carlos Marques[1], Ana Marques[2], Fátima Brandão[3], Joana Pereira[2], Silja Frankenbach[2], Fernando J. M. Gonçalves[2], João Serôdio[2], ***Rute Cesário**[4]*, Joao Canario[5], Mário Pacheco[2] and Patrícia Pereira[2], (1)University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Aveiro, Portugal, (2)University of Aveiro, Aveiro, Portugal, (3)Department of Biology, University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Aveiro, Portugal, (4)IST, Portugal, (5)Instituto Superior Técnico, Portugal*
Halimione portulacoides is a saltmarsh plant with a key role on the mercury (Hg) biogeochemical cycle, namely by accumulating high levels of this metal in its roots. Intriguingly, there is still a poor knowledge on the physiological adaptation mechanisms that allow the plant to deal with such high levels of Hg, including of the highly toxic organic form – methylmercury (MeHg). Disclosing the effects of MeHg on the antioxidant defence system could be particularly relevant on the clarification of that topic.

A long-term experiment was carried out under hydroponic conditions, comprising 1, 7, and 14 days of exposure to waterborne MeHg (1.84 $\mu g\ L^{-1}$). Two different salinities were set (0 and 21 PSU) to explore the interference of this abiotic parameter on MeHg toxicodynamics (biochemical responses related to oxidative stress and photophysiology). Plants were collected in a coastal lagoon (Aveiro Lagoon, Portugal) in summer 2021, namely at a highly contaminated site (Laranjo - LAR) and a reference site (REF), allowing an evaluation of the contamination background interference. Plants were acclimated to the lab for two months before exposure. Leaves and root samples were collected after each exposure time, as well as immediately before exposure (T0) for analysis of antioxidant defences [catalase (CAT), superoxide dismutase (SOD)] and oxidative damage [lipid peroxidation (LPO)], while the photophysiology of the leaves was assessed by pulse-amplitude-modulated (PAM) fluorometry.

Antioxidants displayed variation patterns dependent on the endpoint, but with no clear relation with the plant exposure background. For instance, after 1 day of exposure (at 21 PSU of salinity), CAT activity increased in the leaves of exposed plants both from REF and LAR, while a decrease of SOD was also found after 14 days of exposure (at 0 PSU of salinity) of plants from both sites. Effects of MeHg in the roots seemed to be more prominent when exposure occurred under higher salinity values (21 PSU), as evidenced by an increase of CAT and SOD right after 1 day of exposure, suggesting a fast enhancement of reactive oxygen species. Despite that, no signs of peroxidative damage were detected in any organ, while no photophysiological impairments were recorded in leaves, suggesting that *H. portucaloides* is able tolerate exposure to MeHg. Changes on enzymatic activities were less evident at 7 and 14 days after exposure, corroborating that conclusion on MeHg tolerance by this saltmarsh plant.

3.07.P-Mo188 Application of the Paleolimnological Method to Assess Metal Contamination in Pulp Mill Stabilization Basin Sediments in Coastal Nova Scotia, Canada
***Ian Spooner**[1]*, Kirklyn B. Davidson[2], Baillie Holmes[3], Dewey Dunnington[4], Tony Walker[5] and Craig Lake[6], (1)Earth and Environment, Acadia University, Canada, (2)SGC Industries, St. John, Canada, (3)Stantec Consulting Ltd, Canada, (4)Voltron, Mountain View, California, (5)Dalhousie University, Canada, (6)Dalhousie University, Centre for Water Resources Studies Department of Civil & Resource Engineering, Canada*
The paleolimnological method is well suited to decoupling geogenic and anthropogenic metal(loids) contributions in Boat Harbour, an effluent stabilization basin located in Pictou County, Nova Scotia. Boat Harbour has been impacted by industrial effluents discharged by a bleached kraft pulp mill (1967 to 2019) and a chlor-alkali plant (1971 to 1992). The former estuary now contains >577,000 m^3 of contaminated sediment, impacted by inorganic and organic contaminants, including metal[loid]s and a

variety of persistent organic pollutants. Previous studies indicated that significant knowledge gaps exist in our understanding of the spatial, stratigraphic, and temporal variation of sediment contamination. Comparison of the geochemistry of effluent influenced contaminated sediment and pre-effluent sediment at Boat Harbour to sediment in nearby reference lakes and estuaries was required to understand the degree to which geogenic and atmospheric sources have contributed to metal accumulation in the effluent influenced sediment. A variety of sampling techniques including lakebed sediment gravity and percussion cores were obtained between 2016-2020 to determine spatiotemporal distribution of As, Cu, Pb, and Zn which consistently exceeded guidelines for aquatic sediments. Results demonstrated that there is no distinct spatial trend in metal concentrations though the effluent was introduced from a point source. Temporally variable concentrations of Cu and Zn in the contaminated sediment are associated with effluent from the pulp mill and chlor-alkali plant but also with atmospheric deposition from regional industrial activity. The source of As is dominantly geogenic; As concentration serves as an effective indicator of pre- and posteffluent influenced sediment. Elevated Pb in the contaminated sediment is the result of atmospheric deposition from combustion of fossil fuels as well as bioaccumulation in the pulp mill effluent feedstock. This study demonstrates that undisturbed, time transgressive samples from both impacted sites and reference sites combined with nondestructive, rapid, small sample analytical techniques such as X-ray fluorescence, provide an accurate assessment of sediment metal contaminant sources and distribution, data required to guide remediation and environmental effects monitoring and compliance.

3.07.P-Mo189 *In utero* Maternal Transfer of Heavy Metals in Long-Finned Pilot Whale Mother-Foetus Pairs
Katrin Hoydal[1] *and Halla Weihe Reinert*[2]*, (1)Environment Agency, Argir, Faroe Islands, (2)Faroe Environment Agency, Argir, Faroe Islands*
Long-finned pilot whales from the North Atlantic are highly exposed to heavy metals such as mercury (Hg) and cadmium (Cd). Both Hg and Cd are toxic metals known to cause adverse biological effects, where effects on the nervous system are particularly important, and both liver and kidney can accumulate high levels of both metals leading to damage on these organs. The high metal exposure in pilot whales leads to concern for females transferring the metals to their offspring during pregnancy and lactation, resulting in exposure of the offspring at a vulnerable stage of development, which may lead to subsequent unfavourable effects.

Tissues from pilot whale mother-foetus pairs have been analysed for Hg and Cd to assess the maternal transfer of these metals in pilot whales and their distribution in the body. Muscle samples were analysed for Hg, liver samples for Hg and Cd, and kidney samples for Cd. Muscle and liver samples were also analysed for selenium (Se) because of its involvement in detoxification of Hg (forming HgSe).

The results showed Hg levels in mothers that varied between 1.1 and 2.3 mg/kg ww, whereas the levels in foetuses were between 0.14 and 0.86 mg/kg ww. Hg levels in muscle were found to be between 2 and 12 times as high in mothers than in the foetus (M/F ratios between 1.9 and 11.9), whereas the levels for Hg in liver were between 25 and 325 times higher in the mother than in the foetuses. The Hg concentrations in mothers and foetuses were not correlated in either liver or muscle, but the M/F ratios were negatively correlated with foetus length, reflecting the increased transfer with gestation time. The Hg levels were positively correlated to Se concentrations in liver with higher correlation in mothers than in foetuses.

Cd was not detected in foetus kidney or liver, although the levels in mothers were between 44.7 and 113.2 mg/kg ww, and between 19.4 and 33.4 mg/kg ww in kidney and liver, respectively.

3.07.P-Mo190 Stability of the Macrocyclic Gd-DOTA Contrast Agent (DOTAREM) Under Different Estuarine Environmental Conditions
Ana Guerreiro[1]*, Miguel Caetano*[2] *and* ***Pedro Aboim de Brito***[3]*, (1)Faculdade de Ciências da Universidade de Lisboa, Lisbon, Portugal, (2)University of Porto, Interdisciplinary Centre of Marine and Environmental Research, Portugal, (3)Portuguese Institute of the Sea and Atmosphere, Portugal*
Previous studies have reported gadolinium (Gd) enrichment in rivers and estuaries worldwide due to the Gd-based contrast agents (Gd-CA) used in magnetic resonance imaging (MRI). The Gd-CA use has grown exponentially since the end of the 20th century, and since 2005, the number of MRI scans has increased by 50%, with more scans being performed in countries with highly developed healthcare systems. These compounds have been traced in the aquatic environment for over two decades, but their toxicity, fate, and stability under natural conditions are still poorly understood, compromising the risk assessment of these compounds in the environment, but also on human health. Although the high stability in vitro of the macrocyclic Gd-DOTA complex is recognized, little is known about its stability in the aquatic environment.
Gd-DOTA complex was exposed to different estuarine environmental conditions (temperature, pH, salinity and solar radiation) to assess their stability. Gd-DOTA solutions were processed in a seaFAST-pico saline matrix preconcentration and elimination system and Gd concentrations were determined by ICP-MS (Perkin-Elmer NexION 2000C). Results showed that the complex remained stable in fresh, brackish, and saline water environments, even when exposed to extreme temperatures (40 ºC) or slightly acidic to basic conditions (6-10), for an exposure period of 96 h. However, a small increase in the free Gd concentration was observed after 18 days when exposed to pH <4, in all tested salinities (0, 18 and 36 PSU), with a degradation increase of up to 29%, after 5 weeks of exposure in freshwater. When exposed to direct solar radiation a low Gd-DOTA degradation (4%) was observed after 24 h at salinity 18 PSU, and remained constant until the end of the exposure period (96 h), while the remaining salinities (0 and 36 PSU) showed negligible values.

These results confirm the expected Gd-DOTA complex's high stability under normal environmental conditions even when exposed to high temperatures. Only a slight degradation was observed when exposed to extremely acidic conditions but no degradation was observed for higher pH values. Regarding exposure to solar radiation, although a slight degradation was observed after 24 h, further studies should be carried out in the future, namely, a combination of other parameters, such as the effect of turbidity and depth on the radiation penetration and consequent effect on the complex degradation.

3.07.P-Mo191 Historical Trends of Traditional, Emerging, and Halogenated Polycyclic Aromatic Hydrocarbons in Intertidal Zone from the Yellow Sea Large Marine Ecosystem

Seojoon Yoon[1]*, Seongjin Hong*[2]*, Bong Oh Kwon*[3]*, Jongseong Ryu*[4]*, Jong Seong Khim*[5]*, Wenyou Hu*[6] *and Tieyu Wang*[7]*, (1)Seoul National University of Science and Technology, Korea, Republic of (South), (2)Department of Marine Environmental Science, Chungnam National University, Daejeon, Korea, Republic of (South), (3)Kunsan National University, Korea, Republic of (South), (4)Anyang University, (5)School of Earth and Environmental Sciences & Research Institute of Oceanography, Seoul National University of Science and Technology, Korea, Republic of (South), (6)Chinese Academy of Sciences, China, (7)Shantou University*

Historical trends of traditional polycyclic aromatic hydrocarbons (t-PAHs), emerging-PAHs (e-PAHs), and halogenated-PAHs (Hl-PAHs), including chlorinated-PAHs (Cl-PAHs) and brominated-PAHs (Br-PAHs), were reconstructed to investigate contamination status over the last 80 years. Eleven sediment cores were collected from the intertidal zones of the Yellow Sea Large Marine Ecosystem. The concentrations of all target PAHs were highest in Huludao, Yingkou, Tianjin, and Dandong, which are industrial and urban areas, with a great mass inventory at the Bohai Sea. Historical trends of all target PAHs showed similar increasing trends from the 1950s, reflecting the development history and changes in Korea and China, and high molecular weight (HMW) PAHs have increased faster than low molecular weight PAHs. Positive matrix factorization receptor analysis using all target PAHs showed that the main sources of target PAHs were fossil fuel combustion (35% of total concentration), vehicle emission (33%), and biomass combustion (32%). The contribution of fossil fuel combustion continued to increase in all regions, whereas vehicle emission and biomass combustion varied with region and time. The toxicity equivalency quantity (TEQ) value was highest for t-PAHs (more than 99% of total contribution), followed by Cl-PAHs, Br-PAHs, and e-PAHs at all sites and periods. The concentrations of t-PAHs in the Bohai, Yellow, East China, and South China seas have increased significantly since the 1990s, especially, the concentrations increased more rapidly in the intertidal areas than in subtidal areas. The predominance of HMW t-PAHs and about 83% of the total flux were entering the intertidal zone, suggesting that the intertidal zone is important as a buffer zone for marine pollution. Overall, the present study provides novel information on the contamination history and sources of t-PAHs, e-PAHs, and Hl-PAHs at a large scale, along with insights on future pollution prevention and coastal management.

3.07.P-Mo192 Passive Microporous Polyethylene Tube Samplers as a Novel Approach to Monitor the Occurrence of Organic Contaminants in L´Albufera Natural Park (Valencia, Spain)

Yolanda Soriano Juan[1]*, Rodrigo Alvarez-Ruiz*[1]*, Yolanda Pico*[2]*, Joseph Clokey*[3]*, Sara Ghorbani Gorji*[3] *and Sarit Kaserzon*[4]*, (1)University of Valencia, Spain, (2)Centro de Investigaciones sobre Desertificación, Universidad de Valencia, Moncada, Spain, (3)Queensland Alliance for Environmental Health Sciences (QAEHS), University of Queensland, Australia, (4)University of Queensland, Australia*

Monitoring the presence of pollutants in environmental waters has revealed a large number of emerging contaminants of concern. In surface waters, episodic events such as accidental spills, surface runoff, losses, or deliberate industrial release can be difficult to capture and adequately quantify if water samples are taken at a single point in time that may or may not be representative of the pollutant concentration at the time of sampling. In order to estimate the concentrations of pollutants across a more representative and larger time scale and to be able to accurately assess, passive samplers can provide a complimentary sampling strategy. In the present study, Microporous Polyethylene Tube (MPT) passive samplers were deployed, each containing cylindrical microporous polyethylene tubes with absorbent phases to retain emerging polar pollutants of moderate polarity in 12 sampling points of the L´ Albufera Natural Park (Valencia, Spain). The sampling points differ in their hydrological characteristics and/or source of contamination. Passive samplers were concurrently deployed for durations of both 14 and 28 days and grab samples water were collected at different times to generate complementary data and for comparison (deployment day, 14 and 28 days). MPTs were extracted and analysed in the laboratory in order to quantify a wide variety of emerging contaminants, including pharmaceuticals, pesticides, poly- and perfluoroalkyl substances (PFASs) and phosphorus flame retardants (PFRs) using high performance mass spectrometry (HPLC-MS). In addition, contaminant concentrations were compared across the two different deployment periods (i.e., 14 and 28 days). Comparatively higher concentrations of certain compounds, including 2,4-dimethylphenyl formamide, tebuconazole, prochloraz, etofenprox, and PFOS, were observed. Different contaminants profiles (i.e., PPCPs through WWTPs effluents and pesticides from agricultural runoff reaching the wetlands and channels) were observed. MPT derived water concentrations were comparable to those derived from grab sampling techniques ($p<0.05$, $R^2 >95\%$). Passive samplers proved effective for water sampling by achieving *in situ* concentrations of a range of analytes of concern in the sampled waters.

3.07.P-Mo194 Acute Toxic Effects and Mechanism of Antifouling Paint Particles on Juvenile Rockfish

Seong Hee Mun[1]*, Kwang-Min Choi*[1]*, Dongju Shin*[2,3]*, Youmi Choi*[2,3]*, Moonkoo Kim*[2,3] *and Jee hyun Jung*[2,3]*, (1)Korea Institute of Ocean Science and Technology (KIOST), Korea, Republic of (South), (2)Risk Assessment Research Center, Korea Institute of Ocean Science and Technology, Korea, Republic of (South), (3)Department of Marine Environmental Science, Korea University of Science and Technology, Daejeon, Korea, Republic of (South)*

During hull-cleaning process, the antifouling paint particle produced is often directly discharged into coastal seawater and coastal sediment. Chemical component analysis of hull cleaning wastewater has shown that up to 75% of the biocide present is related to paint particles, which can potentially account for between 6 and 17% of the daily biocide input into a marina. Therefore, antifouling paint particles (APPs) have been spotlighted as a source of metal contamination in coastal sediments, potentially leaching large amounts of copper and zinc into costal aquatic environments. However, there have been few studies assessing the toxic effects of more complex antifouling system mixtures (such as combinations of heavy metals and biocides) on fishery resources. In the study, we evaluate the toxic effects of antifouling paint particles on juvenile rockfish (*Sebastes schlegelii*) which is one of major fishery resources. Paint particle was sampled from dry dock hull cleaning wastewater and 10-, 100-, and 1000-fold dilutions were exposed for 7 days. Zinc was identified to be the major contaminant with the highest concentration in the wastewater. No lethal toxicity was observed during the acute toxic experiment (7 days) in control and exposure groups. GST (glutathione-S-transferase) and SOD (superoxide dismutase) tended to increases at high concentrations. Hepatic ROS (reactive oxygen species) and brain AChE (acetylcholinesterase) activities was increase after exposure to antifouling paint particles. The gene of metallothionine was highly expressed in fish exposed to the paint particle. Some of immune-related genes including the *G-CSF* (granulocyte colony-stimulating factor), *ISG15* (Interferon-stimulated gene 15), *GST,* and *NF-kB* (nuclear factor Kappa-B) were also increased in fish exposed to antifouling paint particles at 24 h than those of the control group fish. Transcriptome analysis in the brain and liver revealed that the genes associated with metabolism, signaling interaction, and the immune system were significantly variated. Moreover, genes encoding proteins, such as vitellogenin and neuropeptide, were among the top-most differentially expressed genes. These results demonstrate the need for proper management to antifouling paint particles contamination in coastal environment.

3.07.P-Mo195 Environmental Fate Modelling of Organic Pollutants From Land-Based and Shipping Emissions (Including Scrubber Water) in the Northern Adriatic Sea Coastal Areas

*Loris Calgaro[1], Elisa Giubilato[1], Manuel Aghito[2], Jukka-Pekka Jalkanen[3], Christian Ferrarin[4], **Elena Semenzin**[1] and Antonio Marcomini[1], (1)University Ca' Foscari of Venice, Italy, (2)Norwegian Meteorological Institute, Norway, (3)Finnish Meteorological Institute, Helsinki, Finland, (4)CNR-ISMAR, Italy*

Transitional, coastal, and marine ecosystems are highly complex and linked systems, subjected to a multitude of different anthropogenic stressors, both from land-based sources (e.g., industrial and agricultural activities) and direct discharges (e.g., shipping emissions). Recently, the adoption of the global limits on sulfur content for marine fuels is causing a drastic increase in the use of shipping emission abatement technologies like exhaust gas cleaning system (scrubbers) as an alternative to the use of cleaner but more expensive fuel types, whose acidic exhaust discharge water contain diverse chemical contaminants. For these reasons, the presence of shipping lanes and ports may significantly contribute to the exposure of chemical pollutants in coastal areas, potentially increasing risks posed to aquatic ecosystems and human health.

Fate and transport modelling offers an effective way to estimate the contribution of shipping emissions to the overall exposure to chemicals in transitional, coastal, and marine waters.

In this work an exposure assessment for benzo(*a*)pyrene and fluoranthene accounting for both land-based sources and shipping emissions was carried out for the Northern Adriatic Sea. The modelling effort, realized within the H2020 “EMERGE” project, focused on the integration of several high-resolution predictive models to help exploring the implications of different abatement emissions techniques in managing environmental risks under current and future scenarios.

In detail, shipping-related emissions of pollutants were simulated with the STEAM (Ship Traffic Emission Assessment Model) model, based on Automatic Identification System data, while land-based emissions were quantified by combining daily river flow measurements with water concentrations from routinely monitoring of each tributary. The newly developed ChemicalDrift model, a chemical transport module part of the open-source Lagrangian framework OpenDrift, was applied for a baseline scenario using 2018 data. Forcing data for the case study area have been obtained from the SHYFEM model (ocean currents, temperature, and salinity) and Copernicus Marine Services (mixed layer depth and winds).

Preliminary results showed that shipping emissions can contribute significantly to the exposure to the selected contaminants, especially during the summer period when water flow from the tributaries reaches its minimum values and the number of cruise ships equipped with open-loop scrubbers increases.

3.07.P-Mo196 A Probabilistic Screening Ecological Risk Assessment of Pharmaceuticals and Plant Protection Products in the Venice Lagoon

***Martina Cecchetto**, Elisa Giubilato, Elena Semenzin, Loris Calgaro, Marco Picone, Annamaria Volpi Ghirardini and Antonio Marcomini, University Ca' Foscari of Venice, Italy*

Understanding the occurrence and behaviour of emerging contaminants in coastal areas is paramount to complement the knowledge on “traditional” and regulated pollutants and to achieve a comprehensive evaluation of environmental quality status. Since the risk posed by these substances in the Venice Lagoon has been poorly investigated, a predictive assessment can shape the development of future water monitoring plans.

For this purpose, a screening ecological risk assessment was performed to identify emerging contaminants that either are expected to pose a significant risk or need to be further investigated due to the uncertainty in the available data. Focusing on two classes of emerging contaminants, i.e., plant protection products and active pharmaceutical ingredients, exposure and effects information was deterministically and stochastically combined to screen ecological risks into categories.

Simulation of the environmental distribution and fate of target chemicals in the Venice Lagoon was achieved through the development of a water emission inventory based on sales data in combination with demographic and economic statistics of the lagoon watershed, followed by the application and evaluation of a multimedia level III fugacity model that considers the processes involved in contaminants' natural attenuation. The so-derived Predicted Effect Concentrations (PECs) were then compared with effect thresholds (Predicted No Effect Concentration, PNEC) estimated from existing ecotoxicological data on acute and chronic effects for marine and estuarine organisms, and from additional ecotoxicity tests assessing larval development and reproduction of the copepod *A. tonsa* and larval development of the bivalve *M. galloprovincialis*.

If the ratio between PECs and PNECs supported a preliminary classification of chemicals based on their level of risk (i.e., *low*, *medium,* or *high*), it was with a probabilistic assessment that risk could be better characterized. By considering PEC and PNEC stochastically distributed, a Monte Carlo simulation allowed to incorporate model and data uncertainty into the calculation of a probability of risk for contaminants associated with a "medium risk" according to the deterministic assessment.

This approach could differentiate chemicals that, based on the estimated risk, should be included in future monitoring plans from those contaminants with great data uncertainty for which new ecotoxicity tests on marine and estuarine species are recommended.

3.07.P-Mo197 Pollutants in Sediment Cores from Lake of the L'Albufera Natural Park

Yolanda Soriano Juan[1]*, Yolanda Pico*[2]*, Vicente Andreu Andreu*[3] *and Eugenia Gimeno Garcia*[4]*, (1)University of Valencia, Spain, (2)Centro de Investigaciones sobre Desertificación, Universidad de Valencia, Moncada, Spain, (3)CIDE (CSIC UV GV), Spain, (4)Desertification Research Centre*

Sediments are excellent archives for studying the long-term variations of pollutants in the environment. For this reason, records derived from the chemical analysis of sediment cores are useful to trace the history of pollutant emissions. This study aimed to assess the vertical variation of organic contaminants and metals in sediment cores collected in two sites of the lake of L´Albufera Natural Park (Valencia) to obtain information regarding historical variation in the composition of sediments. A sediment core sampler (57 mm inner diameter, 1.00 m length; Beeker, Eijelkamp) was used to extract the cores from the lake of L'Albufera. The cores were sampled from boat. The sediment cores were 80–87 cm in length and 5 cm in diameter. The tubes were kept upright in a bucket with ice until they arrived at the laboratory where they were frozen. Once frozen, the tubes were cut into 8 segments of the same thickness (8 slices of 10 cm) using a stainless-steel cutter. Pharmaceuticals, pesticides, poly- and perfluoroalkyl substances (PFASs) were analysed using Orbitrap. The compounds were extracted by different extraction methods and determined both, using wide target screening against a positive list of compounds and non-target screening applying ddMS2 of the 4 more intense ions in each cycle as well as all ions fragmentation. Both positive and negative ionization were used. Also, 24 heavy metals were quantified using ICP-MS, after the appropriate wet digestion extraction procedures. Several organic pollutants, especially pesticides such as Azoxystrobin, Molinate, Tebuconazole, were detected in the sediment in contact with water. Some infiltration of the compounds in the inner layers of sediments were also detected. Regarding heavy metals, their higher concentrations in the more recent sediments reflect increased agricultural and industrial activities. This is supported by the fact that there is an increase in the relative bioavailability of metals as indicated by the values of the total extractable-total ratio when compared to deeper sediments. Superficial sediments provide information on the actual deposited material and the actual status of pollution, but the study of sediment profiles provides information on the historical variation in the composition of sediments settled. These sediments can also be used to examine pollution mechanisms, which are significant for predicting future pollution tendencies and assessing potential environmental risks.

3.07.P-Mo198 Assessing Potential Environmental Impacts of Exhaust Gas Cleaning System (EGCS) Discharges from Cruise Line Vessels

William A. Stubblefield[1]*, Valerie Chatterley*[2]*, Michelle C Knowlen*[3]*, Joy A. Mcgrath*[4]*, Mary Ann Rempel-Hester*[3]*, Dayang Wang*[5] *and Jay Word*[3]*, (1)Oregon State University, (2)Venveco, Seattle, WA, (3)EcoAnalysts, Inc., Port Gamble, (4)Joy McGrath Consulting, (5)Exponent Inc.*

Emissions from the combustion of high sulfur heavy fuel oil (HFO) have been suggested to increase risks to human health and the environment. Beginning in 2020, the International Maritime Organization International Convention for the Prevention of Pollution from Ships (MARPOL) required vessels to comply with new sulfur air emission standards by: 1) using a very low sulfur fuel oil (VLSFO) or 0.1% sulfur marine gas oil (MGO), or 2) installing an "appropriate exhaust alternative method". To comply with the new standards, most cruise ship operators installed Exhaust Gas Cleaning Systems (EGCS) on their vessels. The EGCS removes 98 percent of sulfur oxides from exhaust air emissions, as well as many pyrogenic and petrogenic PAHs and metals, by spraying ambient seawater into the engine exhaust prior to vessel release. EGCS can be operated in a "closed-loop, i.e., minimal overboard discharge, "open loop", discharging EGCS washwater "buffered" with ambient seawater, or hybrid configuration that can be operated in open- or closed-loop mode. The goal of this study was to evaluate potential environmental risks associated with the operation of open-loop EGCS. A combination of analytical determinations (PAHs and metals), modeling of washwater toxicity and postdischarge environmental concentrations, and validation of model predictions using Whole Effluent Toxicity (WET) bioassay methods were employed. Differences in exhaust gas composition have been attributed to engine load, characteristics of the fuel used, and engine differences (e.g., engine make, size, etc.). Possible differences attributable to fuel type were controlled by limiting the study vessels to a single HFO source with a sulfur content of 2.0-3.5%. Engine energy demand could directly affect fuel consumption and washwater composition. Two engine loads were evaluated in this study, low load ($\leq$ 50%, represents "in port operations") and high load ($\geq$70% represents normal transit operations). A representative set of samples were collected from six ships operated under low and high engine loads. Environmental samples were collected from the seawater intake, EGCS waters, and overboard discharge for each scenario. Analytical determinations (PAH and metals) were conducted on all samples. Additionally, WET testing was performed for each overboard discharge sample to determine potential toxicity to the organisms in the receiving waters. Results of all determinations will be discussed.

3.07.P-Mo199 The Effects of Pyridine on the Activity Behaviour of the Common Shore Crab, *Carcinus maenus*

Elea Giraud *and Alex Ford, University of Portsmouth, United Kingdom*

Pyridine is a by-product of several industrial processes and traditionally extracted from coal tar. In November 2021 a mass stranding of dead, twitching, and moribund crustaceans including edible crabs and lobsters were observed off the northeast coast of England leading to speculation that pyridine released from dredging was the causal agent. This led to campaign groups asking for a cessation of dredging activity in the river Tees until the matter had been resolved. To determine the effects of pyridine on juvenile common shore crabs (*Carcinus maenus*) we conducted a four-day and static renewal exposure experiment with concentrations 1, 10, 100, and 1000µg/L concentrations. The mortality was recorded and behaviour measured using a Zantiks LT machine after 2 hours, 24 hours, 48 hours, 72 hours ,and 96 hours. Concentrations were chosen as below those reported to be lethal but represent some environmentally relevant concentrations recorded in the area over the past decade. Specimens and water were frozen for chemical analysis. Preliminary results have demonstrated that at these concentrations no mortality was recorded following four-day exposure. While the study is currently ongoing, the results will provide a better understanding of the effect of pyridine on marine crustaceans and possibly provide insights on whether pyridine dredged from the coastal sediments could have caused the mass extinction of crabs observed in the Northeast of the UK.

3.07.P-Mo201 Plastic Pollution in A Coral Reef Climate Change Refuge

Gal Vered[1,2] *and Noa Shenkar*[3,4]*, (1)Interuniversity Institute for Marine Sciences (IUI), Israel, (2)Life Sciences, School of Zoology, Israel, (3)School of Zoology, George S. Wise Faculty of Life Sciences, Tel Aviv University, Israel, (4)Tel Aviv University, Israel*

The Gulf of Aqaba in the northern Red Sea is considered a coral reef refuge from climate change for the coming decades. However, data regarding the magnitude and impacts of plastic pollution on the coral reefs of the Red Sea are greatly lacking. In the present study, we have: (1) quantified and characterized benthic plastic debris, and microplastic (plastic particles < 5 mm), and tested for the prevalence of plastic-associated chemicals among corals, seawater, and sediment; and (2) tested the effects of plastic-associated chemicals on the reproductive products of common coral-reef invertebrates. For this analysis, we used one environmental concentration and one high laboratory concentration of each compound; dibutyl phthalate (DBP), dimethyl phthalate, (DMP), 4-nonylphenol (4-NP), and bisphenol A (BPA).

Our results conclude that compared to coral reefs in other parts of the world, the Red Sea is less polluted by plastic, with 0.093 ± 0.091 item/m^2 of benthic debris, and 0.55 ± 0.34 microplastic/m^3 sampled from the reef surrounding seawater. Other than the negative effect of 4-NP on the settlement of *Rhytisma fulvum* planulae, we found limited effects testing the environmental concentrations. The high 4-NP laboratory concentration (1000 µg/L) treatment had adverse effects on the soft coral *Rhytisma fulvum*, the stony coral *Stylophora pistillata*, the calcifying hydrozoan *Millepora dichotoma*, and the solitary ascidian *Herdmania momus*. BPA at 1000 µg/L had a significant negative effect on the fertilization of the gametes of the solitary ascidian *Herdmania momus*.

The current study substantially extends the current knowledge base regarding the magnitude and impact of plastic pollution in the Gulf of Aqaba. This research provides a scientific base for effective preservation policies and local management strategies aimed at battling plastic pollution and making the reefs of the northern Red Sea a coral refuge protected from both global and local anthropogenic stressors.

3.07.P-Mo202 Microplastics in Sediment Samples from the San Francisco Bay Area

Lara Dronjak[1]*, Joaquim Rovira*[2]*, Jordi Sierra*[3]*, Diana Lin*[4]*, June-Soo Park*[5] *and Marta Schuhmacher*[6]*, (1)SEKAI CORPORATE TRAVEL S.L.U, Spain, (2)Departament Enginyeria Química, Universitat Rovira i Virgili, Spain, (3)Enginyeria Química, Universitat Rovira i Virgili, Spain, (4)San Francisco Estuary Institute, (5)California Environmental Protection Agency, (6)Chemical Engineering, Universitat Rovira i Virgili, Spain*

San Francisco Bay Area's sediment is currently monitored for a variety of contaminants; however, data regarding microplastics (MPs) are still scarce. Sediment is expected to be a suitable matrix for monitoring MPs levels trends since it is a likely sink for most of the MPs, regardless of their pathway to the Bay. Even buoyant MPs will eventually sink due to biofouling and adsorption of organic and inorganic materials. Moreover, Bay sediment is also an important matrix for monitoring because sediment may be a source of MPs to the Bay food web. This study analyzed MPs (25 µm to 5 mm) in surface sediment samples (n = 8) and sediment core samples (n = 11). Findings provide a preliminary evaluation of MP levels from different regions of the Bay, as well as an indication of temporal trends. Samples preparation included treatment using advanced Fenton's oxidation, and alkaline digestion, followed by enzymatic digestion and density separation ($ZnCl_2$, 1.9 g/mL) in order to remove organic and inorganic matter, respectively. The subsample was subjected to final spectroscopic (µFTIR and RAMAN) confirmation. MPs levels detected along the Bay area ranged from 2.20 MPs/g $_{d.w.}$ to 12.02 MPs/g $_{d.w.}$, with a mean value of 6.38 MPs/g $_{d.w.}$. The most abundant morphology is fibers (66.5%) followed by fragments (22.5%) and films (11%). The sample with the highest MP level was found in the Lower South Bay area, which is expected due to the heavy influence of wastewater treatment plant discharge and urban runoff. The lowest MP level was measured in the North Bay Area. Due to the high heterogeneity in MP levels observed, additional sampling and analysis are necessary to provide clear indications of geographic and temporal trends.

3.07.P-Mo203 Chemical Toxicity of Robotic Hull In-Water Cleaning Wastewater on Embryonic Flounder

Dongju Shin[1,2], *Youmi Choi*[1,3], *Moonkoo Kim*[1,3], *Min-Chul Jang*[4], *Jin-Young Seo*[4], *Jung-Hoon Kang*[1,3], *Kyungsoon Shin*[4] *and Jee hyun Jung*[1,3], *(1)Department of Marine Environmental Science, Korea University of Science and Technology, Daejeon, Korea, Republic of (South), (2)Risk Assessment Research Center, Korea Institute of Ocean Science and Technology (KIOST), Korea, Republic of (South), (3)Risk Assessment Research Center, Korea Institute of Ocean Science and Technology, Korea, Republic of (South), (4)Ballast Water Research Center, Korea Institute of Ocean Science and Technology, Korea, Republic of (South)*

In-water cleaning (IWC) involves the removal of biofilms and foulants from the hull of a ship using brushes or water jets. Several factors determine the potential for environmental harm associated with the release of chemical contaminants into the marine environment during IWC, which can create "hotspots" of contamination in coastal areas. To elucidate the potential toxic effects of IWC discharge, we investigated developmental toxicity in flounder embryos, which are sensitive to chemical contamination. Zinc and copper were the dominant metals, while copper pyrithione was the most abundant biocide associated with IWC discharge in two remotely operated IWC. Discharge from IWC carried by both remotely operated vehicles (ROVs) produced developmental malformations, including pericardial edema, spinal curvature, and tail-fin defects. We also analyzed the transcriptomic analysis to verify the potential effects of ROVs cleaning wastewater by Next-generation sequencing. The differentially expressed genes (DEGs) were identified in embryos exposed to cleaning wastewater from ROVs which is analyzed GO enrichment and gene regulatory analysis. In the network, *TTN, MYOM1, CASP3*, and *CDH2* genes appeared to be key regulators of the toxic effects on muscle development. In embryos exposed to ROV B discharge, *HSPG2, VEGFA,* and *TNF* genes related to the nervous system pathway were affected. These results shed light on the potential impacts of muscle and nervous system development in nontarget coastal organisms exposed to contaminants found in IWC discharge.

3.07.P-Mo204 Experimental Design and Evaluation of an Artificial Bioreef Colonized with *Ostrea edulis* in the Catalan Coast

Jordi Sierra[1], *Nora Exposito Lorenzo*[2], *Joaquim Rovira*[3], *Ignasi Gairin*[4], *Roberta Carafa*[5], *Marta Schuhmacher*[2], *Gabriel Quiroga*[6], *Joaquim Roca*[7], *Jaume Folch*[8] *and Patricia Prado*[9], *(1)University of Barcelona, Spain, (2)Chemical Engineering, Universitat Rovira i Virgili, Spain, (3)Departament Enginyeria Química, Universitat Rovira i Virgili, Spain, (4)IRTA La Ràpita, Spain, (5)AECOM, Spain, (6)Tarraco Diving Center, Tarragona, Spain, (7)Stone. Tecnologia per al foment per a la vida marina, Valls, Spain, (8)Universitat Rovira i Virgili, Spain, (9)IIRTA La Ràpita, Spain*

According to FAO, an artificial reef is a submerged structure deliberately placed on the seabed to mimic some functions of a natural reef, such as protecting, regenerating, concentrating, and/or enhancing populations of living marine resources. The objective of this study was to evaluate the colonization of different materials used to construct an artificial biotope. These reefs were built with a concrete base and different complementary materials were added, such as calcium carbonate, *Posidonia* remains, straw, crushed oyster, coconut fibers, rice husks, among other materials. Subsequently, native *Ostrea edulis* larvae and adults were fixed on them in order to create an artificial bio-reef capable of filtering and cleaning the polluted waters of the coast of Tarragona (Catalonia, NE Spain), impacted by urban and industrialized activities as the most important petrochemical pole of the Mediterranean. The colonization of the materials was evaluated by analysing the photosynthetic efficiency (micro-PAM) of the biofilms attached on it and species diversity. Number of individuals attached on and accumulation in fresh tissues of different pollutants such as metals and microplastics evaluated the capacity of filtering and cleaning water by oyster. Results indicate that materials were rapidly colonized by microalgae species up to 8150 organisms/cm^2 (*Licmophora sp, Thalassionema sp, Cylindrotheca closterium, Grammatophora sp, Pleurosigma sp, Amphora sp, Nitzschia longissima, Cocconeis sp , Navicula sp,* and *Oscillatoria sp.*) and oyster larvae, which these last are not intended for human consumption. The oysters were able to bioconcentrate As, Cd, Hg, Cu, Zn and P, up to 10- to 100-fold with respect to sediments concentration. Oysters also accumulated significant amounts of microplastic particles spanning from 5 to 500 µm size.

3.07.P-Mo205 Ecological Effect Assessment of Microalgae by Suspended Sediment: A Study Using Flow Cytometry

Shinyeong Park[1], *Inha Kwon*[2], *Junghyun Lee*[2], *Changkeun Lee*[2], *Seongjin Hong*[3], *Bong-Oh Kwon*[4] *and Jong Seong Khim*[2], *(1)Seoul National University of Science and Technology, Korea, Republic of (South), (2)School of Earth and Environmental Sciences & Research Institute of Oceanography, Seoul National University of Science and Technology, Korea, Republic of (South), (3)Department of Marine Environmental Science, Chungnam National University, Daejeon, Korea, Republic of (South), (4)Kunsan National University, Korea, Republic of (South)*

As the demand for marine sand mining increases, it is known that suspended sediment caused by marine sand mining has an adverse effect on marine organisms. However, it is focused only on research for fish or invertebrates with high fisheries value, and studies evaluating the effect on microalgae, the primary producers in marine ecosystems, are unknown. In this study, the effect on cell viability of *Phaeodactylum tricornutum*, *Dunaliella tertiolecta*, and *Isochrysis galbana* are representative diatoms, green algae, and haptophytes, caused by suspended sediment was evaluated using flow cytometry. Growth inhibition, a general endpoint, increased as the suspended sediment concentration in all three species increased. The effective concentration of 50% (EC50), the suspended sediment concentration at which 50% of *P. tricornutum*, *D. tertiolecta*, and *I. galbana* showed growth inhibition, was 12 367, 7666, and 10 719 mg/L, respectively. It was found that *D. tertiolecta*, green algae, was most affected by growth inhibition by suspended sediment. Among the several endpoints of cell viability, chlorophyll-*a* appeared to be more sensitive, followed by esterase activity, cell size, and intracellular complexity. As the concentration of suspended sediment increased, it did not appear to affect cell membrane integrity, which can be presumed to lead to death before being affected by cell size and membrane damage. Exposure to suspended sediment in the marine environment can lead to changes in the overall structure of the marine ecosystem due to a decrease in food sources to the upper trophic level. These could be used as basic data for estimating the criteria of suspended sediment in the marine ecosystem according to marine sand mining.

3.07.P-Mo206 Acute Behavioral Changes in Marine Fishes by Exposure to Pile Driving Noise: Indoor Microcosm Study
***Beomgi Kim**, Gayoung Jin, Junghyun Lee, Changkeun Lee and Jong Seong Khim, School of Earth and Environmental Sciences & Research Institute of Oceanography, Seoul National University of Science and Technology, Korea, Republic of (South)*
Underwater noise from anthropogenic activities including pile driving noise during the construction of offshore wind farms has increased in recent decades. Pile driving noise is known to affect the behavior of fish, yet it is limited to some fish species. Here, we investigated changes in behavioral parameters (swimming speed and avoidance distance) of juvenile Japanese sea bass (*Lateolabrax japonicus*), Black sea bream (*Acanthopagrus schlegelii*), and Starry flounder (*Platichthys stellatus*) during the start and end period of pile driving noise exposure. After noise exposure, the swimming speed of sea bass and sea bream showed a negatively significant relationship with sound pressure level (r = -0.71, p < 0.01; r = -0.32, p < 0.05, respectively). Of note, only the sea bass avoided the noise source and avoidance distance was significantly positively correlated with sound pressure level (r = 0.70, p < 0.01). Until the end of noise exposure, some fish seemed to habituate to the noise during short-term exposure (1 h). Only the flounder did not show significant changes in both swimming speed and avoidance distance, during the entire experimental period. We verified that hearing sensitivity would be attributed to the presence or absence of a swim bladder, which is closely related to the perception of sound, in accordance with previous studies. Also, the minimum effect threshold of pile driving noise on the behavioral changes of juvenile sea bass and sea bream was confirmed (≥ 143.1 dB re 1 μPa). In further study, other basic data such as physiological parameters (e.g., oxygen consumption rate) for future marine environmental impact assessment will need to be built.

3.07.P-Mo207 Environmental Risk Assessment – Concept and First Results of the Marine Corophium-Toximeter – Detecting Behaviour of the Marine Amphipod Corophium volutator
***Carolin Floeter**[1], Christina Dannenberg[1], Kimberly Dobritz[1], Florian Schulz[2] and Michael Lechelt[3], (1)Environmental Engineering, Hamburg University of Applied Sciences (HAW), Germany, (2)bbe Moldaenke GmbH, Germany, (3)Institute for Hygiene and Environment, Germany*
The detection, environmental risk assessment, and risk mitigation measures against pollution in coastal and marine areas is due to climate change of great importance for the achievement of the UN Sustainable Development Goals 6 and 14 and also in the context of the implementation of EU strategies, such as the Zero Pollution Target for a Toxic-free Environment and the Marine Strategy Directive.

The aim of the study is to develop a sensitive, ecosystem-relevant test system that can be used as a static system in environmental risk assessment as part of the approval of, e.g. ,veterinary medicinal products in aquaculture and as a continuous monitoring system (early warning system) for coastal and marine waters.

Thus, the commercially available Daphnia-Toximeter (bbe Moldaenke GmbH), which is used for freshwater monitoring with the water flea *Daphnia magna*, is further developed in the present study for estuarine and seawater with the amphipod *Corophium volutator*. The sediment-dwelling *Corophium volutator* is of great ecological importance for the Wadden Sea of the North Sea, occurs also in the Baltic Sea and in estuaries. *Corophium volutator* is used in the standardised acute toxicity test (ISO EN DIN 16712) with the parameter mortality so far. Several studies and review articles have shown that the parameter behaviour in bioassays can be much more sensitive than the parameter mortality. Changes in natural behaviour can have direct or indirect ecological relevance, affecting individual fitness and impairing population dynamics, ecosystem functioning or community structures. A 3D living tube model was developed for the "Corophium-Toximeter", which imitates sediments and their U-shaped living tube. At the current stage of development, artificial seawater as sample water continuously passes through two measuring chambers connected in parallel, each with three crustaceans. The live images recorded with a CCD (couple-charged device) camera are analysed online with an integrated PC with regard to changes in the behaviour of Corophium. The method of image analysis enables a series of measurement procedures and plausibility tests to assess Corophium behaviour based on various criteria, such as average speed, swimming height, position and fractal dimension (curvature). The "Corophium-Toximeter" is still under development; first results with artificial seawater as negative control and a reference substance are shown.

3.07.V Coastal Ecosystems are Critical Areas for the Assessment of Pollutant Exposure

3.07.V-01 Plastic Pollution Ingestion by Coastal-Nesting Seabirds in the Canadian Arctic
***Julia Baak**[1], Jennifer F. Provencher[2], Mark Mallory[3] and Kyle Elliott[1], (1)McGill University, Canada, (2)Environment and Climate Change Canada, Canada, (3)Biology, Acadia University, Canada*
Plastic pollution ingestion by seabirds is an increasing issue worldwide, yet different species can vary in ingestion based on various ecological and morphological differences. This provokes the ecological question of which species are better suited for monitoring plastic pollution ingestion across regions and time. In the Canadian Arctic, we examined plastic ingestion in sympatric northern fulmars (*Fulmarus glacialis*), black-legged kittiwakes (*Rissa tridactyla*), thick-billed murres (*Uria lomvia*), and black guillemots (*Cepphus grylle*). These seabird species forage in different parts of the marine environment around the colonies. Here, we present new data and compare to historical work to better inform plastic pollution monitoring in Canada and across the Arctic. In 2021, 51% of fulmars contained plastic, whereas 7% of kittiwakes contained plastic and both murres and guillemots had none. These results are similar to previous years, where surface-feeding species (fulmars and kittiwakes) contained more plastic than

pursuit-diving species (murres and guillemots). Northern fulmars continue to have significantly higher levels of plastic ingestion than other Arctic-breeding species, emphasizing their utility as a monitoring tool for plastic pollution in the Canadian Arctic.

3.08.A Current State-of-the Art in Understanding the Occurrence and Implications of Plastics in Terrestrial Environments

3.08.A.T-01 Validation of Microplastic Accumulation in Agricultural Fields Receiving Sludge from Wastewater Treatment Plants

***Nanna Dyg Rathje Klemmensen**, Rupa Chand and Jes Vollertsen, Aalborg University, Denmark*

Microplastic is known to accumulate in wastewater treatment sludge in large quantities. The microplastic enters the wastewater treatment plants from urban and household drainage and is concentrated in the sludge during the treatment. Many countries use sludge as a fertilizer, creating a possible pathway for microplastic accumulation in the soil. The extent of this accumulation is, however, still largely unknown.

This study aims to investigate the occurrence of microplastic in the size range of 5000 to 10 µm in fields treated with sewage sludge, to increase the knowledge on microplastic accumulation in such fields and to increase the knowledge on the spatial variation in these fields. In addition, other fields not treated with sludge and samples from nature reserves were analysed and used as baseline.

Samples were collected from a long-term agriculture test fields close to Copenhagen, Denmark. A total of 34 samples were taken from 7 different fields, where 30 samples were collected from three sludge-treated fields. In addition, six samples were taken from other agricultural fields in Denmark which were not treated with sludge, alongside three from Natura 2000 areas.

Approximately 285 g of soil was treated for each sample to extract microplastics. A series of physical and chemical treatments were applied to extract the microplastic from the inorganic and organic matter. Such steps include oxidative treatment, density separation, and enzymatic treatment. The extracted microplastics were analysed using µ-FTIR imaging for particles <500 µm, whereafter the software siMPle was used to analyse the dataset to identify and quantify the microplastics.

Microplastics were observed in all 43 samples, regardless of the origin. The observed concentrations for the sludge-treated samples were, however, higher than other samples, with averages of 12883 ± 9153, 1463 ± 843 and 1431 ± 516 counts per kg dry soil for sludge-treated fields, nonsludge-treated fields, and Natura 2000 samples, respectively. A high standard deviation was seen for all samples, indicating that microplastic is not easily homogenized when entering the terrestrial environment. This also amplifies the importance of sampling strategy, especially if the sampling is done for monitoring purposes.

3.08.A.T-02 Investigating the Co-Occurrence of Macroplastics, Microplastics, and Plasticisers in UK Soils

***Alex Billings**[1], Kevin C. Jones[2], M. Gloria Pereira[1] and David J. Spurgeon[1], (1)UK Centre for Ecology & Hydrology (UKCEH), United Kingdom, (2)Lancaster University, United Kingdom*

The risk posed by plastic waste to terrestrial organisms depends in part on the plastic additives which are released from the polymer matrix during the lifetime of a plastic. Plasticisers are a widely used class of plastic additive. Concerns have been raised in recent years over the endocrine-disrupting potential of some legacy plasticisers (phthalates) which has led to an increase in the use of nonphthalate alternatives (emerging plasticisers). However, there remains a lack of empirical data concerning the relationship between plasticisers and macro- and microplastics in soils.

We conducted a field study with the aim of assessing the co-occurrence and potential sources of macroplastics, microplastics, and legacy and emerging plasticisers in UK soils. Surface plastics (macroplastics) and microplastics (25-567 µm) were characterised and quantified using ATR-FTIR and µ-FTIR spectroscopies. GC-MS was used to quantify 8 phthalate and 3 emerging (adipate, citrate, trimellitate) plasticisers.

Sites adjacent to landfill and urban roadsides exhibited the highest concentrations of contaminants. Polyethene (PE) and polypropene (PP) were the most commonly detected surface plastic polymers (both 47% detection frequency, DF). PE was also the most commonly detected polymer in the microplastic fraction (21% DF), although PP had the greatest mean concentration of all microplastics (7.0 ± 17.2 particles g^{-1} dw). Total mean plasticiser concentrations in urban roadside, landfill, and urban parkland sites were 29.9, 2.5, and 1.4 times greater than in woodland sites. Diethylhexyl phthalate was the most abundant plasticiser (mean concentration 390.0 ng g^{-1} ww, 63.2% DF). The most commonly detected plasticisers were di-n-butyl phthalate (mean concentration 15.4 ng g^{-1} ww, 94.7% DF) and the emerging plasticiser trioctyl trimellitate (13.5 ng g^{-1} ww, 89.5% DF).

Based on the data from this field study, phthalates remain the dominant plasticisers in soils, although emerging plasticisers were detected across all land uses and in comparable concentrations to phthalates. These findings raise questions regarding the accumulation of emerging plasticisers in soils as society shifts away from phthalates. This study represents the first investigation of macroplastics, microplastics, and legacy and emerging plasticisers co-occurrence in field soils.

3.08.A.T-03 Microplastic Interaction with Soil Water - Visualization and Quantification with Dual Neutron and X-Ray Imaging

***Andreas Cramer**[1], Pascal Benard[2], Mohsen Zarebanadkouki[3], Anders Kaestner[4] and Andrea Carminati[2], (1)D-USYS, ETH Zürich, Zürich, Switzerland, (2)Usys, ETH Zürich, Zürich, Switzerland, (3)Life Science, Technical University of Munich (TUM), Germany, (4)Lns, PSI, Instrument Scientist ICON, Villingen, Switzerland*
Soil is considered the largest sink of microplastic in terrestrial ecosystemsthough little is known on implications of microplastic for soil. Since microplastic is initially hydrophobic, crucial for its fate in soils is the interaction between microplastic and water. If microplastic is translocated by water flow and, vice versa, microplastic impacts water flow - to what extent? This is also important for evaluating the degradation of microplastic, as water is needed for colonization by microorganisms. To approach this question, simultaneous imaging of microplastic and water in soils was utilized.

Dual neutron and X-ray imaging at the beamlines ICON and NEUTRA (Paul-Scherrer-Institute) during wetting-drying cycles was applied to trace microplastic-water interactions in aluminum containers filled with sand and microplastic. Simultaneous neutron and X-ray tomography was utilized to capture the initial microplastic configuration in samples. Subsequently, neutron radiographies of deuterated water flow through the sample were recorded. After drying, repeated tomography gave insight into microplastic translocation.
Imaging results showed that regions of major microplastic content are water repellent. Water flow bypasses and microplastic is mainly retained. Resultant air entrapments lead to reduced water contents. In regions of minor microplastic content water can infiltrate. Here, the air-water interface collects isolated microplastic and shifts their distribution towards an enhanced aggregation. Extrapolation of these results to natural soil systems suggests that less water at regions of high microplastic content might limit their degradation due to reductions in hydrolysis, coating, and colonization by microorganisms.

3.08.A.T-04 Effects of Particle Size and Surface Charge Density on the Transport of Nanoplastic Particles Through Porous Media Under Unsaturated Conditions
***Cynthia Rieckhof Rivas**[1], Virtudes Martínez Hernández[1], Raffaella Meffe[1], Ekkehard Holzbecher[2], Raúl Alonso del Águila[3], Leonor Nozal[1], Andreu Rico[4] and Irene de Bustamante[1], (1)IMDEA Water Institute, Spain, (2)GUtech, Muscat, Oman, (3)University of Alcala, Spain, (4)Cavanilles Institute of Biodiversity and Evolutionary Biology, University of Valencia, Spain*
The use of plastic in the agricultural practices can lead to the formation of micro- and nanoplastics (MNPs) by fragmentation and degradation processes. The mobility and transport of these particles towards deeper soil horizons may be influenced by their inherent physicochemical properties and the occurrence of unsaturated conditions. Modelling approaches investigating transport of MNPs through porous media under such conditions are relatively scarce. Therefore, in this study we explored the effects of particle size and surface charge density on the transport of polystyrene nanoplastic particles (PSNPs) through sand with the aim of quantifying such effects through numerical modelling techniques. PSNP infiltration experiments under unsaturated conditions were run in triplicate using an *ad hoc* designed system with glass columns. After a hydrochemical equilibration phase, fluorescent COOH-PSNPs (40 mg L^{-1}) were injected over the sand top surface at a flow rate of 0.5 mL min^{-1}. The effluent was collected every 30 min and PSNP concentrations were measured with a UV-VIS spectrophotometer. The hydraulic transport parameters of the sand were determined with a tracer test performed after PSNP infiltration. Additionally, PSNP transport through the porous media was simulated using ColloidFIT and COMSOL Multiphysics software. The DLVO theory was applied to calculate the total interaction energy between PSNPs and sand surface assisting in data interpretation. Results show that smaller particles reach higher plateau concentrations than larger particles indicating an influence of particle size on the mobility of PSNPs. Mass recovery percentages from each PSNPs confirm that larger particles tend to be more retained in the sand column. Preliminary modelling results show sorption-desorption rates that point at higher retention capacity for larger particles. According to calculated energy interaction forces, electrostatic repulsive forces between sand and PSNPs seem to be predominant under the experimental conditions, and particle retention should be more likely due to physical constraints in the sand pore spaces rather than chemical sorption processes. Regarding the surface charge density, a variation by a factor of 3 of this parameter does not influence the fate of PSNPs. Further experimental and numerical modelling is on-going and will help to gain further insights into MNP transport in porous media and the relevance of different processes on groundwater contamination

3.08.A.T-05 Microplastics in Soil Systems, FromSource to Path to Protection Goals
***Melvin Faber**, Michiel Rutgers, Joris T.K. Quik and Susanne Waaijers-van der Loop, National Institute for Public Health and the Environment (RIVM), Netherlands*
Microplastics can be found everywhere in the world, and in any environmental compartment. During recent years it was discovered that most microplastics may end up in the soil compartment. While the amount of research on microplastics in the soil compartment has increased almost exponentially in the last 5 years, the number of scientific publications are lagging behind these on microplastics in the water compartment. There are indications that microplastics pose a risk to human health and soil life. Therefore, to inform policymakers and risk assessors, RIVM has summarized current knowledge and identified knowledge gaps of microplastics in the soil system. This poster presents the results of this inventory using a conceptual model which addresses topics considered most important for risk assessment. While the model includes several topics, the information presented here focusses on the topics sources, release and emission, fate and transport, and exposure.

3.08.B Current State-of-the Art in Understanding the Occurrence and Implications of Plastics in Terrestrial Environments

3.08.B.T-01 Biodegradable Mulch Films in Agricultural Soils: Analytical Advancements and Biodegradation Dynamics Across Incubation Scales

Flora Wille[1]*, Silvan Arn*[2]*, Mattia Cerri*[2]*, Ralf Kaegi*[3]*, Thomas Bucheli*[4]*, Kristopher McNeill*[2]*, Michael Sander*[2] *and Franco Widmer*[5]*, (1)ETH Zürich, Zürich, Switzerland, (2)Department of Environmental Systems Science, ETH Zürich, Switzerland, (3)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Dübendorf, Switzerland, (4)Environmental Analytics, Environmental Analytics, Agroscope, Zürich, Switzerland, (5)Molecular Ecology, Agroscope, Switzerland*
The market share of biodegradable mulch films is increasing. These films offer an alternative to conventional polyethylene mulch films and, thereby, help to overcome soil plastic pollution. The current European norm for biodegradable mulch film stipulates that at least 90% of the film polymer carbon is converted into CO2 (either in absolute terms or relative to a biodegradable reference material) over a period of two years in laboratory soil incubations. Research is thus needed to understand the factors that govern biodegradation processes and to ensure that biodegradable mulch films indeed biodegrade adequately also in the field in situ. To address these needs, comparative field and laboratory incubations are needed for different soils. This study aimed to a) advance an existing methodology using Soxhlet extraction and proton NMR analysis to quantify residual polymer(s) in soils and subsequently apply this methodology to b) systematically compare biodegradation dynamics of poly(butylene adipate-co-terephthalate) (PBAT) and polylactid acid (PLA) based biodegradable mulch films in laboratory, greenhouse mesocosm and field incubations. Biodegradable mulch film samples as well as positive and negative biodegradation reference materials were incubated at the above-mentioned scales and in three different soils and sampled every ~4 months for a total period of 2 years to quantify remaining polymers. We find that biodegradation rates of PBAT and PLA were strongly soil dependent and that significant differences existed in biodegradation rates and extents between laboratory, greenhouse mesocosm and field incubations. The field incubations showed lowest biodegradation rates not only for PBAT and PLA but also for the positive biodegradation reference polymer. The results support that soil pH, temperature and moisture determine biodegradation because these factors control microbial community composition, microbial and enzymatic activities as well as ester bond hydrolysis of PBAT and PLA. Our study further shows that soil pH could be used as an indicator for biodegradation potential of soils. Furthermore, the results highlight the importance of including positive biodegradation reference materials in incubation experiments, particularly at the field scale. More comparative studies across scales are needed to allow for the prediction of field in situ soil biodegradation rates of polyesters based on their laboratory biodegradation in the same soils.

3.08.B.T-02 Effects of Starch-PBAT Blend Microplastics on Soil Organisms, Microbial Functioning, and Soil Physicochemical Properties in a Mesocosm Study

Sam van van Loon[1]*, Klara Šmidova*[2]*, Sannakajsa Velmala*[3]*, Shin Woong Kim*[4]*, Matthias Rillig*[4] *and Cornelis A.M. van Gestel*[5]*, (1)Vrije Universiteit Amsterdam, Amsterdam Institute for Life and Environment (A-LIFE), Netherlands, (2)RECETOX, Masaryk University, Czech Republic, (3)Natural Resources Institute Finland (Luke), Finland, (4)Freie Universität Berlin, Berlin, Germany, (5)Amsterdam Institute for Life and Environment (A-LIFE), Vrije University Amsterdam, Netherlands*
A large proportion of the estimated 722 kt of agricultural plastics placed on the European market annually ends up in the soil, breaking down into microplastic (MP). To assess the environmental risk of MPs, single species tests are performed, but results are difficult to translate into effects on complex ecosystems. In this mesocosm study, a small ecosystem was recreated to obtain insight into more complex effects of MPs in agricultural soils, like on soil microbiome, physicochemical properties, plants, and invertebrates. Soil columns were filled with Lufa 2.2 soil moistened at 50% water holding capacity, spiked at MP concentrations of 0.025%, 0.05%, 0.2%, and 0.8% (w/w dry soil). Controls were included. The soil cores were preincubated to allow microbiome development for two weeks prior to the start of the experiment. Cress (*Lepidium sativum*) and lettuce (*Lactuca sativa*) were grown in the mesocosms. At t = 0, 4, 8, and 11 weeks lettuce was sampled for analysis of shoot length, fresh and dry weight, number of leaves, specific leaf area, pigmentation, oxidative stress, and antioxidant enzymes. Three species of Collembola, *Sinella curviseta, Heteromurus nitidus,* and *Protaphorura fimata,* were introduced into the mesocosm, to assess effects on community composition. One subadult and one adult of two earthworm species, *Lumbricus rubellus* and *Aporrectodea caliginosa*, were introduced, and checked for survival and reproduction at the end of the experiment. Earthworm survival was not affected by MP exposure, but the total number of juveniles at 0.2% and 0.8% was significantly lower than at 0.025% and 0.05% MPs in the soil. Soil pH (0.01 M $CaCl_2$) was significantly ($p<0.001$) affected at all MP concentrations after 15 weeks (2 weeks incubation and 13 weeks experimental length). Although the exact mechanism behind this pH change is yet to be determined, it may have implications for, e.g., soil invertebrate performance and abundance or nutrient availability. Yet to be determined is whether soil pH is a possible consequence or explanation of the observed effects on microbial activity. Potential ammonification (PAMO), potential nitrification (PAO), basal respiration (BR) and substrate induced respiration (SIR) were all affected by the presence of starch-PBAT blend MPs. This mesocosm study shows the added value of testing more complex systems than single species tests, as many effects were observed at environmentally relevant concentrations of agricultural microplastics in soil.

3.08.B.T-03 Pure Micro- and Macro-LDPE and PP Plastic Negatively Affect Crop Biomass and Nutrient Cycling, and Reduce Soil Moisture and Microbial Biomass with Increasing Concentration

Martine Graf[1]*, Lucy M. Greenfield*[2]*, Michaela K. Reay*[3]*, Rafael Bargiela*[4]*, Gwion B. Williams*[4]*, Charles Onyije*[3]*, Charlotte E.M. Lloyd*[3]*, Ian D. Bull*[3]*, Richard P. Evershed*[3]*, Peter N. Golyshin*[4]*, David R. Chadwick*[2] *and Davey L. Jones*[2]*, (1)Bangor University, United Kingdom, (2)School of Natural Sciences, Bangor University, United Kingdom, (3)Organic Geochemistry Unit, School of Chemistry, University of Bristol, United Kingdom, (4)Bangor University, Centre for Environmental Biotechnology, United Kingdom*
The intense use of agricultural plastic in the form of mulch films over the last 50 years has led to an accumulation of plastic in soil over time, creating a legacy of plastic in agricultural fields. Plastic often contains additives to provide it with the desired properties, e.g., durability, flexibility; however it is still largely unknown how these compounds affect soil properties, potentially influencing or masking effects of the plastic itself. Therefore, in this study the aim was to investigate the effects of pure plastics in

varying sizes and concentrations, to improve our understanding of plastic-only interactions within soil-plant mesocosms. We measured the effects of plastics on key soil (water content, microbial diversity and biomass, soil nutrient content, enzyme activity) and plant properties (growth, chlorophyll content, nutrient content). Maize (*Zea mays* L.) was grown with typical nutrient inputs over eight weeks with addition of pure micro and macro low-density polyethylene (LDPE) and polypropylene (PP) with increasing concentration (equivalent of 1, 10, 25, and 50 years agricultural mulch film use). We found the effect of both macro- and microplastic on soil and plant health is negligible in the short-term (i.e., 1 to <10 years of plastic application). However, for ≥10 years plastic application there was a clear negative effect on plant growth for both macro and micro sized LDPE and PP. Here, we provide vital insight into the effect of both macro- and microplastics on soil and plant properties. Future work is needed to investigate the interaction between macro- and microplastic on soil and plant health, as well as how the findings of this mesocosm study translate to larger-scale field conditions.

3.08.B.T-04 Plastic Mulch and Pesticides Residues Effecting the Lettuce Growth: The Soil Microbiome Perspective
Nicolas Beriot[1], Raul Zornoza[2], Esperanza Huerta Lwanga[3], ***Fanrong Meng[3]*** *and Violette Geissen[3], (1)SLM, Wageningen Environmental Research (WUR), Netherlands, (2)UPCT, Spain, (3)Wageningen University & Research, Netherlands*
In arid and semiarid regions, the use of plastic mulch and pesticides in conventional agriculture is nearly ubiquitous. The most common plastic used for mulching is Low Density Polyethylene (LDPE). LDPE mulch needs to be removed after harvest and LDPE debris accumulates in the environment. Some plastic producers have tried to improve the degradation processes of plastic to avoid plastic mulch removal and plastic debris accumulation by adding pro-oxidant additives to LDPE, so called Pro-oxidant Additive Containing (PAC) plastics or by using biodegradable plastic polymers. However, PAC plastics leave residues when ploughed into the soil and some biodegradable plastic do not degrade as fast as expected in the field conditions. Similarly pesticides are known also to accumulate in the soil.

Studies investigating the effect of these contaminants on the soil fertility most often consider pristine plastic or single pesticides. We investigated the effect of one year incubation of plastic debris and pesticides in soil on the growth of lettuces in south east Spain. More precisely, we tested three plastic mulch residues and 3 commercial pesticides, including a treatment with the cocktail of the 3 pesticides compared to controls for a total of 20 treatments. The plastic mulches were first exposed 3 months to the summer weather in the field, cleaned, cut, grounded into macro- and microplastics debris and added in 1kg soil mesocosm at a 0.2% content w/w. Pesticides were applied 3 times, every 6 months, following the prescribed application doses. The 1kg soil mesocosms were left 1 year, protected from the wind and were irrigated to recreate farming conditions. After one year lettuce seedlings, *Lactuca sativa*, were planted in the incubated soil. The plant growth was assessed during the growing period (number of leaves, chlorophyll content, stomatal conduction) d at the harvest (fresh and dry biomass, leaf area, stem diameter). The soil chemical properties were analysed again. Soil samples were collected for analysis of the bacterial and fungal through 16S and ITS sequencing. Results indicate that lettuces growing in soil incubated with the tested biodegradable plastic produced a significantly lower biomass compared to the control or the soil incubated with LDPE plastic. The microbiome data is being analysed and will be presented during the conference to explore why biodegradable plastic led to less biomass production.

3.08.B.T-05 Disentangling Microplastics Effects on Oxygen Diffusion, Microbial Activity, and Greenhouse Gas Emissions
Jonathan Nunez[1]*, Andrea Carminati[2], Joaquin Jimenez-Martinez[3] and Denise M Mitrano[1], (1)Environmental Systems Science, ETH Zürich, Zürich, Switzerland, (2)Usys, ETH Zürich, Zürich, Switzerland, (3)Department of Civil, Environmental and Geomatic Engineering, ETH Zürich, Zürich, Switzerland*
Understanding the responses of soil ecosystems to the presence of microplastics (MPs) becomes important as multiple stressors can act together to impact this environmental compartment. MPs impact soil structure, nutrient cycling, and greenhouse gas (GHG) emissions. However, the mechanisms underpinning the direction and magnitude of MPs effects on these soil properties are uncertain, mainly due to the lack of knowledge of how the presence of MPs drives changes in soil structure and the subsequent linkages between soil structure and microbial activity. Here, we hypothesized that the presence of MPs affects soil structure, affecting pore connectivity, leading to higher or lower O_2 availability and consequently higher or lower soil respiration. Furthermore, we anticipated that the magnitude or direction of the effects would be dependent on soil texture and the shape of MPs. We spiked PET MPs fibers (500 µm length) and fragments (125 – 250 µm) into custom built rhizotrons (5 x 5 x 1 cm) filled with either clay or sandy loam soils (contrasting textures) with a MPs treatment of 1 w/w%. First, we determined the differences in pore connectivity in air dried soil using the rate of O_2 diffusion as a proxy. Next, we determined the O_2 concentration in the soil in optimal conditions for respiration (50% water holding capacity and addition of 20 mg g soil^{-1} of glucose). O_2 diffusivity and O_2 concentration were determined by mapping O_2 concentrations using optode imaging, over the course of 48 hours. Fluxes of CO_2 were measured under the same conditions by placing replicate set-ups in a Tedlar bag and collecting gas samples for estimates of CO_2 concentration using gas chromatography. O_2 diffusion was faster in the sandy loam compared to the clay soil. The addition of MPs reduced O_2 diffusion rate in the sandy soil but increased it in the clay soil. In optimal conditions for soil respiration, the treatments showed the same trend for O_2 concentrations, suggesting that O_2 concentration in the soil matrix is likely to be regulated by pore connectivity opposed to respiration. Collectively, we show the impacts of MPs addition to soil and their impacts on the linkages between soil structure, microbial activity and GHG emissions. This study can serve as a baseline for understanding the important impacts of MPs have on soil functioning, which is relevant as plastics are increasingly used directly in agriculture and consequently have direct releases to terrestrial ecosystems.

3.08.P Current State-of-the Art in Understanding the Occurrence and Implications of Plastics in Terrestrial Environments

3.08.P-Tu170 Assessing the Impact of Microplastic Extraction Methods on Biodegradable Polymers
Grace Davies[1]*, Martin G.J. Löder*[2]*, Sarmite Kernchen*[2]*, Christian Laforsch*[3]*, Samantha Marshall*[4]*, Massimiliano Mascelloni*[4]*, Stefan Krause*[1] *and Iseult Lynch*[1]*, (1)University of Birmingham, United Kingdom, (2)University of Bayreuth, Germany, (3)University of Bayreuth, Animal Ecology I, Germany, (4)Syngenta, United Kingdom*
Agricultural soil is a sink for microplastics (MPs), with both indirect and direct sources. Indirect sources include the use of sewage sludge as fertiliser, plastic mulching films, atmospheric deposition, irrigation with wastewater, etc. It is difficult to quantify the MPs addition from these sources, but the use of sewage sludge as fertiliser is estimated to add 63-430kt/year of MPs into European farmland.

In comparison, the direct addition of MPs to soil can be quantified. In the EU, direct sources (e.g., the application of controlled release fertilisers, and plant protection products) account for approx. 23,500 tonnes/year of MPs, of which plant protection products account for approx. 1,000 tonnes/year (ECHA, 2019). This is preventable and under new restrictions proposed by the European Chemicals Agency, biodegradable polymers are suggested as future alternatives (ECHA, 2019). It is likely that biodegradable polymers will be used in soil applications and therefore essential that robust extraction and analytical methodologies are developed to monitor their environmental fate. However, such methods for the analysis of MPs in soil have not generally been designed for biodegradable polymers. For environmental soil samples, a combination of density separation with $ZnCl_2$ and enzymatic-oxidative digestion is a promising technique that has been shown to have a high removal efficiency for soil organic material (e.g., Möller et al. 2020).

In this work, enzymatic digestion has been tested on representative polymers polylactic acid (PLA) and poly(r)-3-hydroxybutyrate (PHB). Polymer films were made from powder, then their stability after exposure to the enzymatic-oxidative digestion method was determined. Impacts of each treatment were assessed visually via microscopy and quantitatively by weight and thickness measurements. Surface degradation was measured with attenuated total reflectance Fourier-transform infrared spectroscopy (ATR-FTIR), and polymer molecular weight was measured by gel permeation chromatography (GPC).

Results show variability in the impact on the polymer depending on the treatment used and the application sequence. A combination of both visual assessment and chemical characterisation was needed to determine impacts on polymers. This work highlights the importance of quantifying the impacts of microplastic extraction methods on specific polymers of interest to improve future method development.

3.08.P-Tu171 Suitability of Elutriation for the Extraction of Microplastics from Natural Soils

Kyle Forsythe[1]*, Mason Egermeier*[1]*, Andrea Jilling*[2] *and* ***Jorge Gonzalez Estrella***[1]*, (1)School of Civil and Environmental Engineering, Oklahoma State University, (2)Plant & Soil Sciences, Oklahoma State University*
We evaluated the suitability of elutriation for improving the extraction of microplastics as a function of soil textures. Microplastic pollution in marine environments has been extensively studied in modern literature; however, information about the prevalence of microplastics in freshwater and terrestrial systems is lacking. The lack of published literature regarding the extent of microplastic contamination of terrestrial ecosystems is in part due to the lack of any standardized extraction methodology for microplastics from high-clay and organic-rich soils. In this study, we obtained five samples with textures varying from, 0.1-8.6% organic matter, 16.7-96.3% sand, 2.5-45% silt, and 1.3-50.0% clay and compared the extraction efficiency of an extraction process that included elutriation with a typical direct digestion process. All soils were subjected to microplastic extraction with and without elutriation (direct digestion). Samples were digested in 7.5% NaOCl, then flotation in 5.1M $ZnCl_2$ solution. The number of particles was quantified through staining and fluorescence microscopy. The amount extracted varied from 3300-188 900 particles/kg in elutriated soils and from 3600-153 700 in direct digested soils. Linear regression was used to determine the relationship between relative number of particles extracted (with elutriation vs. without elutriation) and combinations of soil parameters. Correlations were observed between relative extraction quantity and clay content (R^2 =0.64), (clay+OM)/(silt+sand) (R^2 =0.69), (clay+OM)/silt/sand (R^2 = 0.81), $(\text{clay+OM})^{1/2}$/silt/sand (R^2 = 0.88), suggesting that elutriation may be effective as an extraction step for high-sand and silt soils, and should be avoided for high-clay and organic matter soils. Currently, we are validating the plastic composition of the particles using Attenuated Total Reflectance – Fourier Transformed Infrared spectroscopy and quantifying the amount of remaining metals and salts using Inductive Coupled Plasma Mass Spectroscopy and Emission Dispersive X-ray spectroscopy. The information gathered in this study should help other groups in determining the extent of microplastic contamination in Earth's ecosystems by providing viable extraction methodologies for a range of soil types. A rigorous understanding of microplastic prevalence in the environment will aid in determining the impacts associated with microplastic contamination.

3.08.P-Tu172 Shifting to Terrestrial Ecosystems: Characterization of Microplastics in Organic Waste Amendments
Lara Dronjak[1]*, Nora Exposito Lorenzo*[2]*, Joaquim Rovira*[3]*, Esther Marti*[4]*, Vicenc Carabassa*[5,6]*, Irene Raya*[5]*, Marta Schuhmacher*[2] *and Jordi Sierra*[7]*, (1)SEKAI CORPORATE TRAVEL S.L.U, Spain, (2)Chemical Engineering, Universitat Rovira i Virgili, Spain, (3)Departament Enginyeria Química, Universitat Rovira i Virgili, Spain, (4)Universitat de Barcelona, Spain, (5)Universitat Autònoma de Barcelona (CREAF), Spain, (6)Universitat Autònoma Barcelona, (7)Enginyeria Química, Universitat Rovira i Virgili, Spain*
Microplastics (MPs) have been identified as a pollutant of emerging concern and are ubiquitously detected in the natural

environment. One of the major pathways of MPs entering terrestrial ecosystems is through the fertilization of soils with organic wastes. Using organic wastes as soil amendments has some benefits for soil structure, water retention, soil nutrients, organic matter concentration, and soil microbial communities. The aim of the present study is to identify MPs size, morphology, and composition in differently treated organic wastes used in agricultural soils and/or for soil restoration. The organic amendments analyzed (n = 7) are sewage sludge, horse manure, two composts, and two digestates from agri-food industries and selectively separated municipal organic waste, and a biostabilized product from nonselectively separated municipal organic waste. The samples in the laboratory were subjected to pretreatment that consisted of advanced Fenton oxidation, alkaline, and enzymatic digestion, and density separation followed by spectroscopic confirmation. Preliminary data suggested that MPs levels in organic waste amendment samples ranged from 472,324 MPs/kg to 7,142 MPs/kg depending on the origin and the treatment of the organic waste. The most abundant morphology is: fragments, followed by fibers and films. The polymer composition of fragments larger than 0.5 mm was mainly made from PET, PE, and PS; fibers of PES, acrylic, PE, and PA; and films of PE, PP, PVC, and PES. This preliminary investigation is suggesting that MPs are highly presented in organic waste amendments and are a significant source of MPs to agrosystems and restored soils. When organic amendment containing MPs is applied to the soil it can be ingested by the terrestrial biota, entering the food chain, and posing a risk to human health. Samples after anaerobic digestion treatment contain the highest MPs concentrations compared to horse manure which has the lowest. Additional study is needed to fully comprehend the threats that microplastics in organic amendments bring to human and environmental health.

3.08.P-Tu173 Assessing the Plastic Contamination in Agricultural Soils: A Protocol from Nano to Macro Implemented in 220 Fields Across Europe
*Moritz Bigalke[1], Alberto Frache[2], Adrian Grunder[1], Nicolas Beriot[3], Abdallah Alaoui[1], **Fanrong Meng**[4] and Esperanza Huerta Lwanga[4], (1)University of Bern, Switzerland, (2)POLITO, (3)SLM, Wageningen Environmental Research (WUR), Netherlands, (4)Wageningen University & Research, Netherlands*
Plastic use in agriculture has tremendously increased in the past decades resulting in plastic contamination in soils. Several studies intended to quantify the level on the plastic contamination in soil, facing the limitation in size, plastic density, and polymer types. For the project MINAGRIS, a monitoring plan is implemented in 11 Case Study Sites (CSS) across Europe, combining four different protocols to quantify nanoplastics, microplastics, mesoplastics, and macroplastics contamination in soil. The sampling range to 0.1 m3 of soil searched for macroplastics, 500g soil for mesoplastics, 5g soil for microplastics and nanoplastics. Macroplastics and mesoplastic will be quantified by weight, area, and single-point ATR-FTIR. Microplastics will be quantified with Vibrational spectroscopy imaging with MCT FTIR (LUMOS II) and FPA FTIR (Cary 620 FTIR). The identification method for nanoplastic is still under development.

We will present how combining several sampling strategies and analysis protocol we can assess a wide size distribution of plastic debris in soil.

3.08.P-Tu174 Detection and Characterization Methods for Micro(Nano)plastics in Soil
*Gabriella Schirinzi[1], Rita La Spina[2], Claudia Cella[2], Jessica Ponti[2], John Seghers[3], **Francesco Fumagalli**[2] and Douglas Gilliland[2], (1)European Commission, Ispra, Italy, (2)European Commission Joint Research Centre (JRC), Ispra, Italy, (3)European Commission Joint Research Centre (JRC), Belgium*
In the last decades, the use of plastics across all sectors of the economy has generated a global contamination of plastic waste. In the case of environmental soil residuals of mulching in the form of micro(nano)plastic (MNPs) are a major contributor to soil pollution.

To evaluate this contamination, an extraction method of MNPs from soil based on reducing the organic matter content and separating plastic particles from inorganic parts by centrifugation was developed. Specifically, this study was focused on polymeric particles with different densities: polyethylene (PE) and polyvinyl chloride (PVC). As a first step, stability in the digestion reagents, flotation medium and centrifugation time were assessed and optimized. The effect of each factor on nanosized particles was observed by Particles Extinction and Scattering (SPES).
The optimized extraction method was then applied on soil spiked with microplastics, namely commercially available round shaped fluorescent PE, in-house synthesized fluorescent PVC, PE and PVC uncolored fragments. For the first two plastic types, recovery was determined by fluorescent microscopy, while for the latter the Nile Red (NR) staining method was applied to colour particles with the fluorescent dye and being able to distinguish them from inorganic materials under a blue light. The chemical identification was performed by Raman spectroscope (λ = 785 nm).

The results of this study suggest that NR staining does not interfere with Raman analysis when the sample was spiked with pristine particles. However, some limitations may occur with environmental sample since natural aging processes in the environment may oxidize the particles. Regardless, the extraction method developed in this study proves to be a good protocol for the identification of MNPs in environmental soil sample. In addition, since particles may have intrinsic fluorescent properties, they can be more easily localized by light microscopy and identified by Raman thus speeding up the analysis.

3.08.P-Tu175 From Wastewater Treatment Plants to the Terrestrial Environment: Microplastics in Sewage Sludge Compost, Agricultural Soil, and Earthworms
***Niina Kärkkäinen**[1], Salla Kristiina Selonen[2] and Markus Sillanpää[1], (1)Laboratory Centre, Finnish Environmental Institute (SYKE), Helsinki, Finland, (2)Suomen ympäristökeskus (SYKE), Finland*

Wastewater treatment plants have been found to be a significant source of microplastics to the terrestrial environment. After wastewater purification, most of the microplastics in the wastewater influent end up into the resulting sewage sludge, which then can be processed further, for example, into compost. The microplastics enter the environment when the compost is applied as a fertilizer to a soil. From the soil, the microplastics can be digested by soil dwelling organisms, like earthworms. The objectives of this study were 1) to develop sample preparation methods for isolating microplastics from sewage sludge compost, soil and earthworm samples, and 2) to investigate the number concentration of microplastics in these samples. Sewage sludge compost, agricultural soil fertilised with sewage sludge compost, control agricultural soil without compost fertilizer and earthworms taken from the same soils were sampled for microplastics. Sample preparation was tailored to each of these specific sample matrices with methods including sieving, filtering (20 µm), organic matter removal and density separation. The prepared sample was then filtered onto an Anodisc filter (pore size 0.2 µm, diameter 25 mm). An imaging Fourier Transformation Infrared microscope (µFTIR; Lumos II, Bruker) was used to identify the microplastics in transmittance mode. Particular effort was put to mitigate sample contamination. Sample preparation and FTIR-analysis were conducted in a separate, synthetic-fibre-free laboratory meant to be used only for microplastic research. Laboratory blank samples were handled similarly with the real samples to assess the sample contamination from the laboratory environment. In this presentation, the number concentration of microplastics in sewage sludge compost, agricultural soils and earthworms are shown and the links between the microplastic sources and sinks are discussed.

3.08.P-Tu176 Spatial and Vertical Distribution of Microplastic Within the Soil of a Sustainable Urban Drainage System
Max Beaurepaire[1]*, Rachid Dris*[1]*, Johnny Gasperi*[2]*, Marie Christine Gromaire*[1]*, Romain Tramoy*[1] *and Bruno Tassin*[1]*, (1)LEESU, France, (2)Gustave Eiffel University, France*
As urban roads represent a significant aspect of human activity, evaluating their impact as a source of macro-litter and microplastics is necessary to better understand plastic transfer in continental environments. In particular, the microplastic input into soils of sustainable urban drainage systems via urban runoff and their infiltration through soils remain to be assessed. One way to estimate the microplastic input related to road activity and determine the role played by urban runoff in their transport, is to focus on an infiltration ditch on the side of a road.

In this study, the soil of a seepage ditch on the side of a high traffic suburban road in the Parisian region was studied for microplastic content, along with its incoming urban runoff water and outlet water. Soil samples were collected by manually coring at a depth of 35 cm. To assess a potential spatial variation along the seepage ditch, a total of 10 cores were collected. Each core was slighted by depth into 4 samples at [0-5], [5–15], [15–25], [25–35] cm. After collection, microplastics were isolated from the samples using a chemical treatment of organic particles (H_2O_2) followed by a density-based removal of minerals (NaI). Finally, samples were deposited on alumine filters and their microplastic content was determined using an automated Fourier Transform Infrared Micro-Spectroscopy mapping analysis (for particles > 25 µm). Preliminary results showed an overall median concentration of 13.4 MP/g of soil, with no significant difference between samples of different depth. Preliminary results on water samples remain to be assessed, though seem to point toward significantly lower microplastic concentrations at the outlet of the ditch than in the urban runoff (inlet), suggesting that the soil retains efficiently microplastics larger than 25 µm.

3.08.P-Tu177 Exploring the Fate and Impacts of Microplastics in Agricultural Soil: Perspectives from the European Spatial Survey in the PAPILLONS Project
Rachel Hurley[1]*, Sarmite Kernchen*[2]*, Wulf Amelung*[3]*, Melanie Braun*[3]*, Fabiano Convertino*[4]*, Anna Chiara Dell'Acqua*[4]*, Darina Dvorakova*[5]*, Hannu Fritze*[6]*, Cornelis A.M. van Gestel*[7]*, Jakub Hofman*[8]*, Annika Johansson*[9]*, Shin Woong Kim*[10]*, Christian Laforsch*[11]*, Martin G.J. Löder*[2]*, Virtudes Martínez Hernández*[12]*, Raffaella Meffe*[12]*, Antonis D Mistriotis*[13]*, Jana Pulkrabova*[5]*, Sissel Brit Ranneklev*[1]*, Paula E. Redondo*[14]*, Andreu Rico*[12]*, Matthias Rillig*[10]*, Vili Saartama*[9]*, Evelia Schettini*[4]*, Salla Kristiina Selonen*[9]*, Helena Soinne*[6]*, Jyri Tirroniemi*[15]*, Aristeidis S. Tsagkaris*[5]*, Sannakajsa Velmala*[6] *and Luca Nizzetto*[1,8]*, (1)Norwegian Institute for Water Research (NIVA), Norway, (2)University of Bayreuth, Germany, (3)Bonn University, Germany, (4)University of Bari, Italy, (5)University of Chemistry and Technology Prague, Czech Republic, (6)Natural Resources Institute Finland (Luke), Finland, (7)Amsterdam Institute for Life and Environment (A-LIFE), Vrije University Amsterdam, Netherlands, (8)RECETOX, Masaryk University, Czech Republic, (9)Suomen ympäristökeskus (SYKE), Finland, (10)Freie Universität Berlin, Berlin, Germany, (11)University of Bayreuth, Animal Ecology I, Germany, (12)IMDEA Water Institute, Spain, (13)Agricultural University of Athens, Greece, (14)Fundación IMDEA Agua, Alcala de Henares, Spain, (15)Finnish Environmental Institute (SYKE), Helsinki, Finland*
Agricultural soils have been highlighted as an important recipient of microplastic (MP). Several sources or pathways of MP to soils have been identified in the literature but the relative importance of these has not yet been quantified. There is a demand to establish the scales of MP pollution in soils and better understand which conditions lead to high levels of pollution.
The H2020-funded PAPILLONS project (Plastic in Agricultural Production: Impacts, Lifecycles, and LONg-term Sustainability) will address this knowledge gap by conducting a European spatial survey (ESS) of MP pollution in farmed soils. Sampling has been undertaken in seven countries (Finland, Germany, Norway, Spain, Italy, Greece, and the Czech Republic) representing different biogeographic regions and important areas for European agricultural production. Three main sources of MP to soils were identified: 1) use of agricultural plastics, in particular thin films; 2) application of sewage sludge to land; and 3) use of selected compost products suspected to contain MP. Fields were chosen to provide good coverage of each. Control fields were also sampled, representing MP inputs from additional sources such as atmospheric deposition or littering. The objectives of the ESS are: 1) to establish a baseline for MP concentrations in agricultural soils in Europe; 2) to identify the relative contributions from different MP sources; and 3) to unravel how local or regional agricultural practices can influence levels of MPs in soils.

The ESS represents an ambitious study where several components will be investigated. MPs will be analysed in soils, as well as earthworms collected from different soil depths. Soil samples will also be analysed for macroplastics, plastic additive content and several soil properties. The ESS will also investigate biodiversity in fields subject to potential MP sources and control fields; namely, by assessing communities of earthworms and microorganisms. Finally – to accompany field sampling – farmers were asked to complete a questionnaire to obtain information on practices, behaviours, and perceptions related to plastic pollution in European agriculture.
This poster presents the rationale and design for the ESS in the PAPILLONS project. The findings from this study will provide valuable data about relevant sources of MP to agricultural soils in Europe that can be used to tailor effective solutions for reducing MP pollution.

3.08.P-Tu178 Exploring the Fate and Impacts of Microplastics in Agricultural Soil: Perspectives from the Long-Term Field Experiments in Northern, Central, and Southern Europe in the PAPILLONS Project

Salla Kristiina Selonen[1]*, Paula E. Redondo*[2]*, Sylwia Adamczyk*[3]*, Wulf Amelung*[4]*, Matty P. Berg*[5]*, Melanie Braun*[4]*, Darina Dvorakova*[6]*, Hannu Fritze*[3]*, Cornelis A.M. van Gestel*[5]*, Jari Haimi*[7]*, Rene Heyse*[4]*, Jakub Hofman*[8]*, Rachel Hurley*[9]*, Sarmite Kernchen*[10]*, Shin Woong Kim*[11]*, Christian Laforsch*[12]*, Martin G.J. Löder*[10]*, Virtudes Martinez-Hernandez*[13]*, Raffaella Meffe*[13]*, Andreu Rico*[13]*, Johanna Nikama*[3]*, Matthias Rillig*[11]*, Vili Saartama*[7,14]*, Klara Šmidova*[8]*, Helena Soinne*[3]*, Jyri Tirroniemi*[14]*, Aristeidis S Tsagkaris*[6]*, Sannakajsa Velmala*[3] *and Luca Nizzetto*[8,9]*, (1)Suomen ympäristökeskus (SYKE), Finland, (2)Fundación IMDEA Agua, Alcala de Henares, Spain, (3)Natural Resources Institute Finland (Luke), Finland, (4)Bonn University, Germany, (5)Amsterdam Institute for Life and Environment (A-LIFE), Vrije University Amsterdam, Netherlands, (6)University of Chemistry and Technology Prague, Czech Republic, (7)University of Jyväskylä, Finland, (8)RECETOX, Masaryk University, Czech Republic, (9)Norwegian Institute for Water Research (NIVA), Norway, (10)University of Bayreuth, Germany, (11)Freie Universität Berlin, Berlin, Germany, (12)University of Bayreuth, Animal Ecology I, Germany, (13)IMDEA Water Institute, Spain, (14)Finnish Environmental Institute (SYKE), Helsinki, Finland*

Mulching films are widely used in agriculture and horticulture to facilitate cultivation and to improve the yield. They also have some positive environmental aspects by allowing reductions in the use of irrigation water and plant protection products. However, mulching films have also been identified as a source of plastic additive chemicals and microplastics in agricultural soils. Biodegradable mulching films have been developed as alternatives to conventional plastics. Biodegradable mulching films are intended to be left in the field and incorporated into the soil after use. Despite the increase in the use of these new materials, their impacts in soil are still poorly known. Moreover, the impacts of microplastics in soil are mostly studied in controlled laboratory conditions, whilst field studies with varying interactions and environmental conditions are scarce.

In the field experiments of the H2020 funded project PAPILLONS (Plastics in agriculture: impacts, lifecycles and long-term sustainability), the fate and impacts of microplastics are studied in real European agricultural environments. The experiments are being carried out in three different countries representing different vegetation and climate zones in Europe: Finland, Germany, and Spain. In each country, the experiment started in the beginning of the growth season in 2022, by introducing two types of microplastics in the study plots at two concentrations and five replicates. The two types of microplastics were produced by grinding pellets that were made of recycled mulching films: one from conventional polyethylene (PE) films and the other from biodegradable films composed of a blend of starch and polybutylene adipate co-terephthalate (starch-PBAT blend). Both experimental concentrations represent the range found in agricultural soils: 0.005% and 0.05% per dry weight of soil. Malted barley grown in the experimental fields of all three countries. Before seeding and at the end of the two growing seasons, (2022 and 2023), soil samples are taken to analyse physicochemical properties of the soil, microplastics, plastic additives, soil invertebrates and microbial community and activity.
Barley growth, stress indicators, and crop quality are also measured.
In this presentation, this holistic field experiment of PAPILLONS project is introduced. The experiment gives a comprehensive picture of the effects and fate of microplastics in real, varying environmental conditions across Europe.

3.08.P-Tu179 Characterization of Plastic Contamination in Biogenic Matrices Intended for Reuse in Agriculture

Stefano Magni[1]*, Marco Fossati*[2]*, Roberta Pedrazzani*[3]*, Alessandro Abbà*[3]*, Sara Castiglioni*[4]*, Michele Menghini*[3]*, Marta Domini*[3]*, Giorgio Bertanza*[3]*, Andrea Binelli*[5] *and* ***Camilla Della Torre***[5]*, (1)Bioscienze, Università degli Studi di Milano, Italy, (2)Università degli Studi di Milano, Italy, (3)Università degli Studi di Brescia, Italy, (4)Environmental Health Sciences, Istituto di Ricerche Farmacologiche Mario Negri, Italy, (5)Dipartimento di Bioscienze, Università degli Studi di Milano, Italy*

The reuse of treated biogenic wastes in agriculture allows the recovery of nutrients, representing an alternative to their disposal, and contributing to the circular economy. However, the presence of plastics in these matrices, as evidenced by various studies, can lead to further plastic input into agricultural soils, thus rising a question on possible consequences for the environment. Notwithstanding, the current knowledge concerning the presence of plastics in biogenic matrices is very poor. Therefore, the objective of the present study was a quali-quantitative characterization of plastics in different matrices reused in agriculture as: manures, digestate, compost and sewage sludges. Plastics were quantified and characterized in terms of polymer composition, color, shape and size using the Fourier transform Infrared Spectroscopy coupled with an optical microscope (µFT-IR) in Attenuated Total Reflectance (ATR) mode. We measured a variable presence of plastic debris ranging from 0.2 items/g wet weight (w.w.) in manures up to 7 items/g w.w. in sewage sludge. Fibers were the prevalent form and plastics were mostly in the micrometric size. The most abundant polymers were polyester (PEST), polyacrilic rubber, polypropilene (PP) and polyethylene (PE). A different situation has been observed for compost, in which we identified 986 items/g w.w., with a significant increase compared to the other matrices ($p < 0.01$), mostly made of compostable and biodegradable plastics. The remaining 11% of compost consisted in fragments of PEST and PE. Our study showed the presence of plastics in all investigated matrices, albeit with significant differences in the content among compost and the other matrices. A broad monitoring of plastic particles in such residues, to be coupled with an ecotoxicological assessment, should be promoted to guarantee safe agricultural application.

3.08.P-Tu180 A Citizen Science Approach for Identification of Environmental Plastics
Shannon Bartelt-Hunt[1] *and Nasrin Naderi Beni*[2]*, (1)Civil and Environmental Engineering, University of Nebraska - Lincoln, (2)Department of Civil and Environmental Engineering, University of Nebraska - Lincoln*
Terrestrial microplastics (MP) are an emerging environmental challenge. Citizen science is an increasingly important tool for environmental data collection efforts; however, new citizen science approaches are needed to characterize and quantify environmental plastic pollution. As macroplastic waste can further degrade and fragment to the MP size range, identifying micro-, meso-, and macroplastics in the environment can improve MP source tracking. Methods currently used to identify plastic resins require expensive instruments such as Fourier-transform infrared spectroscopy or Raman spectroscopy. In this study, a simple procedure was developed for citizen scientists to identify environmental plastics obtained from various media including water, soil, and sediments. Plastics able to be identified from the method include polystyrene, polyethylene, polypropylene, polyvinyl chloride, nylon, teflon, and polyurethane. The method procedure uses commonly found materials and incorporates three types of tests: density, burning, and solvent tests. The developed procedure was tested by over 100 participants including undergraduate students and community science volunteers. The accuracy of the citizen scientists to identify polyvinyl chloride/teflon was the highest with >95% accuracy. It was determined that the burning test was the most challenging part of the procedure and the lowest percentage of correct answers was observed (65% on average). Environmental macro- and mesoplastics were collected, and were identified using the proposed method with confirmation by atomic force microscopy-based infrared spectroscopy (AFM-IR). Development of an accurate and validated method for identification of environmental plastics can move citizen science efforts focused on plastic wastes beyond bulk MP occurrence to plastic resin identification, which will advance our ability to activate citizen scientist networks to contribute to MP research efforts.

3.08.P-Tu181 Bridging the Identification and Quantification of Microplastic Particles in Agricultural Soil Samples
Fatbardha Igrishta[1]*, Frank Pude*[2] *and Armin Zenker*[3]*, (1)Institut für Ecopreneurship, University of Appl. Sc. Northwestern Switzerland, Switzerland, (2)University of Appl. Sc. Northwestern Switzerland, Switzerland, (3)School of Life Sciences, University of Appl. Sc. Northwestern Switzerland, Switzerland*
Microplastics particles have been detected in the sea, freshwater, land, and air. In addition, plastics have been found to release toxic substances and adsorb pollutants. MP particles have also been experimentally determined in fish and seafood, honey, beer, and salt. To date, there are no established definitions or standardized analytical methods for the detection of microplastic particles. Depending on how the samples were collected, prepared, and analysed, the results could vary by several orders of magnitude. In this this study we investigated the feasibility of using the Agilent 8700 Laser Direct Infrared (LDIR) imaging to characterize and identify MP particles in agricultural soil samples.

Soil samples from different depths (0-30 cm, 31-60 cm, 61-90 cm) were taken at nine locations on farmland near Bonn (North Rhine-Westphalia, Germany). All samples went through different purification steps and a density separation and were subsequently filtered through a gold filter (0,2 µm, 25 mm). After drying the gold filter, it was fixed on a glass slide for the measurement in the LDIR using a drop of water.

An average of 744 859 MP particles/g soil sample were detected in the 27 soil samples. This corresponds to an average of 838 683 MP particles/g at 0-30 cm, 583 980 MP particles/g at 31-60 cm, and 624 268 MP particles/g at 61-90 cm soil depth, with the major polymers identified being polyethylene (PE), polyamide (PA), and other natural polyamides.

3.08.P-Tu182 Method Development for Extraction of Microplastics from Organic Rich Soils
Thilakshani Atugoda[1]*, Richard Brazier*[2]*, Ceri Lewis*[3] *and Mark Hodson*[4]*, (1)Department of Geography, University of Exeter, United Kingdom, (2)University of Exeter, United Kingdom, (3)Biosceinces, University of Exeter, United Kingdom, (4)University of York, United Kingdom*
Microplastics pollution is widespread in all environmental matrices and considered as a major environmental concern. Identification and quantification of microplastics in environmental matrices has been challenging, especially the contamination in terrestrial system is poorly known given due to the complexity of the soil types and lack of standard approach for microplastic extraction. This study presents a comparison of microplastic recovery from different types of soil comprising of a range of complexity particularly with organic matter. Here we used 3 different types of soil with organic matter Lufa 2.0 soil, compost, and topsoil. All the soils were air dried and sieved with 2.0 mm mesh to remove large debris. Soils were amended with 10 particles each of 9 different microplastics comprising different polymers, shapes, sizes, and colours. Fibres were stained with Nile Red prior spiking for better visualization. Organic matter was removed from the soils using an overnight digestion in Fenton's reagent (60% H_2O_2 and $FeSO_4$). After the digestion, microplastics were separated from the digested soil by flotation in a $ZnCl_2$ solution. Samples were centrifuged, and then filtered through a nylon filter. Particles were observed using fluorescence light microscopy and the recovery in each soil type was determined. Microplastic separation performed better in low organic soil with higher recovery. Soils rich in organic matter requires improved protocols involving further purification to gain better recoveries.

3.08.P-Tu183 Status quo of SOil Sampling for Microplastic Analysis (SOSMA)

Kristof Dorau[1], *Martin Hoppe*[1], *Daniel Rückamp*[2] *and Elke Fries*[2], *(1)Groundwater and soil, BGR, Germany, (2)Groundwater and Soil, Federal Institute for Geosciences and Natural Resources, Hannover, Germany*

Determination of microplastics (MP) in soils has gained enhanced scientific attention in the last decade. This talk addresses current state of the art in terms of sampling and sample preparation to derive information on MP content in soils. We conducted a systematic literature review by in-depth screening of more than 100 articles that focused to account for MP burden in soils (particle counts or masses). Most of these studies (63%) focused on known emission pathways with discrete study sites, whereas 37% targeted to delineate MP background contents due to fluvial, marine, or aeolian MP deposition with de-localized MP emission sources. Thereby, 93% of the studies investigated the top 30 cm, which highlights the knowledge gap of MP abundance in the subsoil. Even though soil was the target medium, soil organic matter content, pH, and texture were measured only in 20% of the studies. However, such basic soil parameters need to be considered in particular to evaluate analytical results for MP, e.g., of recovery tests. In terms of spatial distribution of soil samples, random sampling was applied more frequently than sampling of transects and raster sampling. In rare examples, the composite sample taken in the field was based upon a large representative elementary volume (REV) of several 100 kg that was reduced afterwards by quartering and mass reduction. However, the majority of studies followed common procedures where the mass of the composite sample (2.150 ± 1.150 g) constitutes merging of a distinct number of single samples ($n = 5.1 \pm 4.6$). Larger REVs seem promising and might be an aspect to facilitate reproducible and representative analytical results, which needs to be validated for emission-specific MP pathways into soils. In conclusion, the systematic review revealed an incoherence in soil sampling and sample preparation within analytic protocols, which renders a comparison of results challenging.

3.08.P-Tu184 iMulch - An Investigation of the Influence of Polymers on a Terrestrial Ecosystem Using the Example of Mulch Films used in Agriculture

Carmen Wolf[1], *Mike Wenzel*[1], *Matin Funck*[2], *Björn Fischer*[3], *Kristin Nehren*[3], *Ralf Bertling*[4], *Mona Duhme*[4], *Dieter Hennecke*[5], *Karlheinz Weinfurtner*[6], *Martina Roß-Nickoll*[7], *Henner Hollert*[8], *Antonia Weltmeyer*[7], *Kristina Bitter*[7], *Lars Blank*[7], *Pauline Ruiz*[9], *Dusica Banduka*[9], *Christof Asbach*[2] *and Jochen Tuerk*[2], *(1)Institut für Energie- und Umwelttechnik e. V. (IUTA), Germany, (2)Institute of Energy and Environmental Technology e.V. (IUTA), Germany, (3)Fischer GmbH, Germany, (4)Fraunhofer UMSICHT - Institute for Environmental, Safety and Energy Technology, Oberhausen, Germany, (5)Ecological Chemistry, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany, (6)IME Fraunhofer, Germany, (7)RWTH Aachen University, Germany, (8)Evolutionary Ecology & Environmental Toxicology, Goethe University Frankfurt, Frankfurt am Main, Germany, (9)nova Institut GmbH, Germany*

Plastics enter soils directly and indirectly. Mulch films represent an exemplary use of plastics on soils that can lead to direct plastic input. Mulch films are used in agriculture to regulate temperature and moisture in the soil, prevent weed growth and soil erosion during heavy rainfall, and protect crops from pests and predators. It is to be expected that in the course of climate change and the intended reduction in the use of pesticides, there will be a growing use of mulch films in agriculture. Whether the use of mulch films on agricultural land can have a negative effect on the soil was analysed from different perspectives in this project.

- A method for the analysis of microplastics in soil samples was developed for Raman spectroscopy and Thermo extraction desorption Gas chromatography mass spectrometry (TED-GCMS).
- Different soils were analysed for the plastic content and the type of agriculture was correlated to the results
- The aging of the mulch film was analysed in laboratory and mesocosm soil test and additionally in a laboratory sewage treatment plant.
- The transport and fate of the mulch-polymers in soils using ^{14}C marked polymers in outdoor lysimeter experiments was investigated
- Experiments examining effects of the mulch fragments on organism were conducted.
- The “upcycling” of mulch films by bacteria was investigated.
- A life cycle assessment of conventional and biodegradable agricultural mulch films was conducted.
- An avoidance and substitution strategy was derived from the results with the aim of reducing plastic film fragments in the environment.

This presentation will give an overview of the results of this project.

3.08.P-Tu185 Tyre and Road Wear Microplastic Identification and Transport in the Urban Environment

Kate Rowley[1], *Iseult Lynch*[1], *Stefan Krause*[1], *Greg Sambrook Smith*[1] *and John Ravening*[2], *(1)University of Birmingham, United Kingdom, (2)ARUP Ltd.*

Car tyre, brake, and road surface wear materials have been identified as major sources of microplastic pollution in the environment, in particular, in urban areas. Although they have been recognised as significant contributors of microplastic, due to analytical challenges only few studies to date include tyre and road wear particles in quantitative assessments of microplastic pollution. Therefore, we are facing a significant knowledge gap as to how these particles behave in the environment, bearing the risk of significant undetected environmental impacts now, and in the future. As such, this study aims to improve methods for the quantitative analyses of tyre and road wear particles found in environmental samples, in addition to investigating their initial transport pathways away from their site of generation in the urban environment.

Here we present the sampling methodologies developed by us for the collection of atmospheric deposition samples, inclusive of tyre and road wear particles from a major urban road in Birmingham, UK, together with the laboratory methods used to prepare samples for analyses of particles using Pyrolysis GC MS and microscopy. Atmospheric deposition samples were collected for different intensities of traffic flow and across a range of different precipitation events in order to understand how individual environmental factors affect the transport of tyre and road wear particles to the immediate surrounding roadside environment. This ongoing sampling campaign, is currently extended by the sampling of airborne particles, and particles from the direct road runoff, to understand the real time contribution of tyre and road wear particles to each transport route. Pyrolysis GC MS methods for the identification of tyre and road wear particles are being trialled for the identification of 'real world' tyre and road wear particles from environmental samples collected, with the aim to improve marker compounds for particle quantification. We hypothesise that traffic volume and the specific type of precipitation event, including its antecedent conditions, will have the most significant impact on tyre and road wear particle load in the environmental samples collected.

3.08.P-Tu186 Microplastics in Total Atmospheric Fallout: From Lockdown to Business-as-Usual

Max Beaurepaire[1]*, Rachid Dris*[1]*, Johnny Gasperi*[2] *and Bruno Tassin*[1]*, (1)LEESU, France, (2)Gustave Eiffel University, France*

Since the earliest studies on microplastic (MP) pollution in the atmospheric compartment in 2015, a few dozen studies have been published on the subject. Over that period, analytical methods and targeted MPs have evolved. Several factors are suspected by authors to affect MP atmospheric deposition, human activity and precipitation being the leading ones.

In this work, total atmospheric fallout from an urban campus (site A) was sampled over three continuous monitoring campaigns of 4 to 6 months each. Campaigns in site A occurred during the French national lockdown of spring 2020 as human activity was drastically reduced there, and in spring 2021. The monitoring campaign in site B occurred in spring 2021, simultaneously to site A. In all campaigns, precipitations were followed to adjust sampling accordingly.

All samples underwent a density separation followed by a chemical treatment, before they were analysed using an automated µFTIR mapping analysis using a Nicolet iN10 by Thermo Scientific. MPs were identified down to a size of 25 µm, cutoff point determined by the µFTIR detectors.

When pooling all results together, overall median deposition rates of 18.3 MP/m²/d were found. The lowest deposition rates were recorded during the national lockdown monitoring campaign in site A, with a median of 5.3 MP/m²/d compared to 26 MP/m²/d in the same site during normal periods of activity. Based on the rain events and precipitation rates, no clear effect of rain events or accumulated rainfall on microplastic deposition was measured, suggesting the dominant effect observed here was local human activity.

3.08.P-Tu187 Marking Stripes in Durable Woven Mulch Films are Their Major Source of Microplastics

Sarmite Kernchen[1]*, Martin G.J. Löder*[1] *and Christian Laforsch*[2]*, (1)University of Bayreuth, Germany, (2)University of Bayreuth, Animal Ecology I, Germany*

Applying mulch films to fields is a common agricultural practice that increases the quality and yield of cultivated crops. Mulch films act as a shield that protects plants from weeds, insects, and pests, keeps moisture in the soil, protects roots from direct sunlight, prevents soil erosion, and keeps the soil fertile. Recently, however, the application of mulch films to fields has been shown to contaminate soil with macro/micro/nanoplastic particles that can negatively impact soil ecosystems. As impacts are expected to be proportional to soil microplastic (MP) concentrations, it is critical to determine the level of MP pollution in agricultural soils and practices to assess future scenarios and provide guidance for sustainable agricultural policies. Chemical composition, application duration, and end-of-life practices of mulch films are the most important factors affecting the rate of film degradation and subsequent soil contamination with MP.

Next to mulch films made of polyethylene (PE) or biodegradable plastics, durable woven mulch films are also available. While films from PE or biodegradable plastics are not meant for a long-term application, durable woven polypropylene (PP) mulch films promise a multiyear stability. However, these durable mulch films have not yet been studied in detail for their potential as a source of MP. Therefore, in this study, we characterized and quantified MP in German agricultural fields where black woven PP mulch films with green PP marking stripes were applied over a 12-year period. MP particles were extracted from soil samples by density separation, purified using an oxidative-enzymatic protocol and analyzed by micro-Fourier transform infrared spectroscopy, which provided information on the chemical composition, shape, size, and color of the particles. The results showed that PP fragments, apparently derived from the application of mulch films, significantly contaminated the soil. The average MP content per kilogram of soil was 5005±1298 particles, most of which came from a weathered mulch film. Interestingly, the majority of MP particles came from the green marker strips rather than the black fabric. These results suggest a difference in UV stabilizer content between black and green PP material, which needs to be verified by in-depth chemical analysis. Our work highlights the fact that different components of durable woven mulch films may play different roles as significant sources of MP entering agricultural soils.

3.08.P-Tu188 Microplastic Contamination in an Urban River in Germany – Investigating and Tackling the Challenge of Organic-Rich Matrix

Orasai Faikhaw[1]*, Stephan Wagner*[2]*, Robby Rynek*[3]*, Dusan Materic*[3] *and Thorsten Reemtsma*[3,4]*, (1)Department of Analytical Chemistry, Helmholtz Center Hereon, Germany, (2)Institute for Analytical Research, University of Applied Science Fresenius, Idstein, Germany, (3)Department of Analytical Chemistry, Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany, (4)Institute of Analytical Chemistry, University of Leipzig, Germany*

The ubiquitous distribution of microplastics globally has attracted much attention and their contamination in rivers is noted as a substantial environmental problem. Aside from being considered as a transport pathway of land-derived plastic to the ocean, rivers serve as both (temporary) sinks for land-based plastic pollution, as well as future sources due to remobilization. However, the research thus far mainly focuses on larger rivers, while the situation in smaller rivers is poorly understood.

Freshwater samples are often rich in natural particles, complicating microplastic analysis using micro-Fourier-transform infrared spectroscopy (μ-FTIR). The extraction of microplastics from the samples while preserving them is challenging, especially the removal of suspended organic matter particles, which mainly have a density in the same range as most common plastics and are also not possible to remove without chemical digestion.

In the present study, the dynamics of microplastic contamination of an urban subAcatchment, the Parthe river, is investigated. The river is in southeastern Germany and passes through several towns mainly characterized by urban and agricultural land use. In this work, a fractionated filtration sampling device was developed to collect the suspended matter. Samples were collected from two different land use sites once a month for one year to cover all seasons. Since the samples from the Parthe River are rich in suspended organic matter, mainly plant debris, existing (ligno)cellulosic digestion/oxidation methods were tested and optimized. By analyzing the mass reduction, NaOCl oxidation showed the highest efficiency of organic matter removal eliminating up to 97 % weight of the sample matrix. To accomplish microplastic concentration examination, suspended matter samples were purified by combining the optimized protocol including NaOCl treatment and density separation, followed by determining microplastic concentration using μ-FTIR. According to preliminary results, 53 and 57 particles/m^3 of microplastics were found in a sample fraction of 100 - 500 μm from an urban and agricultural area, respectively. Microplastics in the Parthe River samples are predominantly polypropylene (PP) and polyethylene (PE). Our findings will provide a better understanding of the dynamics of microplastic contamination in the urban river and will further identify sources of microplastic contamination in the rural as well as the urban section of the Parthe catchment.

3.08.P-Tu189 Effects of Conventional and Biodegradable Microplastic on Seed Germination and Plant Growth of Food Crops

Laura Zantis[1]*, Anne Wilts*[1]*, Sannakajsa Velmala*[2]*, Sylwia Adamczyk*[2]*, Martina G. Vijver*[3]*, Willie Peijnenburg*[4] *and Thijs Bosker*[3]*, (1)Leiden University, Institute of Environmental Sciences, Netherlands, (2)Natural Resources Institute Finland (Luke), Finland, (3)Leiden University, Leiden, Netherlands, (4)National Institute for Public Health and the Environment (RIVM), Netherlands*

Nano- and microplastic (<100 nm and <5 mm, respectively) pollution is becoming increasingly persistent in all ecosystems and is considered an emerging threat to biodiversity and ecosystem functioning. One major concern is agricultural lands, which have been identified as long-term microplastic sinks. As a result, there is now a push toward developing bioplastics, which can be (partly) broken down after entering the environment. Yet, limited research has been done to compare the impacts of microplastics and bioplastics on terrestrial crop plants. This study aims to examine and compare the effects of artificially weathered conventional polyethylene (PE) and starch-based biodegradable polybutylene adipate terephthalate (PBAT) on four common food crops, including lettuce (*Lactuca sativa* L.), carrot (*Daucus carota*), wheat (*Triticum aestivum* L.), and barley (*Hordeum vulgare*), through two complementary experiments. We investigated the effects of environmentally relevant low, medium, and high (0.01%, 0.1%, 1% w/w) concentrations of weathered PE and PBAT particles on seed germination (acute toxicity: Petri-dish experiment) and plant growth (chronic toxicity: pot-plant experiment), respectively. Our results show adverse effects of both PE and PBAT on crops. When acutely exposed during germination, PE significantly accelerated the germination rate of carrot seeds by two days ($p<0.05$). In addition, both PE and PBAT decreased the root length of lettuce and wheat by up to 36% and 53% respectively ($p<0.05$). Contrary, root length ($p<0.0001$), shoot length ($p<0.05$), and seedling biomass ($p<0.05$) of carrot were increased with up to 86% when exposed to PE and PBAT, respectively. In the pot-plant experiment, PBAT significantly delayed the germination rate of barley ($p<0.05$), and additionally decreased the shoot biomass by 16% after 14 days ($p<0.05$). No significant effects of PE and PBAT were recorded on the seed germination of lettuce. Overall, these results show that the early development of seedlings is mainly impacted, but over time plants might recover mildly. Moreover, biodegradable plastic was more toxic than the conventional plastic highlighting the need to further investigate the effects of micro- and bioplastics on crop plants.

3.08.P-Tu190 Long-Term Effects of Agricultural Microplastics on Earthworm *Eisenia Andrei*; Comparison of Conventional and Biodegradable Plastics

Vili Saartama[1]*, Salla Kristiina Selonen*[2] *and Jari Haimi*[1]*, (1)University of Jyväskylä, Finland, (2)Suomen ympäristökeskus (SYKE), Finland*

Use of plastics is common in modern agriculture, but degradation of plastics in soil is a slow process. Biodegradable plastics have been proposed as a solution for this problem, but little is known about possible long-term effects of plastics, either biodegradable or conventional, on soil organisms. The aim of our study is to find out the possible effects of microplastics from conventional and biodegradable mulching film material on the earthworm *Eisenia andrei.*

We studied two types of microplastics produced by grinding pellets made of recycled mulching films, one from conventional polyethylene (PE) films and the other from biodegradable films composed of starch and polybutylene adipate co-terephthalate (starch-PBAT). We exposed earthworms to these two microplastic types in concentrations of 0%, 0.005%, 0.05%, 0.1%, 0.5%, 1%, and 5% of dry mass. The experiments started with standard reproduction tests with earthworms of parental (P) generation (ISO 11268-2). After the standard tests, we selected 13 juveniles from each test jar for a new set of tests to study the impacts of long-term microplastic exposure on the first offspring generation (F1). We followed the growth and the number of mature individuals every four weeks. In addition to survival, growth, and reproduction, the uptake of microplastics and plastic additives as well as immunological biomarkers in earthworms will be analyzed.

The experiments are still running, and statistical analyses have not been performed yet. The preliminary data suggest that the microplastics have not affected earthworm survival, but the presence of PE in the soil decreased the growth in F1 generation. In contrast, the biodegradable plastic seems to increase the growth of the earthworms in F1 generation. The earthworms in the highest PE concentrations also maturated later.

3.08.P-Tu191 The Effect of Soil Plastic Contamination on Agricultural Production
Franja Prosenc[1,2]*, Urška Šunta, M.Sc.*[2]*, Marjetka Suhadolc*[3]*, Anton Govednik*[3] *and Nina Kacjan Maršič*[3]*, (1)University of Leeds, United Kingdom, (2)University of Ljubljana, Faculty of Health Sciences, Slovenia, (3)University of Ljubljana, Biotechnical Faculty, Slovenia*
Agricultural soils act as long-term sinks for plastic contaminants. Plastics enter agricultural soil through fertilisation with sewage sludge and biowaste compost, which are high in microplastics, or through fragmentation of larger plastics, such as plastic mulching. Sewage sludge is used widely in Europe as a fertiliser. Through this route, it is estimated that between 63 000 and 430 000 tonnes of microplastics are annually deposited on European farmlands. Reports have shown that microplastics affect soil microorganisms, nutrient cycling, and plant growth; however, the effects they exhibit depend on their size, concentration, shape, and composition, therefore the overall effect is extremely hard to determine. This study investigated the effect of 'cocktail' plastic contamination on nitrogen cycling in soil and tomato production. Concentrations, shapes, and compositions of plastics were chosen to resemble plastic contamination found in agricultural soil, fertilised with biowaste compost for 20 years.

The results from a pot experiment, where tomatoes were grown in the presence of meso- and microplastics, will be presented. We investigated the effect of plastic contamination on plant biomass, tomato fruit ripening, and the biochemical composition of tomato fruits. Additionally, we investigated the effect of plastic contamination accumulated in the lower layer of the substrate versus homogeneously distributed plastic contamination. This is because we found that in ploughed fields, most of the plastic contamination is found in the 10-20 cm layer of the soil. We hypothesise that plant biomass will be bigger in the plastic-contaminated substrate due to increased substrate aeration and macroporosity, whereas no effect will be observed in the biochemical composition of tomato fruits. Furthermore, we will present the results from a microcosm experiment, exploring the effects of plastic contamination on nitrate concentration and microbial community composition in soil and organic-rich substrate. We hypothesise that nitrate production will be lower in the plastic-contaminated soils and substrate; however, if contaminated with biodegradable plastics, the nitrate production might be higher.

The results of this study will contribute towards a better understanding of the effects of 'cocktail' plastic contamination in agricultural soil, specifically on nutrient cycling and crop production, and provide an insight into a potential effect on future food security.

3.08.P-Tu192 Biodegradable Plastics – An Improvement or a Hazard to Soil Organisms? Assessment of Effects of Microplastics and Leachates on Earthworms, Plants, and Soil Respiration
Luís André Mendes[1]*, Jorge Domínguez*[1] *and Ricardo Beiras*[2]*, (1)Universidade de Vigo, Spain, (2)University of Vigo, Spain*
Plastic pollution has been the subject of immense news coverage and concern, raising issues regarding environmental safety and long-term impact on the ecosystems. In response, several manufacturing companies have produced biodegradable goods, presented as a safer-by-design solution for the environment, relative to most common fossil-based plastics. However, is this true for soil ecosystems?

In the present study, we propose assessing the response of three different soil components, i.e., invertebrates, plants and microbial respiration, to biodegradable and fossil-based plastics used at environmentally relevant concentrations on 3: following OECD and standard test guidelines. We used powdered plastic samples (particle size <250 µm) and leachates obtained from the same materials, to evaluate whether the source of toxicity was the microplastic itself or the associated additives.

OECD test no. 222 was used to measure survival and reproduction of the model earthworm species *Eisenia andrei* exposed to plastic-contaminated soil for 28 and 56 days. OECD no. 208 guideline was adapted to assess the germination index (GI), relative root growth (RRG), relative seed germination (RSG) and relative shoot growth (RShG) of the garden cress *Lepidium sativum* grown for 7 days in the contaminated soil extracts. Finally, OECD no. 216 guideline was adapted to measure the levels of basal respiration of soil exposed to similar conditions as the earthworms.

Survival of *E. andrei* was not modulated by plastic contaminated soil; however, earthworm reproduction was altered, with significantly fewer cocoons and juveniles produced in soil contaminated with either the powdered plastic or the leachate. Soil basal respiration was significantly increased by low concentrations of FBP leachates. As for the RShG of *L. sativum* was increased by exposure to the leachate but not by powder at similar low concentrations. However, FBP powder induced an increase in GI.

The findings indicate that the use of biodegradable plastics does not yield any improvement regarding negative effects on soil. More importantly, although the earthworm reproduction was directly affected, low concentrations of plastic-based leachate can alter the soil microbial activity in the form of microbial respiration, potentiating plant growth, with consequences on the soil ecosystem.

3.08.P-Tu193 Effects of Agricultural Microplastics on Two Soil Invertebrates: Comparison of Nondegradable and Biodegradable Oil-Based Plastics

Anita Jemec Kokalj[1], *Andraz Dolar*[1], *Ana Nagode*[1], *Tina Petrisic*[2], *Damjana Drobne*[1], *Aleksandra Kuljanin*[3] *and Gabriela Kalcikova*[3], *(1)University of Ljubljana, Biotechnical Faculty, Slovenia, (2)Department of Biology, University of Ljubljana, Biotechnical Faculty, Slovenia, (3)Faculty of Chemistry and Chemical Technology, University of Ljubljana, Slovenia*

Agricultural plastics are considered one of the most important inputs of microplastics into the soil environment. Therefore, terrestrial invertebrates are exposed to various types of microplastics. Biodegradable plastic mulch films have emerged as a sustainable alternative to conventional plastic mulch films in agriculture, promising to reduce soil contamination with plastic residues through in situ biodegradation. However, the biodegradation of such plastics under natural conditions may differ from standardized tests, so they may also become a source of microplastics in terrestrial ecosystems. Currently, there is very few soil ecotoxicity data available for biodegradable plastics. In this context, the aim of this study was to compare the effects of oil-based, non-biodegradable low-density polyethylene (LLDPE) and starch-based, biodegradable butylene adipate-co-terephthalate (PBAT) microplastics cryo-milled from mulch films used in agriculture. The medium size of both types of microplastics was ~500 µm. We investigated the effects on terrestrial crustacean woodlice *Porcellio scaber* and mealworm larvae *Tenebrio molitor* through soil exposure. Woodlice were exposed for 2 weeks following the survival, growth and immune response. Mealworms were exposed for 8 weeks, following the survival, growth, moult, and development (emergence of pupae and adults). The results showed that none of the investigated microplastics affected the survival and growth of woodlice and mealworms, but the immune response of woodlice was induced and moult of mealworms was affected by both types of microplastics. Thus, no clear differences between effects of LLDPE and PBAT were observed. This study suggests that further comparative studies with microplastics derived from non-degradable and biodegradable plastics are of interest.

3.08.P-Tu194 Investigating the Toxicity of Biodegradable Plastic Textile Fibres on the Earthworm Eisenia fetida

Winnie Courtene-Jones[1], *Richard Handy*[1] *and Richard Thompson*[2], *(1)University of Plymouth, United Kingdom, (2)Plymouth University, United Kingdom*

Biodegradable polymers have been proposed as part of the solution to combat rising quantities of plastic in the environment, and have increased in their production over the last decade. Biodegradable plastics have wide application, including in textiles and wet wipes, where fibres may become emitted to the environment through wastewater discharge and the application of biosolids onto agricultural land. Once in the environment, the rate at which biodegradation occurs is poorly evaluated. Additionally, there are notable gaps in assessing the ecotoxicological implications of biodegradable polymers on organisms and ecosystem functioning. This study examined the toxicity of two fibrous biodegradable polymers derived from textiles (viscose and lyocell), compared to a conventional polymer (polyester) on the earthworm, *Eisenia fetida.* Initial 72-hour toxicity tests on damp filter paper were undertaken using a concentration series of fibres (10,000 – 100 fibres/ml; 125 – 300 µm in length), following the OECD method (OECD 207) to establish lethal thresholds. Subsequently, 28-day chronic exposures were carried out for each polymer at a concentration of 100 mg fibres kg^{-1} dw of Lufa 2.2 soil. Earthworms were sampled after 7 and 28 days, recording mortality and mass, along with assessing fecundity and performing behavioural, biochemical and histological analysis. Results indicated that biodegradable fibres induced a similar mortality as polyester over 72-hours (LC_{20}: 0.0308 mg/ml lyocell; 0.0157 mg/ml viscose; 0.0090 mg/ml polyester). Research to establish sublethal effects of biodegradable fibres following the 28-day exposures are ongoing and will be shared during this conference. The results of this work will contribute toward data deficiencies regarding the ecotoxicological implications of biodegradable fibres, which are required for the development of ecological risk assessments.

3.08.P-Tu195 The Impact of Exposure and Uptake of Nanoplastics on Lettuce Growth and Development

Hannah Elizabeth Case[1], *Maya Al-Sid-Cheikh*[1], *Richard Murphy*[2] *and Carol Wagstaff*[3], *(1)Department of Chemistry, University of Surrey, United Kingdom, (2)Centre for Environment and Sustainability, University of Surrey, United Kingdom, (3)Department of Food and Nutritional Sciences, University of Reading, United Kingdom*

Commercial horticultural production practices often use plastics to improve crop quality and yield, which can consequently introduce plastics directly into the soil. The weathering of plastic can cause fragmentation from macro- (> 5mm), to micro- (1 µm – 5 mm) and nanoplastics (< 1000 nm). These particles have the potential to alter soil properties and influence the growth of crops. Here, we aim to investigate the effects of spherical nanopolystyrene particles ~ 20 nm diameter (nPS) on lettuce (*Lactuca sativa*) grown in a 'hydroponic system'. The nPS were synthesised using an emulsion polymerisation and characterised with a variety of techniques. Lettuce seeds were pregerminated then exposed to a range of nPS concentrations (0, 0.01, 0.5, 500, and 1000 mg/L nPS in ¼ strength Hoagland's plant nutrient) for 28 days, changing the nutrient mix every seven days. Preliminary results showed that, in comparison to the negative control, all spiked concentrations had a reduction in plant growth parameters (no. leaves, widest and longest leaf length, total leaf area, and fresh aerial plant biomass). Spikes of 1000 mg/L nPS resulted in coagulation of nanopolystyrene in Hoagland's plant nutrient, resulting in smaller plants than the control, but larger plants than 500 mg/L, likely due to the coagulation causing reduced bioavailability of nanopolystyrene. A germination study was also performed using the same exposure concentrations; however, no statistical difference in root or shoot emergence rate were observed. The preliminary results of this study suggest that nanopolystyrene over a range of concentrations can have a negative impact on lettuce development. However, the mechanism of action is not yet understood. Future research will be performed to determine if lettuce can uptake and translocate nanoplastics. If confirmed, plants could be a potential input of nanoplastics into the food system; and this research can be used to inform industrial practices and new crop cultivation design.

3.08.P-Tu196 Influence of Different Plastic Polymers to the Terrestrial Snail *Cantareus aspersus* During a Life Cycle Experiment

Romain Colpaert[1]*, Sidney Evert-Diaz*[2]*, Dominique Rieffel*[2]*, Annette de Vaufleury Dr*[2] *and Frédéric Gimbert*[2]*, (1)Laboratoire Chrono Environnement, France, (2)University of Bourgogne Franche-Comté, France*

Plastics accumulate in the environment and can be fragmented, leading to the formation of small plastic fragments (<5mm = microplastics, MPs) which can diffuse and accumulate in various ecosystem compartments. While much work on soil invertebrates has focused on short and acute exposure, little work has been done on the chronic effects of these MPs. Hence, the objective of our study was to identify and measure the response of the terrestrial snail *Cantareus aspersus* to the exposure to different MPs through a life cycle experiment.

Juvenile snails (one month old, 1.36 ± 0.2 g) were exposed in triplicate in glass containers to a range of concentrations (0, 0.1, 1, and 10 % w/w in food) of polyethylene (PE), polyamide (PA), and polystyrene (PS) particles, during a 4 month-experiment. The responses monitored were survival, growth, sexual maturation, fecundity, and fertility. Data were described using logistic models to consider the temporal trends of the measured responses over the exposure duration.
The results show a dose response effect of MP exposure for growth and sexual maturity, with in a growth stimulation at 0.1% MP and a growth inhibition at 1 and 10% MP. An earlier sexual maturation was observed at 0.1% MP and a marginal effect of PE at 1%. Fecundity was affected with a polymer effect, especially by PA, with less eggs laid at 1% and 10% and earlier egg laying at 0.1% and 10%. Fertility also showed a polymer effect with earlier hatchings in PA groups, while a contrasted pattern was observed for PS (delayed hatching at 0.1%, earlier at 10%) and PE (earlier hatching at 1%, delayed at 10%). Mortality showed a polymer effect, with no difference in the 0.1% groups, but with an increasing mortality in the controls accordingly to the exposure concentration, when the mortality remains around 4% for MPs-exposed snails.

In this experiment, the snails could potentially be influenced either by the physical effects (for growth), and by chemical effects of the MPs or their additives (for sexual maturity, reproduction, mortality). An additive related endocrine disruption could here disturb both sexual maturity and lower reproduction traits, influencing the energy reserve of the snails and ultimately leading to an increased survival of the animal. This work highlights the relevance of taking together a wide range of biological endpoints considering different aspects of the life cycle to decipher subtle physiological effects of MPs on soil invertebrates.

3.08.P-Tu197 Does the Co-Existence of Biodegradable Microplastics and Cadmium Affect the Behaviours of Earthworms Differently from Non-biodegradable Microplastics and Cadmium?

Xiao Xiao[1]*, Mark Hodson*[2] *and Brett Sallach*[2]*, (1)Environment and Geography, University of York, United Kingdom, (2)University of York, United Kingdom*

Biodegradable polylactic acid (PLA) has been developed to replace non-biodegradable conventional polyethylene (PE), addressing environmental plastic pollution, particularly in the use of arable mulches. Furthermore, fluctuating temperatures and UV radiation can lead to fragmentation of plastic sheeting and the formation of microplastics (MPs) and MPs providing the opportunity to interact with other common contaminants such as cadmium (Cd), which might pose risks to soil organisms. Laboratory exposures, using earthworms as a key soil organism suggest that the combined effects of non-biodegradable MPs and Cd in soil can lead to synergistic toxic effects. Moreover, a differential performance for maize and arbuscular mycorrhizal funi (AMF) co-exposed to Cd and either non-biodegradable PE or biodegradable PLA and Cd in soil has been detected, but comparatively little is known about the effects of metal-contaminated biodegradable MPs on earthworms. Given this large knowledge gap, it is important to consider the possible interaction between non-essential metal Cd and biodegradable MPs when evaluating the risk that both pose to terrestrial organisms and compared to non-biodegradable MPs-metal interactions. Therefore, experiments to test the single and combined effects of MPs and Cd on the response of earthworms, both biodegradable and non-biodegradable MPs are warranted. We carried out avoidance and exposure tests to investigate whether the co-existence of biodegradable microplastics and cadmium affected the behaviour of earthworms differently from non-biodegradable microplastics and cadmium. In our avoidance tests, earthworms were exposed to 0.3 wt % MPs and / or 0, 0.1, 1.0, and 10 mg / kg Cd. We found a significant difference ($P < 0.05$, Holm-Sidak pairwise multiple comparison) in earthworms avoidance between the 0.3 wt % of biodegradable PLA and non-biodegradable PE as well as between all 100 mg / kg Cd treatments and other Cd concentrations treatments (0, 0.1, 1.0, and 10 mg/kg). As for our exposure experiments, earthworms were exposed to 0, 0.1, 0.3 and 3.0 wt % PLA MPs and 0, 1.0, 5.0, 10, 15, 30, 50 and 100 mg/kg Cd both as separate MPs and Cd treatments and in combination. We detected that there was no significant difference in earthworms weight change between all PLA concentrations ($P = 0.174$), and all Cd levels ($P = 0.797$).

3.08.P-Tu198 Extent and Impact of Microplastics on Availability of Soil Nutrients: A Trade-off Assessment

Joanna Jesionkowska[1]*, Yoseph Araya*[1]*, Pallavi Anand*[1]*, Peter Vale*[2] *and Wesley Fraser*[3]*, (1)Open University, United Kingdom, (2)Severn-Trent Water, United Kingdom, (3)Oxford Brookes University, United Kingdom*

Ever since the invention of plastics, Microplastic (MPs) pieces are spread ubiquitously, however previous studies mainly had focused on pollution in aquatic systems. More recently, research is focusing on the fate and impact of microplastics on terrestrial ecosystems. In this connection, urban and agricultural soils are an important long-term sink for microplastics. Microplastics may enter the soil through application of sewage sludge and compost, irrigation, plastic mulching, littering, as well as atmospheric

deposition. Microplastics in soil undergo translocation, erosion, degradation, and leach to groundwater, before subsequently taken up by plants and get transferred along the food chain.
While water treatment plants effectively remove microplastics from influent water, microplastics get concentrated in the sludge. This sewage is subsequently spread in agricultural soils for crop production. On the positive side, sewage sludge can supply a large part of the nitrogen or phosphorus that most crops need. It's also a good source of organic matter that can improve the water-retaining capacity and structure of soil. On the other hand, sludge often contains potentially toxic elements, such as heavy metals, pathogens, antibiotics, as well as microplastics. Once in soil, microplastics could induce changes in soil fertility and also pose a potential threat to plant performance and crop productivity.
The objective of this study is to review the extent of microplastics added from the sludge on agricultural land, the potential impacts of sludge amendment on nutrient availability and soil biota. The current study will analyse the data about sludge application and nutrients levels from farmland in central UK and relate these levels in soil with amount of added microplastics.

3.08.P-Tu199 Exploring the Fate and Impacts of Microplastics in Agricultural Soil: Perspectives from the Single-species Testing in the PAPILLONS Project

***Anita Jemec Kokalj**[1], Salla Kristiina Selonen[2], Cornelis A.M. van Gestel[3], Andraz Dolar[1], Damjana Drobne[1], Darina Dvorakova[4], Jakub Hofman[5], Lotte de Jeu[3], Gabriela Kalcikova[6], Sarmite Kernchen[7], Christian Laforsch[8], Martin G.J. Löder[7], Sam van van Loon[3], Jana Pulkrabova[4], Vili Saartama[9], Aristeidis S Tsagkaris[4], Klara Šmidova[5], Rachel Hurley[10] and Luca Nizzetto[10], (1)University of Ljubljana, Biotechnical Faculty, Slovenia, (2)Suomen ympäristökeskus (SYKE), Finland, (3)Amsterdam Institute for Life and Environment (A-LIFE), Vrije University Amsterdam, Netherlands, (4)University of Chemistry and Technology Prague, Czech Republic, (5)RECETOX, Masaryk University, Czech Republic, (6)Faculty of Chemistry and Chemical Technology, University of Ljubljana, Slovenia, (7)University of Bayreuth, Germany, (8)University of Bayreuth, Animal Ecology I, Germany, (9)Finnish Environmental Institute (SYKE), Finland, (10)Norwegian Institute for Water Research (NIVA), Norway*

Agricultural plastics are considered one of the most important inputs of microplastics into the soil environment. EU Horizon 2020 project PAPILLONS aims to explore various aspects of micro and nanoplastics (MNP) resulting from the use of agricultural plastics, such as sources, environmental fate and ecological effects in agricultural soils. Within the latter, the special focus is to investigate the effects on terrestrial invertebrates. For this purpose, we designed a single-species testing approach using an array of organisms from different taxonomic groups (insects, crustaceans, annelids, nematodes): earthworms (*Eisenia andrei*), springtails (*Sinella curviseta*; *Ceratophysella denticulata*, *Folsomia candida*, *Heteromurus nitidus*), enchytraeids (*Enchytraeus crypticus, E. albidus*), nematodes (*Caenorhabditis elegans*), woodlice (*Porcellio scaber)*, mealworms (*Tenebrio molitor*) and ants (*Lasius niger*). In this presentation, we will first briefly introduce the test set-up with each of the test organism focusing on the long-term exposure and endpoints that demonstrate chronic effects (growth, reproduction, development, moult). Where possible, multigenerational effects were followed. In the second part, we will demonstrate the approach to soil ecotoxicity testing of MNP focusing on the following relevant issues: 1) selection of relevant agricultural microplastics, 2) selection of relevant exposure concentrations, 3) measures taken to ensure the homogeneity of MNP distribution in test soil, 4) MNP and plastic additive analysis in soil and organisms, and 5) monitoring of soil physico-chemical properties in soil during the experiments. We will show some examples of how these issues have been considered through a case study of two types of microplastics produced by grinding pellets from recycled mulch film: one from conventional polyethylene (LLDPE) films and the other from biodegradable films composed of starch and polybutylene adipate co-terephthalate (starch-PBAT).

3.08.P-Tu200 Effects of Nano- & Microplastics on Terrestrial Plants are Ubiquitous and Widespread: A Systematic Review

***Laura Zantis**[1], Caterina Borchi[2], Martina G. Vijver[3], Willie Peijnenburg[3], Sara Di Lonardo[4] and Thijs Bosker[3], (1)Leiden University, Institute of Environmental Sciences, Netherlands, (2)Department of Civil and Environmental Engineering, University of Florence, (3)Leiden University, Netherlands, (4)Research Institute on Terrestrial Ecosystems (IRET), National Research Council (CNR)*

Over the last years there has been significant research on the presence and effects of plastics in terrestrial systems. Here we summarize current research findings on the effects of nano- and microplastics (NMPs) on terrestrial plants, with the aim to determine patterns of response and sensitive endpoints. We conducted a systematic review (based on 78 studies) on the effects of NMPs on germination, plant growth and biochemical biomarkers. The majority of studies to date have used pristine polystyrene or polyethene particles, either in a hydroponic or pot-plant setup. Our results show that effects on plants are widespread. We noted similar responses among plant species, and between monocots and dicots to NMPs, except for consistent lower germination in dicots due to NMPs. Our results also highlight variation in sensitivity of endpoints to NMPs. During early development, germination and root growth are more strongly affected compared to shoot growth. NMPs induced similar adverse growth effects on plant biomass and length in the most tested plant species (lettuce, wheat, corn, and rice) irrespective of the polymer type and size used. Moreover, biomarker responses were consistent across species; chlorophyll levels were commonly negatively affected, while stress indicators (e.g., ROS or free radicals) and stress respondents (e.g., antioxidant enzymes) were consistently upregulated. Importantly, effects were commonly observed at environmentally relevant concentrations for most endpoints. These findings clearly indicate that NMPs have a wide ranging and ubiquitous impacts affecting plant performance. Importantly, most studies have been conducted under highly controlled conditions and with pristine plastics, raising the urgent need to test under more environmentally realistic condition to ensure the lab-based studies can be extrapolated to the field.

3.08.P-Tu201 Effects of Microplastic on a Non-target Organism: Cellular Effects on the Lichen

Gintare Sujetoviene *and Diana Miškelytė, Vytautas Magnus University, Lithuania*

Although plastic pollution is most visible in the environment of anthropogenic sites, there is increasing evidence of microplastics entering the remote environment. As this pollution is becoming an increasingly global issue, lichens as one of the well-known biomonitors of pollution may be useful, although to the best of our knowledge there are no studies on the effects of microplastics at cellular level. The aim of the study was to evaluate the toxic effects of polypropylene (PVC) on viability of terrestrial biota (non-target organism) - the lichen *Ramalina fastigiata*. Thallus of lichen were incubated with significant environmental microplastic concentrations and changes in the photosynthetic apparatus (chlorophyll fluorescence, reduction of chlorophyll a content) and permeability of cell membranes were determined. The study shows that exposure at low ($\mu g\ L^{-1}$) microplastic concentrations (within the range of concentrations detected in the environment), induce disturbances in the physiological state of the lichen *R. fastigiata*. In addition, the preliminary results of this work highlight the potential negative impacts of uncontrolled use of microplastics on the components of the environment.

3.08.P-Tu202 Microplastic Distribution in Sewage Sludge Amended Soil - The Advantage of Complementary Uses of Py-GC/MS and micro-FTIR Imaging

Wiebke Mareile Heinze[1]*, Zacharias Steinmetz*[2]*, Nanna Dyg Rathje Klemmensen*[3]*, Jes Vollertsen*[3] *and Geert Cornelis*[1]*,*
(1)Swedish University of Agricultural Sciences (SLU), Sweden, (2)University of Kaiserslautern-Landau (RPTU), Germany, (3)Aalborg University, Denmark

Sewage sludge application to agricultural land has been associated with elevated microplastic (MP) loads on soil. Although laboratory studies suggest that microplastics may be transported to deeper soil layers by bioturbation and percolation in macropores, these transport processes have hardly been assessed in field trials yet. There is furthermore a strong divide between studies, either applying spectroscopic methods focusing on particle counts and properties, and thermoanalytical techniques which primarily yield total polymer masses. Field studies analysing both the mass distribution of MPs in soil and particle shapes and sizes are still scarce but needed to better understand their distribution in soil.

We analysed soil core samples along 90 cm depth profiles from agricultural long-term field studies in Sweden to which sewage sludge was applied since 1996. First, we used solvent-based pyrolysis gas chromatography – mass spectrometry (Py-GC/MS) to identify samples of interest. Samples with exceptionally high MP concentrations were subsequently analysed with micro-Fourier Transform Infrared spectroscopy (micro-FTIR) imaging for characterizing sizes, polymer type, and shape associated parameters. The highest MP mass concentrations were found in and directly below the plough layer, successively decreasing with depth, but still detectable at 40 cm depth. We inferred that the observed decreasing mass concentration with depth is probably a result of larger MP particles being retained in the topsoil, a combined result of particle and soil properties. Transport of larger MPs in clayey soils such as at our study site is highly dependent on the presence of large macropores. Consequently, we suspect that smaller MPs are more easily and preferentially transported downwards. While Py-GC/MS measurements enable rapid screenings for MP concentrations, micro-FTIR improves our understanding of the observed distribution and MP mobility. Combining these methods could potentially allow for more time-efficient, targeted MP monitoring in the future.

3.08.P-Tu203 Study of the Combined Effect of Microalgal Biomass and Microplastics in the Soil on the Retention of Three Pesticides

Urška Šunta[1]*, Franja Prosenc*[1,2]*, Kristina Žagar Soderžnik*[3]*, Tjaša Griessler Bulc*[1] *and Mojca Bavcon Kralj*[1]*, (1)University of Ljubljana, Faculty of Health Sciences, Slovenia, (2)University of Leeds, United Kingdom, (3)Department for nanostructured materials, Jozef Stefan Institute, Slovenia*

Modern agriculture heavily relies on the addition of fertilisers on the fields and the use of pesticides to achieve the maximum crop yields per season. The most commonly utilised fertilisers are the chemically produced ones, while organic fertilisers such as manure as used to a lower degree. Another form of organic fertiliser has been proposed, e.i. microalgal biomass. The addition of microalgal biomass to the soil was found to promote plant and root growth and improve the fruit quality, and the elemental composition of the soil. From the sustainability point of view, the circularity of the nutrients is achieved if microalgal biomass from a nature-based wastewater treatment process is used. Microplastics (MPs) in agroecosystems mainly originate from soil amendments, mulching, surface runoff, and atmospheric deposition. MPs have been reported to play a role in the soil microbiome functioning, plant growth, and transport of chemical contaminants, like pesticides. This study aimed to determine the differences in the retention of three model pesticides in soil amended with microalgal biomass, and in MPs spiked soil amended with microalgal biomass. Selected model pesticides were acetamiprid (ACE; log Kow 0.80), chlorantraniliprole (CAP; log Kow 2.76), and flubendiamide (FLU; log Kow 4.20), while MPs particles used were polyethylene terephthalate, polystyrene, and polyethylene, in size range from 100 µm to 1 mm. Pesticides solutions (1 mg/L and 5 mg/L) were added to the mixtures of soil-MPs, soil-microalga biomass, and soil-microalgal biomass-MPs to illustrate the pesticides' application rate of 2 mg/kg and 10 mg/kg, respectively. Solutions were left to stir, and after an hour, the concentrations of pesticides were determined by high-pressure liquid chromatography. Results showed that the overall retention of pesticides depended on the Kow of model pesticides (FLU > CAP > ACE) at both pesticide's application rates. At the higher application rate, we observed that the soil amended with microalgal biomass and polluted with MPs retained more pesticides compared to the soil only amended with microalgal biomass and also compared to the soil only spiked with MPs.

3.08.P-Tu204 Microplastics in Soil Systems, From Source to Path to Protection Goals

Melvin Faber*, Michiel Rutgers, Joris T.K. Quik and Susanne Waaijers-van der Loop, National Institute for Public Health and the Environment (RIVM), Netherlands*

Microplastics can be found everywhere in the world, and in any environmental compartment. During recent years it was discovered that most microplastics may end up in the soil compartment. While the amount of research on microplastics in the soil compartment has increased almost exponentially last 5 years, the number of scientific publications are lagging behind these on microplastics in the water compartment. There are indications that microplastics pose a risk to human health and soil life. Therefore, to inform policymakers and risk assessors, RIVM has summarized current knowledge and identified knowledge gaps of microplastics in the soil system. This poster presents the results of this inventory using a conceptual model which addresses topics considered most important for risk assessment. While the model includes several topics, the information presented here focusses on the topics sources, release and emission, fate and transport, and exposure.

3.08.P-Tu205 Iron Oxide Nanoparticles Enhance Plastic Biodegradation

Nhung Nguyen *and Alena Sevcu, Technical University Liberec, Czech Republic*

Bio-based plastics (BPs), produced from renewable biomass sources, are increasingly being used in commertial products and applications, especially bridgeable plastics. Therefore, their biodegradability and environmental fate continues to be an important subject of investigation. The soil bacterium *Ideonella sakaiensis* is owing a PETase enzyme capable to degrade conventional PET plastics. Fe_3O_4 nanoparticles are regarded as safe material providing an essential element for bacterial growth. In this study, we explored beneficial properties of both *I. sakaiensis* and Fe_3O_4 to degrade BPs PET and commercially available PET indicated by scanning electron microscopy (SEM), bacterial growth (CFU) and gene expression for PETase. Bacteria-plastic interaction was observed under epifluorescence microscopy and SEM characterized plastic surface. The first results show that after five days, bacteria degraded BPs PET to micro- and mm size debris. We presume that Fe_3O_4 nanoparticles can enhance the BPs PET biodegradation. Further, we will perform the same experiment on commercially available PET to obtain a complete picture.

3.08.P-Tu206 Polyethylene Microplastics Influence the Distribution of Ivermectin in Soil

Johannes Junck[1] *and Rolf-Alexander During*[2]*, (1)Department of Soil Science and Soil Conservation, Justus Liebig University Giessen, Germany, (2)Justus Liebig University Giessen, Germany*

Microplastics are found in almost every natural environment. A large number of studies has already investigated the role of microplastics as vectors for organic pollutants in aquatic ecosystems. However, the impact of microplastics on the distribution and transport of organic pollutants in soil remains unclear. In this study, we therefore investigated sorption and desorption of the hydrophobic antiparasitic agent ivermectin in soil under the influence of microplastics. Ivermectin is applied extensively in veterinary medicine worldwide and enters the soil via animal excretions. Batch sorption experiments were performed to evaluate the effect of low-density polyethylene (LDPE) microplastics (particle size 100 200 µm) at addition rates of 0% (control), 0.3% and 3% (w/w) in a reference soil (LUFA 2.4). The lower rate (0.3%) was selected as an environmentally relevant concentration of microplastics, while the higher rate (3%) represented an extreme scenario in the soil. The ivermectin concentrations assessed ranged from 15 to 1.500 µg L^{-1} and covered two orders of magnitude. Samples were analyzed via high performance liquid chromatography using fluorescence detection (HPLC-FLD) after derivatization. Resulting sorption and desorption isotherms were fitted to the Henry model. The distribution coefficient for LDPE microplastics (K_{MP}) in the soil-water system was calculated based on the highest amount microplastics added (3% LDPE). The addition of microplastics significantly influenced sorption of ivermectin in soil. Hence, distribution coefficients K_D of 420 L kg^{-1} (0% LDPE), 431 L kg^{-1} (0.3% LDPE) and 586 L kg^{-1} (3% LDPE) were calculated showing the highest sorption at 3% LDPE. Desorption of ivermectin in soil was similarly affected resulting in desorption coefficients K_D^{des} of 643 L kg^{-1} (0% LDPE), 719 L kg^{-1} (0.3% LDPE) and 742 L kg^{-1} (3% LDPE) with the lowest desorption at 3% LDPE. The K_{MP} was 5.549 L kg^{-1} indicating a high affinity of ivermectin for LDPE microplastics. The results imply that the presence of microplastics reduces the mobility of ivermectin in soil by increasing the sorption capacity and decreasing the desorption rate. LDPE therefore can be a sink for ivermectin in the soil environment. This may affect the uptake of ivermectin by plants and soil organisms such as earthworms.

3.08.P-Tu207 Plastic in Agricultural Production: Impacts Life cycles and Long-term Sustainability: Introducing PAPILLONS

Luca Nizzetto[1]*,* ***Rachel Hurley***[1]*, Demetres Briassoulis*[2]*, Salla Kristiina Selonen*[3]*, Sannakajsa Velmala*[4]*, Szabolcs Zoldreti*[5]*, Matthias Rillig*[6]*, Jakub Hofman*[7]*, Andreu Rico*[8]*, Christian Laforsch*[9]*, Cornelis A.M. van Gestel*[10]*, Pierfrancesco Cerruti*[11]*, Anita Jemec Kokalj*[12]*, Wulf Amelung*[13]*, Evelia Schettini*[14]*, Janusz Zimmy*[15]*, Thijs Bosker*[16]*, Mirco Bundschuh*[17]*, Rong Ji*[18]*, Thomas Puetz*[19]*, Jana Pulkrabova*[20] *and Anne Deininger*[1]*, (1)Norwegian Institute for Water Research (NIVA), Norway, (2)Agricultural University of Athens, Greece, (3)Suomen ympäristökeskus (SYKE), Finland, (4)Natural Resources Institute Finland (Luke), Finland, (5)Farm Europe, Brussels, Belgium, (6)Freie Universität Berlin, Germany, (7)RECETOX, Masaryk University, Czech Republic, (8)IMDEA Water Institute, Spain, (9)University of Bayreuth, Animal Ecology I, Germany, (10)Amsterdam Institute for Life and Environment (A-LIFE), Vrije University Amsterdam, Netherlands, (11)Institute for Polymers, Composites and Biomaterials, National Research Council of Italy (IPCB-CNR), Italy, (12)University of Ljubljana, Biotechnical Faculty, Slovenia, (13)Bonn University, Germany, (14)University of Bari, Italy, (15)Plant Breeding and Acclimatization Institute, IHAR, Poland, (16)Leiden University, Netherlands, (17)iES Landau, Institute for Environmental Sciences, University of Kaiserslautern-Landau (RPTU), Germany, (18)Nanjing University, China, (19)Forschungszentrum Jülich, Germany, (20)University of Chemistry and Technology Prague, Czech Republic*

Plastics is an increasingly important commodity in agricultural production. However, some use and inappropriate waste management can result in the release of plastic debris to soils. The long-term impacts of these materials on soil ecosystem quality and functioning, and agricultural sustainability is uncharted. Knowledge and understanding of mechanisms and processes controlling releases, behaviour, fate and impacts of plastic pollution from both conventional and degradable polymers, as well as

their chemical additives on soil ecosystem and its productivity is mostly missing. PAPILLONS is a research and innovation action funded by the EU under the Horizon 2020 framework programme. The goal is to elucidate sustainability of plastic use in European agriculture in relation to releases and impacts of micro- and nano-plastics (MNPs) and their chemical additives in soil. Through novel applications of state-of-the-art analytical chemistry, materials science, and a series of multipronged experiments (from in-vitro to the field scale), we will elucidate sources, behaviour and impacts of particles in both micro- and nano-scales on agricultural soil ecosystems. We will take advantage of the cross-disciplinary synergies in integrative case studies, jointly addressing these knowlege gaps in different biogeographic, agricultural, and socioeconomic regions of Europe. Research tasks include: 1) inventorying usage of agricultural plastics and waste generation in Europe. 2) quantification of MNP release rate from prevalent agricultural plastics through ageing and fragmentation experiments; 3) assessments of MNP transport within soil and to groundwater, freshwater, biota and crops; 4) surveying current levels of plastic contamination in European agricultural soils; 5) elucidation of long-term impacts on soil properties and ecosystem services, looking at effects on biodiversity and functioning in soil invertebrate and microbial communities; 6) Assessment of stakeholder perspectives on the socioeconomic sustainability of plasticulture.
We address long-term implications of plastic pollution to tackle impacts on soil productivity, crop quality, agricultural yield. PAPILLONS uses a multi-actor approach whereby scientists in the areas of agronomy, environmental science, ecology, chemistry, engineering, economics and social sciences meet a diverse group of actors in the farming, industry, services and policy sectors to co-create knowledge.

3.08.P-Tu208 Shape as a Controlling Factor in Weathering of PET as a Precursor to Microplastic Formation
Barbora Pinlova[1]*, Aurelio Borzi*[1] *and Bernd Nowack*[2]*, (1)EMPA Technology and Society Lab, Switzerland, (2)Empa – Swiss Federal Laboratories for Material Science and Technology, Switzerland*
Plastic debris is exposed to a range of factors in the environment that lead to weathering of the material. The process of weathering results in changes in the material including surface cracking and enhances brittleness. Furthermore, weathering is considered a precursor to fragmentation and microplastic formation. However, the knowledge on the chain of these events is limited, especially how the form of the polymer affects the weathering. Therefore, a comparative study of the weathering process of polyethylene terephthalate (PET) was performed. PET in three different forms was exposed to UV light for three months. The samples included PET fibers, films, and pellets. Moreover, the effect of hydrolysis was studied by submerging half of the samples in water. The progress of weathering was investigated with scanning electron microscopy every 15 days. Additional analysis was performed on selected samples by Raman spectroscopy, x-ray diffraction analysis, and gel permeation chromatography. It was concluded that the weathering conditions as well as the specific properties of the plastics influence the development of the features related to weathering. It was shown that the combination of photo-oxidation and hydrolysis quickened the process. Sole hydrolysis did not seem to result in any damages on the material, while the exposure to the UV light led in changes in crystallinity and surface alterations, which were spotted in the final days of the experiment. While crack development was observed on pellets, films were indented with pits and fibers with grooves. The samples exposed to UV light while submerged in water started displaying signs of mage after 15 or 30 days of the weathering. While pellets immediately started to crack, films and fibers were first covered with pits, which then transformed into cracks. Each PET form showed a unique crack pattern, likely related to the production process. Moreover, the crack pattern was recognized to be a template to the surface layer ablation which was observed when additional mechanical stress was applied. Therefore, the size and quantity of the fragments could be estimated. It was suggested that 1.4-7.9 million microplastic fragments can be released from one cm^2 of a weathered PET film and 0.4-2.2 million from the same surface area of a pellet. Moreover, additional particles were seen emerging on the surfaces of the weathered samples that could be an additional source of microplastics produced during weathering.

3.08.PC Current State-Of-the Art in Understanding the Occurrence and Implications of Plastics in Terrestrial Environments

3.08.P-Tu170 Assessing the Impact of Microplastic Extraction Methods on Biodegradable Polymers
Grace Davies[1]*, Martin G.J. Löder*[2]*, Sarmite Kernchen*[2]*, Christian Laforsch*[3]*, Samantha Marshall*[4]*, Massimiliano Mascelloni*[4]*, Stefan Krause*[1] *and Iseult Lynch*[1]*, (1)University of Birmingham, United Kingdom, (2)University of Bayreuth, Germany, (3)University of Bayreuth, Animal Ecology I, Germany, (4)Syngenta, United Kingdom*
Agricultural soil is a sink for microplastics (MPs), with both indirect and direct sources. Indirect sources include the use of sewage sludge as fertiliser, plastic mulching films, atmospheric deposition, irrigation with wastewater etc. It is difficult to quantify the MPs addition from these sources, but the use of sewage sludge as fertiliser is estimated to add 63-430kt/year of MPs into European farmland (Nizzetto et al. 2016).
In comparison, the direct addition of MPs to soil can be quantified. In the EU, direct sources (e.g., the application of controlled release fertilisers, and plant protection products) account for approx. 23,500 tonnes/year of MPs, of which plant protection products account for approx. 1,000 tonnes/year (ECHA, 2019). This is preventable and under new restrictions proposed by the European Chemicals Agency, biodegradable polymers are suggested as future alternatives (ECHA, 2019). It is likely that biodegradable polymers will be used in soil applications and therefore essential that robust extraction and analytical methodologies are developed to monitor their environmental fate. However, such methods for the analysis of MPs in soil have not generally been designed for biodegradable polymers. For environmental soil samples, a combination of density separation with $ZnCl_2$ and enzymatic-oxidative digestion is a promising technique that has been shown to have a high removal efficiency for soil organic material (e.g., Möller et al. 2020).

In this work, enzymatic digestion has been tested on representative polymers polylactic acid (PLA) and poly(r)-3-hydroxybutyrate (PHB). Polymer films were made from powder, then their stability after exposure to the enzymatic-oxidative digestion method was determined. Impacts of each treatment were assessed visually via microscopy and quantitatively by weight and thickness measurements. Surface degradation was measured with attenuated total reflectance Fourier-transform infrared spectroscopy (ATR-FTIR), and polymer molecular weight was measured by gel permeation chromatography (GPC).
Results show variability in the impact on the polymer depending on the treatment used and the application sequence. A combination of both visual assessment and chemical characterisation was needed to determine impacts on polymers. This work highlights the importance of quantifying the impacts of microplastic extraction methods on specific polymers of interest to improve future method development.

3.08.P-Tu171 Suitability of Elutriation for the Extraction of Microplastics from Natural Soils
*Kyle Forsythe[1], Mason Egermeier[1], Andrea Jilling[2] and **Jorge Gonzalez Estrella**[1], (1)School of Civil and Environmental Engineering, Oklahoma State University, (2)Plant & Soil Sciences, Oklahoma State University*
We evaluated the suitability of elutriation for improving the extraction of microplastics as a function of soil textures. Microplastic pollution in marine environments has been extensively studied in modern literature; however, information about the prevalence of microplastics in freshwater and terrestrial systems is lacking. The lack of published literature regarding the extent of microplastic contamination of terrestrial ecosystems is in part due to the lack of any standardized extraction methodology for microplastics from high-clay and organic-rich soils. In this study, we obtained five samples with textures varying from, 0.1-8.6% organic matter, 16.7-96.3% sand, 2.5-45% silt, and 1.3-50.0% clay and compared the extraction efficiency of an extraction process that included elutriation with a typical direct digestion process. All soils were subjected to microplastic extraction with and without elutriation (direct digestion). Samples were digested in 7.5% NaOCl, then flotation in 5.1M $ZnCl_2$ solution. The number of particles was quantified through staining and fluorescence microscopy. The amount extracted varied from 3,300-188,900 particles/kg in elutriated soils and from 3,600-153,700 in direct digested soils. Linear regression was used to determine the relationship between relative number of particles extracted (with elutriation vs without elutriation) and combinations of soil parameters. Correlations were observed between relative extraction quantity and clay content (R^2=0.64), (clay+OM)/(silt+sand) (R^2=0.69), (clay+OM)/silt/sand (R^2=0.81), $(clay+OM)^{1/2}$/silt/sand (R^2=0.88), suggesting that elutriation may be effective as an extraction step for high-sand and silt soils, and should be avoided for high-clay and organic matter soils. Currently, we are validating the plastic composition of the particles using Attenuated Total Reflectance – Fourier Transformed Infrared spectroscopy and quantifying the amount of remaining metals and salts using Inductive Coupled Plasma Mass Spectroscopy and Emission Dispersive X-ray spectroscopy. The information gathered in this study should help other groups in determining the extent of microplastic contamination in Earth's ecosystems by providing viable extraction methodologies for a range of soil types. A rigorous understanding of microplastic prevalence in the environment will aid in determining the impacts associated with microplastic contamination.

3.08.P-Tu175 From Wastewater Treatment Plants to the Terrestrial Environment: Microplastics in Sewage Sludge Compost, Agricultural Soil, and Earthworms
***Niina Kärkkäinen**[1], Salla Kristiina Selonen[2] and Markus Sillanpää[1], (1)Laboratory Centre, Finnish Environmental Institute (SYKE), Finland, (2)Suomen ympäristökeskus (SYKE), Finland*
Wastewater treatment plants have been found to be a significant source of microplastics to the terrestrial environment. After wastewater purification, most of the microplastics in the wastewater influent end up into the resulting sewage sludge, which then can be processed further, for example, into compost. The microplastics enter the environment when the compost is applied as a fertilizer to a soil. From the soil, the microplastics can be digested by soil dwelling organisms, like earthworms. The objectives of this study were 1) to develop sample preparation methods for isolating microplastics from sewage sludge compost, soil and earthworm samples, and 2) to investigate the number concentration of microplastics in these samples. Sewage sludge compost, agricultural soil fertilised with sewage sludge compost, control agricultural soil without compost fertilizer and earthworms taken from the same soils were sampled for microplastics. Sample preparation was tailored to each of these specific sample matrices with methods including sieving, filtering (20 µm), organic matter removal and density separation. The prepared sample was then filtered onto an Anodisc filter (pore size 0.2 µm, diameter 25 mm). An imaging Fourier Transformation Infrared microscope (µFTIR; Lumos II, Bruker) was used to identify the microplastics in transmittance mode. Particular effort was put to mitigate sample contamination. Sample preparation and FTIR-analysis were conducted in a separate, synthetic-fibre-free laboratory meant to be used only for microplastic research. Laboratory blank samples were handled similarly with the real samples to assess the sample contamination from the laboratory environment. In this presentation, the number concentration of microplastics in sewage sludge compost, agricultural soils and earthworms are shown and the links between the microplastic sources and sinks are discussed.

3.08.P-Tu189 Effects of Conventional and Biodegradable Microplastic on Seed Germination and Plant Growth of Food Crops
***Laura Zantis**[1], Anne Wilts[1], Sannakajsa Velmala[2], Sylwia Adamczyk[2], Martina G. Vijver[3], Willie Peijnenburg[4] and Thijs Bosker[3], (1)Leiden University, Institute of Environmental Sciences, Netherlands, (2)Natural Resources Institute Finland (Luke), Finland, (3)Leiden University, Netherlands, (4)National Institute for Public Health and the Environment (RIVM), Netherlands*
Nano- and microplastic (<100 nm and <5 mm, respectively) pollution is becoming increasingly persistent in all ecosystems and is considered an emerging threat to biodiversity and ecosystem functioning. One major concern are agricultural lands, which have been identified as long-term microplastic sinks. As a result, there is now a push towards developing bioplastics, which can be

(partly) broken down after entering the environment. Yet, limited research has been done to compare the impacts of microplastics and bioplastics on terrestrial crop plants. This study aims to examine and compare the effects of artificially weathered conventional polyethylene (PE) and starch-based biodegradable polybutylene adipate terephthalate (PBAT) on four common food crops, including lettuce (*Lactuca sativa* L.), carrot (*Daucus carota*), wheat (*Triticum aestivum* L.) and barley (*Hordeum vulgare*), through two complimentary experiments. We investigated the effects of environmentally relevant low, medium, and high (0.01%, 0.1%, 1% w/w) concentrations of weathered PE and PBAT particles on seed germination (acute toxicity: Petri-dish experiment) and plant growth (chronic toxicity: pot-plant experiment) respectively. Our results show adverse effects of both PE and PBAT on crops. When acutely exposed during germination, PE significantly accelerated the germination rate of carrot seeds by two days ($p<0.05$). In addition, both PE and PBAT decreased the root length of lettuce and wheat by up to 36% and 53% respectively ($p<0.05$). Contrary, root length ($p<0.0001$), shoot length ($p<0.05$) and seedling biomass ($p<0.05$) of carrot were increased with up to 86% when exposed to PE and PBAT respectively. In the pot-plant experiment, PBAT significantly delayed the germination rate of barley ($p<0.05$), and additionally decreased the shoot biomass by 16% after 14 days ($p<0.05$). No significant effects of PE and PBAT were recorded on the seed germination of lettuce. Overall, these results show that the early development of seedlings are mainly impacted, but over time plants might recover mildly. Moreover, biodegradable plastic was more toxic than the conventional plastic highlighting the need to further investigate the effects of micro- and bioplastics on crop plants.

3.08.P-Tu190 Long-term Effects of Agricultural Microplastics on Earthworm *Eisenia Andrei*; Comparison of Conventional and Biodegradable Plastics

***Vili Saartama*[1]*, Salla Kristiina Selonen*[2] *and Jari Haimi*[1]*, (1)University of Jyväskylä, Finland, (2)Suomen ympäristökeskus (SYKE), Finland*

Use of plastics is common in modern agriculture, but degradation of plastics in soil is a slow process. Biodegradable plastics have been proposed as a solution for this problem, but little is known about possible long-term effects of plastics, either biodegradable or conventional, on soil organisms. The aim of our study is to find out the possible effects of microplastics from conventional and biodegradable mulching film material on the earthworm *Eisenia andrei.*

We studied two types of microplastics produced by grinding pellets made of recycled mulching films, one from conventional polyethylene (PE) films and the other from biodegradable films composed of starch and polybutylene adipate co-terephthalate (starch-PBAT). We exposed earthworms to these two microplastic types in concentrations of 0 %, 0.005 %, 0.05 %, 0.1%, 0.5 %, 1 % and 5 % of dry mass. The experiments started with standard reproduction tests with earthworms of parental (P) generation (ISO 11268-2). After the standard tests, we selected 13 juveniles from each test jar for new set of tests to study the impacts of long-term microplastic exposure on the first offspring generation (F1). We followed the growth and the number of mature individuals every four weeks. In addition to survival, growth and reproduction, the uptake of microplastics and plastic additives as well as immunological biomarkers in earthworms will be analyzed.

The experiments are still running, and statistical analyses have not been performed yet. The preliminary data suggest that the microplastics have not affected earthworm survival, but the presence of PE in the soil decreased the growth in F1 generation. In contrast, the biodegradable plastic seems to increase the growth of the earthworms in F1 generation. The earthworms in the highest PE concentrations also maturated later.

This study is part of a PhD project which focuses on the long-term effects of microplastics on earthworms in agricultural soils.

3.08.P-Tu202 Microplastic Distribution in Sewage Sludge Amended Soil - The Advantage of Complementary Uses of Py-GC/MS and micro-FTIR Imaging

***Wiebke Mareile Heinze*[1]*, Zacharias Steinmetz*[2]*, Nanna Dyg Rathje Klemmensen*[3]*, Jes Vollertsen*[3] *and Geert Cornelis*[1]*, (1)Swedish University of Agricultural Sciences (SLU), Sweden, (2)University of Kaiserslautern-Landau (RPTU), Germany, (3)Aalborg University, Denmark*

Sewage sludge application to agricultural land has been associated with elevated microplastic (MP) loads on soil. Although laboratory studies suggest that microplastics may be transported to deeper soil layers by bioturbation and percolation in macropores, these transport processes have hardly been assessed in field trials yet. There is furthermore a strong divide between studies, either applying spectroscopic methods focussing on particle counts and properties, and thermoanalytical techniques which primarily yield total polymer masses. Field studies analysing both the mass distribution of MPs in soil and particle shapes and sizes are still scarce but needed to better understand their distribution in soil.

We analysed soil core samples along 90 cm depth profiles from agricultural long-term field studies in Sweden to which sewage sludge was applied since 1996. First, we used solvent-based pyrolysis gas chromatography – mass spectrometry (Py-GC/MS) to identify samples of interest. Samples with exceptionally high MP concentrations were subsequently analysed with micro-Fourier Transform Infrared spectroscopy (micro-FTIR) imaging for characterizing sizes, polymer type, and shape associated parameters. The highest MP mass concentrations were found in and directly below the plough layer, successively decreasing with depth, but still detectable at 40 cm depth. We inferred that the observed decreasing mass concentration with depth is probably a result of larger MP particles being retained in the topsoil, a combined result of particle and soil properties. Transport of larger MPs in clayey soils such as at our study site is highly dependent on the presence of large macropores. Consequently, we suspect that smaller MPs are more easily and preferentially transported downwards. While Py-GC/MS measurements enable rapid screenings for MP concentrations, micro-FTIR improves our understanding of the observed distribution and MP mobility. Combining these methods could potentially allow for more time-efficient, targeted MP monitoring in the future.

3.08.V Current State-Of-the Art in Understanding the Occurrence and Implications of Plastics in Terrestrial Environments

3.08.V-01 Can Wastewater Treatment Plants' Mitigate Microplastic in Terrestrial Environment? – A Comparative Study of Sludge Treatments

Asta Hooge Poulsen[1], *Henrik Hauggaard-Nielsen*[2], *Gry Lyngsie*[2] *and Kristian Syberg*[2], *(1)Science and Environment, Roskilde University, Denmark, (2)Roskilde University, Denmark*

The aim of this study is to quantify the efficiency of different sludge treatments capabilities of removing microplastic (MP) from sewage sludge at wastewater treatment plants (WWTPs).

Sludge treatments are the last stop before sludge fraction leaves the WWTP. ~99% of MP entering WWTPs is presumed to be retained in the sludge fraction, hereby becoming a relevant potential route for environmental exposure, if MP is not removed in the sludge treatment. Sludge is worldwide used as fertilizer on agricultural fields, and MP in sludge fraction can both influence the terrestrial environment as well as being transported to the aquatic environment.

At WWTPs sludge treatments primary function is to aggregate solid fraction in sludge and reduce water content. However some sludge treatments also have the ability to influence the concentrations of MP in sludge, hereby reducing the environmental impact. New technologies such as Pyrolysis are emerging as a new way of removing contaminants and could potentially remove MP at WWTPs.

Standard practice today includes mechanical dewatering, where polymer emulsion can be added to the process to increase the dewatering process. This could result in an increased MP abundance.

This study aims at assessing the effectiveness of different sludge treatments in removing MPs in sludge. This is done by assessing MPs in sludge pre and post treatment with biological degradation technologies (Sludge mineralization/Reedbed systems) and gas producing technologies (Incineration, pyrolysis and anaerobic digestion) as well as mechanical dewatering.

This also includes an analysis of polymer emulsion used at the WWTPs to determine whether these products increase MP abundance in sludge fraction.

Samples of sludge before and after treatment are gathered from five different WWTPs, purified and analysed using FTIR to determine plastic polymers and concentrations, generating the much-needed understanding of how these treatment technologies can help minimize the MP contamination emitted from WWTPs.

3.08.V-02 Towards Quality Assured Measurements of Microplastics in Soils Using Fluorescence Microscopy

Nhu Le Quynh Phan[1], ***Crispin Halsall***[2], *Melanie Braun*[3] *and Wulf Amelung*[3], *(1)Lancaster Environment Centre, Lancaster University, United Kingdom, (2)Lancaster University, United Kingdom, (3)Bonn University, Germany*

Monitoring microplastics (MP) in agricultural soil has become an area of great research interest, given the potential hazards posed by microplastics to the soil ecosystem and human health. Measuring particle number concentration is essential in this context, particularly for ecotoxicology. Various analysis methods have been developed so far, albeit the results are often inconsistent, difficult to compare and uncertain. Among these methods, fluorescence spectroscopy-Nile Red staining has progressed as a low-cost, relatively simple-to-use approach for analysing a broad spectrum of microplastics in complex environmental matrices like soils. However, validated sample preparation and analytical methodologies, with quality controls and assurance, are often lacking and difficult to establish but are essential for reliable measurements. Therefore, this study aims to establish an assured, reproducible fluorescent-based methodology for analysing MP in soil, which discriminates MP size and type present in different soil types. Eight MP types (including both non-biodegradable and biodegradable plastics) within three size categories (dia. 500-1000 µm, 100-250 µm and 10-150 µm) were "spiked" into three different agricultural soils (loam-reference soil, clay, and sandy soils) for a comprehensive assessment of the fluorescence microscopy methodology. As a tool to shorten the analysis time, a digital image analysis pipeline using Image J was developed, which allowed for fully automatic quantification of MP in the samples. Validation of the ImageJ method shows a high accuracy (88% match to true observation) for MP particles on a filter without a soil matrix. Recoveries ranged from 80-90% for MP with sizes from 500-1000 µm regardless of the soil types, whereas those for smaller MP (10-250 µm) varied between different soils and plastic types, with the lowest values observed in clayey soil and for biodegradable plastics. The results probably reflect the complexity of clay soil owing to a high presence of soil organic matter and very small and negatively charged mineral particles and the possible degradation of biodegradable plastics during their extraction from the soil. This helps to better understand the MP loss during sample preparation and due to the nature of the soil and plastic interactions. A relationship between the microplastic mass and the corresponding particle number was established in this study, which enabled the conversion between mass and particle number data.

3.09 Emerging Organic Contaminants in the Oceans: Local Sources, Long-Range Environmental Transport and Impact of Climate Change

3.09.T-01 Exposing Marine Microbial Communities to Organophosphate Ester Flame Retardants and Plasticizers Along the Atlantic Ocean

Jon Iriarte, *Núria Trilla, Naiara Berrojalbiz, Jordi Dachs and Maria vila-Costa, Environmental Chemistry, Spanish Research Council (CSIC), Institute of Environmental Assessment and Water Research (IDAEA), Spain*

The widespread usage of organophosphate esters (OPEs) as flame retardants and plasticizers has led to their ubiquitous presence in the environment. This fact, together with their potential toxic effects on humans and ecosystems, has caused them to be considered organic pollutants of emerging concern. In addition, OPEs are potential phosphorus (P) sources that can cause an anthropogenic perturbation of the P marine biogeochemical cycle. However, no international regulation exists to tackle the increasing emissions of OPEs. It is necessary to understand their biogeochemistry in order to improve risk assessments and regulation.

To help understand the biogeochemistry of OPEs in the open ocean we performed a series of experiments during the ANTOM oceanographic cruises with the objective of determining the role that marine bacteria play (usually underestimated) in the fate of these compounds. Briefly, these experiments consisted of incubating for 48h at dark 2L of surface seawater where a mixture of 6 known OPEs had been spiked. We measured the OPE concentrations at the beginning and at the end of the incubations and we characterized the bacterial populations by 16S Amplicon sequencing. Additionally, we measured prokaryotic cell abundance, bacterial production, and inorganic nutrient and total organic carbon (TOC) levels. Concurrently, bacterial production was used to estimate nutrient limitations in each experiment in short-term nutrient enrichment bioassays.
Here I present the first results of the experiments carried out during the ANTOM-1 oceanographic campaign, which consisted of a longitudinal transect across the Atlantic Ocean. Bacterial production results, estimated as incorporation rates of H^3-leucine, showed an increase in the bacterial activity after 48 hours of incubation. The analysis of the bacterial community composition resulted in an enrichment of at least 8-fold of the genera *Alteromonas, Pseudoalteromonas,* and *Sulfitobacter.* Although there is no evidence in the literature of these genera being able to degrade OPEs, all of them are known to be opportunistic taxonomic groups. Data from the quantification of the OPE levels and other measurements will allow us to understand what triggered these changes.
These experiments will shed light on the interactions between marine bacteria and OPEs in the open ocean under different biogeochemical regimes, and will help understand the biogeochemistry and fate of OPEs in the environment.

3.09.T-02 Investigating the Presence and Impact of Pharmaceuticals in Stony Corals from Shallow and Deep Sites in the Red Sea
***Gal Navon*[1]*, Noa Shenkar[2], Dror Avisar[1] and Aviv Kaplan[1], (1)Tel Aviv University, Israel, (2)School of Zoology, George S. Wise Faculty of Life Sciences, Tel Aviv University, Israel*
The increasing global use of pharmaceutically active compounds (PhACs) and their insufficient removal by sewage treatment plants results in their chronic input into coastal waters, where they pose a threat to marine organisms. Numerous studies investigate the presence and effects of PhACs in various marine organisms. However, available data regarding the presence of PhACs in corals worldwide is scarce. In a recent study, 14 antibiotics were detected in coastal corals from the South China Sea in concentrations of 28 ng/g dry weight tissue. Moreover, information regarding the effects of PhAC contamination on corals is highly limited, in comparison to assessment of the hazardous effects of heavy metals, microplastics and personal care products. The main goal of this study is to examine the presence of PhACs in corals from the Israeli Red Sea coral reefs and investigate their potential effects according to their mode of action. Eighty coral samples of the branching *Acropora* sp. and the massive *Favites* sp. were collected from four shallow and deep sites (5-12 m and 30-40 m, respectively). Chemical analysis is currently in progress and will include 25 compounds from the most common subscribed drugs in Israel, as reported by the main health services providers. Isotopic labeled standards will be used to quantify recovery rates and validation. Samples will undergo lyophilization, Accelerated Solvent Extraction (ASE), Solid Phase Extraction (SPE) and analysis will be performed by Ultra-Pressure Liquid Chromatography (UPLC) coupled with a Triple-Quad MRM Mass Spectrometer. Preliminary results demonstrate the presence of 14 out of 14 analyzed PhACs in Red Sea coral samples. In addition, in order to understand the potential physiological effects of PhACs, alteration in protein expression in response to PhACs exposure, under controlled laboratory conditions, will be examined in *Favites* sp. and *Acropora* sp. samples. Each coral species will be exposed to a mixture of environmentally detected PhACs for 14 days in different concentrations; 0=control, X (environmentally relevant concentration), 10X, and 100X. Total proteins will be extracted and processed at the Smoler Proteomics Center, Technion, Haifa. Protein profiles will be analyzed using Perseus software. The study will yield essential information regarding the presence of various PhACs in stony corals from a tropical ecosystem and the potential effects of PhACs contamination on coral physiology.

3.09.T-03 Short, Medium and Long-chain Chlorinated Paraffins and Dechloranes in Marine Mammals from Norway
*Clare Margaret Andvik[1], Eve Jourdain[2], Anders Borgen[3], Haug Tore[4], Richard Karoliussen[2] and **Katrine Borga**[1], (1)University of Oslo, Norway, (2)Norwegian Orca Survey, Norway, (3)Norwegian Institute for Air Research (NILU), Norway, (4)Institute of Marine Research, Norway*
Marine mammals are considered sentinel species for the marine ecosystem health due to the bioaccumulation of legacy and emerging contaminants in their tissues. Data on the presence, levels and distribution of many chlorinated paraffins and dechloranes, however, remain missing or incomplete for many whale species from Norway. The aims of this study were 1) to conduct the first screening of chlorinated paraffins and dechloranes in marine mammals from Norway and 2) investigate inter-species differences due to trophic position. We collected samples from 32 stranded whales of nine different species from Norway 2015-2020, including one neonate killer whale (*Orcinus orca)* of approximately 10 days of age, in addition to 14 minke whales obtained in 2019 from the annual harvest in the Barents Sea.
Levels of short chain chlorinated paraffins ranged from 10 ng/g lw (minke whale) to 1575 ng/g lw (sperm whale), medium chain from 2 ng/g lw (fin whale) to 2383ng/g lw (sperm whale) and long chain chlorinated paraffins from 2 ng/g lw (harbour seal) to 1093 ng/g lw (minke whale). Levels were highest in the minke, killer and sperm whales, with approximately three fold higher levels in subadult female minke whales than male minke whales. All chlorinated paraffins were also detected in the neonate killer whale, in levels similar to adults, which gives the first evidence of maternal transfer in killer whales.
Dechloane 602 was the only dechlorane found in all of the samples, and we found the highest levels in the killer whales (mean 4.8 ng/g lw, excluding one individual suspected of eating seals with a level of 79 ng/g lw), followed by the sperm whales (1.8 ng/g lw). The lowest levels were found in the humpback whales (mean = 0.05 ng/g lw). The killer whale neonate had approximately three times lower levels than adults.

We found higher levels of chlorinarted paraffins and dechloranes than other Arctic marine mammals. Our study illustrates the importance of regular screenings of contaminants in Arctic wildlife.

3.09.T-04 Sand and Mussels as Indicators of Volatile Methylsiloxanes in Coastal Areas

Nuno Ratola[1]*, Sofia Ferreira*[2]*, Francisco Sánchez Soberón*[2]*, Javier Castro-Jimenez*[3]*, Pedro Jiménez-Guerrero*[4]*, Francisco Cereceda-Balic*[5]*, Ximena Fadic*[5]*, João Pedro Coelho*[6] *and Vera Homem*[2]*, (1)Universidade do Porto, Faculdade de Engenharia, Portugal, (2)University of Porto, LEPABE, ALiCE, Portugal, (3)Chemical Contamination of Marine Ecosystems, IFREMER, France, (4)GMAR - University of Murcia, Spain, (5)Universidad Técnica Federico Santa María, Chile, (6)University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Portugal*

Volatile methylsiloxanes (VMSs) have been recently identified as emerging organic contaminants with potential harmful effects to the environment. Due to their high vapor pressure and compatibility with numerous ingredients used in formulations, they are widely used in numerous domestic and industrial applications, highlighting its intensive use in personal care products (PCPs). This is one of the main reasons for the presence of these compounds in the environment, namely in coastal areas. The increased use of these products particularly in summer, due to sunscreens and other cosmetics, has led to the need to study the associated anthropogenic impact and a possible time trend.

In this work, sand and mussels were chosen to give an idea of the presence of seven VMSs (3 linear: L3,L4,L5 and 4 cyclic: D3,D4,D5,D6) in mineral and biota matrices. The analysis in both cases was done by optimizing and validating a QuEChERS extraction protocol, with the quantification done by GC-MS.

Individual VMSs were detected in all sand samples with concentrations ranging from n.d. to 33±7 ng/g dw. As expected, cyclic VMSs were detected with greater frequency and concentration than linear, namely the less volatile ones, such as D5 and D6, which is probably associated with the higher frequency of deposition and permanence in the sand. In general, VMS levels were higher in the Canary Islands (Spain) than in other countries. VMSs were detected also in all mussel samples, and the cyclic ones in higher levels, again D5 and D6 (max 53±12 and 27.2±0.8 ng/g ww, respectively).

The geographical distribution of VMSs in coastal areas is linked to the temporal trends, as the warmer months tend to attract much more people to these areas than in the rest of the year. Moreover, intra-day study showed that VMS levels tend to follow the beach attendance. Mussels follow a similar trend, but with the important finding that the depuration made befor comercialization is key to reduce the exposure of humans to VMSs by ingestion.

3.09.T-05 Long-range Environmental Transport of Legacy and Emerging Per- And Polyfluoroalkyl Substances in the Global Ocean and Polar Regions

Zhiyong Xie*, Helmholtz Center Hereon, Germany*

Owing to the unique properties, per- and polyfluoroalkyl substances (PFASs) can be transported from continental sources to remote areas through both atmosphere and ocean currents, and have been widely presenting in all environmental compartments in remote Arctic and Antarctic. The neutral PFAS, such as FTOHs, Me/EtFOSE and FOSE mainly partition to air, and travel with air masses from source regions to the remote oceans. While ionic PFASs mostly accumulate in surface waters, and their long-range environmental transport. In the polar regions, phtotodegradation and reaction with OH, Cl or O_3 radicals are the major pathways to eliminate neutral PFAS from the Atmosphere and transform to ionic PFAS, especially in spring and summer. Moreover, reemission of PFAS from cryosphere may lead high levels in the coastal waters of the arctic and Antarctic. The objective of this work is to present the spatial distribution and temporal trends of legacy PFAS and to highlight the occurrences of the emerging PFASs in the Atlantic ocean and polar regions.

3.09.P Emerging Organic Contaminants in the Oceans: Local Sources, Long-Range Environmental Transport and Impact of Climate Change

3.09.P-Mo208 Where to Look – Stability and Seawater-particulate Partitioning of PPCPs

Lisbet Sorensen[1]*, Ingrid Alver Hovsbakken*[2]*, Mari Creese*[1]*, Ewa Wielogórska*[1]*, Antonio Sarno*[1] *and* ***Ida Beathe Overjordet***[1]*, (1)SINTEF, Norway, (2)Norwegian University of Science & Technology (NTNU), Norway*

Pharmaceuticals and personal care products (PPCPs) the environment via wastewater from urban, domestic, and industrial areas, in addition to sewage, aquaculture and agriculture runoff. Many PPCPs are only partly removed in water treatment, meaning small amounts are continuously released into the environment, and environmental concentrations worldwide are reported in the ng-µg/L range.

While some PPCPs are easily degradable in environmental conditions, others are more persistent, meaning they are less easily degraded and can stay in the environment for long periods of time. Degradation is dependent on parameters such as physical and chemical properties of the individual compounds, and environmental conditions. Many pharmaceuticals are already known to be able to adsorb to sediment particles and these mechanisms can act as a sink for accumulation of these compounds. If pharmaceuticals adsorb and migrate into marine sediments, their persistence can increase in comparison to their persistence in the water column. This can affect their bioavailability and transport pathways.

By exploring the stability and adsorptive properties of PPCPs onto particles relevant for marine conditions, we can better understand their environmental behaviour and transport potential. This study investigated the PPCP sorption capacity of inorganic (kaolin) and biotic (*Rhodomonas baltica*) marine particles, and further investigated the adsorption mechanisms between pharmaceuticals and kaolin, through exploring adsorption kinetics and isotherms.

Overall it was demonstrated that many PPCPs are stable in seawater for long enough to be transported and interact with marine particles. None of the PPCPs sorbed to the algae in the batch experiment, and thus further investigations focused on determining sorption kinetics and isotherms to the inorganic particle kaolin. Sorption kinetics revealed a better fit of the pseudo-second order model than the pseudo-first order. The sorption rates increased with increasing amounts of particles in the system. The isotherm experiments revealed that the experimental data fit best to the Sips isotherm, a 3-parameter model. The 2-parameter Langmuir model also fit the data well. The Sips model revealed a temperature dependence for the Sips affinity constant, K_S, and the maximum adsorption capacity, q_{max}. K_S decreased with increasing temperatures, while q_{max} increased.

3.09.P-Mo209 Addressing the Importance of Microplastic Particles as Vectors for Long-range Transport of Chemical Contaminants: Perspective in Relation to Prioritizing Research and Regulatory Actions

***Todd Gouin**, TG Environmental Research, United Kingdom*

Over the last several years there has been increasing concern regarding the environmental fate and potential global transport of plastic debris, particularly in the form of microplastic particles (MPs). The global transport of MPs has also triggered concerns regarding the potential role that its mobility may represent towards influencing the long-range environmental transport (LRET) of particle-bound chemicals, particularly the large number of chemicals known to be added to plastic. is presentation considers the various lines-of-evidence that might be used to demonstrate the LRET of MPs, such as data reporting their presence in remote locations and models that have been developed to estimate their environmental fate and transport. When considering the available information, several challenges and uncertainties can be identified that limit the ability to differentiate local versus global sources of plastic debris and MPs in the environment and their potential to act as vectors of LRET for plastic additive chemicals (PACs). Ther is thus an urgent need towards a coordinated strategy for the development of holistic mechanistic modeling and standard sampling and analytical methods that can strengthen our overall understanding of the environmental fate, transport, and exposure of MPs. Knowle e of the polymer composition, size and shape of MPs and their potential mobility under different environmental conditions can be used to a) identify potential geographic hotspots and b) evaluate the types of PACs that may be associated with those materials and which can be used to help inform the application of models for characterizing and quantifying their leachability. When combined with derivation of emission factors of PACs from in-use products and subsequent environmental release scenarios, a holistic exposure assessment may potentially be realized that strengthens and improves our overall understanding of environmental human health implications related to the environmental fate of MPs.

3.09.P-Mo210 Understanding the Source and Environmental Fate of Tyre Wear Emissions

***Nick Molden** and Ime Usen, Emissions Analytics, United Kingdom*

Tyres are complex products, with sophisticated physical design and chemical composition. They must deliver a range of often conflicting performances including slow wear (for maximum life), low rolling resistance (to reduce carbon dioxide emissions and fuel consumption), wet grip and low noise. There exist regulatory and labelling requirements around these. Where information is currently lacking is in the wear rates and chemical composition of the tyres. This is relevant to the amount material released into the environment, where it goes and what damage it does to human and animal health, and the environment more widely. The demonstrated link between the 6PPD preservative in tyres and the death of salmon and trout in the US is important context to this work.

The context of this work is emerging regulation of tyre wear, from the proposed banning of 6PPD in California to the potential UNECE/EU regulation of tyre wear rates. Research is currently limited on the nature of tyre wear particles and in what proportions they get distribution into air, water and soil.

This presentation will focus on understanding the nature of tyre wear emissions, by first of all understanding the chemical composition of original tyres. It will draw on Emissions Analytics' tyre material database, which typically identifies over 400 organic compounds in each tyre, using its optimised process of thermal desorption and pyrolysis, coupled with two-dimensional gas chromatography and time-of-flight mass spectrometry. will go on to perform equivalent chemical analysis on tyre wear material collected from vehicles in real-world operation, and relating that back to the composition of the original tyre.

Finally, an approach to assessing the presence of tyre wear particles collected in environmental matrices will be shown. It will move beyond using a small number of tracer compounds to determine environmental distribution, towards a fuller multi-compound 'fingerprinting' approach using the ability of two-dimensional chromatography.

3.09.P-Mo211 Quantitative Screening of Organic Plastic Additives in Beach Sand Using QuEChERS

***Javier Castro-Jimenez**[1] and Nuno Ratola[2], (1)Chemical Contamination of Marine Ecosystems, IFREMER, France, (2)Universidade do Porto, Faculdade de Engenharia, Portugal*

This work presents an expedite and environment-friendly analytical protocol based on QuEChERS technology for the simultaneous determination of organophosphate and phthalate esters (OPEs and PAEs, respectively) plastic additives in beach sand, a pollution indicator of coastal areas, often under important anthropogenic pressure. OPEs and PAEs are among the most widely distributed organic plastic additives in the marine environment, which may present a risk for the wildlife and human health. The QuEChERS protocol used is an adaptation of a previously reported method allowing the quantitative screening of OPEs and PAEs in other marine matrices, such as sediments and marine biota, optimized now for the analysis of these contaminants of emerging concern in beach sand. The application of the protocol to real samples included validation via recovery and repeatability assays. A total of sixteen additives (9 OPEs and 7 PAEs) were analyzed by GC-MS. Method recoveries at two spiking levels (25 and 100 ng sample^{-1}) varied from 76 ± 30% to 58 ± 15% (mean ± SD) for OPEs and from 64 ± 16% to 60 ± 10% for PAEs. Mean (n=3) relative standard deviations ranged from 4.4 ± 0.9 % to 10.6 ± 0.8 %, indicating a good method repeatability. Results from an initial screening in selected beach sand samples collected in NW Mediterranean Sea (Marseille, France) confirmed the presence of both OPEs and PAEs in this matrix. Overall, most PAEs were detected (detection frequency, DF=86%) and concentrations ranged from 21 to 29 ng g^{-1} dw (sumPAEs). OPEs exhibited a lower DF (33-67%) and concentrations were also lower compared to PAEs, varying from 2 to 4 ng g^{-1} dw (sumOPEs). Tris-(2-chloro, 1-methylethyl) phosphate (TCPP) and diethylhexyl phthalate (DEHP) exhibited the highest concentrations among OPEs and PAEs, respectively. These two additives have been reported as hazardous chemicals and are also classified (or suspected) endocrine disruptors. Despite the limited number of explored beaches, these results show the applicability of our method to investigate the environmental occurrence of these plastic additives in sand. A wider survey, considering also beaches from different European countries is ongoing.

3.09.P-Mo212 Watch List of Substances under the Water Framework Directive: Work in Progress

Oihana Solaun[1]*, Joana Larreta*[2]*, Germán Rodríguez*[1]*, Ángel Borja*[1]*, Ester López-García*[3]*, Bozo Zonja*[3]*, Miren López de Alda*[3]*, Damià Barceló*[3] *and Jesus Alberto Manzanos*[4]*, (1)AZTI, Spain, (2)FUNDACION AZTI, SUKARRIETA, Spain, (3)Spanish Research Council (CSIC), Institute of Environmental Assessment and Water Research (IDAEA), Spain, (4)Basque Water Agency (URA), Spain*

The watch list of substance is articulated through implementing decisions determined by the Commission and it is updated every two years. The first list was published in 2015 (EU Decision 2015/495) and contained ten substances or group of substances. In the subsequent updates (EU Decision 2018/840, EU Decision 2020/1161 and EU Decision 2022/1307), some of the substances were removed from the list, and some other were identified as suitable candidates to be included in it. Many of these substances, including herbicides, pesticides, fungicides, personal care products, pharmaceuticals such as antibiotics, antidepressants, and fungicides among others, are substances in everyday use, but their effects on the environment are little or no studied at all. The continuous monitoring period for each substance included in the watch list should not exceed four years, and the monitoring of substances must obtain high quality data on their concentrations in the aquatic environment, which implies having validated and consolidated methods.

These constant changes do not allow a good consolidation of analytical methods, so that when a method have been optimised, it has to be modified to include the determination of the new substances, or a new method have to be developed. In addition, if methodology changes, consistent time series beyond 4 years are difficult to obtain.

In the Basque coast, southwest Bay of Biscay, the Basque Water Agency (URA) has been promoting the study of emerging substances on the watch list since 2017. Grab water samples have been collected quarterly (spring, summer, autumn, winter) at emission points of some wastewater treatment plants, and at their receiving waters (transitional or coastal waters).

Obtained results, available upon request to URA, could be useful for the purpose of supporting the determination of the risk these substances could pose to the environment, and the prioritisation of substances to be included in the future list of priority substances.

3.09.P-Mo213 Spatial Distribution and Time Trends in Cyclic and Linear Siloxanes in Sediment From Semi-enclosed Bays of Korea Between 2013 and 2021

Wenming Chen[1]*, Yujin Kang*[1]*, Hyun-Kyung Lee*[1]*, Jae-Eun Lim*[1] *and* ***Hyo-Bang Moon***[2]*, (1)Hanyang University, Korea, (2)Department of Marine Science and Convergence Engineering, Hanyang University, Korea*

Siloxanes are contaminants of emerging concerns in aquatic environment. Sediment was collected from semi-enclosed bays of Korea in 2013 and 2021 to grasp the spatial distribution, potential sources, and time trends in siloxanes. Cyclic and linear siloxanes were detected in all sediment samples, indicating ubiquitously contaminated. Highest siloxane concentrations were observed in sediment near the outfall of wastewater treatment plant, implying a major source of siloxanes to the coastal environment. The concentrations of cyclic and linear siloxanes in sediment were not changed between both years, indicating continuous contamination for the last two decades. The consumption of siloxanes in the Korean industrial market is still large and continues to increase. Multivariate statistical analysis showed the different contamination patterns of siloxanes, depending on the sampling locations and industrial types. All sediment samples were dominated by cyclic siloxanes, such as D5 and D6 because the Korean industrial market has been dominated by cyclic siloxanes.

3.09.P-Mo214 Per- and Polyfluoroalkyl Substances (PFAS) in Flatfish and their Prey: Occurrence and Trophic Transfer

Yann Aminot[1]*, Nadège Bely*[1]*, Guillaume Bernard*[1,2] *and Aourell Mauffret*[1]*, (1)IFREMER, France, (2)University of Bordeaux, France*

Submarine continuations of river deltas, such as marine prodeltas and mud patches, are key components of the land-sea continuum which can be geographically separated from river estuaries. Such highly dynamic systems are submitted to both natural and anthropogenic disturbances, and are essential areas for juvenile stages in the life cycle of most marine exploited species, but remain poorly studied with regards to contaminant transfers. We study here the West Gironde Mud Patch (SW France), taken as a model of marine offshore system under anthropogenic pressure. Among contaminants of emerging concern, per- and polyfluoroalkyl substances (PFAS) are a family of thousands of non-naturally occurring chemicals reported for their ubiquitous presence in the environment. Evidence for their persistence, bioaccumulative and toxic properties has led to major concerns, prompting a global call for a better management of this chemical class as a whole. PFAS stability in environmental waters and a rather limited affinity to particles has made oceans the largest environmental reservoir of historically released PFAS. Conversely, there is still a dramatic lack of knowledge on the exposure of marine biota to PFAS, and on their subsequent bioaccumulation and potential toxic effects, beyond the most studied PFOS and long-chain perfluorocarboxylates (PFCAs). In this presentation, we describe the occurrence and profiles of PFAS in the common sole *Solea solea* and in benthic invertebrates composing its diet. We conducted a thorough sampling of over 17 benthic species from the studied site in two contrasted seasons. Perfluorosulfonates, PFCAs and precursor compounds were analysed by liquid chromatography coupled to tandem mass spectrometry after a 2-step clean-up of the extracts. Our results indicate relatively high levels of PFAS in such offshore environments, with average PFOS concentrations in sole muscles at 3.4 ± 1.9 ng/g dw, and sum C_{8-15} PFCA at 4.3 ± 4.1 ng/g dw. The precursor compounds FOSA and n:3 FTCAs were also observed. In benthic invertebrates, the contamination profiles were species-dependent and differed from those observed in the soles. This indicated that trophic transfer is associated with a change of contamination profiles, further discussed in this communication. This study provides essential data to describe contamination levels and fate and, *in fine*, benthic habitat ecological quality in offshore systems.

3.09.P-Mo215 Understanding Mercury and Chlorinated Paraffins Biomagnification by Identifying Dietary Patterns in Killer Whales in Norway

Carl Johan Ludwig Fagerlund[1], *Eve Jourdain*[2], *Clare Margaret Andvik*[3], *Bo Yuan*[4], *Anders Ruus*[5] *and Katrine Borga*[3], *(1)Department of Biosciences, UiO, Norway, (2)Norwegian Orca Survey, Norway, (3)University of Oslo, Norway, (4)Stockholm University, Sweden, (5)Norwegian Institute for Water Research (NIVA), Norway*

In Norway, the killer whale *(Orcinus orca)* could be considered a fish specialist, feeding mainly on Atlantic herring (*Clupea harengus)*, however there has been increasing observational evidence for other prey types. Analysis of nitrogen and carbon isotopic ratios in skin of killer whales with known predation history further supported interindividual dietary variations in this population. Notably, while some killer whales appear to be fish-specialists, others also include marine mammals into their diet. Being an apex predator with long life span and thick blubber layer, the killer whales are vulnerable to biomagnifying pollutants such as methyl mercury (MeHg), especially when feeding on high trophic level mammal prey.

Our understanding of the dietary patterns of killer whales in Norway is far from complete. Specifically, the scope of predation on marine mammals is unknown, i.e., what proportion of killer whales in Norway include mammals in their diet and in which proportion. Seasonal switch between alternative fish resources is also poorly understood. As diet correlates with pollutant exposure, resolving dietary patterns, in parallel with studies of pollution is necessary to better understand pathways of contamination.

In this study, stable isotopes are analyzed in killer whale tissue samples as well as in known and other putative prey species with the aim of mapping the regional food web.

Bayesian statistical modeling will be used to estimate the diet composition of the killer whales based on stable isotopic nitrogen $\delta^{15}N$ and carbon $\delta^{13}C$ values, followed by an estimation of the trophic position of each investigated species and killer whales. Total mercury (Hg) concentrations up to 5.4 µg/g d.w measured in killer whale skin have previously been reported. Additionally, persistent organic chemicals chlorinated paraffins (CPs), from very-short-chain to long-chain classes have been found in killer whale blubber and muscle tissue. Biomagnification of total Hg and CPs in killer whales, and in a selection of prey species, will be estimated and compared. There are still few studies of CPs biomagnification in marine food webs and wildlife. This study will add to our database and aid in gaining more insight into interindividual dietary variation in killer whales in Norway. Furthermore, including the multiple species in the food web combined with contaminant analysis will likely give a greater understanding of the behavior of Hg and CPs in the killer whale food web.

3.09.P-Mo216 Role of Marine Zooplankton in Long-Distance Transport of Pharmaceuticals From European Waters to the Arctic

Ida Beathe Overjordet[1], *Ewa Wielogórska*[1], *Magda Caban*[2], *Sławomir Kwaśniewski*[3], *Dominika Walecka*[3], *Ingrid Ellingsen*[1], *Konstantinos Kotzakoulakis*[1], *Antonio Sarno*[1], *Roland Kallenborn*[4], *Mari Creese*[1], *Lisbet Sorensen*[1], *Trond Nordtug*[1], *Katarzyna Smolarz*[5], *Adam Sokołowski*[2] *and Filip Spiralski*[2], *(1)SINTEF, Norway, (2)University of Gdansk, Poland, (3)IO PAS, Poland, (4)Norwegian University of Life Sciences (NMBU), Norway, (5)Division of Marine Ecosystems Functioning, University of Gdansk, Poland*

In recent years, several pharmaceuticals and personal care products (PPCPs) have been observed in marine environment as many of them do not decompose completely in sewage treatment. Some of these biologically active compounds have been shown to accumulate in or adsorb on living organisms. Marine organisms, such as zooplankton, may therefore act as vectors in long-distance transport of PPCPs from polluted coastal waters into pristine environments, such as the Arctic, where they can negatively affect marine biota. To investigate whether such transport occurs, we collected zooplankton from surface water layers at 20 sites on the route of northward transport of Atlantic water masses from the North Sea to the Fram Strait. Sampling sites were located in areas representing marine domains influenced by both coastal and Atlantic currents. After lyophilisation, samples were subjected to ultrasonic-assisted extraction in a mid-polar environment. Concentration of 36 commonly used PPCPs (including antibiotics, antidepressants, stimulants) and pesticides was measured using Liquid Chromatography – Mass Spectrometry (LC-MS). Additional samples for determining zooplankton taxonomic composition and estimating the biomass at the sampling sites were collected and analysed to help explain potential patterns in PPCPs contents. In the research area the most abundant species were *Oithona similis* and *Calanus finmarchicus,* while zooplankton biomass was dominated by *C. finmarchicus* and *Parasagitta elegans* (in the North and Norwegian seas) or *Eukrohnia hamata* (Fram Strait region). Despite the dominance of the ubiquitous *Oithona similis* or widespread boreal species (*P. elegans*, *E. hamata*) in the species composition, demographic structure of *Calanus finmarchicus* suggests the presence of different biogeographical domains on the route of northward transport of Atlantic waters.

3.09.P-Mo217 Declining Concentrations of Chlorinated Paraffins in Endangered St. Lawrence Estuary Belugas (*Delphinapterus leucas*): Response to Regulations or a Change in Diet?

Antoine Etienne Simond[1], *Peter Ross*[2], *Jory Cabrol*[3], *Véronique Lesage*[3], *Stephane Lair*[4], *Million Woudneh*[5], *Diwen Yang*[6], *Hui Peng*[6], *Katerina Colbourne*[7] *and Tanya Brown*[7], *(1)Simon Fraser University, Canada, (2)Ocean Wise Conservation Association, Canada, (3)Maurice Lamontagne Institute, Fisheries and Oceans Canada, Canada, (4)University of Montreal, Canada, (5)SGS*

AXYS Analytical Services, Canada, (6)University of Toronto, Canada, (7)Fisheries and Oceans Canada, Canada
Very high levels of industrial contaminants in St. Lawrence Estuary (SLE) beluga whales represent one of the major threats to this population classified as endangered under the Species at Risk Act in Canada. Elevated concentrations of short-chained chlorinated paraffins (SCCPs) were recently reported in blubber of adult male SLE belugas. SCCPs are complex mixtures of alkanes of varying chain length (10 to 13 carbons) with varying degree of chlorine content (30 to 70% by mass) that have been used in North America primarily as lubricants and coolants in metal working fluids. SCCPs have the potential to biomagnify in marine food webs, and have been found to induce neurotoxic and endocrine disrupting effects in mammals and to potentially alter lipid and amino acid metabolisms in belugas. Recent regulations for SCCPs in North America, combined with their replacement by medium- (MCCPs) and long-chained chlorinated paraffins (LCCPs), highlight the importance of tracking this toxic chemical class. The objectives of this study were to evaluate (1) levels and profiles of chlorinated paraffins (CPs) in samples obtained from carcasses of adult male, adult female, juvenile, newborn, and fetus beluga, and (2) trends in adult male belugas between 1997 and 2018. Factors potentially influencing CP temporal trends such as age, feeding ecology and sampling year were also explored. SCCPs dominated (64 to 100%) total CP concentrations across all age and sex classes, MCCPs accounted for the remaining proportion of total CPs, and LCCPs were not detected in any sample. The chlorinated paraffin homolog that dominated the most in beluga blubber was $C_{12}Cl_8$. Adult male SCCP concentrations from this study were considerably lower (> 2000-fold) than those reported in 2020, likely reflecting a previously erroneous overestimate due to the lack of a suitable analytical method for SCCPs at the time. Both SCCPs and total CPs declined over time in adult males in our study (rate of 1.67 and 1.33% per year, respectively), presumably due in part to the implementation of regulations in 2012. However, there is a need to better understand the possible contribution of a changing diet to contaminant exposure, as stable isotopic ratios of carbon also changed over time.

3.10 Establishing the State-of-the-Science in Human Exposure to Micro- and Nanoplastic

3.10.T-01 Secondary Nanoplastics Released from Food Packaging: Quantification and Formation Mechanisms

*Claudia Cella, **Francesco Fumagalli**, Dora Mehn, Rita La Spina, Douglas Gilliland and Andrea Valsesia, European Commission Joint Research Centre (JRC), Italy*

Reliability of studies on micro(nano)plastics exposure becomes crucial to understand their potential hazard to environment and human health. However, analytical challenges limit our understanding of their formation and detection, thus hampering further investigation of their origins and effects. Plastic items are widely diffused in food packaging and they could potentially release secondary micro(nano)plastics during use in every-day life. So far, a validated and harmonized strategy to tackle this issue is not available. Here, we provide a combined approach to quantitatively and qualitatively detect the release of micro and especially nanoplastics in water matrixes and to estimate direct consumer exposure during common use of different food packagings.
We demonstrated that plastic breakdown to micro and nanoplastic can occur during the normal use of polyethylene (PE) sealing of drinking water bottles, rice cooking bags and ice-cube bags as well as of polyamide-6 teabags. In particular, PE cap sealing of the water bottles could release particles with a size distribution ranging from few hundred nanometers up to about one micron and we estimated a mass release to be in the order of few tenths of nanograms per opening/closing cycle. Additionally, the mechanical stress altered the physical-chemical characteristics of the generated nanoplastics and degraded their material properties, thus complicating the spectroscopic chemical identification. Furthermore, we highlighted the importance of using spectral databases that are not limited to just plastic materials, since released micro and nanoplastics from ice bags and rice cooking bags were contaminated with dyes and food residues. Finally, in the case of polyamide teabags, classical Fourier transform infrared (FT-IR) spectroscopy was used to measure the mass of released material. Here, temperature was shown to have a strong impact on the morphology and aggregation status of the released particles so posing scientists and legislators with a challenging question: should we consider keeping the heat-released material after cooling as being “oligomeric” or should we take into account the possible formation of nanoplastics?

3.10.T-02 µRaman Analysis of Airborne Indoor Microplastics down to 1 µm – Should Facemasks be Recommended?

***Luca Maurizi**[1], Laura Simon-Sanchez[1], Alvise Vianello[2], Jes Vollertsen[2] and Asbjørn Nielsen[1], (1)The Built Department, Aalborg University, Denmark, (2)Aalborg University, Denmark*

Inhalation of microplastics (MPs) mainly occurs in indoor environments and may potentially represent the main source of intake. Most of the atmospheric MPs are fibers, probably released from synthetic clothes and textiles. Sources of MP fragments can be legion, for example building materials, abrasions of plastic products, landfilling, and waste incineration. Consequently, the MP morphology, mobility, and composition in indoor environments depend on the type of activity performed not only at the chosen location but also in its surroundings. There is the need for improved analytical methods for small (1–10 µm) airborne MPs, to assess the potential risks associated with their introduction into the human organism. Moreover, several works recognized that airborne MPs may lead to the “fiber paradigm” (increased bioreactivity due to the fiber shape). Generally, the inhalation of airborne particles is driven by their aerodynamic equivalent diameter (AED), on which the so-called PM classification was based. In particular, the PM10 (AED <10 µm) and PM2.5 (AED <2.5 µm) particles can reportedly penetrate the low respiratory tract and PM2.5 was even found in the alveoli. The present work investigates the presence of indoor airborne MPs down to 1 µm in four different locations (a workshop, an office, and two apartments), the effect of human activity on airborne MP abundance, and whether wearing facemasks would limit its intake.
Indoor air was sampled with a pump (~2 L/min) through a 1 µm Silicon filters with 13 mm of diameter (Smart Membranes GmbH, Germany) hosted in a stainless steel sampling funnel (EMD Millipore Corporation, USA). Each sampling event took 24 hours and was repeated during a workday and a day in the weekend to account for the different levels of human activity in the sampling locations over time. Each sample was taken in triplicate: without facemask, with a surgical mask, and with an FFP2

mask mounted onto the inlet of the sampling funnel. The filters were then directly analyzed with Raman micro-spectroscopy (Horiba Sas, France). Moreover, the sub-micron fraction will be qualitatively explored with Atomic Force Microscopy (AFM) to assess the presence of nanoplastics (NPs), providing novel and valuable knowledge on indoor MP and NP pollution.
The low-cost sampling method and the absence of sample preparation render the present method applicable to monitoring indoor environments with regard to human airborne MP intake.

3.10.T-03 What if You Eat Nanoplastic? An In Vitro Study of Nanoplastics' Gastrointestinal Digestion Using Model Food Matrices for Bioavailability Assessment

***Maria Hayder*[1]*, Annemarie van Wezel[2], Gert-Jan Gruter[3,4] and Alina Astefanei[5], (1)HIMS, University of Amsterdam, Netherlands, (2)University of Amsterdam, Institute for Biodiversity and Ecosystem Dynamics, Netherlands, (3)University of Amsterdam, Netherlands, (4)Avantium Support BV, Netherlands, (5)University of Amsterdam, HIMS, Analytical Chemistry Group, Netherlands*

Nanoplastics, defined as plastic particles smaller than 1000 nm, remain one of the major environmental concerns. According to the current state of knowledge, macroplastic waste pervades into the environment and subsequently undergoes fragmentation to smaller fragments, reaching sizes of nanometer range. Due to their sizes, nanoplastics are known for their propensity to absorb in tissues of living organisms, from where they can be moved to food chain and eventually ingested by humans. There is evidence that nanoplastics have detrimental influence on living cells. However, the behaviour of plastic particles in conditions of human digestive tract has not yet been scrutinized, leaving a knowledge gap regarding the fate of nanoplastics between ingestion and absorption to human cells. Moreover, the influence of food matrix, with which particles are most probably ingested, on the risk of being absorbed, has not been investigated either.
To fulfill this gap, research was conducted on four model polymer nanoparticles: polystyrene of 50 nm and 200 nm, with and without surface functionalization by carboxyl groups, and on PLGA nanoparticles as a common biodegradable polymer. All particles were submitted to gastrointestinal digestion simulated *in vitro* by a two-step incubation with gastric and intestinal juice. After each step particles were analyzed by asymmetric flow-field flow fractionation with multi-angle lights scattering detection (AF4-MALS), which is a size-based separation technique. Additionally, for the largest particles, SEM measurements were conducted. The results showed that all polymer particles agglomerate during gastrointestinal digestion. The degree of agglomeration is, however, dependent on the particle characteristics.
We are now focusing on studying the influence of food matrix on the digestion process. For that, we carry out in vitro digestion and analysis as described above on polymer nanoparticles together with food products of high content of proteins, fats and complex sugars. We evaluate the impact of each of those substances separately and of the mixture of them, imitating an average meal. We hope to contribute in this way to the general knowledge on the hazards that nanoplastics may pose to the consumers.

3.10.T-04 Identifying Matrix Interferences in Analysis of Human Exposure to Polymers

***Cassandra Rauert**, Nathan Charlton and Kevin Thomas, University of Queensland, Australia*

Plastics pollution permeates all environmental compartments and whilst it is known that humans are constantly exposed to micro (<5 mm) and nanosized plastics (<1 mm), there are still large knowledge gaps on the extent of this exposure. The lack of current information on exposure and fate of polymers following exposure stems from challenges in the analysis of complex environmental matrices. Recently chemicals containing long chain hydrocarbons, such as stearates, have been identified as potential matrix interference in the analysis of polyethylene, providing false positive results. This study investigated the potential matrix effects from triacylglycerols (fatty acid type lipids) on analysis of polyethylene using pyrolysis gas chromatography mass spectrometry (Pyr-GCMS). A significant interference was observed from the three triacylglycerols tested (saturated, monounsaturated and polyunsaturated lipids). Subsequently, an effective enzyme digested method was developed to digest the triacylglycerols into smaller molecules that were removed using accelerated solvent extraction. The method was validated using food matrices (egg, milk, lamb), with excellent polyethylene recoveries from spiked samples (100-120%). This study presents for the first time an effective and optimised method for extraction and analysis of polyethylene from medium to high lipid content matrices and highlights the importance of assessing the matrix being extracted to improve confidence in reported polymer concentrations.

3.10.T-05 Micro- and Nanoplastic Quantification in Human Blood

***Marthinus Brits*[1]*, Martin van Velzen[1], Feride Öykü Sefiloglu[1], Lorenzo Scibetta[1], Quinn Groenewoud[1], Juan Garcia-Vallejo[2] and Marja Lamoree[1], (1)A-Life, Vrije University Amsterdam, Netherlands, (2)Amsterdam UMC, Netherlands*

The recent detection of micro and nano-plastic (MNP) particles in blood revealed that microplastics are taken up in the human body and transported via the bloodstream. These scientific findings received significant attention and impacted the understanding of human internal microplastic exposure. The toxicity of MNPs may be influenced by multiple physical characteristics such as shape, size, and polymer type and composition. The occurrence of MNPs in lung tissue supports human inhalation as a route of environmental exposure. In addition, MNPs were also reported in human breastmilk and human placenta, indicating that the unborn foetus and new-borns are exposed. The quantitation of MNPs in biological matrices and their possible effects and interactions are still poorly investigated, mainly due to the lack of robust methods with a high degree of sensitivity and selectivity. Pyrolysis-gas chromatography coupled to mass spectrometry (Py-GC-MS) has been successfully applied for the detection of several polymers in environmental samples. Using this destructive method, MNP particles (size range larger than 700 nm) were recently analysed in human whole blood samples. In this study, we present a robust and sensitive sample preparation and analytical method using Py-GC-MS. To ensure the accuracy of the analytical method, method validation was performed using an in-house quality control (QC) sample spiked with six polymers (polyvinyl chloride (PVC), poly(methyl methacrylate) (PMMA), polypropylene (PP), polystyrene PS), polyethylene (PE) and polyethylene terephthalate (PET)). The method was applied to measure plastic particles in 70 human whole blood samples from healthy volunteers. The QC samples were included in batch analysis to assess the reproducibility. The average recoveries for each polymer showed acceptable accuracy, ranging from 77 to 132%. Analysis done on blood samples (n=70) showed that PMMA, PP, PE, PET and PVC were identified and quantified. The method applied could extract, identify and quantify low concentrations of major polymers used in plastics. Suitable quality control measures should be included in Py-GC-MS analyses to assess the reproducibility and effective recovery of polymer particles. The results from this study have shown that plastic particles were detected in blood and are therefore bioavailable for uptake into the human system.

3.10.P Establishing the State-of-the-Science in Human Exposure to Micro- and Nanoplastic

3.10.P-Th188 Establishing a Methodology for Analysis of Microplastics in Drinking Water in the European Union
*Susanne Belz, Claudia Cella, Otmar Geiss, Rita La Spina, **Francesco Fumagalli**, Dora Mehn, Douglas Gilliland and Birgit Sokull-Kluettgen, European Commission Joint Research Centre, Italy*
Food and drinking water are probably the most discussed sources of concern regarding human exposure to microplastics. Globally, microplastics have been shown to be present in water with sizes from a few µm to several mm. Reported concentrations typically range from an upper level of several hundred particle per litre to values which are often much less than the equivalent of 0.1 particle/litre. In the European Union (EU), the analysis of microplastic compositions indicates that about 90% of the particles are distributed amongst seven polymer types and concentrations are usually below 1 particle per litre - with the majority of samples being found to have concentrations significantly below 0.1 particle per litre. Even if the actual concentration levels of microplastics in drinking water across Europe seem to be low, the 2021 recast of the European Union’s Drinking Water directive includes provisions for future monitoring of microplastics in domestic water supply chains. Consequently, the European Commission has the obligation to adopt a methodology for measuring microplastics in drinking water until January 2024. Establishing a methodology includes critical evaluation of already existing data on microplastics contamination in drinking water, careful consideration of the availability, capabilities and robustness of already existing sampling and analytical methods. The low levels reported by literature suggest that instrument sensitivity will be a major limiting factor in determining an appropriate methodology. Our presentation highlights some key input elements examined at the selection of the possible technological solutions from the basic choice between mass or number based concentration to the applicability for wide scale monitoring purposes. The poster also presents a range of options for future recommendations including the fundamental components of selected approach(es) as well as the suggestions for descriptors to be reported with the intention of discussing still plausible details with the experts of the field.

3.10.P-Th189 Microplastics in UK Drinking Water; Implications for Human Exposure
***Muneera Faraj Almansoori**, Mohamed Abou-Elwafa Abdallah and Stuart Harrad, University of Birmingham, United Kingdom*
Microplastics are microscopic particles less than 5 mm. There is an increased concern for public health as MPs have been found in tap and bottled water. These MPs cause adverse health effects because of their polymeric composition, additives, or other compounds or microorganisms adsorbing onto their surfaces. Few studies have detected MPs in bottled and tap water, although the current state of knowledge on MPs pollution in drinking water is still very limited. This study investigated the presence, concentrations, and size distribution of MPs in 85 tap water samples in the United Kingdom, as well as 85 samples of bottled UK from 16 different popular brands with various packaging. Sample preparation involved a vacuum filtration with filter membrane 0.2µm pore size, digital microscopic and µ-FTIR using the PerkinElmer 400 Spotlight imaging system. The average MPs in TW was 81 ± 64 MPs/L with minimum 6 MPs/L and maximum 415 MPs/L, with an average size of 12.3 ± 1.8 µm. For the BW in different types of packing, the average of MPs was 51 ± 19 MPs/L with minimum and maximum of 12 MPs/L and 88 MPs/L. The average particle size was 10.4 ± 0.73 µm. The most frequently detected polymer types were PVC, PET in TW and in PVC, PP in BW. In terms of morphology, fragments and fibres were the most abundant MPs constituting 89% and 90% of MPs detected in tap water and bottled water, respectively. Using the average recommended daily water intake by the national academy of medicine USA, the corresponding average exposure of UK adults to MPs via drinking tap water was estimated at 189 and 138 MPs/day for men and women, respectively. Lactating and pregnant women, who consume more water, will be exposed to an average of 194 and 153 MPs/day. While infants 41 MPs/day, and toddlers 66 MPs/day, are exposed at lower levels due to less consumption of water. This lower daily exposure should be considered with caution, given their lower body weight, and incompletely developed immune/endocrine systems. Exposure through drinking bottled water is generally less than that from tap water, given the smaller number of MPs in bottled water. These emerging contaminants may come from the water source, the surrounding airborne environment, or the pipets that transfer the water. Our data provide clear evidence on the presence of MPs in UK bottled and tap water and raise concern over the potential adverse health impacts on the UK population from inadvertent exposure to MPs via drinking water.

3.10.P-Th190 Food Packaging as a Source of Micro- and Nanoplastics in Food: A Systematic Evidence Map
***Lisa Zimmermann**[1], Birgit Geueke[2], Martin Wagner[3], Amanda A Durkin[4] and Jane Muncke[2], (1)Food Packaging Forum (FPF), Switzerland, (2)Food Packaging Forum Foundation, Switzerland, (3)Norwegian University of Science & Technology (NTNU), Norway, (4)Utrecht University, Netherlands*
Plastic food packaging plays a central role in modern food supply enabling transportation, storage, and marketing. However, the normal use of food packaging, such as bottle opening, can lead to the abrasion of micro- and nanoplastics (MNPs) which have been detected in a variety of foods. And, humans ingest these MNPs with their foods and beverages which may lead to adverse

health impacts. To better understand food contact materials as MNP exposure source, the MNPs present in food and their origin (e.g., certain types of plastic food contact materials) need to be evaluated.
Therefore, we provide an overview of the available scientific evidence on MNPs that are generated by the use of plastic food packaging or other plastic food contact articles (e.g., food processing equipment) and are released into food. We compiled a systematic evidence map by searching PubMed, Web of Science, and ScienceDirect for relevant studies published until the end of 2022, screening them for eligibility, and extracting the data.
We present an openly available database that summarizes the current knowledge on food packaging as a source of MNPs into food. We provide an overview of the MNP quantities detected in food and their characteristics (e.g., size, polymer type), the food or food simulant type they were detected in, and the polymer and usage type (e.g., bottle, wrap, as well as single vs. repeat use) of the food contact articles the plastic particles originated from. Furthermore, we identify pertinent knowledge gaps and provide recommendations for further research. We also evaluate if the applied methods and experimental setups allow for robust evidence that the MNPs detected in food originated from a plastic food contact article. We propose a best-practice methodology for investigating the migration of MNPs from food packaging. Since MNPs are a novel type of contaminant originating from (plastic) food packaging, our methodological approach is inspired by the common, legally required practice to assess the migration of chemicals from food contact materials. Based on the outcome, we will address gaps and may recommend precautionary methods for industry and policy to reduce MNP exposure via the normal use of plastic food packaging.
Overall, our systematic evidence mapping can guide future research concerning study objects, methods, and ways of reporting.

3.10.P-Th191 Microplastics in White Shrimp from Traditional Markets in Semarang, Indonesia

*Inneke Hantoro[1], **Frank G.A.J. Van Belleghem**[2], Ansje Löhr[2], Budi Widianarko[1] and Ad M. J. Ragas[3], (1)Soegijapranata Catholic University, Indonesia, (2)Department of Environmental Sciences, Open University, Netherlands, (3)Environmental Science, Radboud University, Netherlands*

Numerous studies have examined the presence of microplastics in various types of seafood. Moreover, some studies have observed that marketed seafood contains more microplastics compared to freshly harvested seafood. Investigating microplastic contamination in seafood circulating in markets is necessary as the majority of people buy seafood from traditional markets and the concentration of microplastics can change during transport from the production site to the market. White shrimp (*Litopenaeus vannamei*) is a seafood species that is widely available in Semarang, as Central Java province is one of the largest producers of white shrimp in Indonesia. The aim of this study was to investigate the concentrations and characteristics of microplastics in white shrimp collected from traditional markets in Semarang. White shrimp were therefore collected from six traditional markets and mixed and randomly selected up to 15 shrimp of similar size (7.5 – 10 cm) per market. After digestion with 30% H_2O_2 20:1 (v/w) and separation with a saturated NaCl solution (1.2 g/mL), the microplastic concentration and characteristics were determined under a light microscope and polymer identification was carried out with µ-FTIR analysis. Microplastics (MP) were detected in all samples at concentrations ranging from 1.20 ± 0.98 to 2.98 ± 2.21 MP/g wet weight. MP concentrations in white shrimp were 5 to 17 times lower compared to shrimp from supermarkets in Singapore and 0.77 to 8.6 times lower than shrimp from polyculture ponds in central Thailand, but 3 to 17 times higher compared to white shrimp from several supermarkets in South Korea. Fragments were the most common MP morphotype found, ranging from 73% to 89%. This result differs from other studies that found film and fiber to predominate. Based on the size distribution, particles with a size range between 20 and 100 µm predominate, i.e. 59-72%, but also MP particles > 100-1000 µm in size were found in Semarang white shrimp (24-39%). Methyl cellulose is the most common particle in white shrimp (50.6%), followed by the polyethylene group (28.2%), rubber (11.8%) and polyethylene-polypropylene copolymer (7.1%). These results indicate that attention needs to be paid to the handling of white shrimp during transportation, distribution and presentation in the market.

3.10.P-Th192 Analysis of Microplastics in Various Foods and The Assessment of Aggregate Human Exposure via Food Consumption

***Dat THANH Pham** and Jung-Hwan Kwon, Korea University, Korea*

Evidence of MPs occurring in humans has been recently demonstrated. The primary route of human exposure to MPs is through the consumption of contaminated food and water. However, the mass of microplastic exposure is not well defined, restricting the human health risk assessment. The transformation of microplastic counts into a mass value can be uncertain due to the unstandardized methods of calculation and analyzing microplastics in various food matrices. Therefore, this study proposes optimal analytical methods for eight types of food, including 90 products of salt, soy/fish sauce, seafood, seaweed, honey, beers, and beverages. Microplastics could originate from external sources such as manufacturing processes rather than from food. Subsequently, human exposure to microplastics of each food type was reported in terms of the number and mass of particles per week per person by simple calculation and Monte Carlo simulation. Geometric means and standard deviations of parameters were used to alleviate the influences of outliers in the data set, providing more reliable measurements. The determinations revealed that average adult Koreans likely ingest 1.4×10^{-4} and 3.1×10^{-4} g of MPs per week, respectively. The findings of this study extend the understanding of microplastic occurrence in food and contribute to the development of human health risk assessments.

3.10.P-Th193 Characterization and Quantification of Tire and Road Wear Particles and Microplastic Polymers in Air and Human Blood Samples

***Lorenzo Scibetta**[1], Esther Lenssen[2], Marthinus Brits[1], Feride Öykü Sefiloglu[1], Martin van Velzen[1], Quinn Groenewoud[1], Gerard Hoek[3], Raymond Pieters[3] and Marja Lamoree[1], (1)A-Life, Vrije University Amsterdam, Netherlands, (2)Institute for Risk Assessment Sciences, Utrecht University, Netherlands, (3)Utrecht University, Institute for Risk Assessment Sciences, Netherlands*

Micro and nano-polymer pollution can be found ubiquitously in all environmental compartments. To understand the human exposure to tire and road wear particles (TRWP) and micro and nanoplastics (MNPs) from the air, a real case scenario experiment was run in 3 different locations in Utrecht (The Netherlands). Therefore, PM10 was sampled on quartz filters were sampled using a high-volume pump and human blood was obtained from 25 volunteers that participated in the study. The polymers measured in this study were polyethylene (PE), polystyrene (PS), polyvinylchloride (PVC), polymethyl methacrylate (PMMA), polyethylene terephthalate (PET), polypropylene (PP), natural rubber (NR), and styrene butadiene rubber (SBR). For the analysis of the quartz filters, a sensitive method was developed for the characterization and quantification of rubber and microplastic polymers using sonication of the quartz filters followed by pyrolysis gas chromatography-mass spectrometry (Py-GC-MS). Quality assurance and quality control (QA/QC) parameters were assessed, including extraction efficiency (recovery), method specificity (pyrolysis temperature optimization and unique pyrolysates selection), and sensitivity (LOD/LOQ). Moreover, the method was validated using the 5 different polymers (PE, PP, PS, PVC, and PMMA) with a size range between 1 and 5µm. In addition, the method for the quantification and characterization of MNPs in human blood developed by Leslie et al. (2022) was adapted with some improvements for the analysis of TWRPs. For the validation, NR and SBR were used for the assessment of the same QA/QC parameters described above. By using these two methods, a total of 225 blood samples and 20 quartz filters will be analyzed to study human exposure to MNPs and TWRPs via the air. The aim is to quantify and characterize TRWPs and MNPs to understand the exposure and potential human health effects of plastic and rubber pollution between an urban park, a busy traffic road, and a road near a roundabout.

3.10.P-Th194 MPs In the Indoor Air: Implications for Human Exposure

***Hassan Ageel**, University of Birmingham, United Kingdom*

Microplastics (MPs) are a group of emerging contaminants that have attracted increasing scientific and societal attention over the past decade due to their ubiquitous detection in all environmental compartments. So far, most studies on MPs focus on characterizing their occurrence, fate, and impact in the aquatic environment. Very little is known about the magnitude, patterns, and associated risks of human exposure to MPs, particularly indoors. Airborne MPs may cause adverse effects on human health through inhalation, including respiratory, immune and reproductive toxicity, according to the Agency for Toxic Substances and Disease Registry (ATSDR). Critical evaluation of the existing literature revealed the presence of MPs at higher concentrations in indoor air (from homes and offices) compared to outdoors. This raises concern given that people spend most of their time indoors.

This study applied a combination of active and passive air sampling techniques to investigate the abundances, morphology, and composition of MPs in indoor air samples collected from homes (n=30) and work placement (n=30) in Birmingham, UK. MPs analysis was conducted using Perkin-Elmer spotlight 400 imaging system. Average concentration of MPs in the active air samples was 16.2 ± 5.1 MPs/m3 in homes and 13.1 ± 6.7 MPs/m3 in offices. For atmospheric deposition samples (passive sampling), the average MPs concentrations were 3464.3 ± 1464.2 MPs/m2/day in homes and 4334.2 ± 2462.5 MPs/m2/day in offices.

In terms of morphology, various shapes of MPs (e.g., fiber, foam, and fragments) were identified, with fibres and fragments constituting 90% of the identified MPs in all studied samples. The average MPs size (on the longest dimension) in active air samples was 10.65 ± 5.55 µm, while much larger particles were detected in atmospheric deposition samples with an average size of 21.13 ± 10.62 µm. A broad range of polymer types was identified including PP, PE, PET and PS as the most abundant polymers. Using our active air sampling data combined with inhalation rates from USEPA exposure factors handbook, the average daily inhalation exposure of UK adults and toddlers at home was estimated at 3.1 ± 0.98 and 4.4 ± 1.4 MPs/kg body weight/day, respectively.

3.10.P-Th195 Method of Deriving Exposure Factor for Exposure Assessment of Microplastics During Activities in the Living Environment

***Yeonjung jung Park**[1], Heekyung Bae[2], Juhye Son[2] and Jeonggue PARK[3], (1)Chemical Management Institute, TO21, Chemical Management Institute, Korea, (2)TO21, Chemical Management Institute, Korea, (3)Korea Environment Institute (KEI), Korea*

Microplastics have recently been recognized as a serious environmental problem, and interest in microplastics is increasing worldwide. Research related to the exposure assessment of microplastics in the living environment is currently insufficient, and it is difficult to acquire the exposure assessment methodology and applicable exposure factor of microplastics. Therefore, in this study, a data survey study was conducted to obtain information available for assessing microplastic exposure during activities in the living environment, such as exposure factor, exposure route, and exposure scenarios. Among household chemical products, laundry detergents, cleaning agents, microfibers, and disposable masks are products that are likely to cause microplastic exposure to humans and the environment, so they were selected as the products to be investigated in this study. A survey was conducted on the selected products to derive exposure factors. The purpose of the survey was to set the exposure scenario, derive the exposure factor, and obtain the necessary information to set the exposure assessment model, and the survey was conducted by dividing the questionnaire according to the characteristics of each target product. In the case of masks, exposure may vary depending on the material (KF94, KF80, dental mask, etc.) and shape (bird's beak type, dome type, etc.), and in the case of microfibers, it is necessary to consider whether a dryer is used or not, so a differentiated survey was conducted for each product. The exposure factor derived from this study is expected to be used as basic data for preparing exposure assessment techniques and performing risk assessment for household chemical products such as cleaning agents and laundry detergents, and products of social interest, such as textiles and masks.

3.10.P-Th196 A New Route of Exposure for Microplastics: Contact Lenses

***Sevda Eryilmaz Soydan**, Fatma Nur Eraslan, Mine Sağdıç Ulusoy, Mansoor Ahamd Bhat and Eftade Emine Gaga, Environmental Engineering, Eskişehir Technical University, Turkey*

Humans are exposed to microplastics due to their various physical and chemical properties such as small size, surface area, and strong biological penetration ability to reach and penetrate various organs including the placenta and brain. Contact lens and lens cleaning solutions have been investigated as a source of microplastics that may cause this exposure. Within the scope of the study, a lens solution used daily for one month was sampled from a volunteer lens wearer. Daily exposure to microplastics in the used lens solution was analyzed. The used lens solutions collected daily were collected in 5 ml vials. An appropriate procedure was applied to the lens solution. Afterward, the solutions were visually analyzed using a stereo microscope and imaging with Image J software. Color, size, and shape analysis was performed for the used lens solution of each day and the chemical characterization was performed after visual analysis. In addition, a questionnaire was applied in which the volunteer talked about his daily activities. The color and polymer type of personal belongings (towels, bed linen, clothes, etc.) containing polymers that they used in their daily activities, which could be a possible source, were recorded in the survey. The results of the survey and the analysis results of the lens solution were correlated with each other. The widespread presence of MPs in lens solutions has confirmed and provides the foundation for future studies into understanding the human exposure pathways.

3.10.P-Th197 In vitro Bioaccessibility and Human Dermal Exposure Assessment of Brominated Flame Retardants in Microplastics

*Stuart Harrad[1], Mohamed Abou-Elwafa Abdallah[1] and **Ovokeroye A Abafe**[2], (1)University of Birmingham, United Kingdom, (2)Geography, Earth and Environmental Sciences, University of Birmingham, United Kingdom*

Human exposure to microplastics (MP) is currently understood to occur via three distinct pathways including ingestion, inhalation and dermal contact occasioned by the presence of MPs in consumer products, dusts, water, air and foodstuff. Evidence of health effects associated with direct exposure to pristine MPs are lacking, however, there is an enormous concern over the toxicity of plastic additives (e.g. flame retardants (FR), per and polyfluoroalkyl substances (PFAS), phthalates etc.) released from MPs upon contact with human.

In this study, we optimized an *In vitro* physiological based extraction test by using synthetic sweat/sebum mixture (SSSM) to provide new understandings into the dermal bioaccessibility of various FRs from two MP standard reference materials (ERM 590 and ERM 591) and a polystyrene with known concentrations of FRs. The bioaccessible fractions of brominated flame retardants in these MPs were used to quantify their dermal exposure dose. All the studied BFRs were bioaccessible to varying degree. The daily exposure dose ranged from 0.05 – 22.34 ngkg^{-1}bw d^{-1} and 0.001 – 0.37 ngkg^{-1}bw d^{-1} fo high and low MP intakes, respectively. Whil for toddlers, they ranged from 0.5 – 230 ngkg^{-1}bw d^{-1} and 0.01 – 3.85 ngkg^{-1}bw d^{-1} respectively for high and low MP intakes. For HBCDDs, the DED ranged from 1.13 – 6.27 ngkg^{-1}bw d^{-1} and 0.02 – 0.10 ngkg^{-1}bw d^{-1} for dermally exposed adult, while for toddlers, it ranged from 11.80 – 65.10 ngkg^{-1}bw d^{-1} for the high and low exposure scenarios, respectively.

3.10.P-Th198 A Comparative Study of Digestion Methods for Qualitative and Quantitative Analysis of Microplastics in Animal Tissues

***Yukari Ishikawa**[1], Cristina Di Fiore[2] and Stephanie Wright[3], (1)School of Public Health, ERG, Imperial College London, United Kingdom, (2)Department of Agricultural, Environmental and Food Sciences, University of Molise, Italy, (3)School of Public Health, Imperial College London, United Kingdom*

Microplastic (MP) pollution is ubiquitous in air, water, and soil, and contaminates the food chain. MP ingestion in animals and presence in human stool has been reported. This raises concerns about their potential absorption, distribution, and elimination *in vivo* and their health effects, but to obtain scientific data on this, it is first necessary to establish suitable analytical methods. This often involves either concentrating the sample on a filter and performing qualitative analysis using Raman or Fourier Transform-Infrared micro-spectroscopy, or solvent-extracting the sample for quali-/quantitative analysis using pyrolysis-Gas Chromatography Mass Spectrometry. The MP accumulated in animal and human tissues are hypothesised to be smaller and in more trace amounts than those in environmental samples. This presents challenges in the separation of MP from different tissues, such as muscle or fat, the need for lower detection limits, and background contamination prevention. This study aims to overcome these challenges, by optimising tissue digestion methods for the separation of MP from organic matter.

H_2O_2, Fenton's reagent, 1M-KOH and 5M-KOH were selected from the literature as the agents to test. Control and MP-spiked mock samples (n=3, beef steak, lamb liver) were prepared and used to (1) compare digestion efficiency (% weight reduction), (2) compare MP recovery (% weight reduction), and (3) observe impacts on MP (observing changes in colour, size, and shape). For MP-spiked mock samples, a known amount of MP (PS, PP, PE, PA or PVC) was mixed into the minced meat before forming into pellets and freezing.

The digestion efficiencies of 30%-H_2O_2, Fenton's reagent, 1M-KOH and 5M-KOH were 80.1%, 88.4%, 97.1% and 95.6%, respectively. For performance, operational safety and Green Chemistry principles, 1M-KOH is preferred. The overall average recoveries of PS, PP, PE, PA and PVC (n=3) was 98%. No physical change was visibly observed when exposed to 5M-KOH. Digestion efficiency, MP recovery and the agent's impacts on MP were obtained and discussed to determine the most suitable digestion method for the analysis of MP in animal tissue. It was concluded that 1M-KOH is the best digestion method. Future plans include a more in-depth investigation of the impact of tissue type (muscle, fat, or organ) on digestion efficiency.

3.10.P-Th199 An Enzymatic Digestion Protocol for the Characterization of Micro- and Nanoplastics in Maternal and Fetal Tissues

*Laura Miranda Zoutendijk[1], Laurens Dirk Bernardus Mandemaker[1], **Lisa Zimmermann**[2], Bert Marc Weckhuysen[1] and Florian Meirer[1], (1)Chemistry, Utrecht University, Netherlands, (2)Food Packaging Forum (FPF), Switzerland*

Plastic can break down into smaller particles, called microplastics (<1 mm) and nanoplastics (<1 μm) (MNPs). The fate of these particles and their effect on human and animal health is still mostly unknown. Studies show environmental pollutants may have

an adverse health effect on the developing fetus, which makes the human placenta an important matrix in researching MNPs' health effects.
We focus on digestion protocols for placenta tissue to enable in-depth characterization of MNPs present in these samples. We aim for combining mass-based analysis with (spectro)microscopic techniques, to determine particle mass, number, morphology and chemical composition. To enable MNP characterization, the biological matrix has to be pre-processed to filter out components interfering with analysis. A successful digestion needs to sufficiently remove biological matrix, while assuring stability of MNPs in terms of chemistry, morphology, and particle number. To assess success of the digestion method and subsequent analysis, samples were spiked with a known concentration of well-defined commercial MNPs, namely fluorescent polystyrene (FPS) spheres.
1g of placenta tissue with known concentrations of FPS MNPs was digested with five different enzymes combined with three different buffers. Digestion was followed by filtration over a 700 nm pore size glass fiber filter. The amount of tissue left on the filter and the color of the filter were used as indicators for the success of the digestion. The obtained liquids were filtered over 90 nm pore size alumina filters which were analyzed with Confocal Fluorescence Microscopy (CFM) and Scanning Electron Microscopy (SEM). Our first results show that FPS MNPs were recovered from digested samples with no visible changes in morphology.
An enzymatic digestion protocol has been tested and optimized for the characterization of FPS MNPs in human placental tissue. At this stage Proteinase K in TRIS-HCl, pancreatin in TRIS-HCl and trypsin in PBS were found most suitable for tissue digestion. PS MNPs were found back after digestion and remained stable under the conditions used in this protocol. Our next steps will address recovery rates to further establish suitable digestion protocols for both mass-based and imaging analytical methods. This development in digestion methods for complex matrices is an important step in creating a risk assessment of MNPs to the unborn child.

3.10.P-Th200 Progress Towards Accurate Detection, Characterization, and Exposure Assessment of Micro- and Nanoplastics to Support Risk Assessments for Early-Life Health Within the Aurora Project
*Laurens Dirk Bernardus Mandemaker[1], Florian Meirer[1], Laura Miranda Zoutendijk[1], Justin Michael Boucher[2], Jane Muncke[2], **Lisa Zimmermann**[3], Matthew Boyles[4], Majorie van Duursen[5], Markus Forsberg[6], Tim Nawrot[7], Petra Pribylova[8], Martine Vrijheid[9], Douglas Walker[10], Virissa Lenters[11] and Roel Vermeulen[12], (1)Chemistry, Utrecht University, Netherlands, (2)Food Packaging Forum Foundation, Switzerland, (3)Food Packaging Forum, Switzerland, (4)Institute of Occupational Medicine, (5)Amsterdam Institute for Life and Environment (A-LIFE), Section Environment & Health, Vrije University Amsterdam, Netherlands, (6)University of Eastern Finland, Finland, (7)Hasselt University, Belgium, (8)Recetox, RECETOX, Masaryk University, Czech Republic, (9)Barcelona Institute for Global Health, Spain, (10)Icahn School of Medicine at Mount Sinai, (11)Universitair Medisch Centrum Utrecht, Netherlands, (12)Utrecht University, Netherlands*
Being able to accurately detect and characterize micro- and nanoplastics (MNPs) is a crucial first step in assessing human exposure to MNPs and their potential impacts on early-life health—which is the goal of our five-year, EU-funded Horizon 2020 research project, AURORA. However, detecting and characterizing MNPs, especially nanoplastics (NPs), in complex human tissues comes with significant analytical challenges. NPs are too small for light-based microscopy such as UV, IR, or visible (spectro-) microscopy. Besides their small size, the weight-per-particle decreases dramatically from micro to nanoplastics, making mass-based characterization techniques difficult even with (relatively) larger particle numbers. To complicate the situation further, NPs primarily consist of carbon, hydrogen, and oxygen, which makes them chemically similar to the organic matter that surrounds them in tissue samples limiting the use of imaging methods based on element contrast or spectroscopy methods.
To enable better characterization and exposure assessment of MNPs in complex tissue samples, including human placentas and blood, we are developing new sampling and analysis standards that combine approaches to consider both quantitative and qualitative information by using both mass-based and numerical techniques. We have combined several micro-spectroscopic techniques that go beyond the diffraction limit, including for example confocal fluorescence microscopy, atomic force microscopy (AFM) derived techniques like AFM-IR, or quantitative nanomechanical mapping. Another approach is correlative imaging such as scanning electron microscopy combined with Raman or IR micro-spectroscopy. In addition, we have optimized sample preparation using digestion protocols to remove natural organic matter, thereby ensuring that the MNPs do not change chemically or morphologically. Efforts are also being made to determine recovery rates of the sample preparation techniques.
In the AURORA project, we are advancing analytical methods to detect NPs, characterize their physical-chemical properties, and assess mass-based levels in European birth cohort samples. These methodological advances will allow for improved quantitative assessments of exposure during pregnancy and early life as well as potential associated risks.

3.10.P-Th201 Chemicals in Medical Plastics
***Tiffany Ramos**[1], Kristian Syberg[2], Agathe Bour[2] and Bethanie Carney Almroth[3], (1)Science and Environment, Roskilde University, Denmark, (2)Roskilde University, Denmark, (3)University of Gothenburg, Sweden*
The healthcare sector has a primary focus to ensure that patients receive quality and comprehensive care. However, research is beginning to suggest that the healthcare sectors reliance on single use plastics challenges that goal. Plastic products are highly favorable in society for their wide range of application and convenience and specifically within healthcare for the ability of products to arrive sterilized and ready for use. However, the versatility of plastic products is the result of additives, plasticizers, and chemicals that are added to the polymers to obtain the desired qualities. Studies have shown that some chemicals, such as BPA (bisphenol-a), can leach from the plastic product and affect the consumers of the product. The effects of these chemicals, including BPA and others, have been proven to range from reproductive impairments to the development of cancer. Furthermore, these chemicals have the potential to be released into the environment at the end-of-life phase of the product. When considering

the healthcare sector and their reliance of single use plastics specifically, the concern of leaching chemicals to vulnerable groups of patents becomes high. Additionally, when considering the recyclability of these products, it becomes paramount to consider the substitution of these chemicals to ensure the circularity of polymers within the value chain. In this comprehensive literature review, chemicals such as BPA, PVC, and PFAs which are commonly found in plastic products will be addressed with a specific focus on healthcare products and the potential affect these chemicals can pose on human health. Specific products will be identified and recommendations to phase out the use of these chemicals to producers of medical products and devices will be addressed. At last, in line with the circular economy action plan and upcoming UN treaty on plastics, the policy proposal of removing or phasing out these chemicals in plastic products will be suggested as a main focus.

3.10.V Establishing the State-of-the-Science in Human Exposure to Micro- and Nanoplastic

3.10.V-01 Development of Analytical Methods for Detection of Nanoplastics in Fish
Milica Velimirovic[1]*, Géraldine Dumont*[1]*, Kristof Tirez*[1]*, Claude Belpaire*[2]*, Caroline Geeraerts*[2]*, Stefan Voorspoels*[1] *and Frank Vanhaecke*[3]*, (1)Flemish Institute for Technological Research, Belgium, (2)Research Institute for Nature and Forest (INBO), Belgium, (3)Ghent University, Belgium*
Due to the mismanagement of the corresponding waste, plastic pollution is so ubiquitous and pervasive that it has become a threat to the environment and human health. The slowly degrading/fragmenting plastic debris forms a highly heterogeneous group of particles with different sizes (i.e., from centimeter over millimeter and micrometer to nanometer scale), shapes, densities, and chemical compositions. Detection, quantification and source identification of nanoplastics (NPs, 1-1000nm) in different matrices is still one of the largest challenges in this context due to the lack of adequate sample preparation procedures and straightforward analytical techniques for their characterization and quantification. Taking into account that food is one of the major exposure routes of NPs for humans and the potential risk for human health, it is of crucial importance that appropriate analytical methods for the analysis of NPs in food are developed.
In the framework of the EU-funded research project MS4Plastics (H2020-MSCA-IF-2020 - Grant Agreement No 101023205) different extraction protocols were tested to isolate NPs (polystyrene standards with particle size of 60, 90, 150, 240, 500 or 1000nm) from the fish muscle tissues (skin removed) of specimens of European eel (Anguilla anguilla) sampled in Flemish fresh-waters. Several approaches including (1) acid digestion, (2) alkaline digestion, (3) solvent extraction and/or (4) enzymatic digestion were tested to investigate whether the developed extraction protocols could affect the NPs size that was measured by using dynamic light scattering. Finally, the possibility of using (1) asymmetrical flow field-flow fractionation (AF4) hyphenated to ultraviolet–visible spectroscopy (UV/VIS) and multi-angle laser light scattering (MALLS) and (2) pyrolysis–gas chromatography–mass spectrometry (Py-GC/MS) as tools for characterization of isolated NPs were investigated.
The state of the art of the sample preparation methods selected with detection of NPs by AF4-UV/VIS-MALLS and Py-GC/MS will be presented, their performance will be evaluated, and the challenges that had to be addressed will be discussed.

3.10.V-02 Uptake and Distribution of Polyisobutylene Microplastic in the Gut of Zebrafish Following Dietary Exposure
Abass Toba Anifowoshe[1] *and Upendra Nongthomba*[2]*, (1)Department of Molecular Reproduction, Development and Genetics, Indian Institute of Science, India, (2)Department of Molecular Reproduction, Development and Genetics, Indian Institute Of Science, India*
Polyisobutylene (PIB) is a kind of elastomer that has excellent properties in terms of gas and moisture impermanence, damping, chemical and oxidative stability, and so on. Because of its great flexibility at room temperature, resistance to heat, and capacity to transmit gases, it finds widespread application in a number of industrial settings. These include tire inner liners and tubes, sealants, adhesives, condenser caps, pharmaceutical stoppers, and chewing gums. Although PIB biodegrades in water, the effect of its micro-size on toxicity has not been investigated. Here, we assessed the toxicity and accumulation of PIB using a zebrafish model and synthesized and characterized micro-size PIB. The zebrafish has several desirable characteristics as a study model, including its short generation time, optical transparency, high reproductive rate, and high ability to adapt to new environments, a high-quality vertebrate model for toxicology studies. We synthesized pristine and fluorescence PIB-microplastic (MP) with particle sizes of ~2-5µm using the solvent evaporation technique. During a 21-day feeding study, adult zebrafish were given food containing either 2.7×10^2 or 5.2×10^2 PIB-MP particles per liter. Within 21 days, PIB-MP accumulated in the fish gut, and the histopathology data demonstrate that this accumulation of PIB-MP in all the gut areas resulted in the aberrant architecture of the GIT. Interestingly, an analysis of fish behavior revealed a remarkable increase in their aggressiveness and pronounced alteration in the locomotor activity of the exposed groups. Evaluation of the metabolic changes caused by PIB-MP and comprehensive characterization of gut microbial compositions in zebrafish exposed to PIB-MP is ongoing but preliminary studies suggest that the distribution of these particles in the gut could alter the metabolites resulting in microbiota dysbiosis. However, further study is required to validate this, which we will present at the meeting.

3.11 Fate of Organic Contaminants in the Soil-Plant Continuum – Coupled Processes and Appraisal of Potential Impacts and Risks

3.11.T-01 Investigation of Uptake and Translocation of Plant Protection Agents by Crops via HPLC-HR-MS and MALDI-MSI
Daniel Skoczowsky *and Sebastian Zühlke, Technical University Dortmund, Germany*
Knowledge about the uptake and translocation, as well as metabolization of pesticides in crops is of great importance to human health and sustainable plant protection. Due to differences in experimental setups of plant uptake studies, such as varying growth

stages, composition of nutrient solution and other ambient influences, a comparison of uptake between different plants or plant protection agents often proves difficult. We established a simple and comparable hydroponic plant uptake study design and developed a suitable multi-component extraction method resulting in high recoveries while showing low matrix interference. We conducted several hydroponic plant uptake experiments to gain knowledge about the behavior of six physicochemically different pesticides, namely chlorpyrifos, tebuconazole, metalaxyl-m, fluopyram, spirotetramat and imidacloprid, taken up by maize and other important crops. Experiments at well defined BBCH were conducted in a plant chamber which enables constant and reproducible ambient parameters like light intensity, light duration, temperature and relative humidity. After harvesting, plant material was freeze dried, crushed and homogenized. Highly selective and sensitive HPLC-HR-MS^n was used for unambigeous identification and quantitation of initial compounds and their metabolites in roots, stem and leaves. MALDI-MSI at high spatial resolution allows precise localization of target compounds and insights into mechanistic processes inside the plant. We report new findings on the plant uptake of the pesticides in correlation with their physicochemical parameters, keeping a set of key parameters constant during the uptake experiments.

3.11.T-02 Contaminants of Emerging Concern in the Reclaimed Wastewater- Soil- Plant Continuum
***Evyatar Ben Mordechay**[1], Jorge Tarchitzky[1], Vered Mordehay[1], Yehoshua Maor[2] and Benny Chefetz[1], (1)Hebrew University of Jerusalem, Israel, (2)Phytor Lab, Israel*
Reclaimed wastewater irrigation has become a common agricultural practice in water-scarce regions. This practice exposes the agricultural environment to a wide range of contaminants emerging concerns (CECs). Once in the soil, CECs may undergo several processes such as degradation (mainly biodegradation), sorption to soil particles which is affected by the CEC's physicochemical properties and the soil organic matter content, and plant uptake. Generally, non-ionic and relatively lipophilic CECs can passively cross the root semipermeable membrane, whereas charged CECs may interact with the negatively charged membrane and as a consequence, their uptake would be hindered. CEC translocation from root to shoot in the xylem depends on its solubility in water and transpiration stream. In the current study, we used data collected from 445 fields irrigated with reclaimed wastewater to provide comprehensive insights regarding the fate of CECs in the irrigation water-soil-plant continuum. Leafy vegetables, carrots, oranges, tangerines, tomatoes, potatoes, avocados, and bananas were sampled in the study and are representative of the various plant parts. All irrigation water, soil, and plant samples were contaminated with CECs between 4-46, 1-21, and 0-13 analytes per sample, for the different media respectively. The reduction in the occurrence of CECs in the soils as compared to irrigation water was probably a result of rapid biodegradation in the soils. The further reduction in the occurrence of CECs in crops was a result of the semipermeable root membrane which acted as a soil-plant barrier.
Irrigation water post-soil-aquifer treatment exhibited the lowest occurrence and concentrations of CECs as compared to other wastewater treatments. These results are attributed to the long residence time in the soil aquifer and the infiltration through the sand. This trend continued to the soils and the irrigated plants, indicating the importance of the CECs concentration in the irrigation water. Within the plant, leaves exhibited the highest CECs occurrence and concentration. This results from to the passive uptake of CECs into the plant roots and translocation towards the leaves via the xylem with the water stream. Our data suggest that the soil acts as a reservoir for persistent CECs which retain and accumulate in the irrigated soils. These CECs may be released to the soil solution during the rainy season or between irrigations and be bioavailable for plant uptake.

3.11.T-03 Effect of Irrigation Alternation on the Accumulation of Contaminants of Emerging Concern in Common Vegetables
***Qingyang Shi** and Jay Gan, Department of Environmental Sciences, University of California, Riverside*
Recycled water has been regarded as a promising alternative water resource to alleviate water scarcity in agriculture. However, the potential risk of accumulation of contaminants of emerging concern (CECs) in plant tissues due to recycled water irrigation hinders the acceptance and adoption of such reuse. In the present greenhouse study, we propose a hybrid irrigation scheme as a means to reduce CEC accumulation in plants. The concentration of 11 commonly occurring CECs in plant tissue in different growth stages was compared between two treatment sets: one group received CEC-spiked water for the whole growth period; the other group was only exposed to CECs for half of the period and was switched to clean water irrigation afterwards. Three types of vegetable were cultivated, including radish, lettuce and tomato, representing a root, leafy and fruit vegetable, respectively. It may be expected that alternating to freshwater for the second half of the growing season could significantly reduce CEC accumulation in the final edible produce, as time is allotted for extensive metabolism and growth dilution to eliminate CECs. Through evaluating a practice that aims to reduce the accumulation in the edible part of vegetables with a simple modification, findings from this study may minimize human exposure risk, promote public awareness of water resue practices, and improve the safe reuse of marginal waters.

3.11.T-04 A Novel Modelling Approach to Prioritise Pharmaceuticals with an Accumulative Potential Within Crops - A Wastewater Irrigation Scenario
***John Henry Nightingale**[1], Andrea Lorena Garduno Jimenez[2], Stefan Trapp[3] and Laura Carter[4], (1)University of Leeds and Fera Science, United Kingdom, (2)University of Leeds, United Kingdom, (3)Technical University of Denmark, Denmark, (4)School of Geography, University of Leeds, United Kingdom*
Wastewater irrigation creates a route for human pharmaceuticals to reach agricultural soils, although very little is known regarding the potential for numerous human pharmaceuticals to accumulate in arable crops with experimental studies primarily focussing on a handful of chemicals. To bridge this knowledge gap a novel modelling approach was developed which utilised high resolution mass spectrometry datasets to define which pharmaceuticals are potentially present in wastewater irrigation following their detection in effluents. In total 178 pharmaceuticals were evaluated across various processes from, consumption –

wastewater treatment plant (WWTP) - irrigation – plant accumulation. In a first step physiochemical properties and chemical fate parameters (degradation and sorption in soil and sludge) were predicted, the outputs of which were then used within our defined framework comprising of 1. Activity SimpleTreat (WWTP fate), 2. PEC_{soil} (wastewater irrigation), and 3. a plant uptake model for *Zea mays*. The modelling framework was applied to evaluate three wastewater irrigation scenarios from regions with high wastewater reuse (Israel, Australia, and California). The top ten pharmaceuticals that were accumulated in *Zea mays* root, shoot, and fruit following wastewater irrigation were, piracetam > primidone > carbamazepine > mycophenolic acid > levetiracetam > warfarin > captopril > sulindac > acetaminophen > losartan (> 1.5 mg/kg FW). Factors affecting pharmaceutical accumulation were, consumption, degradation (sludge and soils), sorption, and the octanol-water partition coefficient. A compound specific effect was observed with regards to soil properties and pharmaceutical accumulation in plant. For example, between pH's of 5.4 and 7.7 the total primidone accumulation varied between 4.65 and 6.88 mg/kg (FW) respectively, whereas for warfarin little differences were observed (1.68 and 1.78 mg/kg). Our results highlight where future research efforts need to focus in terms of chemicals of interest which are currently not research priorities (e.g., piracetam). The human environmental risk assessment does not consider non-potable sources for pharmaceuticals to reach the environment, which is a problematic given that this process is increasing and has greater rate of application than that of sludge/manure applications. Therefore, the presented methods will be beneficial in building a regulatory framework as well as the benefits that arise from fate screening.

3.11.T-05 A Novel Mechanistic Model to Describe the Fate of Chemicals in the Soil-plant Continuum
*Giuseppe Brunetti[1], **Radka Kodesova**[2] and Jiří Šimůnek[3], (1)University of Natural Resources and Life Sciences, Austria, (2)Soil Science and Soil Protection, Czech University of Life Sciences Prague, Czech Republic, (3)University of California, Riverside*
Plants represent the most common pathway into the human food chain for environmental pollutants. Chemicals are taken up by plant roots from the soil and then translocated towards the edible parts, where they are bioaccumulated or eventually metabolized. These transport mechanisms are driven by the physicochemical interaction between soil, plant, and atmosphere. It is thus important to develop numerical tools that are able to accurately predict the fate of contaminants in this complex domain. With this in mind, in a series of recent studies, we developed a numerical framework that couples the widely-used model HYDRUS with the multi-compartment dynamic plant uptake routine. The resulting model mechanistically describes water flow, root uptake, and reactive solute transport in the soil, and is able to predict the fate of neutral and ionizable compounds in multiple plant compartments. The model has been successfully calibrated and validated against experimental data on the translocation and tranfromation of neutral (carbamazepine and its metabolite carbamazepine 10,11-epoxide) and ionic (citalopram, fexofenadine, irbesartan, sulfamethoxazole, clindamycin and its metabolite clindamycin sulfoxide) compounds in green pea plants. To favor its widespread adoption, the model has been coupled with a graphical user interface and included in the HYDRUS software suite. In this study, we provide an overview of the model structure, and report some of the most meaningful experimental scenarios that demonstrate its predictive capabilities.

3.11.P Fate of Organic Contaminants in the Soil-Plant Continuum – Coupled Processes and Appraisal of Potential Impacts and Risks

3.11.P-Mo218 Uptake of Pharmaceuticals into Edible Crops: A Field Case Study
***Minna Saaristo**[1], Kara Fry[2], Adam Wightwick[2], Erinn Richmond[2] and Mark P Taylor[2], (1)EPA Science, Environment Protection Authority Australia, (2)Environment Protection Authority Australia*
Irrigation with treated wastewater has been shown to introduce pharmaceutical and personal care products (PPCPs) into the environment. Further, use of treated wastewater in agriculture can lead to soil contamination with PPCPs and their metabolites, providing a route for accumulation in edible crops. Despite this, limited knowledge exists on the risks that irrigation of treated wastewater poses to non-target organisms and human health. Accordingly, the aim of this study is to determine the number, type and concentrations of pharmaceuticals and personal care products (PPCPs) in edible crops in market gardens and pasture in Victoria, Australia. Specifically, this study has four specific aims: (1) determine concentration of pharmaceuticals in irrigation water and soil; (2) quantify the concentration of pharmaceuticals in crops for human and animal consumption (florets, leaves, root) irrigated with A and B class irrigated water; (3) investigate the presence and potential of pharmaceuticals to bioaccumulate in plants subject to irrigated water; (4) assess the associated potential risk to human health through consumption of edible crops irrigated with treated wastewater. The study analyses samples from two different recycled water irrigation scenarios: (1) class A market garden crops; (2) class B-C pasture for livestock grazing in Victoria. For both scenarios, two farms will be selected along with a reference site (total of 6 sites: 2 market gardens, 2 pastures for livestock grazing, 2 reference sites). The selected reference farms occur in the same geographical region as the irrigated sites and grow the same crop type as the scenario farms but without recycled water. For both scenarios (market garden & pasture), 10 crops are collected from each site. From each plant, its leaves, floret, and roots will be analysed for PPCPs. In addition, 10 surface soil samples and 6 water samples (pre- and post-irrigation) will be analysed for PPCPs at each site. In total, 30 water, 138 plant, and 69 soil samples will be analysed. This will be one of the first studies investigating uptake of pharmaceuticals and personal care products into edible crops and pastures in Victoria (Australia), and we will be presenting the study in full detail in the conference.

3.11.P-Mo219 Mobility of Selected Micropollutants in Agricultural Soils of the Czech Republic
*Radka Kodesova[1], **Antonín Nikodem**[2], Vit Kodes[3], Ganna Fedorova[4], Martin Kočárek[2], Miroslav Fér[2], Helena Švecová[5], Ales Klement[2] and Roman Grabic[5], (1)Soil Science and Soil Protection, Czech University of Life Sciences Prague, Czech Republic, (2)Czech University of Life Sciences Prague, Czech Republic, (3)Czech Hydrometeorological Institute, Czech Republic, (4)University of South Bohemia in Ceske Budejovice, Faculty of Fisheries and Protection of Waters, Czech Republic,*

(5)University of South Bohemia in České Budějovice, Czech Republic
The sorption of organic contaminants in soils and sediment is a crucial factor affecting their mobility in the vadose zone environment. The Freundlich sorption isotherms were evaluated for eleven micropollutants and eight soils. The highest Freundlich sorption coefficients, K_F, were obtained for triclosan (324 ±153 $cm^{3/n}\mu g^{1-1/n}g^{-1}$) followed by sertraline (120±74), venlafaxine (74.3±41.2), telmisartan (33.3±13.6), atorvastatin (8.66±4.78), bisphenol S (8.03±4.87), lamotrigine (6.92±3.02), 2-phenyl benzimidazole-5-sulfonic acid (3.77±2.25), memantine (3.42±1.64), 1-methyl-1H-benzotriazole (2.05±0.99), and valsartan (0.88±0.89). The K_F values for the individual compounds were correlated with soil properties. Multiple linear regressions were used to derive equations for predicting the K_F values using the soil properties included in the map of agricultural soils of the Czech Republic. These equations always indicated positive correlations with oxidizable organic carbon and clay content. They also included either a negative or positive correlation with pH_{KCL}. A positive correlation with pH_{KCL} was obtained for venlafaxine, memantine, and sertraline, which were mostly positively charged. A negative correlation with pH_{KCL} was obtained for the remaining compounds. These equations, the soil map, and the database of soil properties were used to predict the K_F value distributions within the Czech agricultural soils. It resulted in similar K_F distributions' patterns for valsartan, lamotrigine, atorvastatin, and telmisartan (with a positive correlation between K_F and hydrolytic acidity), which considerably differed from the K_F patterns for the other compounds (with a positive correlation between K_F and base cation saturation or organic carbon content). These maps were used to delineate areas with a leaching potential of the compounds towards groundwater that will serve as a tool for assessing a potential groundwater vulnerability. This information will be used to improve the monitoring of groundwater quality within the Czech Republic, to identify areas unsuitable for broader utilization of wastewater for irrigation or stabilized sludge as a soil amendment, or to propose the safe application of these products onto agricultural soils.

3.11.P-Mo220 The Behavior of Sertraline in Soil-plant System

Ales Klement[1]*, Radka Kodesova*[2]*, Helena Švecová*[3]*, Martin Kočárek*[1]*, Miroslav Fér*[1]*, Antonín Nikodem*[1]*, Ganna Fedorova*[4] *and Roman Grabic*[3]*, (1)Czech University of Life Sciences Prague, Czech Republic, (2)Soil Science and Soil Protection, Czech University of Life Sciences Prague, Czech Republic, (3)University of South Bohemia in České Budějovice, Czech Republic, (4)University of South Bohemia in Ceske Budejovice, Faculty of Fisheries and Protection of Waters, Czech Republic*
The behavior of sertraline in soils and plants has been investigated in several of our studies. In the framework of these studies, contradictory results were obtained. It has been discovered that this compounds sorbs very strongly in soils because the sorption of this compound, which occurs in soils predominantly in a cationic form, is mainly driven by the ionic bonding onto the negatively charged surface of soil constituents. The average Freundlich sorption coefficient in 8 soils was 120±74 $cm^{3/n}\mu g^{1-1/n}g^{-1}$. Another study showed that desorption of this compound, which frequently occurs in sewage sludge from wastewater treatment plants, from this material is very low (i.e., desorbed fraction < 1%). This finding is consistent with previous observations.
On the other hand, it has also been found that in some soils, as Chernozems developed on loess, this compound can be easily taken up by plants (in this case spinach), accumulated in roots and even in plant leaves, contrary to its considerably lower uptake and low accumulation in plants planted in Cambisols. Finally, our recent study showed that despite its expected high sorption in soils and low desorption rate from sewage sludge, this compound could leach from soil beds amended with sewage sludge or composted sewage sludge, which were exposed to natural climatic conditions and drip irrigation. We assume that the binding of this compound to dissolved organic matter and/or the activity of plant roots could explain this finding. Further studies are needed to reveal mechanisms controlling sertraline behavior in the soil-plant environment.

3.11.P-Mo221 Contamination of Water, Soil and Plants by Micropollutants from Treated Wastewater and Wastewater Treatment Plant Sludge

Radka Kodesova[1]*, Helena Švecová*[2]*, Ales Klement*[3]*, Miroslav Fér*[3]*, Ganna Fedorova*[4]*, Antonín Nikodem*[3] *and Roman Grabic*[2]*, (1)Soil Science and Soil Protection, Czech University of Life Sciences Prague, Czech Republic, (2)University of South Bohemia in České Budějovice, Czech Republic, (3)Czech University of Life Sciences Prague, Czech Republic, (4)University of South Bohemia in Ceske Budejovice, Faculty of Fisheries and Protection of Waters, Czech Republic*
Several studies have shown that plants can absorb various micropollutants. One of the sources of micropollutants in the soil can be treated wastewater or sewage sludge. Previous studies were usually carried out in controlled conditions, i.e., greenhouses, etc. This study aimed to find out how the monitored compounds would behave in real conditions. For this purpose, nine raised beds were constructed at the wastewater treatment plants for České Budějovice, in which a mixture of vegetables (lettuce, onions, and carrots) or corn was grown in 2021. Several scenarios were considered: some beds were irrigated with treated wastewater, others were treated with sewage sludge, beds with composted sludge, and control beds (i.e., no source of contamination). Samples of treated wastewater and water drained from the beds, soil, and plants were taken during the year. Of the 77 substances analyzed, 59 were detected in wastewater and 11 in water that percolated through the beds irrigated with wastewater (e.g., telmisartan, gabapentin, and 1H-benzotriazole). Fourteen and ten compounds were found in sewage sludge and composted sludge, respectively, but only two substances (sertraline and 1H-benzotriazole) in water that leached through the beds with these sources of contamination. Compounds mostly did not accumulate in soils irrigated with wastewater. Low concentrations were found for telmisartan, carbamazepine, venlafaxine, and tramadol. In the case of both biosolids, gradually decreasing concentrations were observed for citalopram, sertraline, and telmisartan. Five substances were identified in lettuce and onion leaves and eight in carrot roots irrigated with wastewater (e.g., gabapentin, carbamazepine, and tramadol). In the case of corn plants, the compounds' concentrations were mainly below the limit of their quantification.

3.11.P-Mo222 Pharmaceuticals and Trace Metals Interaction Within The Water-soil-plant Continuum

Lesly Ayala Cabana[1]*, Ana de Santiago Martín*[2]*, Raffaella Meffe*[2]*, Isabel López*[2]*, Beatriz Peinado*[2]*, Leonor Nozal*[2] *and Irene de*

Bustamante[2], (1)Soil and water quality in the environment, IMDEA Water Institute, Spain, (2)IMDEA Water Institute, Spain
The use of water resources highly impacted by the discharge of wastewater treatment plant (WWTP) effluents to irrigate crops may pose a global health risk related to food safety and soil quality. The objective of the study is to evaluate the effect of the interaction of pharmaceuticals (Phs) and trace metals (TMs) within the water-soil-plant continuum by considering plant uptake, the generation of transformation products (TPs), the dynamics in interstitial water, and the impact on the soil enzyme activity. We conducted a bioassay experiment with *Lactuca sativa* L. and an agricultural soil from an area irrigated with surface water impacted by WWTP effluents. Seedlings were grown during 45 days in a growth chamber and twice-a-week drip irrigated with synthetic water spiked with 7 TMs (100 µg L-1), 15 Phs (10 µg L-1), or 7 TMs + 15 Phs. A control (without spike) was included. The interstitial water was sampled weekly using rhizon samplers. TMs, major elements (MEs), Phs, and TPs were analyzed in leaves (internal and external), roots, soil, and water samples. Soil β-galactosidase, urease, phosphatase, and arylsulfatase activities were measured. Results show that the distribution pattern of some Phs, TMs, and MEs in plant tissues is significantly impacted by Ph-TM interaction. When Phs are added with TMs, diazepam tends to translocate towards the external leaves rather than remaining in the roots. On the contrary, the content of carbamazepine in external leaves is significantly higher when the irrigation water is not spiked with TMs. Metabolization processes are also observed. Several TPs are detected in different plant tissues, such as carbamazepine 10,11-epoxide, atenololic acid, o-desmethylvenlafaxine, paraxanthine, and cotinine. The TPs o-desmethylvenlafaxine and paraxanthine are not detected in the interstitial water suggesting their formation as a consequence of the plant metabolism. The Ph-TM mixture in the irrigation water has a significant negative effect on the uptake of TMs and causes a ME imbalance. Conversely, the levels of Cd in leaves are above the EU limits and detected levels are even higher in the presence of Phs. Concerning the interstitial water, Cr, Cu, and Zn concentrations are lower in the presence of Ph-TM suggesting that Phs favour TM sorption. Soil enzyme activity is stimulated in presence of Phs (with or without TMs), suggesting that the enzyme-producing microbial population is favoured.

3.11.P-Mo223 Understanding Bioavailability of Unregulated Organic Chemicals (UOCs) in Land Applications of Biosolids
***Nicole M Dennis**[1], Qingyang Shi[1], Yaxin Xiong[1], Parminder Kaur[1], Aspen L Smith[1], Nathan Darlucio Sy[1], Meixian Cao[1,2] and Jay Gan[1], (1)Department of Environmental Sciences, University of California, Riverside, (2)Chinese Academy of Sciences, China*
Biosolids (i.e., treated sewage sludge) are a highly underutilized resource for agricultural purposes. The land application of biosolids offers multiple benefits over the environmentally detrimental disposal methods such as landfilling and incineration. These benefits include improvements to soil health and plant nutrition. However, biosolids contain hundreds of unregulated organic chemicals (UOCs) leading to concerns that may hamper its expanded use on food crops and delay the realization of a circular economy. Therefore, a significant research need is to determine which biosolids-borne UOCs pose a high risk to ecosystem and human health when biosolids are land applied to agricultural crops at environmentally realistic rates. To begin addressing questions of environmental risks of UOCs, a plethora of data are necessary, including baseline occurrence, fate, and transport data, particularly for those UOCs that may be persistent in soil, chronically toxic, and/or bioaccumulative. Central to characterizing environmental risks of biosolids land applications is the mobility and bioavailability of biosolids-borne UOCs, which dictate the offsite transport potential and likelihood for bioaccumulation by food plants and/or soil-dwelling organisms such as earthworms.
In this study, we evaluated the use of thin-film passive samplers as a biomimetic tool to estimate the bioavailability of priority UOCs in biosolids-amended soil and assess the feasibility of using such bioavailability measurements to predict their bioaccumulation in earthworm and edible plant tissues. The thin-film passive samplers were calibrated and optimized through laboratory experiments. They were then imbedded in field plots amended with biosolids at different rates. Passive samplers, along with soil samples, earthworm samples, and various vegetables (at maturity) were collected and analysed for about 40 target UOCs. Our results are expected to allow for rapid assessment of chemical bioavailability and prediction of bioaccumulation for an extremely diverse chemical mixture and contribute to a holistic human health and ecological risk assessment. In this presentation, we will provide an overview of our research on the development of the thin-film based bioavailability method for UOCs, and applications under field conditions.

3.11.P-Mo224 The Biodegradation and Sorption of Pharmaceuticals in Amended Soil with Bio-based Fertilizers
***Yan Dong**[1], Boris Jansen[2], John Parsons[3], Antonia Praetorius[2], Rick Helmus[4] and Chris Slootweg[5], (1)1091 BD, University of Amsterdam, Netherlands, (2)University of Amsterdam, Institute for Biodiversity and Ecosystem Dynamics, Netherlands, (3)Ibed, University of Amsterdam, Netherlands, (4)University of Amsterdam, Netherlands, (5)Van 't Hoff Institute for Molecular Sciences, University of Amsterdam, Netherlands*
The application of bio-based fertilizers (BBFs) is a promising avenue to close nutrient loops and increase the sustainability of agriculture world-wide. However, the application of BBFs also holds the risk of introducing harmful organic pollutants to the soil. Numerous studies on pharmaceuticals focus on aquatic environments or sediment, whereas relatively little is known about their fate in soil.
Biodegradation and sorption are two fundamental processes that determine the persistence and bioavailability of organic pollutants like pharmaceuticals in the soil [1, 2]. Their sorption can be expected to be compounds specific, as it is related to specific functional groups and the biogeochemical characteristics of the soil. The introduction of pharmaceuticals to the soil via BBF application could influence their subsequent biodegradation and sorption behaviour In the soil via interactions with the BBF matrix such as sorption prior to application.
To fill this knowledge gap, we employed soil biodegradation experiments to explore the fate of 9 common pharmaceutical compounds added directly and via BBFs in an agricultural field trials as part of the large, ongoing European research project

LEX4BIO. Subsequently, the half-lives and biodegradation rates were calculated to indicate their biodegradation and persistence. Finally, sorption experiments were employed to unravel underlying mechanisms governing the observed patterns.

3.11.P-Mo225 Environmental Fate of the Newly Discovered Sulfonated and OH-Sulfonated-PCBs: A Preliminary Evaluation

Jessica Palladini[1]*, Elisa Terzaghi, PhD*[2]*, Renzo Bagnati*[3]*, Alice Passoni*[3]*, Angelo Maspero*[4]*, Giovanni Palmisano*[4] *and Antonio Di Guardo*[2]*, (1)Department of Science and High Technology, University of Insubria, Italy, (2)Department of Science and High Technology (DiSAT), University of Insubria, Italy, (3)Istituto di Ricerche Farmacologiche Mario Negri, Italy, (4)University of Insubria, Italy*

More than one hundred environmental contaminants belonging to the new classes of sulfonated and OH-sulfonated-PCBs were recently discovered. These chemicals originate from PCBs, but the metabolic pattern leading to their formation is not clear yet. One hypothesis is the oxidation of PCBs by Cytochrome P450 followed by the action of glutathione S-transferase (GST) and other enzymes.

Sulfonated-PCBs were first discovered in polar bear serum and then they were also measured, along with OH-sulfonated-PCBs, in the National Priority Site (SIN) for Remediation (SIN Brescia-Caffaro). This site, located in Italy, was heavily contaminated by the Caffaro plant which produced PCB mixtures until 1984 for various industrial applications. These new PCB metabolites, representing approximately 1% of parent compounds in soil, are not well characterized yet. Neither information on their precise chemical identity, their measured physical-chemical properties, their fate in the environment nor on their ecotoxicity and toxicity is available. Therefore, more attention should be focused on these new environmental contaminants to understand their potential environmental risk.

It has recently been demonstrated that sulfonated and OH-sulfonated-PCBs can bioaccumulate in earthworms and enter the food chain. They could also represent a risk for surface water and groundwater contamination, as their polar nature may enhance their movement with runoff and percolating water into the soil. Hence the importance of investigating the environmental fate of the novel PCB metabolites, which is the aim of the current work. To do so, different experiments were performed: adsorption to soil, degradation in soil (using different plant species selected based on their ability to degrade PCBs), bioaccumulation in roots and leaching behaviour in a soil column. The results obtained showed that sulfonated and OH-sulfonated-PCBs are persistent chemicals, might accumulate in biota and easily move to deeper soil layers due to their low soil-water partition coefficient (Kd). These preliminary data represent the first experimental information regarding their behaviour in the environment and will be useful for further investigations.

3.11.P-Mo226 Back to the Roots: The Impact of Roots on the Uptake and Translocation of a Model Compound in Hydroponic Cultivated Tomato Plants

Alexander Dorn*, Tobias Breuer, Thomas Augustin, Klaus Hammel and Marc Lamshöft, Bayer AG - Crop Science Division, Germany*

Plant uptake of chemicals by roots is an important component of the environmental risk assessment. In soil as well as in hydroponic solutions, the uptake of Carbendazim was retarded. It remained unclear, to what extent the physiology of roots regulated the uptake of Carbendazim. There are two different transport pathways in the roots, namely the apoplastic pathway via the cell walls and the symplastic pathway throughout the cells. The casparian strip is a barrier for the apoplastic pathway directing it to the symplastic pathway. Entering the symplast and finally the xylem requires the passage of a lipid membrane, which steers the translocation of nutrients or chemicals from the roots to the shoots.

In this work we aim to elucidate the uptake and subsequent translocation of Carbendazim using hydroponic studies with intact plants and such with their roots cut off, so that Carbendazim could enter the phloem and xylem directly. The differences observed between these experimental setups are analysed for a better mechanistic understanding of root uptake and translocation processes of PPP in plants. The hypothesis is that the Casparian stripe represents a barrier which slows down the transport of Carbendazim and retards the translocation to the above ground parts of the plant.

The study results will allow to answer the hypothesis that the uptake of Carbendazim is retarded by the root of tomato plants and to quantify the temporal development of Carbendazim concentrations in different plant compartments. Potential differences of transpiration and Carbendazim mass flow between the plants with and without roots will be evaluated and be discussed.

This work is part of a project investigating uptake, transformation and translocation processes of chemicals in the soil plant continuum. The experimental results will be used also for simulation studies with multicompartment plant modelsin order to improve a mechanistic understanding of these plant processes. Details will be presented during the meeting.

3.11.P-Mo227 MALDI Mass Spectrometry Imaging to Track the Uptake and Systemicity of Agrichemicals in Crop Plants

Michael Kubicki*, Marc Lamshöft and Andreas Lagojda, Bayer AG - Crop Science Division, Germany*

Agrochemicals such as fungicides, herbicides, or insecticides are widely used worldwide to control weeds, pests, and diseases to reduce the loss in crop production and increase yield and quality of crop products. Successful control and safe usage of these types of compounds depend on the compound reaching the target site within the crop plant. Therefore, monitoring agrochemical distribution within plant tissues delivers significant insights into agrochemicals adsorption, distribution, metabolism, and elimination (ADME). Visualizing and quantifying agrochemical the uptake often requires a combination of techniques which usually utilize isotope labelling such as radioactive beta emitters like ^{3}H or ^{14}C and include combustion analysis, scintillation counting, autoradiography, and radio-high-performance liquid chromatography (HPLC). A major limitation of these methods is that they rely on radiosynthesis. High-resolution mass spectrometry combined with chromatographic techniques are used to assess ADME parameters by offering a powerful platform for the detection and characterization of plant protection products and their

metabolites. It provides accurate mass measurements by large full-scan sensitivity, leading to structure information of unknown biotransformation products. However, only limited information about the spatial distribution of target analytes is available due to the extraction step prior to analysis. Matrix-assisted laser desorption/ionization mass spectrometry imaging (MALDI MSI) has become a valuable analytical tool and can be used as a label-free, semi-quantitative alternative technique to visualize the spatial distribution of a range of compounds like agrochemicals and endogenous compounds (e.g., amino acids, polysaccharides, proteins) *in situ*.
Several mass spectrometry imaging experiments of selected plant tissues (e.g., roots, stem, leaf) were carried out on a Q-Exactive HF-X™ Hybrid-Quadrupole Orbitrap mass spectrometer, coupled to an AP-SMALDI5AF ion source. Mass spectra with high mass accuracy and high mass resolution were acquired for the precise identification of target molecules by the detection of monoisotopic masses of interest. Measurements were performed with a high spatial resolution of 20 – 50 µm step size to distinguish the distribution of selected target molecules in particular areas of interest. The obtained spatial information delivers new insights into the root uptake and systemicity of the agrochemicals within plants.

3.11.P-Mo229 OECD Round Robin Test to Evaluate a New Test Design to Determine Plant Root Uptake for Regulatory Environmental Fate Modelling

Marc Lamshöft[1]*, Maximilian Küppers*[1]*, Carola Schriever*[2]*, Herbert Resseler*[3]*, Petra Volz*[2] *and Xiao Zhou*[4]*, (1)Bayer AG - Crop Science Division, Germany, (2)BASF SE, Germany, (3)Syngenta Agro, Germany, (4)Corteva Agriscience*

In 2018 an OECD project lead by the German Federal Environmental Agency (UBA) started to develop a test guideline for the determination of plant root uptake for regulatory environmental fate modelling. The project builds on the study design that was developed from the outcome of a stakeholder workshop and subsequent discussions with academia, regulatory and industry.
The OECD experts from academia, industry and regulatory who are working on the project recommended testing 14- and 28-days old plants instead of testing plant of uniform age. Additionally, uptake should be tested at three test item concentrations (0.5, 1.0 and 2.0 µmol/L) instead of one and the incubation period should be reduced from 8 days to of 48 h. Moreover, modifications to several experimental parameters were suggested.
After a pretest with wheat and oil seed rape plants had confirmed that the suggested changes were technically feasible, a round robin test (10 laboratories) was conducted in 2021-22. Uptake of [^{14}C]-1,2,4-triazole in a hydroponic test system was studied at concentrations of 0.1, 1.0 and 10.0 µmol/L with 15- and 30-days old wheat plants that were incubated for 48 h at pH 5.5 and pH 7.5.
The average Transpiration Stream Concentration Factor (TSCF) value was 0.54 ± 0.19 over all test concentrations and both pH values. The low data variance demonstrated the robustness of the test design. The results confirmed that significant biomass increase, and water consumption correlates with a consistent root uptake of the test item. Furthermore, a radioactive recovery between 95-105 % is an indication for a reliable test.
Additional important learnings from the test should be considered in the OECD test guideline, e.g., the relevance of accurate determination of evaporation from the hydroponic test system, describing plant growth with BBCH codes instead of plant age in days.
The overall results will be acknowledged to set up the test protocol of a new OECD guideline in 2023/24. The final version of the study design of the intended OECD guideline is considered appropriate to produce reliable data on plant uptake to be used as input for refined exposure modelling. An explicit guidance, on how to integrate the study design into the regulatory process is aimed to be developed based on the final OECD test guideline.

3.11.P-Mo230 Are Existing Lab-Based Equations Suitable to Predict Organic Contaminant Bioaccumulation in Plants in More Realistic Conditions?

Elisa Terzaghi[1]*, Gianmaria Cetti*[2]*, Alessia Lipari*[2]*, Gianluca Rubello*[2] *and Antonio Di Guardo*[1]*, (1)Department of Science and High Technology (DiSAT), University of Insubria, Italy, (2)University of Insubria, Italy*

Organic contaminant (OC) accumulation in plants from air and soil represents the first step in the food web uptake, affecting both human and ecosystem exposure and effects. Therefore, the quantification and the prediction of OC plant uptake is fundamental for assessing ecological risk.
To estimate such uptake, several equations are available in the literature, mostly developed in lab conditions, to obtain the root and the stem concentration factors (RCF and SCF). These equations are used even in regulatory predictive approaches to predict the exposure through the food chain.
Many of the studies performed so far mainly included short-term laboratory and greenhouse experiments, using hydroponic systems or spiked soils. These types of experiments allow to produce results under controlled conditions, but they generally diverge from realistic field conditions. Plant uptake experiments performed in field-like conditions as well as field studies could provide important information to improve the ecological realism when modeling the uptake of OCs by plants.
The aim of this work was to assess the suitability of the existing lab based predictive equations in estimating the root and stem uptake of Polychlorinated Biphenyls (PCB) for several herbaceous and woody species. More specifically, we performed a long-term (18 months) greenhouse experiment with a weathered contaminated soil and five plant species and a field study in a heavily PCB contaminated agricultural site. More than 80 PCB congeners were measured in soil and plant biomass by GC-MS. The obtained data were used to developed new RCF and SCF predictive equations considering more realistic conditions that were later compared to those reported in the literature.
Concerning root uptake, the existing laboratory-based predictions were considerably lower, up to about 2 orders of magnitude (expecially at increasing hydrophobicity) with respect to semi-field and field results. For stem uptake equations the difference was even higher (up to about 3 orders of magnitude) probably because of the relevance of another uptake path (i.e., air).

This study highlighted that the existing lab-based equations underestimate the bioaccumulation in plants; therefore, semi-field and field studies are necessary to obtain more realistic predictions of OC bioaccumulation.

3.11.P-Mo231 Do 17-B-Estradiol and Diclofenac, Found in Wastewater Reused for Irrigation, Have Genetic Effects on Crops?

Andrea Lorena Garduno Jimenez[1] *and Laura Carter*[2]*, (1)University of Leeds, United Kingdom, (2)School of Geography, University of Leeds, United Kingdom*

Contaminants of emerging concern (CECs) such as pharmaceuticals, antibiotics and natural and synthetic hormones, have been shown to be ubiquitous in the agricultural environment. This is mainly due to otherwise beneficial practices such as wastewater reuse for irrigation and replacing synthetic fertilisers with wastewater derived biosolids and animal manures and slurries. CECs have been shown to alter the gene expression of crops which can result in negative impacts on crop health; for example by causing flowering times to be out of synch with pollinator's lifecycles. There is an urgent need to understand the effects CECs on crops at environmentally realistic concentrations and application scenarios.

A greenhouse experimental trail to explore the fate and effects of two CECs of interest, namely the prevalent natural steroid hormone 17b-estradiol and non-steroidal anti-inflammatory drug diclofenac is near completion. To date, 17b-estradiol has been shown to promote plant growth, whilst diclofenac has been shown to hinder it, and an explanation for this effect remains elusive. A genetic mechanistic understanding of the effect of these two CECs will lead to a better understating of how these pollutants can affect crops at a genetic level. This study compares the gene expression (using proteomics), the uptake and metabolism (using targeted and untargeted liquid-chromatography mass spectrometry and metabolomics) of 17b-estradiol diclofenac on the different parts of the radish plant. The results will indicate whether current realistic exposure scenarios are of concern when reusing waste streams in agriculture. Furthermore, understating genetic mechanistic effects of two CECs known to have opposite effects will reveal how these pollutants can effect crops at a genetic level.

3.11.P-Mo232 Ecotoxicity Risk Assessment of the Plant Biostimulant Strigolactone (SL-6)

Steven Brooks[1]*, Daria Popa*[2]*, Zheng Congying*[3]*, Maria Christou*[4]*, Ana Almeida*[1]*, Tania Gomes*[1]*, Li Xie*[1]*, Sergey Shaposhnikov*[3] *and Florin Oancea*[5]*, (1)Norwegian Institute for Water Research (NIVA), Norway, (2)SR UCECHIM, Romania, (3)NorGenoTech, (4)Norwegian Insitute for Water Research, Norway, (5)ICECHIM, Romania*

A risk assessment on the aquatic toxicity of the plant biostimulant strigolactone (SL-6) was performed using a suite of standardised bioassays representing different trophic groups and acute and chronic endpoints. In freshwater, three trophic groups of algae, crustacea and fish were used. Whilst in marine waters, algae (unicellular and macroalgae), Crustacea and Mollusca were employed. In addition, the genotoxicity of SL-6 was determined with the comet assessment performed on unicellular algae, oysters and fish embryos. This is the first time ecotoxicity tests have been performed on SL-6, which is a phytohormone developed for agricultural use. In freshwater, the lowest LOEC was measured in the unicellular algae at 0.31 mg/L SL-6. Although, similar LOEC values were also found for malformations in zebrafish embryos (LOEC 0.33 mg/L). Consistent malformations of pericardial oedemas and yolk sac oedemas were identified. In marine species, the lowest LOEC was found for *Tisbe battagliai* mortality at an SL-6 concentration of 0.1 mg/L, this was also the lowest LOEC in all species tested. Significant genotoxicity was observed above control levels at 0.031 mg/L SL-6 in both unicellular algae and the zebrafish embryo. Genotoxicity was also observed in the oyster embryos but at higher concentrations with a LOEC of 0.03 mg/L. When applying the simple risk assessment, calculated predicted no effect concentration (PNEC) for the ecotoxicity tests and the genotoxicity tests were 0.3 µg/L and 0.01 µg/L respectively based on conservative assessment factors.

3.11.P-Mo233 Effects of BPA, BPS, and their Mixtures on Seed Germination – Assessed by the Combination of Germination Index (GI) and LC-MS Based Accumulation of Chemicals and Metabolites Profiling

Seungyun Baik[1]*, Miso Hwang*[2]*, Sara Farmahini Farahani*[3]*, Jihyun Chun*[2]*, Hyunki Cho*[2] *and Chang Seon Ryu*[4]*, (1)Environmental Safety Group, KIST Europe Forschungsgesellschaft mbH, Germany, (2)ESG, KIST Europe, Germany, (3)Bsg, KIST Europe, Germany, (4)KIST Europe, Germany*

Substances of the bisphenol group are well-known environmental endocrine disruptors and their adverse effects on different environmental organisms and even humans have been assessed by many different methods. Wide spread use of these substances increases the detected areas and concentrations of them and this may lead to the potential risks of the environment and humans. Among all these substances, bisphenol-A (BPA) and bisphenol-S (BPS) are of special concern due to their high volume of usage compared to the other substances. Therefore, analysis of the effects from the existence of BPA and/or BPS in soils with environmentally relevant concentrations is of interest. Phytotoxicity microbiotest has been used to monitor environmental pollutants in soils and sediments, and the effects by toxicants can be estimated by germination index (GI) calculated from the seed germination and root elongation. In this work, different concentrations of BPA, BPS, and the mixture of BPA and BPS were exposed to *Sinapis alba* (*S. alba*) seeds and the effects were analyzed by GI after 3 days of exposure. In addition, accumulation of BPA and BPS to each of three different compartments, roots, stems, and leaves, were quantified by HPLC-MS analysis. GI for BPA and BPS exposure of 1, 10 and 25 µM are calculated as 124.9 ± 5.2, 134.0 ± 19.0, 98.6 ± 12.1 and 145.4 ± 18.8, 105.9 ± 28.0, 68.2 ± 9.4, respectively. These results indicate that the seeds exposed to higher concentration of both BPA and BPS may have some inhibition effects but exposed to lower and environmentally relevant concentrations of both BPA and BPS may have some promotion effects. Accumulation of the substances on each compartment was different for the exposed substances, having accumulated BPA and BPS concentrations on roots, stems, and leaves for 25 µM exposure were 0.051, 0.020, and 0.026 µM, and 0.520, 0.033, and 0.282 µM, respectively. Water solubility may have a big role on the accumulation results due to about 10 times higher water solubility for BPS compared to BPA. Using high resolution LC-QToF-MS, DIA non-targeted metabolomics was conducted. For this data analysis, MS-Dial, a powerful open science tool for MS annotation, was used and meaningful data were achieved. This combination method of GI, quantitative analysis, and *in Silico* annotation methods for metabolites would provide the future directions regarding higher plant phytotoxicity bioassay due to the deliverable and detailed data on the effects.

3.11.P-Mo234 Pharmaceuticals and Antibiotic Resistant Genes Detection in Horticultural Soils After Irrigation With Reclaimed Wastewater

Lucas Leonel Alonso[1,2]*, Maddi Salvoch*[3]*, Marc Castaño Trias*[3]*, Evangelios Statiris*[4]*, Jose Luis Balcazar*[3]*, Gianluigi Buttiglieri*[3] *and Sara Rodriguez-Mozaz*[5]*, (1)UNLP-CONICET, Argentina, (2)Quality Area, Instituto Català de Recerca de´l Aigua, Spain, (3)Instituto Català de Recerca de´l Aigua, Spain, (4)National Technical University of Athens, Greece, (5)Catalan Institute for Water Research (ICRA), Spain*

The demand for water suitable for irrigation in areas with freshwater scarcity implies adequate wastewater treatment systems that do not generate a risk for agroecosystems, including the organic micropollutants commonly found in wastewater (e.g., pharmaceuticals). Under the H2020 HYDROUSA project a wastewater treatment system has been installed in the Greek island of Lesvos, consisting of a combination of upflow anaerobic sludge blanket reactor, a constructed wetland, and UV disinfection. The objective of this study was to evaluate the input of pharmaceuticals, from the reclaimed water (RW) into arable soils, during the growth cycle of lettuce crops during summer and winter. Tap water (TW) was used as a negative control to irrigate the soil. Soil samples (NS) were taken before the first crops irrigation, two weeks after, and at harvesting time (40 days). Once the plant was harvested, the bulk soil (BS) attached to the roots was collected individually. The roots were then soaked in a NaCl solution (RS), and the soil bonded to the roots interface was collected in the solution, which finally was filtered to separate the solids (for microbiological analysis). For the pharmaceutical analysis, ultrasound extraction and SPE were performed for the NS and BS soils. The RS solutions were extracted by SPE. A total of 70 compounds were analyzed in a quadrupole linear ion trap tandem mass spectrometry (UHPLC-QqLIT). Pharmaceuticals (more than 15 analytes) were detected in soils at both campaigns, and in the different types of samples (soils and rhizosphere solution). A higher occurrence and concentration of compounds was observed in the BS when compared to NS, in the plots irrigated RW but not for the TW. Analgesics and antiinflamatories were the most detected group ($p<0.05$) in both seasons and in every irrigated soil. Summer campaign showed higher concentration for most of the compounds, especially for cardiovascular and psychiatric drugs ($p<0.05$), which were found in a range (sum) between 0.036-236 µg/kg and 0.055-302 µg/kg. While antibiotics were less frequently detected than other pharmaceuticals, possibly due to their shorter half-lives in soils, detections of sulfamethoxazole and enrofloxacin indicate their reach to soils. Additional microbial analysis for the determination of antimicrobial resistant genes are being processed at the moment, and will contribute with information regarding the impact of the influx of these pollutants on the soils.

3.12 HR-MS Analysis of Metabolites and Transformation Products of Organic Pollutants - What Remains Unknown

3.12.P-Th202 In-Stream Attenuation of Pharmaceuticals and Their Transformation Products in Intermittent Streams

Olga Gómez Navarro[1]*, Serge Chiron*[2] *and Sandra Pérez*[1]*, (1)Onhealth, IDAEA-CSIC, Spain, (2)University of Montpellier, France*

The increasing use of pharmaceuticals and hence their widespread occurrence in the aquatic system arises concern on their potential ecological and human health effects. But what happens once in the environment? In the environment, pharmaceuticals may suffer from different stressing conditions due to solar irradiation, temperature, microorganisms, undergoing transformations by means of hydrolysis, photolysis or biodegradation forming transformation products (TPs). Little is known about their fate and possible natural in-stream attenuation by either biodegradation or photolysis, thus to expand our knowledge on the occurrence of pharmaceuticals and their TPs, both laboratory and field studies were performed. Two intermittent rivers were studied from Spain and Greece where the discharge effluent as well as the upstream and downstreams points were analysed. Samples were extracted using solid phase extraction and analysed using liquid chromatography coupled to a high resolution mass spectrometer (LC-HRMS). Target analysis of over 100 pharmaceuticals was performed and over 50 pharmaceuticals were detected and quantified. At the same time, lab-scale photodegradation studies were performed to identify and detect transformation products. Venlafaxine and losartan were frequently detected and the generation and identification of the corresponding photo-transformation products (photo-TPs) under lab-scale photolysis was studied. A retrospective analysis was then performed to search for these photo-TPs in the real samples. Concerning venlafaxine four TPs were detected however it remains very challenging to be able to distinguish between human metabolites and natural in-stream attenuation (biodegradation or photolysis). Hence further studies are necessary to better understand the fate of these contaminants and to be able to assess the health of a watercourse.

3.12.P-Th203 Biological Transformation of the Insect Repellent Icaridin and its main Transformation Product Icaridin-acid – Kinetics and Transformation Pathway

Sabrina Quanz[1]*, Nils Keltsch*[2]*, Sandro Castronovo*[2]*, Peter Schweyen*[2]*, Michael Schluesener*[2]*, Arne Wick*[2] *and Thomas A Ternes*[3]*, (1)G2-Aquatic Chemistry, Federal Institute of Hydrology, Germany, (2)G2-Aquatic Chemistry, German Federal Institute of Hydrology, Germany, (3)G Qualitative Hydrology, German Federal Institute of Hydrology, Germany*

Icaridin (ICN) is a widely used insect repellent and a substitute for *N,N*-Diethyl-*m*-toluamid (DEET) since the end of the 1990´s. ICN is removed rather efficiently in waste water treatment plants (WWTPs) likely by biological transformation, which might explain, that it has been rarely detected in the aquatic environment. However, already back in 2004 T. P. Knepper showed, that ICN is mainly transformed to icaridin-acid (ICN-acid) by oxidation of the primary alcohol of ICN. The further transformation of ICN-acid was not elucidated in this study and due to lacking commercially available reference standards, knowledge about the occurrence and environmental fate of ICN-acid is still scarce. To fill this gap, a reference standard of ICN-acid was synthesized and characterized in-house. To investigate the degradation kinetics and further transformation of ICN-acid, batch experiments were performed in a mixture of activated sludge and effluent taken from the WWTP Koblenz (Germany). For the reason of comparison, experiments were also conducted with ICN. Both, ICN and ICN-acid, were spiked in various concentrations between 10 and 1000 µg/L and incubated under oxic conditions. Furthermore, one non-spiked control and one autoclaved control with a spike level of 100 µg/L (ICN and ICN-acid) were used to facilitate identification of transformation products (TPs) and differentiate between abiotic and biotic degradation, respectively. Samples were taken repeatedly during an incubation period of 21 days and analyzed by triple quadrupole mass spectrometry for quantification and determination of degradation kinetics. First results confirme that ICN is mainly transformed to ICN-acid and that this TP is further transformed by biologically-mediated processes. The degradation kinetic of ICN was faster (k_{biol}= 31 ±2 L g_{ss}^{-1} day^{-1}) than that of ICN-acid (k_{biol}= 2 ± 0.1 L g_{ss}^{-1} day^{-1}). For detection and identification of the TPs of ICN-acid, measurements via high-resolution mass spectrometry will be performed. Degradation kinetics of ICN and ICN-acid and proposed transformation pathways of ICN-acid will be presented at the conference. Furthermore, environmental samples will be analyzed afterwards to detect ICN-acid and the identified TPs in the aquatic environment. With the results of this study, the degradation behavior and occurrence of ICN and ICN-acid in the environment should be unraveled and thus also the potential impact on the environment assessed in more detailed.

3.12.P-Th204 Analysis of Urinary Biomarkers for the Selection of the Most Suitable Personal Protection Equipment for E-waste Dismantlers
Sandra Callejas Martos[1]*, Aleix Balasch Garcia*[2] *and Ethel Eljarrat*[3]*, (1)Environmental Chemistry, Spanish Research Council (CSIC), Institute of Environmental Assessment and Water Research (IDAEA), Spain, (2)IDAEA-CSIC, Spain, (3)Spanish Research Council (CSIC), Institute of Environmental Assessment and Water Research (IDAEA), Spain*
Recycling electronic waste (e-waste), which includes electrical goods such as computers, TVs, and mobile phones, has gained importance. This is primarily because these gadgets are constructed mostly of precious and reusable materials like plastic and metal. Recycling e-waste facilities might be regarded as hot spots of air pollution, considering how much particulate matter (PM) is released during working hours. These emitted PMs contain hazardous materials like plasticizers and flame retardants (FRs), which are proven to have toxic effects on human health. Previous research [1] has described how plastic additives are present in the air of recycling plants and how their employees have been exposed to them. As a continuation of this study, the main objective of this work is to study the use of precautionary measures, in particular the use of personal protective equipment (PPE), to reduce the e-waste dismantlers' exposure to these contaminants. Two different facemasks (Surgical and FFP3) were compared. The assessment was done by evaluating the exposure through the analysis of metabolites in urine.
For that purpose, an intensive sampling campaign has been performed in two working areas of a recycling facility located in Catalonia (an area for cathodic ray-tube (CRT) TV dismantling and a grinding area). A group of selected volunteers wears, during all their working days (8 hours) one of the compared facemasks. Then, the first urine sample of the following morning was collected for analysis. Additionally, the workers also wore silicone necklaces during their work day. They were used to assess human exposure to these hazardous substances associated with plastic. Analysis were performed using LC-MS/MS methodologies, and different plasticizers and FRs were determined, including organophosphate esters (OPEs), and phthalates, among others.
High levels of plastic additives are found in silicone necklaces, which demonstrates that e-waste dismantlers are exposed to these contaminants by inhalation and dermic absorption. Additionally, urine samples confirm the exposure suffered, since the biomarkers of these chemicals are present. Although the exposures suffered by the workers in the same area are similar, the urine samples show differences between the workers that wear FFP3 and surgical masks. Workers that wear FFP3 masks present lower levels of biomarkers, which gives evidence of the higher protection presented by these facemasks against plastic additives.

3.12.T-01 Molecular Insights into Biodegradability of Ozonation Products from Effluent Organic Matter
Elaine Jennings[1]*, Millaray Sierra Olea*[2]*, Uwe Hübner*[2]*, Thorsten Reemtsma*[1] *and Oliver Lechtenfeld*[1]*, (1)Department of Analytical Chemistry, Helmholtz Center for Environmental Research, Germany, (2)Technical University of Munich (TUM), Germany*
Ozonation has so far been assumed to increase the biodegradability of effluent organic matter (EfOM), but some compounds have been found to produce stable ozonation products (OPs) resistant to biological degradation. Recent advancements in analytical methods, specifically isotopic labeling with heavy ozone and analysis of resulting EfOM OPs by liquid chromatography coupled to ultra-high resolution mass spectrometry, have broadened our understanding of ozonated EfOM composition. So far no studies have investigated on a molecular formula level the biodegradability of OPs from EfOM.
Wastewater effluent was ozonated with mass labeled (^{18}O) ozone to generate labeled OPs. The effluent was inoculated with biologically active preconditioned sand and underwent biodegradation for 28 days. The OPs were detected with LC-FT-ICR-MS. While most molecular formulas detected in ozonated EfOM are biodegradable, just over a quarter were recalcitrant to biodegradation. Most CHNO and CHNOS formulas are readily biodegradable, but 28% and 16%, respectively, are recalcitrant. Of the labeled OPs, 31% remain detectable after 28 days. The majority of recalcitrant labeled OPs are from the CHO and CHNO formula class. Some of the CHNO formulas may have N-oxide functional groups, a stable functional group formed during ozonation.
While most products with ^{18}O have similar rates of removal among the isotopologues in a series, some ^{16}O isotopologues are recalcitrant with their ^{18}O counterparts readily biodegradable. The difference in detected biodegradability implies the possible formation of OPs during biological treatment.
Track: 3. Environmental Chemistry and Exposure Assessment: Analysis, Monitoring, Fate and Modelling

Session: 3.13: HR-MS Analysis of Metabolites and Transformation Products of Organic Pollutants - What Remains Unknown
Elaine Jennings[1] (Presenting Author), Millaray Sierra Olea[2], Uwe Hübner[2], Thorsten Reemtsma[1], Oliver Lechtenfeld[1], (1)Helmholtz Centre for Environmental Research, Germany, (2)Technical University of Munich, Germany

3.12.T-02 An Interactive App to Curate Transformation Product Information from Text Mining Results
***Emma Helena Palm**, Jessy Krier and Emma Schymanski, University of Luxembourg, Luxembourg*
An important consideration for understanding the hazards posed from different compounds is the transformation products (TPs) they form once they enter the environment. Unfortunately, there is much less information available for TPs than their parent compounds, while most of the information is text based in journal articles and databases. This makes it difficult to access and include into identification workflows based on high resolution mass spectrometry (HR-MS) and other analyses.
One such database with text-based TP information is PubChem, which contains a lot of TP information, especially in the "Metabolism and Metabolites" section. In addition, PubChem runs a text mining software (LeadMine), which identifies chemical names in the text-based sections of the database. To better utilize this information, we have built a shiny app which will allow users to go through the text mined information in the Hazardous substance databank (HSDB) dataset to identify which of the extracted chemical names are TPs. After downloading the entire HSDB dataset and filtering based on the precursor compounds of interest, the app will display the structure of the precursor and the potential TP extracted via text mining, together with the HSDB text snippets to allow the user to identify whether the extracted structure is indeed a TP of the precursor. The information can then be saved in a table and downloaded for further analysis, or central upload as formal transformation reactions. In addition, the user has the option of saving the chemical names of TPs not identified by the text mining software together with their SMILES, to fill database gaps.
The app has so far been applied to compounds from several datasets (28 from the NORMAN-SLE and 8 from the PubChem PFAS Tree, as well as 33 PBT compounds on the SIN-list). Of the 366 chemicals identified by the text mining software, 60 were new reactions that were not already available in the transformation products dataset in PubChem, the majority of which were found among the NORMAN and PBT compounds. Among these reactions were transformation products of azo dyes such as benzidine which has carcinogenic properties. In addition, some persistent substructures were identified in the TPs. This shows promise for expanding the current TP datasets available in databases such as PubChem as well as for improving TP suspect lists and furthering the understanding of the fate of environmental contaminants.

3.12.T-03 HRMS Analysis of Antimicrobial Peptide Biotransformation Mediated by Extracellular Wastewater Peptidases
***Natalie Wichmann**[1], Richard Gruseck[2] and Michael Zumstein[2], (1)University Vienna, Austria, (2)University of Vienna, Austria*
Substantial fractions of human-administered antibiotics are secreted into wastewater streams in their still active form. When antibiotics are not removed during the wastewater treatment process, they can enter the environment and have adverse effects on ecosystems. It is assumed that the presence of antibiotics in wastewater as well as in natural systems contributes to the emergence and spread of antibiotic resistance genes in these systems. Several antimicrobial peptides (AMPs) emerged in the last decades as particularly promising antibiotic candidates because of their low tendency to evoke resistance in pathogenic bacteria. What remains unknown is whether and how AMPs are transformed during the wastewater treatment process and whether transformation would result in an inactivation of the AMPs. To shine light on the fate of AMPs in wastewater, we quantified extracellular peptidase activities in wastewater at different stages of the treatment process at four different full-scale WWTPs. Finding highest extracellular peptidase activity in raw wastewater, we incubated a set of ten different AMPs with cell-free extracts of raw wastewater. We quantified AMP concentrations during these incubations using liquid chromatography coupled to high-resolution mass spectrometry (HPLC-HRMS) and found large variations in the susceptibilities of the different AMPs to hydrolysis by wastewater peptidases. For rapidly hydrolyzed AMPs, we performed suspect screening to identify products of single amide hydrolysis events. We subsequently selected the most persistent hydrolysis products and obtained custom-synthesized peptide standards for an absolute quantification of product concentrations. By comparing the transformation products for all WWTP extracts, we found a high similarity of formed products between the WWTPs, showing that peptidases in raw wastewater are not only specific, but seem to have some conserved specificity across the tested WWTP influents. Overall, this study provided insights into peptidase specificities of raw wastewater and the findings might contribute to the development of sustainable peptide-based antibiotics.

3.12.T-04 What Sample Information Is Lost from Sampling to Analysis During Non-Target Analysis?
***Bastian Schulze**[1], Amy Heffernan[2], Saer Samanipour[3], Kevin Thomas[1] and Sarit Kaserzon[1], (1)University of Queensland, Australia, (2)Eurofins Environment Testing Australia & New Zealand, Australia, (3)University of Amsterdam, Netherlands*
Non-target analysis is becoming a popular tool for elucidation of chemical constituents, including chemicals of emerging concern and their transformation products, and comparison of samples, without the need for prior knowledge. However, reliability and reproducibility of obtained results can be influenced by changes in a sample over short or long term (i.e. within timeframes of analysis). For example, for some compounds, degradation starts immediately following sample collection, and is then influenced by temperatures and time until analysis. So far, most research has looked into degradation of specific compounds, via target analysis, so that results can later be corrected using chemical-specific degradation rates. While this is not a viable option for non-target analysis, due to the number of analytes, knowledge of the fraction of sample loss between sample collection and analysis is important for the understanding of chemical fate and risk. Therefore, we aimed to document the change in sample profile in the immediate-to-short term i.e. the first 24 hours following a typical wastewater sampling scenario, using a non-target approach. For this we obtained a wastewater sample from a manhole in a suburban area in Australia and commenced measurement using Liquid chromatography coupled to High resolution mass spectrometry (LC-HRMS) within 90 minutes of sample collection. The sample

was then kept in the autosampler and re-analyzed 47 times over a 24-hour period and in triplicates each day over 6 days. Additionally, a sample kept at ambient temperature was measured on days 2 to 6 for comparison. Fold changes were calculated for the features in the aligned feature list, based on which features got classified as “Eliminated”, “Decreased”, “Unchanged”, “Increased” and “Formed”. Results show the decrease in intensity and elimination of some compounds over time, while others increase in intensity or have been formed as part of the transformation process. These findings will have implications for the use of NTA, especially when conducting temporal / spatial assessments.

3.12.P HR-MS Analysis of Metabolites and Transformation Products of Organic Pollutants - What Remains Unknown

3.12.P-Th205 Multiple Deuterium Labelling: New Insights Into the Fate of Organic Pollutants in Natural Waters

Shuxian Gao[1]*, Elaine Jennings*[1]*, Thorsten Reemtsma*[1,2] *and Oliver Lechtenfeld*[1,3]*, (1)Department of Analytical Chemistry, Helmholtz Center for Environmental Research, Germany, (2)Institute of Analytical Chemistry, University of Leipzig, Germany, (3)ProVIS – Centre for Chemical Microscopy, Helmholtz Center for Environmental Research, Germany*

Organic pollutants (OPs) can undergo many interactions with molecules of dissolved organic matter (DOM) in water, e.g., to form bound residues (BRs) under solar irradiation. High resolution mass spectrometry (HRMS) is a powerful tool for the screening of complex reaction products from OPs, including BRs. While ^{15}N and ^{18}O have been used for the identification of BRs and transformation products (TPs) from DOM, generic stable isotope labelling is still missing for OPs with different elemental compositions. Deuterium (^{2}H, or D) is a promising option due to its low natural abundance and universal binding to the carbon backbone. Using ^{2}H labelled chemicals during transformations lead to the formation of labelled TPs and BRs, but also results in an increase of false-positive assignments which cannot be easily validated by existing algorithms. Here, we used multiple deuterium labelling (DxL) to examine the formation of ^{2}H labelled TPs and BRs, and developed a data processing pipeline for the validation of ^{2}H formulas.
Data from photo irradiation experiments of carbamazepine (CBZ), an antiepileptic drug, were used for testing the robustness of the data processing pipeline. Irradiation experiments were conducted using a solar simulator. Duplicates of 50 µM CBZ and CBZ-D_{10} were mixed with a DOM standard and irradiated for 24 h. Samples were analysed using a reversed-phase liquid chromatography system coupled to a Fourier-transform ion cyclotron resonance mass spectrometer.
Using a new data processing pipeline, false-positive molecular formulas could be identified and excluded, resulting in less than 1% multiple assignments. Over 4000 BRs were identified based on ^{2}H formulas. The 3-quinolinecarboxylic acid (3-QCA) transformation pathway, which has been previously described using ^{15}N labelling, was confirmed with corresponding D_5 formulas, indicating the robustness of the applied filters. However, D_4 formulas represented > 25% of all BRs, pointing to a previously unconsidered pathway of CBZ photolysis/BR formation. Overall, our results suggest that DxL in combination with HRMS and advanced data processing is a promising approach to investigate the formation of BRs and to study the fate of OPs in the environment.

3.12.P-Th206 Phototransformation of Pharmaceuticals in Temporary Rivers Under Simulated Sunlight in Real Environmental Conditions

Maria Vittoria Barbieri*, Rayana Manasfi and Serge Chiron, University of Montpellier, France*

Phototransformation of pharmaceuticals has mostly been investigated in permanent rivers and scarcely in temporary effluents, where the lack of dilution capacity led to an overall increase of pharmaceuticals concentrations. The major factors contributing to in-stream pharmaceuticals attenuation include sorption, photo- and biotransformations, but the relevance of each process and the transformation products (TPs) generated are compound specific. In the case of polar compounds which tend to remain in the water phase, photodegradation may predominate. However, the majority of phototransformation studies at lab scale do not include real environmental conditions, which should be covered for a better understanding of the attenuation mechanisms in water systems. In this work, we hypothesized that Cu might play a contribution in the photodegradation because several pharmaceutical classes are known to form photoreactive complexes with Cu. The objectives of this study were to investigate the presence of pharmaceuticals along two river stretches and perform phototransformation experiments to study kinetics, TPs, and reaction pathways of selected pharmaceuticals under simulated sunlight irradiation in the presence or absence of dissolved Cu^{2+} / Fe^{3+} ions in real environmental conditions. All samples derived by photolysis experiments were filtered and directly analyzed by liquid chromatography high-resolution mass spectrometry (LC-HRMS). The results showed the occurrence of 13 compounds in POCIS extracts, including β-blockers and psychiatric drugs, with most of them undergoing dissipation to different extent along the river stretches. Oxazepam, venlafaxine and fluconazole were selected for photodegradation experiments. In all cases, photodegradation resulted to be faster in the presence of Cu^{2+} and Fe^{3+} ions than direct photolysis, with the complete attenuation of oxazepam and venlafaxine after 21 hours experiment, and 80% attenuation of fluconazole after 20 hours. A total of 14 TPs were identified and confirmed. In most of the cases, the degradation pathways included oxidation and hydroxylation mechanisms with formations of TPs already found in previous studies; however, new TPs were identified for the first time in this study, especially TPs formed only in the presence of dissolved Cu^{2+} and Fe^{3+} ions. Some of the identified TPs were confirmed to be present in the real water samples, confirming the role of phototransformation in pharmaceuticals attenuation.

3.12.P-Th207 Exploring the Profile of Pesticides and Transformation Products in Stormwater Events of Agricultural Area Using Extensive LC-HRMS Screening

Daeho Kang *and Junho Jeon, Department of Environmental Engineering, Changwon National University, Korea*

The intestive use of pesticides and the formation of active trasnformation products (TPs) are of increasing concern as they are intensively detected in agricultural areas. Stormwater event would transfer massive amount of pesticides to adjunct surface waters, posing potential risk to aquatic organisms. Yet, comprehensive understanding for occurrences and profiles of pesticide and TP in stormwaters remains limited. In this study, the extensive screening method using LC-HRMS was developed not only for 384 targets, but also for suspects and unexpected substances. To enrich stormwater samples, the SPE method using a multi-layer cartridge was applied. High frequency composite sapling (sampling interval: 1hr) was conducted to explore time-dependent contaminant profiles during the stormwater events in an agricultural area. The target screening successfully measured 56 pesticides and 4 TPs in the stormwaters. The priority pesticides included bromobutide with the highest event mean concentration (EMC) of 1,460 ng/L, followed by bentazone (1,180 ng/L), bensulfuron-methyl (790 ng/L), and climbazole (670 ng/L), which are highly relevant to major crop in the study area. Neonicotinoid insecticides (i.e., imidacloprid, thiamethoxam, clothianidin) showed high risk quotient exceedance rates (>80%). Compound profiles were featured with maximum concentrations within 2-4 hours of initial rainfall (first-flush). The suspect and non-target screening (SNTS) was applied to identify TPs of pesticides. The non-target peaks were obtained with software-aid procedure (enviMass v4.1), and then were matched with exact mass of predicted TPs using feasible biological reactions for the degradation of pesticides. Further structure elucidation step for TPs was performed with the interpretation of data-dependent MS2 (ddMS2). Consequently, 32 TPs for 11 pesticides were tentatively identified with confidence level above 2. Typically, neonicotinoid insecticide showed analogous degradation products (nitroso→desnitro→urea). Pesticides and TPs showed rapid concentration increases within a week after the field applications, and then returned back to a base level after about 90 days. The occurrence profile of pesticides and TPs in agricultural field was highly affected by the application period and the precipitation intensity. The high RQ evaluation for neonicotinoids indicates the potential hazard to aquatic organisms in adjunct streams after stormwater events.

3.12.P-Th208 Simple and Rapid Quantification of Per- And Perfluoroalkyl (Pfas) Compounds in Sea Water

*Jessica Smith[1], Jack Steed[1], Fred Van Geenen[2] and **Jianru Stahl-Zeng**[3], (1)SCIEX, United Kingdom, (2)SCIEX, Netherlands, (3)SCIEX, Germany*

The ocean has been termed by many a “terminal sink” for PFAS; with reports of PFOS, PFHxA and PFOA being abundant in surface and subsurface seawater. Seafood consumption is one major pathway for human PFAS exposure, however, the distribution and abundance of PFAS in seawater is still poorly understood. Recent advancements suggest that one source of PFAS in seawater could be due to petroleum being released into the sea.

The European Parliament and Council of the European Union have recently published directive that has set limits on PFAS in drinking water to 500 ng/L for all PFAS compounds identified, and 100 ng/L for a subset of PFAS compounds that are potentially detrimental to human health.

With PFAS regulations tightening and concerns of PFAS exposure from seafood, it is paramount we monitor the PFAS levels in seawater. We provide a robust and sensitive method for PFAS detection and quantification in seawater.

Mixed standards were prepared at a ratio of 2.5 mL LC-MS water to 2 mL 50:50 acetonitrile/methanol +0.22% formic acid to construct a calibration curve between 0.2-1000 ng/L. Samples were prepared with 2.5 mL of seawater from the Irish Sea added to 2 mL of 50:50 acetonitrile/methanol + 0.22% formic acid solution prior to analysis.

Chromatographic separation was performed using a Phenomenex Luna Omega PS C18, 100 Å, 100 x 2.1 mm, 3 µm , and a Phenomenex Gemini C18, 110 Å, 100 x 2.0 mm, 3 µm delay column. The injection volume was 50 µL. Mobile phase A was 20 mM ammonium acetate in water and mobile phase B was methanol. The MS was operated in electrospray ionization in negative ion mode.

The method is presented to quantify PFAS compounds in seawater down to the sub-ng/L range. Both an external standard calibration curve and standard addition workflows were implemented. The analytical method provides a simple, reproducible, and robust sample preparation with no SPE needed. Good chromatographic peak-to peak separation was achieved with a total run time of 12 minutes. Excellent sensitivity was achieved with LOQ values at sub-ng/L levels . Accuracy (%) and average accuracy (%) were within acceptable criteria (70%-30%) and area %CV was ≤4.26% for spiked seawater samples against an external standard calibration curve, confirming robustness and reproducibility. An external calibration curve in solvent and a standard addition workflow was implemented to further confirm the concentration of PFAS compounds detected in un-spiked seawater.

3.12.P-Th209 Diurnal Profiles of Organic Marker Compounds in Atmospheric Secondary Organic Aerosol During Summertime in Melpitz, Germany

***Jan Beck**, Dominik van Pinxteren, Laurent Poulain and Hartmut Herrmann, Atmospheric Chemistry Department, Leibniz Institute for Tropospheric Research, Germany*

Atmospheric aerosol particles consist of numerous organic substances which can have primary or secondary sources. Secondary organic aerosol (SOA) is formed by oxidation of biogenic and anthropogenic volatile organic compounds (VOCs) and can contain tens of thousands of different organic substances. The organic composition is not only highly complex but also subject to constant dynamic changes. Previous measurement campaigns with online aerosol mass spectrometers (AMS) provided a wealth of insights into bulk SOA, but are limited in terms of describing SOA at the molecular level. Time resolved measurements of individual molecules, which can serve as marker compounds of specific emission sources or formation pathways, are scarce. Therefore, in this study, particulate matter (PM) samples were collected at 4-hour intervals over six weeks at a rural site in Melpitz, Germany during the ACD@SummerHome 2021 campaign. The collected samples were subsequently analyzed by LC/HR-MS and IC/HR-MS to quantify 46 different organic compounds including mono-, di-, tricarboxylic acids, markers for monoterpenes, organosulfates, and inorganic anions. For example, the concentration of oxalic acid varied between 39 and 832 ng m^{-3}, with higher values during the day than at night. Such a recurring diurnal profile can be observed for almost all investigated substances. Based on this, we examined the daily profiles within analyte groups. For the substance class of dicarboxylic acids, we noticed that the shorter the chain length, the later in the day the concentration maximum occurs. From the literature it is known that short-chain dicarboxylic acids can be formed from long-chain dicarboxylic acids through photochemical processes. Our results are consistent with this, as the last oxidation product of dicarboxylic acids, oxalic acid, has its daily maximum between 2 and 6 pm. We found the same correlation for the oxidation markers of monoterpenes. The oxidation products of the first generation, pinic acid and pinonic acid, reach their maximum between 6 and 10 am, while late transformation products such as 3-methyl-1,2,3-butanetricaboxylic acid and diaterpenylic acid acetate peak in the afternoon and then drop again in the evening. Overall, the presented measurements help to understand atmospheric transformation processes both at the molecular level as well as at rather short time scales.

3.12.P-Th210 Non-targeted Analysis for Metabolites of ATBC and ATEC by LC-Q-ToF-MS after Exposure to Human Liver Microsomes

***Younglim Kho*[1]*, Sunghoon Yeo*[2]*, Hyeri Jeon*[3]*, Na-Youn Park*[3] *and Kyunghee Ji*[4]*, (1)Health, Environment & Safety, Eulji University, SeongNam, Korea, (2)AB SCIEX, Korea, (3)Eulji University, SeongNam, Korea, (4)Yongin University, Korea*

DEHP is a plasticizer that softens plastics and is widely used daily, but it is an endocrine disruptor and has a harmful effect on the human body. To replace DEHP, the use of alternative plasticizers is increasing. However, there is not enough research on the metabolic process of alternative plasticizers. This study was conducted using human liver microsome (HLM) to understand the metabolic process of alternative plasticizers through non-targeted analysis.
ATBC and ATEC were selected as target substances among alternative plasticizer substances judged to require metabolite search. Non-targeted analysis was performed using LC-Q-ToF-MS (ABSCIEX 7600) to identify the metabolites of ATBC and ATEC after exposure these substances to HLM.
As a result of non-targeted screening of metabolites of ATBC and ATEC using HLM, we were able to identify several metabolites which were known as metabolites of ATBC and ATEC in human experiments. In the case of ATBC, 9 metabolites were identified including TBC, ADBC, DBC and 10 metabolites were identified for ATEC including TEC, ADEC, DEC.
We identified the metabolites of ATBC and ATEC through this study, and in the future, we plan to determine the biomarker of these alternative plasticizers and will also use these biomarkers for human biomonitoring.

3.12.P-Th211 Deconjugation of Diclofenac Glucuronide in Wastewater – Not As Straight Forward As We Thought

***Caterina Zillien*[1]*, Daniel Blanco-Ania*[2]*, Ana Rios Miguel*[1]*, Henry Beeltje*[3]*, Fredericke Hannes*[4] *and Ad M. J. Ragas*[5]*, (1)Radboud University, Netherlands, (2)Synthetic Organic Chemistry, Radboud University, Netherlands, (3)Netherlands Organisation for Applied Scientific Research (TNO), Netherlands, (4)Deltares, Netherlands, (5)Radboud University Nijmegen, Netherlands*

Diclofenac is a prominent example for the detrimental effects that human pharmaceuticals can have on ecosystems. After oral intake, diclofenac (DCF) is extensively metabolized and excreted mainly as conjugate metabolites. It has been demonstrated that deconjugation of glucuronide conjugates can lead to re-transformation of the parent compound. This process has not yet been tested empirically for DCF in wastewater but it offers an explanation for observed negative removal efficiencies of DCF during wastewater treatment. The aim of this study was to investigate the fate of DCF and three of its human metabolites in wastewater and activated sludge. Particularily, we aimed at studying the kinetics of the re-transformation of diclofenac glucuronide (DCF-gluc) to DCF under biotic and abiotic conditions. Laboratory batch experiments using raw wastewater and activated sludge were conducted in triplicate to assess to what extent deconjugation of DCF-gluc could play a role in sewer systems. We aimed at quantifying the kinetics of deconjugation of DCF-gluc in wastewater and activated sludge from secondary wastewater treatment. The concentration of DCF and its metabolites were measured via LC-MS/MS. Our preliminary results suggest that DCF-gluc disappears quickly (<1h) from wastewater not necessarily due to enzymatic deconjugation but due to pH-induced hydrolysis occurring from pH6 and above. This suggests that deconjugation of DCF-gluc cannot explain negative removal efficiencies observed at WWTPs because DCF-gluc might already be fully converted to DCF in the sewer system. Mass balances for each of the incubations indicated an increase of DCF of up to 134% over 24h. Relative to t_0, DCF concentrations increased most in the incubations containing activated sludge (+25%, 0.01 sd), while concentration in incubations containing only wastewater increased by 18% (sd 0.01) and 17% (sd 0.02). No significant increase was observed for the autoclaved control incubations (+2%, sd 0.01). Unexplained surplus concentrations of DCF between 5.8 and 18.9 µg/L were observed after 24 h. This suggests an additional yet unidentified source of DCF was present, particularly in the biologically active incubations.

3.12.P-Th212 Metabolite Screening of the Mycotoxins Enniatin B and Beauvericin

***Carey E Donald*[1]*, Marc H.G. Berntssen*[2]*, Kai Kristoffer Lie*[1]*, Alberto Celma*[3] *and Lubertus Bijlsma*[4]*, (1)Havforskningsinstituttet/Institute of Marine Research, Norway, (2)Norwegian Institute of Marine Research, Norway, (3)Swedish University of Agricultural Sciences (SLU), Sweden, (4)University Jaume I, Spain*

Plant products are increasingly being used as feed ingredients, and with this change comes new pollutant concerns. With this shift the contaminants of concern are changing from persistent organic pollutants to those associated with crop production and storage, like pesticides and mycotoxins. Mycotoxin contaminations arise from mold growth, and occur under interactions of complex environmental conditions that are shifting under climate change. Two emerging lipohilic mycotoxins, enniatin B (ENN) and beauvericin (BEA), were recently reported in aquafeeds and farmed fish, but are not currently regulated. Both mycotoxins have demonstrated toxicity and are metabolized in mammalian and avian species, but knowledge on metabolization in fish remains limited. In this study, a novel non-targeted screening workflow was applied to unravel the metabolites of the two mycotoxins. Samples were obtained from a 3-month controlled feeding trail in which Atlantic salmon were fed a control diet, or diets spiked with ENN or BEA. Tissue samples (liver, kidney, muscle, and brain, 0.4-0.6 g) were extracted and screened on two ion mobility(IMS)-HRMS instruments against a library that included *in silico* predicted candidates along with predicted retention time (RT) and collision cross section (CCS) values. Data were processed after peak picking by applying the filters for mass error, theoretical fragments, RT, and CCS. Data were examined graphically to select clusters of tentative detections that had unique RT and CCS profiles in treated samples. We confirmed ENN in 12 of 12 samples, and the internal standard in 30 of 36 samples. BEA was observed in only 3 of 9 samples. Most of these "false negatives" detections are likely due to higher limits of detection on the QToF instrument compared to QQQ. RT and CCS predictions were within 1.2 minutes and 2%, respectively for the mycotoxins. We found two types of metabolites for ENN: hydroxy- and dihydroxy-ENN isomers, chiefly in liver samples Hydroxy- and dihydroxy-ENN had matches with 5 and 2 theoretical fragments, respectively. Other metabolites were not detected, namely demethylated variants, which have been reported in *in vitro* studies. No metabolites of BEA were detected. The non-target screening strategy applied demostrates how IMS-HRMS and prediction tools can provide new knowledge towards a group of contaminants of emerging concern under climate change, in a more time- and cost-effective manner.

3.12.P-Th213 Measurement and In Silico Prediction of Pharmaceutical Biotransformation in Receiving Water

Olukemi Oloyede[1], *Leon Barron*[2], *Russell Davenport*[3] *and Irene Bramke*[4], *(1)Environmental Research Group, Imperial College London, United Kingdom, (2)School of Public Health, Imperial College London, United Kingdom, (3)Newcastle University, United Kingdom, (4)Global Environment, AstraZeneca, Netherlands*

Water and effluent quality monitoring methods in the UK are predominantly focused on organic matter (nitrogen, phosphorus levels) whereas pharmaceuticals and their transformation products (TPs) are not monitored routinely in river water. A European Commission report in 2020 details a shortlist of several anti-microbial pharmaceuticals in the next EU Water Framework Directive (WFD) "watch list" to be closely monitored in inland surface waters and to further the understanding of any effects. Antimicrobials such as sulfamethoxazole and clotrimazole are pharmaceuticals that are of particular concern, increasingly being detected in surface water and soils across Europe and are toxic and mobile in the aquatic environment.

This project aims to fill a research gap in the lack of predictive understanding of pharmaceutical transformation and degradation; high resolution analytical methods have been developed for in silico identification of pharmaceuticals and their TPs but do not provide information about the mechanisms or pathways of transformation. It will determine the transformation rate of prioritised compounds (including those in the EU WFD "watch list") and investigate their transformation pathways to help gain a better understanding of their fate in river water. The microbial and chemical data derived from these studies will be used to create a machine learning based model that can help predict the biotransformation of pharmaceuticals in river water.

Suspect screening in high resolution mass spectrometry (HRMS) has been used to detect and identify pharmaceuticals and their TPs in wastewater impacted rivers, as well as the use of online predictive transformation tools such as BioTransformer and EAWAG-Biocatalysis/Biodegradation Database/ Pathway Prediction System (EAWAG—BBD/PPS). Compounds of interest to be shortlisted were prioritised in terms of prevalence and by risk quotient which included carbamazepine and venlafaxine. Future analysis will look at targeted quantitative analysis on spiked river water and sterile artificial freshwater in aerated glass containers will be conducted using liquid chromatography tandem mass spectrometry (LC-MS/MS) to measure the amount of transformation of selected pharmaceuticals in river water over time up to 6 months (using at least two environmentally relevant concentration levels of 200 and 2000 ng/L).

3.12.P-Th214 The Fate of Trimethoprim, Caffeine and Sulfamethoxazole during Sub-critical Water Regeneration of Activated Carbon

Pierre Oesterle[1], *Christine Gallampois*[2] *and Stina Jansson*[2], *(1)University of Umea, Sweden, (2)University of Umea, Sweden*

Throughout the years, wastewater treatment plants have been adding to tertiary treatments a polishing step aimed at removing/degrading micropollutants (e.g. pharmaceuticals). The most common treatments are ozonation and activated carbon. Ozonation is efficient at degrading pharmaceuticals however its byproduct could be more harmful than the initial molecules and create as well higher amount of ammonia enhancing eutrophication.

Activated carbons instead adsorbs and concentrates micropollutants on its surface and can then be discarded or regenerated. Chemical and thermal regeneration techniques are often used however they require either the use of chemicals (creating more potential pollution) or are energy intensive. In our study, we instead used hydrothermal technology by degrading pharmaceuticals adsorbed on spent carbonaceous material under sub-critical water. We therefore chose to degrade three pharmaceuticals (Trimethoprim, sulfamethoxazole, caffein) and characterize their transformation products under hydrothermal conditions between 160 to 280°C in water and then with the presence of activated carbon. The extracts were analyzed in LC-MS-QTOF on HILIC and C18 columns. For single compound degradation, trimethoprim had a high amount of transformation products (>10) compared to caffeine and sulfamethoxazole (<4). Most of these transformation products had hydroxylated substitutions or additions and at temperature higher than 200°C there has been an increase of smaller transformation products as well as an increase in partial mineralization at 240°C and above. This study also compares the transformation products observed with the ones produced in presence of activated carbons to determine if the transformation products are re-adsorbed on the surface of the char or stay in the water phase after several cycles of regeneration.

3.12.P-Th215 Assessment of the Potential Biotransformation of Pharmaceuticals in Zebrafish Embryos, Utilizing LC-HRMS Techniques

Eleni Panagopoulou, *Dimitrios E. Damalas, Eleni Aleiferi, Vasiliki Tzepkinli and Nikolaos Thomaidis, National and Kapodistrian University of Athens, Greece*

Pharmaceuticals and their transformation products (TPs) are widely detected in the aquatic environment and may bioaccumulate in aquatic organisms. Zebrafish (Danio rerio) embryo (ZFE) has emerged as a powerful alternative model-organismv in ecotoxicological studies for evaluating the effects of xenobiotics in aquatic organisms. Biotransformation constitutes an important factor in toxicokinetic studies, since sometimes, metabolites may exhibit higher toxicity than the parent compound. Identification

of biotransformation products (bio-TPs) is a challenging task, and the lack of available reference standards makes it more difficult. LC-HRMS offers a powerful approach to detect and identify these bio-TPs. Despite HRMS high applicability, separation of isomeric bio-TPs is not always possible. Hydrophilic interaction liquid chromatography (HILIC) could be used as a complementary chromatographic mode for orthogonal identification of bio-TPs. Additionally, Trapped Ion Mobility (TIMS) it is a very promising technology for the separation of isomers and could provide additional experimental evidence to enhance the identification confidence.
The aim of this study was to investigate the biotransformation capacity of ZFE exposed to different pharmaceuticals and to identify the tentative bio-TPs, utilizing LC-HRMS. Furthermore, the added value of TIMS was investigated for the identification of bio-TPs and the separation of isomers.
For the extraction of pharmaceuticals in ZFE samples, organic solvents were added, and a bead-beating homogenization process was followed. The ZFE extracts were analyzed by reversed phase liquid chromatography (RPLC) and HILIC, in both positive and negative ionization, by LC-ESI-QTOF. The extracts were also analysed with LC-TIMS-TOF-MS to introduce an additional dimension of separation, and to acquire more “clear” mass spectra. Target-screening approach was followed for the identification of the parent compounds, whereas the identification of tentative bio-TPs was performed through in-house developed suspect and non-target screening workflows. Collision cross section (CCS) values were used as additional experimental evidence for the identification.
Overall, bio-TPs from both oxidative and conjugative metabolic reactions were identified. The analytical data of this study, highlight that information in two orthogonal chromatographic techniques in combination with CCS values provided additional evidence to support the identification of bio-TPs.

3.12.P-Th216 Assessment of Carbamazepine Uptake and Metabolisation by *Lavandula dentata*, Juncus Sp. and *Salicornia europaea* Using Semi-targeted Computational Analysis Tool
Rut Fernandez-Torres[1], *Miguel Ángel Bello-López*[2] *and Sofia Barreales- Suarez*[3], *(1)University of Sevilla, Spain, (2)Departamento de Química Analítica. Facultad de Química, Universidad de Sevilla, Spain, (3)Universidad de Sevilla, Spain*
Pharmaceutical products are the emerging contaminants that probably have aroused the most interesting in the last decade because they are biological active substances, and most of their degradation and metabolic products have also biological activity. Their metabolites and degradation products can persist for a long time in the environment being even more toxic than the original compound. The scientific community is therefore concerned about their dangerousness on all kind of ecosystems and their possible harmful effects on human health.In this work, the use of a computational tool have been used for the assessment of carbamazepine metabolism pathways in plants subjected to uptake assays.
Thus, three plants with high occurrence in the natural protected area of Doñana National Park (Spain) have been irrigated with three aqueous carbamazepine solutions (10 ng·mL-1, 700 ng·mL-1 and 10 µg·mL-1) and periodically, stems, leaves and roots were sampled and analysed. Total carbamazepine uptakes through the assay was evaluated and discussed showing clear dependence on plant type/part, irrigation concentration solution and assay time. In addition, a chromatographic analysis using a quadrupole- time-of-flight (Q-TOF) mass spectrometer was conducted, recording the simultaneous low- and high-fragmentation mass spectra to further computational processing using MetabolynxTM software which predicts metabolic pathways for possible ‘expected’ and ‘unexpected’ metabolites according to their *m/z* and fragmentation patterns. Several possible carbamazepine metabolites corresponding to various metabolism pathways have been identified and, where possible, their relative abundance have been discussed. Confirmation was carried out by analysing the high-energy spectra obtained at the characteristic retention time and the fragmentation patterns obtained for each compound.
The use of computational tools like MetabolynxTM have been demonstrated useful for studies that involve the search of metabolites and/or the confirmation of metabolism pathways in the studied plants.

3.13.A Human and Veterinary Pharmaceuticals in the Environment – Risk, Prioritisation & New Insights

3.13.A.T-01 Data Gap-driven Prioritization of Active Pharmaceutical Ingredients Based on Predicted Environmental Risk
Cristiana Cannata[1], *Thomas Backhaus*[2], *Maria Caraman*[3], *Anna Lombardo*[4], *Stewart Owen*[5], *Rhys Whomsley*[3] *and Ad M. J. Ragas*[6], *(1)Radboud University Nijmegen, Netherlands, (2)University of Gothenburg, Sweden, (3)European Medicines Agency, Netherlands, (4)IRCCS Istituto di Ricerche Farmacologiche Mario Negri, Italy, (5)Astrazeneca UK, United Kingdom, (6)Environmental Science, Radboud University, Netherlands*
The emission of active pharmaceutical ingredients (APIs) to the environment is an issue of increasing concern. In the European Union, an environmental risk assessment (ERA) for marketing authorization applications of medicinal products is mandatory since 2006. A comprehensive ERA is lacking for most medicines approved prior to 2006, and many pharmaceuticals have hardly any ecotoxicological data associated with them. This makes it difficult to establish their true environmental risk.
Performing ERA studies on more than 1500 APIs is unfeasible, as it would require an unacceptable number of in vivo studies and a considerable amount of time and economical resources. Considering the ethical, technical and financial limits, there is a need to identify high-priority APIs based on their predicted environmental risk and relevant data gaps.
The different approaches that can be adopted to prioritize APIs include the exposure-based approach, the hazard-based approach, and the risk-based approach. In this work, we followed a risk-based prioritization approach, combining the environmental exposure concentration (measured or predicted environmental concentration; MEC or PEC, respectively) with the Predicted No Effect Concentration (PNEC).
We collected ERA data for 1402 APIs and used different approaches to estimate exposure and effects. By combining this information, we calculated the risk quotients and developed six risk rankings including more than 1000 APIs of human medicinal

products authorized in Europe. We monitored the data availability of the top-ranking APIs from the three most relevant rankings. Finally, we identified 15 test candidates with limited ERA data that are likely to pose a potential risk to the environment, so that additional ERA data can be gathered and a more detailed ERA can be performed.

3.13.A.T-02 Prioritisation of Companion Animal Parasiticides in UK Rivers

Isla Thorpe[1]*, Andrew Beckerman*[2]*, Caroline Dessent*[3]*, Carmel Ramwell*[4]*, Susan Zappala*[5] *and Alistair B.A. Boxall*[3]*, (1)Environment and Geography, University of York, United Kingdom, (2)University of Sheffield, United Kingdom, (3)University of York, United Kingdom, (4)Fera Science, York, United Kingdom, (5)Joint Nature Conservation Committee, United Kingdom*

Companion animal parasiticide products are widely used to treat and prevent parasitic infestations. However, the ecotoxicological risks of these products has likely been insufficiently considered in existing regulatory risk assessments due to the assumption that exposure is negligible. With approximately 20 million cats and dogs in the UK, many being treated regularly with parasiticides, this assumption may be incorrect. Research focused on a wider range of APIs and determining an understanding of the levels of exposure and thus potential risk is necessary. Therefore, the aim of this research is to predict environmental concentrations of APIs used as companion animal parasiticides to enable the future prioritisation of these active substances based on their potential environmental risk profiles. A review of current available companion animal parasiticide products used for cats and dogs was conducted to determine the current available APIs in use within the UK. Predicted Environmental Concentrations (PECs) were then estimated for two exposure pathways: down the drain exposure and a diffuse exposure, through using simple algorithms and assumptions. A total of 124 parasiticide products were found to be in use within the UK, each containing one or more APIs. Classes of active ingredients identified within the products included; neonicotinoids, isoxazolines, macrocyclic lactones and phenylpyrazoles, with 31 APIs contained within the companion animal products. PECs were estimated for all 31 APIs for both down the drain and diffuse exposure pathways. Predicted concentrations arising from down the drain and diffuse emission pathway ranged from 0 to 42.37 ng/l with imidacloprid, praziquantel, fenbendazole and fluralaner predicted to occur at the highest concentrations. Through this work on predicting environmental concentrations of APIs used within parasiticide products for different pathways, work is ongoing to produce a relative ranking of all 31 of these active substances with the potential greatest environmental risk. Therefore, enabling further research to be conducted reducing existing data gaps through focusing on specific APIs of potential concern.

3.13.A.T-03 Regional Scale Modelling of Pharmaceutical Pollution in Rivers by Integrating Rural and Urban Sources

Francesco Bregoli[1,2]*, Leo Posthuma*[3]*, Nikola Rakonjac*[4]*, Caterina Zillien*[5]*, Peter Vermeiren*[5]*, Erwin Roex*[3]*, Erwin Meijers*[6] *and* ***Ad M. J. Ragas***[7]*, (1)Environmental Science, Radboud University, Netherlands, (2)Water Resources and Ecosystems, IHE Delft Institute for Water Education, Netherlands, (3)National Institute for Public Health and the Environment (RIVM), Netherlands, (4)Wageningen University & Research, Netherlands, (5)Radboud University, Netherlands, (6)Deltares, Netherlands, (7)Radboud University Nijmegen, Netherlands*

Contaminants of emerging concern (CECs) can threaten aquatic ecosystems and human health. Both rural and urban areas are main sources of CECs to the environment. In rural areas, veterinary pharmaceuticals (VPs) are used to prevent diseases and protect the health of farm animals. The excrements of medicated animals are spread as manure to agricultural lands, where, after rainfall, VPs can be mobilized and reach surface waters through runoff. In urban areas, pharmaceuticals excreted by humans are collected in sewage systems and are only partially removed in wastewater treatment plants (WWTPs). Eventually, pharmaceuticals can reach surface waters through discharge of WWTP effluent. Currently, most of the predictive models only consider one source type, e.g. WWTPs or agricultural land. This limits their prediction performance since many CECs are being emitted by multiple source types. Therefore, this study aims to integrate urban and rural sources of CECs in one regional water quality assessment.

We predicted the concentration of CECs in the Eem river basin, the Netherlands, given land-use data combined with hydrological modeling. This allows for integrated evaluation of rural and urban emissions. These emissions were predicted with models developed within the context of the SUSPECt project (https://cec-partnership.nl/web/index.php/projects/suspect). CECs exposures were predicted with the Dutch National Water Quality Model where WWTPs emissions were included as point sources and rural emissions as diffuse sources. The temporal resolution of the model hydrology is seasonal. This is key to analyze the temporal variation of concentration due to manuring of agricultural lands which mainly occurs in Spring.

Predicted concentrations were successfully compared to measured concentrations taken in the SUSPECt project and from the database of the KIWK project (www.kennisimpulswaterkwaliteit.nl) for 6 compounds: carbamazepine and fipronil (only urban sources) and trimethoprim, sulfamethoxazole, permethrin and dexamethasone (urban and rural sources).

The model train demonstrated to be a useful tool to disentangle the contribution from rural and urban sources which in different seasons may have different predominance. Our modelling approach can be generalized to land uses of the whole of the Netherlands. The land-use based predictive approach is a novel, practical tool to support decision making to reach the EU-WFD targets for the regional scales.

3.13.A.T-04 Modelling Multitudes of Pharmaceuticals in the Global River System at High Spatial Resolution to Prioritize Substances that Cause the Highest Risk

Heloisa Ehalt Macedo[1]*, Bernhard Lehner*[1]*, Jim Nicell*[1]*, Usman Khan*[1]*, Eili Klein*[2] *and Günther Grill*[1]*, (1)McGill University, Canada, (2)Center For Disease Dynamics, Economics & Policy, United States*

As an alternative to resource-consuming extensive monitoring, contaminant fate models may be used to provide information to support the development of targeted local monitoring schemes in regions of highest exposure to pharmaceuticals in the environment as well as the prioritization of substances that require further investigation. In this work, a global contaminant fate

model (called HydroFATE) was developed with the objective of estimating the concentration of contaminants of emerging concern (including pharmaceuticals) in the global river network at a high spatial resolution (500 m). The structure of HydroFATE is based on vector routing, which besides its spatial precision being higher than in global pixel-based models, it is also faster to process. This key aspect allows for more complex analyses, including repeated execution of multiple substances and different scenarios in a short period of time, making HydroFATE a capable tool to inform on the prioritization of substances.
In the model, the contaminant emission is calculated based on consumption per capita and population density. Then, the contaminant loads of treated or untreated wastewaters are reduced either by centralized or decentralized wastewater treatment, by natural attenuation in soils and runoff, and/or by decay processes in rivers and lakes. HydroFATE was validated using measurements and applied to estimate the concentrations of the 40 most widely used antibiotics in households worldwide. These concentrations were compared to established no-effect thresholds of environmental exposure to detect potential risk. We found that the largest extent of rivers with high exposure are in Southeast Asia, the most densely populated region in the world. The main contributors of exposure were found to be amoxicillin, ceftriaxone, and cefixime.
In summary, HydroFATE combines information on river characteristics and connectivity, known characteristics of substances and their behaviour in the aquatic environment, domestic contaminant pathways to the river system, and water quality risk thresholds in a single global model, providing users with new holistic and quantitative information to support decision making and prioritization efforts at large scales.

3.13.A.T-05 Probabilistic Assessment and Prioritisation of Future Pharmaceutical Environmental Risks
*Samuel Welch[1], Merete Grung[1], Anders Madsen[2] and **Jannicke Moe**[1], (1)Norwegian Institute for Water Research (NIVA), Norway, (2)Hugin Expert, Denmark*
Understanding pharmaceuticals' contributions to future environmental risk requires consideration of how the environment, population and climate will evolve in the future. Forecasts of these factors are uncertain, and will become more so further into the future – making probabilistic environmental risk assessment, which retains uncertainty, a valuable tool for exploring future risk. We present an Object-Oriented Bayesian network for the prediction and prioritisation of environmental risk posed by six Active Pharmaceutical Ingredients (APIs) in Norway, across two time points (2020 and 2050), eleven counties, three population (low, main, high), and four wastewater treatment (WWT) scenarios (current, upgrade of all to at least secondary, upgrade to tertiary, best possible removal). Sales weights of APIs were predicted by year and population from historic sales, and used to predict environmental concentrations in WWT influent, effluent, and surface waters. Surface water Risk Quotients (RQ) per API were predicted under each scenario, and a Sum of RQ and joint probability of RQ threshold exceedance calculated across the 6 APIs. We found that in 2020, predicted SumRQ was highest in urban counties with higher population density and better wastewater treatment infrastructure, and lower in rural counties. By 2050, risk was consistent across urban and rural counties, but lower in peri-urban counties.
Comparing Sum of RQ in rural and urban counties, and Norway in 2050 (default population scenario), risk is expected to increase if WWT is upgraded to secondary or tertiary due to lower removal of risk-driving APIs under these treatments. Risk in urban counties is mostly unaffected due to the efficient technologies already used in WWT. However, both in rural counties and across the whole country, switching to the best available treatment technology is expected to lower overall risk.
Under low, main and high population scenarios Norway's population could range from 4.5 to 7.5 million, but little effect was seen on risk. Perhaps as population growth drives both modelled sales and dilution, Sum RQ across the whole country was predicted to drop in the low growth scenario and be unaffected by high growth.
This work represents a useful case study for the use of a spatial and temporally discretised Bayesian network for prediction of environmental risk and identification of APIs driving risk distributions with the full consideration and transparent presentation of uncertainty.

3.13.B Human and Veterinary Pharmaceuticals in the Environment – Risk, Prioritisation & New Insights

3.13.B.T-01 Effect of Lowering pH and Increasing Temperature on Toxicity of Sulfamethoxazole to *Daphnia magna*
***Katarzyna Bethke**[1], Klaudia Kropidłowska[2], Weronika Koczur[1], Magda Caban[1] and Piotr Stepnowski[1], (1)University of Gdansk, Poland, (2)Chemistry, University of Gdansk, Poland*
The problem of global warming is intensively studied. However, little is said about its impact on the toxicity of pharmaceuticals, new emerging pollutants with not fully understood environmental impact. To date, there is little knowledge of the problem and continued experimental research is required. Scientists stress that the problem of global warming can result in changes in the population of organisms and even lead to their extinction. In addition, the presence of pharmaceuticals, may intensify the negative effects of global warming, hence in-depth studies should be conducted. Therefore, it was decided to study the toxicity of sulfamethoxazole (antibiotic widely used in veterinary medicine) under the influence of predicted climatic changes: firstly, under the increase in temperature, secondly under the decrease in pH, finally under the influence of a combination of both stressors. A crustacean *Daphnia magna* was taken as target water organism. Acute and chronic toxicity tests were carried out in accordance with OECD guidelines 202 and 211. These experiments allowed the determination of EC_{50} and NOEC and LOEC parameters for sulfamethoxazole. High-performance liquid chromatography with a DAD detector was used as the quantification technique during the experiments to check the actual sulfamethoxazole concentration. These studies, combined with available literature data, concluded that the toxicity of sulfonamides increases with increasing temperature and decreasing pH. In addition, it was shown that exposure of *D. magna* to synergistic effects of both stressors causes the greatest toxic effect. Chronic toxicological tests showed a negative effect of low concentrations of sulfamethoxazole on *D. magna* reproduction, which is important due to the

presence of sulfamethoxazole in the environment. Thus, this research contributes to the understanding of the broad problem of the effect of pharmaceutical toxicity on aquatic organisms.

3.13.B.T-02 Molecular, Biochemical and Cellular Effects of Single and Combined Pharmaceuticals in *Mytilus galloprovincialis*

Marica Mezzelani[1], *Michela Panni*[2], *Alessia Saccardi*[2], *Giuseppe D'Errico*[2], *Stefania Gorbi*[2] *and Francesco Regoli*[2], *(1)Marche Polytechnic University, Italy, (2)Polytechnic University of Marche (UNIVPM), Italy*

The environmental consequences of pharmaceuticals in aquatic environments are now recognized as a real problem due to a global-scale distribution and detrimental outcomes for non-target organisms. The capability of marine species to simultaneously accumulate various typologies of pharmaceuticals has recently been shown, along with the onset of deleterious effects caused by single active ingredients and affecting the organismal health status. Despite this evidence, mechanisms of interactions and adverse outcomes of low levels of pharmaceuticals mixtures have received so far limited attention. In this respect, the present study was aimed to investigate interactive effects of antidepressants, lipid lowering agents, antiepileptics, cardiovascular and non-steroidal anti-inflammatory drugs in the Mediterranean mussels *Mytilus galloprovincialis.* A series of *in-vivo* experimental plans was set up exposing mussels for up to 30 days to various environmentally realistic concentrations (0.5-1μg/L) of selected pharmaceuticals both alone and in mixtures. Analyses of drugs bioaccumulation were integrated with early molecular responses measured as changes in transcriptomic profile, functional analyses at cellular level through a large panel of ecotoxicological biomarkers including alterations of the immune system, variations of oxidative stress biomarkers, onset of genotoxic damage and changes in distribution of lipids, proteins and carbohydrates. The overall results were finally integrated through a quantitative Weight Of Evidence (WOE) model that elaborates specific hazard indices based on the number, magnitude and toxicological relevance of observed responses. Interactive and competing mechanisms among tested drugs modulated bioaccumulation and biological responses, allowing to further measure changes in transcriptomic profile and the onset of detrimental effects, with both synergistic and antagonistic interactions depending on investigated mixture and endpoint. The elaboration of overall results through the quantitative WOE model provided new perspectives for a more comprehensive risk assessment of environmental mixtures of pharmaceuticals.

3.13.B.T-03 A Year-long Study of the Occurrence and Risk Assessment of Over 140 Contaminants of Emerging Concern in a Range of Aquatic Matrices in the Republic of Ireland

Helena Rapp Wright[1,2], *Fiona Regan*[3], *Blanaid White*[1] *and Leon Barron*[4], *(1)Dublin City University, Ireland, (2)Imperial College London, United Kingdom, (3)Water Institute, Dublin City University, Ireland, (4)School of Public Health, Imperial College London, United Kingdom*

Contaminants of emerging concern (CECs) are increasingly being shown to occur in water samples across the world, and their risks require further investigation. The breadth of such compounds is increasing and there is a constant need for reliable analytical methods for identification and their determination. Despite being a developed country in the European Union (EU), knowledge of the nature and extent of contamination of water bodies with CECs in Ireland is limited.

In this study a broad range of >140 CECs including pharmaceuticals, pesticides, and personal care products were monitored monthly in influent and effluent wastewater and receiving surface waters at a rural and urbanised area over a year period. Across all samples, 58 CECs were detected, where venlafaxine, currently under the "EU-Water Framework Directive Watch List", obtained the highest concentration in influent overall (8,273 $ng \cdot L^{-1}$). Wastewater treatment efficiency was assessed, and high removals, >98%, in both areas were observed for compounds such as azithromycin and EE2. A further reduction from the CEC effluent concentration compared to surface waters was observed (≥~93%). Correlation between surface air temperature and CEC wastewater concentrations were also investigated. Lastly, an environmental risk assessment was performed using risk quotients (RQs), showing an ΣRQ magnitude lower in surface waters when compared to effluent.

For the first time, the temporal and spatial occurrence of >140 CECs were monitored in the aquatic environment and WWTPs over a period of a year at two sites in Ireland. Several quantifiable and unmonitored chemical residues were present in these locations, but their risk to aquatic wildlife was lower in comparison to other developed states. The monitoring data will enable risk-based prioritisation for monitoring these pollutants for Irish water catchments, providing a comprehensive insight into the occurrence, fate and impact of CECs in Irish waters.

3.13.B.T-04 Occurrence of Emerging Contaminants in Wastewater and Groundwater in Botswana

Kgato P Selwe[1], *J Brett Sallach*[2] *and Caroline Dessent*[3], *(1)Chemistry, University of York, United Kingdom, (2)Department of Environment & Geography, University of York, United Kingdom, (3)University of York, United Kingdom*

Emerging contaminants (ECs) represent a wide range of chemical compounds and their occurrence in the environment is a global concern; however, little is known about their occurrence and exposure in many parts of the world including southern Africa. It is essential that the levels of ECs are monitored closely as many of these compounds, e.g. pharmaceuticals, are designed to produce effects at very low concentrations and exposure should be limited in order to mitigate potentially harmful ecotoxicological impacts.

Monitoring of ECs has been possible due to increased capability of analytical instrumentation and methodology such as non-targeted and suspect screening through the use of chromatographic separation techniques coupled with High Resolution Mass Spectrometry (HRMS). However, One significant challenge in environmental monitoring of ECs is that investigations are limited to developed countries due to the accessibility to analytical instrumentation. Thus, we evaluated wastewater treatment plants as a source of ECs in Gaborone, Botswana as well as ECs in groundwater using HRMS with non-targeted and suspect screening methods.

Screening for 5942 biologically active compounds, a total of 28 compounds were detected at least once, including 26 pharmaceuticals and two illicit drugs (2-Ethylmethcathinone and 11-nor-9-carboxy-Δ9-tetrahydrocannabinol) that have been a source of concern for authorities in Botswana recently. This represents the first detection of illicit drugs in wastewater in Botswana. The highest number of detections were in influent wastewater (26 ECs) followed by effluent wastewater (10 ECs) and lastly, groundwater (4 ECs).
17 emerging contaminants detected in the influent water were not detected in the effluent waters, suggesting some level of reduced emissions from wastewater treatment. The remaining nine chemicals were detected at lower intensities, a qualitative proxy for incomplete removal, in the effluent samples. Sulfamethoxazole was detected in wastewater effluent and non-target analysis revealed its human metabolite, N4-acetylsulfamethoxazole, was present in influent wastewater samples. Two anti-retroviral compounds (abacavir and tenofovir) were detected in influent and effluent sources. This confirms that wastewater treatment plants are a source of biologically active chemical pollution to the environment in Botswana and will help inform prioritization efforts for monitoring and remediation that is protective of these ecosystems.

3.13.B.T-05 Presence & Removal of Psychopharmaceuticals & Transformation Products from Dutch Wastewater Streams

Charlie Davey[1]*, Antonia Praetorius*[2]*, Thomas L. ter Laak*[3] *and Annemarie van Wezel*[2]*, (1)University of Amsterdam, Netherlands, (2)University of Amsterdam, Institute for Biodiversity and Ecosystem Dynamics, Netherlands, (3)KWR Water Research Institute, Netherlands*

Psychopharmaceuticals are primarily used to treat psychological disorders, as well as other conditions relating to the nervous system and are known to affect non-target organisms in the environment at very low concentrations. The occurrence of many psychopharmaceuticals in the water cycle remains an understudied topic, with data lacking for many compounds. Therefore, the current study aimed to provide insights into the presence and removal of psychopharmaceuticals and their transformation products in Dutch wastewater streams employing target and suspect analysis. 51 target compounds were selected based on high (Dutch) prescription or high environmental risk indicated in literature. A suspect list was also generated based on the 200 psychopharmaceuticals prescribed in the Netherlands, plus 6000 predicted transformation products of these compounds. Solid Phase Extraction (SPE) was carried out on 24h composite samples from the Wastewater Treatment Plants (WWTPs) of 6 Dutch cities. From each location both effluent and influent samples were collected from at least 7 days. Separation and detection were performed with UHPLC-qTOF-HRMS. Suspect screening was performed using the open-source platform PatRoon 2.0, and select suspects with high structural similarity to targets underwent semi-quantification.
Based on initial results, 34 target compounds were detected in the effluents ranging from 1 – 2,500 ng/L, while 36 were detected in the influents, ranging from 1 – 250,000 ng/L. Ongoing analysis shows that suspect compounds, including both parent compounds and transformation products, are detected in both types of water samples. Since many suspect compounds have target analogues, these could therefore be semi-quantified, indicating that transformation products are often found in higher concentrations than parent compounds.
Utilising PatRoon 2.0 and semi-quantification in tandem allowed to quantify more compounds than previous studies. Moreover, we revealed the presence of several transformation products, which are often overlooked. The results of the present study highlight that wastewater matrices contain abundant numbers of psychopharmaceutical transformation products and, like some of the parent compounds, these are not removed sufficiently even from modern Dutch WWTPs. Analysis is still ongoing, but it is likely to be concluded that modern WWTPs require upgrades to lower the quantities of these compounds released into the aquatic environment.

3.13.C Human and Veterinary Pharmaceuticals in the Environment – Risk, Prioritisation & New Insights

3.13.C.T-01 Contribution of Septic Tanks to Pharmaceutical Concentrations in Rivers

Maike Wilschnack[1]*, Bess Homer*[2]*, Elise Cartmell*[2]*, Kyari Yates*[1] *and Bruce Petrie*[1]*, (1)Robert Gordon University, United Kingdom, (2)Scottish Water*

Pharmaceuticals are emerging contaminants in the environment. Due to their incomplete removal in conventional wastewater treatment works (WWTW) and their ubiquitous presence in influent, treated wastewater discharges are considered the main entry source of pharmaceuticals into the environment. So far, research has focused on centralised WWTW and the receiving surface waters. However, it is conservatively estimated that 7% of the Scottish population, are served by a septic tank. Septic tanks are typically located in rural and semi-urban areas and treat wastewater of individual or small groups of houses.
Five septic tanks (with 217 – 475 PE) discharging to four different rivers in Scotland were monitored for 69 pharmaceuticals between October 2021 and September 2022. A seasonal effect on the sum of concentrations of pharmaceuticals in influent and effluent can be observed. In all septic tanks, the lowest concentrations were reported in February during heavy rainfall. Findings indicate that pharmaceuticals concentrations in septic tank effluents can exceed concentrations typically reported in centralised WWTW effluents. For instance, venlafaxine was determined at concentrations up to 1.2 $\mu g\ L^{-1}$ in septic tank effluent, approximately two-times higher than previously reported maximum concentrations in the UK. Initial data has shown correlations between the concentrations of some pharmaceuticals and sanitary determinands. For instance, metformin and the biological oxygen demand have a correlation coefficient of 0.9 in septic tank effluent ($n = 30$).
River water samples were collected quarterly upstream ($n = 20$) and downstream ($n = 20$) of the effluent discharge point. The contribution of the septic tanks to the sum of pharmaceuticals detected in the river varies from no difference between upstream and downstream concentrations to an increase of 95%. Detection frequencies vary between the different analytes. The frequently consumed drug paracetamol was detected in 75% of the upstream samples at concentrations from 0.3 to 404 ng L^{-1}, and in 95% of the downstream samples at concentrations from 0.3 to 1548 ng L^{-1}. In contrast, the beta-blocker atenolol was not detected

downstream, and in 25% of the upstream samples at concentrations from 0.1 to 3.4 ng L^{-1}. Risk quotients (RQ) were calculated from the environmental concentration and the predicted no effect concentration. The highest RQ was found for ibuprofen (RQ = 13) in a downstream sample in August.

3.13.C.T-02 Sewage Overflows and Historical Landfills Affecting Pharmaceutical Pollution in Scottish Rivers: Spatiotemporal Distribution and Hazards

John Wilkinson[1] *and Alistair B.A. Boxall*[2]*, (1)Environment and Geography, University of York, United Kingdom, (2)University of York, United Kingdom*

Active pharmaceutical ingredients (APIs) are known contaminants in the aquatic environment linked to sources including sewage treatment effluent, combined sewage overflows (CSO), among others. For example, recent evidence suggests that landfills, particularly those built prior to regulatory requirements for base lining systems, may also be a source. As APIs are designed to interact with highly conserved molecular receptors, their occurrence is of ecological concern.

Despite decades of research, few studies monitor APIs across large geographical catchments and/or collect samples over long time periods (e.g., >6 months). Here we present a year-long study of APIs in 11 rivers of the Firth of Forth catchment (Scotland, UK) representing the chemical fingerprint of approximately 1.5 million people (27% of the Scottish population). Duplicate river water grab samples (n=26 sites and 624 total samples) were obtained monthly for 1 year up-/downstream of potential sources of organic contaminants (e.g., sewage treatment plants, agricultural, poultry rearing, landfill and industrial areas). Targeted analysis occurred for 70 analytes using high performance liquid chromatography tandem mass spectrometry generating 43,680 chemical determinations.

APIs were quantified in all but 1 sampling site with the most contaminated rivers being those in the most highly populated regions of the catchment surrounding the city of Edinburgh. In total, 33 analytes were detected. The most contaminated site was consistently a location on the river Carron (Grangemouth) 7 km downstream from a historic landfill which erodes into the river during high-flow conditions. Here, cumulative concentrations of the studied contaminants (mean=9097ng/L) were typically 2-3-fold higher than the next most contaminated location. Highest concentrations were observed in July and August which coincided with low-flow conditions or during periods of suspected CSO events. Contaminants with >75% detection frequency included caffeine, carbamazepine, codeine and gabapentin. Comparison of the measured concentrations to apical and non-apical predicted no effect concentrations (PNECs) in the literature showed that concentrations of amitriptyline, diltiazem, paracetamol and metformin exceeded non-apical PNECs in 25%, 14%, 11% and 3% of the collected samples respectively. This work highlights the effects of different API sources on environmental concentrations and ecological risk across large spatial and temporal scales.

3.13.C.T-03 Seasonal Speciation of Pharmaceuticals Within a Full-Scale Free Water Surface Constructed Wetland in England

Emma Vaughan[1]*, Barbara Kasprzyk-Hordern*[2]*, Jannis Wenk*[3]*, Ruth Barden*[4]*, Richard P Evershed*[5] *and Charles Tyler*[6]*, (1)Chemistry, University of Bath, United Kingdom, (2)Department of Chemistry, University of Bath, United Kingdom, (3)University of Bath, United Kingdom, (4)Wessex Water, United Kingdom, (5)Organic Geochemistry Unit, School of Chemistry, University of Bristol, United Kingdom, (6)University of Exeter, United Kingdom*

Treated wastewater is a major source of pharmaceuticals and their metabolites in the aquatic environment in the UK due to their widespread use. Conventional wastewater treatment systems are not designed to effectively remove these organic micropollutants. Consequently, complex mixtures are consistently released into the environment at low concentrations posing potential risks to aquatic ecosystems and human health. As a tertiary step in wastewater treatment, constructed wetlands offer a low-carbon treatment solution for removal of pharmaceuticals and other chemicals of emerging concern. Adoption of this nature-based technology in the UK is limited, and most of the current literature refers to pilot scale and mesocosm systems. This research assesses seasonal speciation of pharmaceuticals within a full-scale free water surface constructed wetland in South-West England which receives effluent from a rural wastewater treatment plant (2,000 population equivalent). The wetland was installed by Wessex Water in 2020 to comply with obligations under the UK Water Industry National Environment Programme.

Three sampling campaigns were carried out during the first year of operation. Water and sediment samples were prepared by solid phase extraction and the QuEChERS method, prior to analysis by ultra-high performance liquid chromatography coupled with tandem mass spectrometry (UPLC-MS/MS). Of 139 chemical targets, > 80 were identified in wetland water samples including pharmaceuticals and their metabolites, illicit drugs, and lifestyle chemicals. Efficiency of removal from the aqueous phase is compound dependant, with ≥ 90% removal of some compounds (e.g., quinolone antibiotics and statins) and poor removal or increase of others (e.g., macrolide antibiotics and nicotine). As expected, the wetland appears most efficient in the summer months. Biodegradation and photodegradation are considered dominant removal mechanisms based on seasonal variability in removal efficiencies and metabolites. Partitioning to sediments appears to have a minor role, with fewer compounds quantifiable in sediments. Some concentrations exceeded literature predicted no effect concentrations in wetland effluent, but nevertheless the wetland acts to significantly reduce dissemination of pharmaceuticals from treated wastewater into the wider environment. Detailed assessment of removal mechanisms may be used to determine optimal operational parameters for similar systems installed in the UK in future.

3.13.C.T-04 Environmental Safety of Parasiticidal Veterinary Medicinal Products for Companion Animals from a European Regulatory Perspective: Challenges and Knowledge Gaps

Haru Kroneis[1]*, Benoit Courty*[2]*, Silke Hickmann*[3]*, John Jensen*[4]*, Boris Kolar*[5]*, Ludek Blaha*[6]*, Rene van Herwijnen*[7] *and Ricardo Carapeto-García*[8]*, (1)Austrian Medicines and Medical Devices Agency (AGES MEA), Austria, (2)French Agency for Veterinary Medicinal Products (ANMV), France, (3)German Environment Agency, Germany, (4)Department of Ecoscience, Aarhus*

University, Denmark, (5)National Laboratory of Health, Environment and Food, Slovenia, (6)RECETOX, Masaryk University, Czech Republic, (7)National Institute for Public Health and the Environment (RIVM), Netherlands, (8)Veterinary Medicines Department, Agencia Española De Medicamentos Y Productos Sanitarios (AEMPS), Spain
In the last decades, much effort has been invested in the development of suitable active substances and well-adapted medicinal products to improve user and animal safety, as well as the efficacy of parasiticidal medicinal products for cats and dogs. At the same time, research into the environmental safety of such products has been neglected, in spite of their evident insecticidal and acaricidal effects.The assumption of the guideline on environmental risk assessment (VICH GL 6) is that the treatment of companion animals only leads to negligible environmental exposure and thus no experimental Phase II risk assessment is required. This presentation will give background information on regulatory aspects associated with the topic of the environmental safety of (ecto-) parasiticidal veterinary medicines for companion animals and spotlight the major scientific knowledge gaps that lead to the most significant regulatory challenges in the EU.
Major knowledge gaps identified that hamper regulatory decision making and that prevent from the performance of a quantitative and product based risk assessment are related to: (i) the lack of robust environmental exposure models (PEC derivation), (ii) real world evidence from aquatic hot-spots (e.g. dog swimming areas or in the vicinity of WWTP influents and effluents), (iii) real world evidence from urban and peri-urban terrestrial ecosystems exposed to excreta from treated animals, and (iv) data on the environmental fate and behaviour (including sewage sludge and sediment) of active substances used. Such knowledge gaps exist for most active substances used in ectoparasiticidal veterinary medicines for companion animals, however, are most pronounced for newly developed substances, many of which are persistent and can be classified as PFAS.
This regulatory perspective may provide the scientific community with important considerations for developing targeted research strategies to investigate the environmental concentrations, behaviour and safety of parasiticidal veterinary substances for companion animals, as well as suggestions for environmental modelling parameters.

3.13.C.T-05 Proposal for Strengthening the ERA Whilst Maintaining Access to Human Medicinal Products – The Extended ERA Approach
Samuel K Maynard[1]*, Todd Davidson*[2]*, Jan Wölz*[3]*, Thomas Hutchinson*[4] *and Kirsty Reid*[5]*, (1)Global Sustainability, Astrazeneca UK, United Kingdom, (2)Bristol Myers Squibb, (3)Research & Development, Pharmaceuticals, Bayer AG - Pharmaceuticals, Germany, (4)R&D Global Safety Assurance, United Kingdom, (5)Efpia*
One of the unintended results of delivering medicines to patients is that the Active Pharmaceutical Ingredients (APIs) contained in medicines can enter the environment through excretion after patient use. It is therefore essential to assess the potential impact APIs can have on the environment. To that end, since 2006, it is mandatory to include an **environmental risk assessment (ERA)** as part of regulatory marketing authorisation application (MAA).
The current ERA has been invaluable to assessing the environmental risk of APIs since 2006. Learnings from the assessment of potential environmental risks (both by industry and by regulators) over the years show that further improvements could be made. With the ongoing revision of the EU-Pharmaceutical legislation, (Directive 2001/83 EC), there is an opportunity to address and implement such improvements. This presentation outlines the extended ERA (eERA) approach to addressing the concerns with the current process. Critically, this approach would extend and strengthen the existing ERA framework beyond the initial, single medicinal product-based assessment in the EU, without compromising patient access to medicinal products.
The eERA approach proposed here by the three pharmaceutical industry trade associations (EFPIA, AESGP and Medicines for Europe) is designed to address the current challenges with ERA and strengthen the ERA process in the EU. Some of these challenges with the current ERA approach identified and proposed to be addressed by the eERA are summarised below: 1) Insufficient transparency and accessibility to environmental data and risk assessments of APIs 2) Potential for duplication of testing 3) Potential for conflicting risk conclusions 4) Calls to include ERA conclusions in the MAA evaluation process 5) Environmental risk resolution burden on the 'last to market'
The eERA addresses these challenges and the risk of APIs from three different perspectives: Situation 1 – new innovative APIs fulfilling an unmet need in patients; Situation 2 – off-patent APIs or APIs post data exclusivity; and Situation 3 – so-called legacy APIs on the market (marketed before 2006) without sufficient environmental data to conclude on risk. The eERA approach presented demonstrates numerous benefits in overcoming these limitations, while not compromising patient access to medicinal products.

3.13.P Human and Veterinary Pharmaceuticals in the Environment – Risk, Prioritisation & New Insights

3.13.P-We119 Prioritisation of Pharmaceuticals for Assessment of Exposure and Risks to Terrestrial Ecosystems
Nahum Peter Ashfield[1]*, Alice H.L. Marshall*[2]*, Rosie J Lennon*[1]*, Sylvia Escher*[3] *and Alistair B.A. Boxall*[2]*, (1)Department of Environment and Geography, University of York, United Kingdom, (2)University of York, United Kingdom, (3)Fraunhofer ITEM - Institute for Toxicology and Experimental Medicine, Germany*
Concerns over environmental exposure to active pharmaceutical ingredients (APIs) has been increasingly reported in the literature, with the aquatic compartment being the predominant focus. Many attempts have been made to prioritise APIs based on their potential to impact the aquatic environment. Less attention has, however, been given to the prioritisation of APIs in the terrestrial environment, despite being released to terrestrial systems during sewage sludge amendment or wastewater irrigation. Here, APIs were prioritised based on exposure and risk to terrestrial ecosystems using data from the NHS England 2018 Prescription Cost Analysis. Compounds assumed to be in use by approximately 1% of the population were considered within the prioritisation, with predicted environmental concentrations (PECs) in wastewater being generated and refined using API-specific excretion rates (where available). The European Medicine Agency (EMA) threshold of 0.1 μgL^{-1} in wastewater effluent was used

to further focus the list of study APIs, with an additional safety factor applied to hormones and anti-cancer drugs. PECs for sludge and wastewater effluent were then obtained which were subsequently used to derive soil and porewater PECs. Exposure predictions were then combined with predictions of ecotoxicity and bioaccumulation to derive risk quotients for soil invertebrates and birds and mammals. APIs were then ranked by exposure and risk to terrestrial ecosystems. From the initial screening of the top 217 compounds, Lactulose, Paracetamol and Metformin were the most prescribed in terms of mass, with antibacterial and antidepressant drug classes appearing most frequently within the prioritisation list. Considering parent compound excretion, Lactulose, Metformin and Gabapentin had the highest PECs in influent, at 1.42, 0.21 and 0.05 mgL^{-1} respectively. Montelukast and Atorvastatin however, showed the greatest risk of bioaccumulation in earthworms, with predicted Log bioconcentration factors of 7.42 and 4.82. The toxicity ranking is ongoing. Refining terrestrial risk assessment based on exposure, through consumption and resulting PECs, provides a useful method in which to prioritise pharmaceutical compounds for experimental study and model validation. The adaptability of this method to consider different consumption, wastewater treatment and both sludge and reclaimed water application scenarios, presents the means to contribute to future prioritisations in terrestrial systems.

3.13.P-We120 An Optimized Risk Assessment for Prioritization of Pharmaceuticals and Personal Care Products in Four Major Rivers in South Korea

Jun Yub Kim*, Jaehyun Park, Dong-Geun Song and Sang Don Kim, School of Earth Science and Environmental Engineering, Gwangju Institute of Science and Technology, Gwangju, Korea* Pharmaceuticals and Personal Care Products (PPCPs) may exist in low concentrations in environmental matrixes, but pseudo-persistent and toxicity at low concentrations can lead to detrimental effects on organisms, such as endocrine disruption. In this study, an optimized aquatic ecological risk assessment of 137 PPCPs was conducted with the application of methodology developed by the NORMAN network. Prior to risk assessment, the Measured Environmental Concertation (MEC) of PPCPs was investigated via an application of multiresidue screening method using LC-HRMS in a spatiotemporal manner. Predicted No Effect Concentration (PNEC) was derived from different types of PNEC based on data availability, Environmental Quality Standards (EQS), PNEC derived from available toxicity data for aquatic species with an application of safety factor, and predicted PNEC derived from the predictive model. Among 137 PPCPs and 84 PPCPs were quantified above the LOQ with concentrations ranging from 1 ng L^{-1} to 51 μg L^{-1} (e.g., metformin). An optimized risk assessment was evaluated based on two indicators, the *Frequency of Exceedance* and the *Extent of Exceedance*. Spatial *Frequency of Exceedance* of the PNEC was calculated by the proportion of the number of sites with concentration exceeding PNEC and a total number of sampling sites, and 13 PPCPs posed a potential risk to aquatic organisms. Among 13 PPCPs, the proportion of clotrimazole and carbamazepine that exceeded their respective PNECs were 1 and 0.97, respectively. *The Extent of Exceedance* of the PNEC, identical to the Risk Quotient (RQ) approach, was calculated as 95th percentile upper confidence limit of all MEC values divided by the PNEC and classified them as low risk if exceedance is greater than or equal to 0.1, moderate risk for ranging from 0.1 to 1 and high risk for above 10. 18 PPCPs were identified as posing a risk, and similar to results obtained from the frequency of exceedance, carbamazepine (RQ=37.9) and clotrimazole (RQ=17.4) were classified as high risk, and 5 PPCPs were classified as moderate risk. Unlike the sub-score methods developed by NORMAN Network, values obtained from two indicators were multiplied for further prioritization. As a result, carbamazepine, clotrimazole, azithromycin, dichlorvos, flubendazole, imidacloprid, clarithromycin, galaxolidone, valsartan acid, diclofenac acid, ranitidine, venlafaxine, climbazole were ranked respectively as priority compounds that posed risk to aquatic ecosystem.

3.13.P-We121 Prioritization, Learnings, and Strategies to Close Data Gaps of the Active Pharmaceutical Ingredient Disulfiram

Jan Wölz*[1], Natalie Burden[2], Cristiana Cannata[3], Anja Coors[4], Samuel K Maynard[5], Caroline Moermond[6], Stewart Owen[7], Ad M. J. Ragas[3], Susanne Schwonbeck[8], Helmut Segner[9] and Peter W. Wilson[10], (1)Research & Development, Pharmaceuticals, Bayer AG - Pharmaceuticals, Germany, (2)NC3Rs, London, United Kingdom, (3)Radboud University Nijmegen, Netherlands, (4)ECT Oekotoxikologie, Germany, (5)Global Sustainability, Astrazeneca UK, United Kingdom, (6)National Institute for Public Health and the Environment (RIVM), Netherlands, (7)Astrazeneca UK, United Kingdom, (8)Fraunhofer ITEM - Institute for Toxicology and Experimental Medicine, Germany, (9)University of Bern, Switzerland, (10)Sanofi, France*

Today there are many active pharmaceutical ingredients (APIs) on the market which were registered as human medicinal products before 2006. Environmental risk assessments (ERA) were only requested by EU authorities thereafter. Hence, many APIs lack environmental data and full environmental risk assessments may be highly uncertain.

One of the aims of the IMI PREMIER project (www.imi-premier.eu) is highlighting methodologies to prioritise the closing of existing data gaps for APIs without an ERA. Within the project, at least 25 APIs shall be prioritized either due to their mode of action (MoA) or risk related criteria. Ecotoxicological tests will subsequently be performed for these APIs.

Disulfiram was among the APIs which were prioritized and ranked high for risk related criteria. Some relevant and reliable data was identified in the ECHA database during a systematic literature search to identify data relevant for ERA. Disulfiram is also used in, e.g., adhesives and sealants, which explains the assessment under REACH. Only a limited number of peer-reviewed studies were found to be relevant and these were then CRED assessed for reliability. In the end, appropriate chronic aquatic toxicity data on fish was missing, but experimental data would potentially not be required when applying a decision tree developed for legacy pharmaceuticals that aims to reduce *in vivo* fish testing.

We will present the API prioritization process of disulfiram within PREMIER, learnings, and strategies to identify the benefits of closing the data gap on fish with experimental studies or substituting data.

3.13.P-We122 Monitoring Pharmaceuticals Consumption using PERK: A Study Utilizing Prescription Data Collected at the River Catchment Level with High Spatial Resolution

*Kishore Kumar Jagadeesan[1], Kathryn Proctor[1], Ruth Barden[2] and **Barbara Kasprzyk-Hordern**[1], (1)Department of Chemistry, University of Bath, United Kingdom, (2)Wessex Water, United Kingdom*
The prescription data of selected pharmaceuticals were utilized to predict their concentrations in the wastewater influent. A combined wastewater-based epidemiology and environmental risk analysis protocol was developed. Prescription data for the catchment area is derived from England's National Health Services monthly prescription database using PrAna. Using PERK, predicted environmental concentration (PEC) of pharmaceuticals were estimated and validated against measured environmental concentration (MEC). The wastewater monitoring data obtained from five different wastewater treatment plants in the Southwest of England (WWTP A to E) were used.
The model can predict accurate results for 16 pharmaceuticals (0.5 < PEC/MEC < 2) and acceptable results for 31 out of 36 pharmaceuticals (0.1 < PEC/MEC < 10), according to comparisons between predicted environmental concentrations (PEC) of pharmaceuticals in wastewater influent ($PEC_{influent}$) and measured environmental concentrations (MECinfluent) reported in prior study. 28 of the pharmaceuticals that were studied were prescription-only medicines (POM). The model achieved accurate results for 12 pharmaceuticals and acceptably accurate results for 24 out of 28 pharmaceuticals in POM, where prescription counts are presumed to be a good indicator of use. For most of the pharmaceuticals under study at the five WWTP locations, there were similar variation between measurements and prescriptions.
Pharmaceutical removal percentage (Removal%) was calculated using measured effluent and influent concentrations. The Removal% and $PEC_{influent}$ were used to predict the PEC values in effluent ($PEC_{effluent}$). Metformin, tramadol, naproxen, and carbamazepine were the top five medicines found in wastewater at all five study sites, with values from 0.3 to >25 g/L. Due to both their high consumption and low removal rates in WWTP, the top five pharmaceuticals had $PEC_{effluent}$ levels that were high (>4 g/L) in the wastewater effluent at WWTP D. As part of the environmental risk assessment (ERA), the PEC to predicted no effect concentrations (PNEC) ratio for several pharmaceuticals was also computed.

3.13.P-We123 Innovative Data Visualisation Tool to Explore Relationships Between Pharmaceutical Prescribing and Environmental Occurrence

***Lydia Niemi**[1], Mark A. Taggart[2], Stuart Gibb[2], Sharon Pfleger[3], Karin Helwig[4], Elise Cartmell[5], Bess Homer[5], Fiona Whyte[6] and Lindsey Green[6], (1)Environmental Research Institute, North Highland College, University of the Highlands and Islands, United Kingdom, (2)Environmental Research Institute, University of the Highlands and Islands, United Kingdom, (3)NHS Highland, (4)Glasgow Caledonian University, (5)Scottish Water, (6)Scottish Environment Protection Agency*
The presence of pharmaceutical residues in the aquatic environment is recognised internationally as an important public health and environmental issue. Pharmaceuticals are continuously introduced into effluent-receiving surface waters due to their incomplete removal within wastewater treatment plants (WWTPs). The environmental fate and risks of these residues are not fully characterised, but many compounds are of ecotoxicological and regulatory concern due to adverse effects in non-target organisms at environmentally relevant concentrations.
To develop a deeper understanding of this issue in Scotland, representatives from the environment, water and healthcare sectors formed the One Health Breakthrough Partnership. With researchers, this partnership performed a baseline assessment of pharmaceuticals in Scotland's water environment and developed the first national database combining data from regulatory monitoring, published and grey literature. The database was collated into an open-access, interactive data visualisation tool to combine national environmental data and community prescribing data on pharmaceuticals.
The environmental dataset, containing >3000 datapoints, representing 60 pharmaceuticals in 11 distinct environmental matrices, was first interrogated to explore spatial trends and environmental risk. Spatial analysis revealed relationships with population demographics, with significant monitoring gaps in rural areas of Scotland, and most monitoring targeting "high risk" locations e.g., directly downstream of WWTPs. Preliminary risk assessment, based on a holistic consideration of risk quotients, detection frequencies and prescription volumes, identified several substances with higher ecotoxicological risk in inland surface waters, and risk of driving antimicrobial resistance (based on minimum inhibitory concentrations). Environmental data has been matched to standardised quantities of drugs prescribed, by health board, GP practice and drainage operational area, enabling users to view both datasets over a range of spatial scales. Future analysis will interrogate prescription trends to explore possible relationships between prescribing and environmental occurrence of pharmaceuticals. The tool will continue to be developed and updated as data becomes available. It is envisioned to be used by stakeholders to inform the development of substance specific and location specific interventions to reduce potential risks to environmental and human health.

3.13.P-We124 Modeling the Sustainable Re-Use of Treated Water Containing Active Pharmaceutical Ingredients for Land Application

*Virginia Houck, Norman D Forsberg and **Andrew C Newcombe**, Arcadis*
Treated water is increasingly being re-used as irrigation to help achieve sustainability objectives in pharmaceutical manufacturing processes. Potential re-use of treated water can reduce discharge directly to waterbodies or sewage treatment plants and is important for water conservation. Treated water from pharmaceutical manufacturing processes may contain low levels of active pharmaceutical ingredients (APIs) and any sustainable re-use requires an understanding of the fate and transport of these compounds in the environment and their associated environmental risk.
Using a conservative screening level modeling approach, we customized USEPA's Pesticide Root Zone Model (PRZM) to simulate spray irrigation applied to established turf. Model inputs include soil, climate, and API properties, as well as the API production schedule and proposed irrigation practices at the facility. Modeled estimates of predicted environmental concentrations (PECs) of APIs in soil, surface water runoff, and leachate to groundwater were calculated by the model on a daily time step over a period of ten years and compared with environmental threshold limits. An automated optimization routine was developed to

determine PECs of an API in treated water (or the irrigation rate) appropriate for remaining below the environmental thresholds for the API. This screening level modeling approach for re-use of treated water enables a facility to potentially maximize treated water reuse, minimize treated water discharge, identify appropriate treatment technologies, and minimize potential to exceed relevant threshold levels in soil, surface water, and groundwater as a component of a sustainability objective.

3.13.P-We125 Human Plasma Protein Binding is a Good Predictor of Sludge Sorption For Cationic Pharmaceuticals

Joanne Elmoznino[1]*, Gemma Janer,*[2]*, Leonel Reis da Silva Torrao*[3] *and Birk Poller*[4]*, (1)Pfizer, (2)Novartis Pharma, Spain, (3)PKS/in vitro ADME, Novartis Pharma, Spain, (4)Global HSE, Novartis Pharma, Spain*

The sludge:water partitioning coefficient (Kd_{sludge}) is a key predictor of the fate of pharmaceuticals in sewage treatment plants. As such, Kd_{sludge} is of great importance for the prediction of surface water concentrations and so is accurately evaluated by means of the OECD TG 106 assay for the regulatory environment risk assessment (ERA) of human pharmaceuticals. For many legacy pharmaceuticals currently on the market, measured Kd_{sludge} data is not available, thus modeling their fate in sewage is often based on the octanol:water partition coefficient (Kow) even though Kow is not a reliable predictor of sorption for ioniazable compounds such as pharmaceuticals. While complex polyparameter models may be able to better predict sorption, a simple linear regression model would be preferable in terms of transparency and ease of implementation for regulatory purposes.

Extensive datasets gathered during drug development are worth exploring for estimating environmental fate and effects. Human plasma protein binding (HPPB) is assessed to facilitate prediction of pharmacokinetic parameters and efficacy. This assay shares conceptual similarities with sludge adsorption study, as sorption is evaluated towards an organic substrate with a net negative surface charge. Therefore, this study examined the possibility to predict Kd_{sludge} from HPPB data.

HPPB data, log Dow (octanol:water ~pH 7), and Kd_{sludge} data was collected for 75 pharmaceuticals, classified according to the predominant ionic species ~pH 7. Linear regression results indicate that log Dow is a reasonably good predictor of Kd_{sludge} for neutral pharmaceuticals, but a rather poor predictor for cationic pharmaceuticals. However, HPPB is a better predictor of the Kd_{sludge} for cationic pharmaceuticals, with an even stronger correlation than the one between log Dow and Kd_{sludge} for neutral pharmaceuticals. The results of this study suggest that for cationic legacy pharmaceuticals, easily accessible HPPB data may be used to predict partitioning in sewage with reasonable accuracy. HPPB data could also be used to estimate the likelihood that a terrestrial assessment will be triggered in the ERA.

3.13.P-We126 Water Pollution from Pharmaceutical Use in Livestock Farming: Assessing Differences Between Livestock Types and Production Systems

Lara Wöhler[1]*, Rick Hogeboom*[1]*, Markus Berger*[2] *and Maarten Krol*[1]*, (1)University of Twente, Netherlands, (2)Technical University Berlin, Germany*

Livestock production is considered as major source of pharmaceutical emissions to the environment. The current scientific discourse focusses on measuring and modelling emissions as well as assessing their risks. While several studies evidence the severity of pharmaceutical pollution resulting from livestock farming, differences in pollution between livestock types and production systems are largely unknown. In fact, there is no comprehensive analysis of factors influencing pharmaceutical use – the emission's source - in the diverse production systems. To address these knowledge gaps, the present research develops a framework to investigate pharmaceutical pollution from different livestock production systems. Using the framework, a first pilot assessment is conducted comparing pollution from organic and conventional cattle, pig and chicken production systems for selected indicator substances, covering antibiotics, antiparasitics, hormones and NSAIDs. Hereto novel qualitative information about influential factors for pharmaceutical use and pollution (which is used where public databases lack statistics) is combined with quantitative data (e.g. about the environmental behavior of specific substances). Both, framework development and pilot assessment base on interviews and literature. The analysis shows that factors across a pharmaceutical's entire lifecycle influence pollution. However, not all of them are livestock type or production system dependent. The pilot assessment reveals that differences in pollution potential between conventional and organic production exist, but for antibiotics, NSAIDs (and partially antiparasitics) some factors lead to higher pollution potential in conventional, others in organic systems. For hormones we identified a comparatively higher pollution potential from conventional systems. Among the indicator substance, the assessment over the entire pharmaceutical lifecycle illustrated that flubendazole in broiler production has the highest per unit impact. The framework (and insights from the pilot assessment) are useful to identify which substances, livestock types, production systems, or the combination thereof has high or low pollution potential. This knowledge can serves more sustainable agricultural management and ultimately less pharmaceutical pollution.

3.13.P-We127 Occurrence of Veterinary Antibiotics and Effect on the Change of Microbial Community in the Watershed

Sung Chul Kim[1]*, Jin Wook Kim*[1]*, Young Kyu Hong*[1]*, Song-Hee Ryu*[2] *and Oh Kyung Kwon*[3]*, (1)Chungnam National University, Daejeon, Korea, (2)Rural Development Administration, Korea,(3)Han Kyung National University, Gyeonggi-do, Korea*

Recently, concern has been increased on the released veterinary antibiotics (VAs) in the environment because of adverse effect on ecosystem and production of antibiotic resistance genes (ARGs). The main purpose of this research was i) to monitor the occurrence of VAs in the surface water, soil, and sediment, and ii) to identify the change of microbial community in the sediment due to released VAs. Total of 12 VAs including four different classes (penicillins, tetracyclines, macrolides, and sulfonamides) was measured using liquid chromatography-tandem mass spectrometry (LC/MS/MS) in the surface water, soil, and sediment. Metagenomic analysis was performed using the Illumina Miseq platform to understand the change of bacterial community in sediment. The result showed that seven VAs were found at five locations, and the detected mean concentration of VAs was ranged 0.02–0.31 μg/L, 1.37-142.78 μg/kg and 3.73–9.04 μg/kg in surface water, soil and sediment samples, respectively. Change of microbial community was also observed that the most dominant species was *firmicutes* and main source of released VAs can be effluent from the livestock manure treatment plant and the runoff from the livestock farms. In addition, the relative abundance of bacteria such as *Clostridium butyricum*, *Clostridium saudiense* and *Clostridium gasigenes* were higher in confined and dense livestock farm than in other places. Released VAs from the animal farm can change the microbial community in the watershed and further study should be necessary to verify the production of ARGs due to residual of VAs in the environment.

3.13.P-We128 Analysis of Pesticides, Pharmaceuticals and Personal Care Products in Drinking and Environmental Water by Direct Injection Using UPLC-MS/MS
***Claudia Rathmann**[1], Janitha De Alwis[2] and Hannah Willmer[3], (1)Waters Corporation, Germany, (2)Food and evironment, Waters Corporation, United Kingdom, (3)Waters Corporation, United Kingdom*
Monitoring for harmful substances in drinking and environmental water is essential for protecting human health and maintaining good environmental quality standards. Making accurate measurements at ultra- low levels is an essential part of any monitoring program. As more and more pesticides, pharmaceuticals and personal care products (PPPCP) are released into the environment, there is a growing demand for analytical methods with multiple compound groups.
The purpose of this work was to demonstrate a direct injection UPLC-MS/MS method for the ultra-low level determination pesticides, pharmaceuticals and personal care products in drinking and environmental waters. The method performance study was completed on an ACQUITY Premier^{TM} LC System with a Xevo TQ Absolute^{TM} mass spectrometry system.
A method validation study was carried out on drinking water and 2 environmental water matrices. The method performance was assessed using 3 spike levels at 10, 20, and 100 ng/L for all analytes, with 6 replicates at each level. Average method performance for trueness, repeatability, linearity, and sensitivity was assessed through inter and intra-laboratory studies.
Using direct injection on Xevo TQ Absolute^{TM} system removes sample preparation and enables a simple, high-throughput analysis of PPPCP in drinking and environmental waters.

3.13.P-We129 Monitoring of Pharmaceutically Active Compounds in River Water from Tagus River Basin (Spain)
***Silvia Royano**, Adrián de la Torre, Irene Navarro and María de los Ángeles Martínez, CIEMAT, Spain*
Pharmaceutically active compounds (PhACs) are molecules designed to interact with human or animal receptors but if they are present in the environment is because of their excessive use. More specifically, PhACs are mainly introduced in surface waters through wastewater discharges. Their presence in water can result in public health or environmental problems like antibiotic-resistant bacteria or endocrine disruptions and, consequently, some of these PhACs have been included in the Surface Water Watch List by the European Commission.
To address this issue, 77 river water samples were collected from 13 sampling points located throughout the Tagus river basin between 2020 and 2022. Then, the presence of 23 analytes belonging to several groups of PhACs as antibiotics, β-blocker agents, psychiatric drugs, analgesics, anti-inflammatories, lipids regulators, fungicides and anthelmintics were determined. Tagus River is the longest river of the Iberian Peninsula (1007 km, 80600 km^2 basin) and travels in an east-west direction, from the Central Spanish Plateau to Lisbon (Portugal) with an average annual flow of 456 m^3/s.
Filtered samples (1L) were spiked with deuterated internal standards and extracted by solid phase extraction using Oasis HLB (500 mg, 6mL) cartridges and eluted with MeOH. Instrumental analysis was carried out with a UHPLC-MS/MS system. Chromatographic separation was made by an ExionLC system coupled to a Triple Quad™ 3500 MS/MS system for the MS/MS analysis. MRM mode was performed to acquire two transitions per target analyte. The method was validated and method limits of quantifications ranged between 5 and 25 ng/L. Recovery for deuterated standards were always between 70 and 120%.
Excluding miconazole (<MLOQ), all the analytes were quantified in water samples. The antidepressant desvenlafaxine dominated PhAC levels (10.9 µg/L mean and 100% quantification frequency, Qf) followed by the antibiotic erythromycin anhydrous (3.2 µg/L mean and 82% Qf) and β-blockers irbesartan (745 ng/L mean and 82% Qf) and valsartan (526 ng/L mean and 88% Qf).
Sampling points located close to highly populated areas showed higher water PhAC concentrations.

3.13.P-We130 Antibiotics and Emerging Pathogens in the Ebro Delta, and the Albufera of Valencia
***Maria Garcia Torné**[1], Irene Falcó[2], Esteban Abad[3], Marta Llorca[3], Gloria Sánchez[2] and Marinella Farre[3], (1)Spanish National Research Council (CSIC), IDAEA, Spain, (2)IATA CSIC, Spain, (3)IDAEA-CSIC, Spain*
Urban rivers are impacted ecosystems which may play an important role as reservoirs for antibiotic-resistant (AR) bacteria. The primary goal of this work was to assess antibiotics, the prevalence of antibiotic resistance, antibiotic resistance genes (ARGs) and bacteria (ARBs) in two selected areas in Spain, the Ebro Delta, which is a sewage-polluted river, and the Albufera of Valencia, which is a freshwater lagoon on the Gulf of Valencia in eastern Spain.
Main antibiotics groups were assessed by ultra-performance liquid chromatography coupled with high-resolution mass spectrometry tandem mass spectrometry (UPLC-HRMS/MS). ARGs were detected using qPCR to assess aquatic habitats' emerging microbial contaminants vulnerability. *Escherichia coli* and ARB were grown in parallel by cultivation methods.
Despite the occurrence of antibiotics being detected in almost all the samples, the concentrations were ranging between the MLOQ and 3.7 µg/L. The most detected groups were quinolones such as ciprofloxacin and ofloxacin, the macrolides antibiotics such as azithromycin, beta lactam antibiotics as carbapenems, and sulphamide antibiotics such as sulfamethoxazole, and trimethoprim. In case of bacteria, despite the microbial load decreases in effluent compared to influent wastewater (2-3 log10 on average), the reductions between upstream and downstream wastewater do not comply with the latest European standards, Regulation (EU) 2020/741 of the European Parliament and of the Council on minimum requirements for water reuse.
To conclude, thanks to the possible determination of ARGs and ARBs in samples, this work will provide a methodology which can be used as an early indicator for the tracing of pathogens and ARGs. Moreover, fecal contamination (*E. coli* and microbiological indicators) has been found in surface waters, even in treated water sources.

3.13.P-We131 Understanding the Connectivity of Pharmaceutical Pollution in River Catchments

Julia Costescu[1], *Louise Bracken*[2], *Laura Turnbull-Lloyd*[1], *Sim Reaney*[1] *and Damian Crilly*[3], *(1)Durham University, United Kingdom, (2)Northumbria University, United Kingdom, (3)Environment Agency (England), United Kingdom*

The near ubiquitous presence of pharmaceutical compounds in environmental waters represents an emerging cause for concern, but gaps remain in our understanding of how human and veterinary pharmaceuticals enter and travel through river catchments. A more holistic approach is needed in order to develop effective management strategies that conform to the catchment-based approach, although this is complicated by the patchy nature of available monitoring data for river water and by the significant seasonal variation in concentrations which makes comparisons even within datasets tenuous. Here, an exploration of pharmaceutical concentrations across the Aire catchment in the UK aims to provide insight into how the underlying connectivity of the catchment system, conceptualized as a source-pathway-receptor model, may determine observed patterns of contamination. To account for temporal variations of inputs and flow, samples collected on two separate occasions (corresponding to low and high flow conditions, respectively) were used to create two spatial snapshots for contamination with nine representative compounds. The snapshots were then used to explore spatial patterns in the catchment and what factors – topographic, physico-chemical, or related to potential sources and pathways for pharmaceutical pollution – may influence them. For the first snapshot, conducted in low flow conditions, none of the locations had concentrations above the limit of detection for five of the nine target analytes (Atenolol, Diclofenac, Erythomycin, Iopromide and Sulphadiazine). Results for the detected compounds have emphasized the difference in spatial patterns based on use category: as opposed to the veterinary use compound (Cypermethrin), the human use compounds (Carbamazepine, Lidocaine and Sucralose) showed significant correlation to contributing area, as well as to population served by the wastewater treatment plants upstream of the sampling sites and corresponding estimates for amounts of prescribed active ingredient. Sucralose also produced strong correlations to Carbamazepine and Lidocaine, supporting its use as a proxy for contamination with human pharmaceuticals, alongside the more frequently cited Carbamazepine. Ultimately, this research will inform the development of a graph representation of the system, used to assess the relative contribution of different pathways as they connect to the river channel and to inform as to the best intervention points within the catchment.

3.13.P-We132 Ecotoxicological Impact of Environmental Pharmaceuticals and Their Mixtures

Michela Panni[1], *Marica Mezzelani*[2], *Giuseppe D'Errico*[1], *Maura Benedetti*[1], *Stefania Gorbi*[1] *and Francesco Regoli*[1], *(1)Polytechnic University of Marche (UNIVPM), Italy, (2)Marche Polytechnic University, Italy*

Investigations on adverse outcomes of pharmaceuticals mixtures represent nowadays a research priority to characterize the risk for marine ecosystems. Indeed, an increasing number of studies have recently highlighted the simultaneous occurrence of anti-inflammatories, lipid-lowering agents, cardiovascular and psychiatric drugs in seawater, sediment and aquatic wildlife. Evidence of pharmaceuticals capability to interfere with biochemical and physiological processes in non-target species, revealed the urgent need to prioritize the environmental sustainability of the most widespread compounds and the development of comprehensive risk assessment procedures. In the present study, the ecotoxicological potential of 15 pharmaceuticals belonging to different therapeutic classes was investigated through a battery of bioassays which includes the algal growth inhibition of *Phaeodactylum tricornutum,* the embryotoxicity assay with *Paracentrotus lividus* and the bioluminescence test with *Aliivibrio fischeri*. Pharmaceuticals were dosed both alone and in mixtures, at two different environmentally realistic concentrations (1µg/L and 10 µg/L). Overall results were finally elaborated through a quantitative Weight Of Evidence (WOE) approach, which assign to each bioassay specific weights and thresholds based on the measured endpoint and sensitivity of the tested species, to finally provide a cumulative level of hazard of the entire bioassays battery. Obtained results highlighted different sensitivity of tested species toward selected pharmaceuticals and mixtures, with major effects on *P. tricornutum* and *P. lividus*. Although the overall elaboration with the WOE model revealed limited acute toxicity of pharmaceuticals, higher level of hazard was measured for mixtures compared to single compounds. Noteworthy, in mixtures the higher toxicity was not related to an exposure dose or to the number of combined drugs, suggesting the need of future investigations to unravel mechanisms of interaction among these molecules. In conclusion, the impact of pharmaceuticals cannot be predicted only by the evaluation of acute toxicity, and our results suggest the importance to integrate acute toxicity data with bioaccumulation and long-term detrimental effects for a more comprehensive risk assessment of these emerging contaminants in marine ecosystems.

3.13.P-We133 Residues of Drugs Used to Treat Diseases of Affluence and their Effects on Zebrafish Embryos (*Danio rerio*)

Denisa Medková[1,2,3], *Aneta Hollerová*[4,5], *Pavla Lakdawala*[6], *Nikola Hodkovicova*[4], *Jana Blahova*[6], *Eva Postulkova*[7], *Zdenka Svobodova*[5] *and Jan Mares*[7], *(1)Deparment of Zoology, Fisheries, Hydrobiology and Apiculture, Mendel University, Czech Republic, (2)Department of Animal Protection and Welfare & Veterinary Public, University of Veterinary Sciences Brno, Czech Republic, (3)Department of Animal Breeding, Animal Nutrition and Biochemistry, University of Veterinary Sciences Brno, Czech Republic, (4)Department of Infectious Diseases and Preventive Medicine, Veterinary Research Institute, Czech Republic, (5)Department of Animal Protection and Welfare & Veterinary Public Health, University of Veterinary Sciences Brno, Czech Republic, (6)Department of Animal Protection and Welfare and Veterinary Public Health, University of Veterinary Sciences Brno, Czech Republic, (7)Department of Zoology, Fisheries, Hydrobiology and Apiculture, Mendel University, Czech Republic*

In recent years, the incidence of diseases of affluence, such as diabetes mellitus, cardiovascular diseases, high blood pressure, and high cholesterol has been constantly increasing. Due to the increased prescription and consumption of drugs used to treat these diseases, concentrations of their residues are rising in the aquatic environment alarmingly. Common technologies used in wastewater treatments plants are not able to remove pharmaceutical substances completely. Thus, the residues of still biologically active substances enter surface waters and can be potentially dangerous for non-target aquatic organisms. The aim of the study was to evaluate effects of commonly used pharmaceuticals metoprolol, enalapril (at the concentration 0.1; 10; 100; 1 000, and

100 000 µg/L) metformin (at the concentration 1; 10; 100; 1 000, and 100 000 µg/L) on the embryonic stages of zebrafish (*Danio rerio*) using the embryonic acute toxicity test according to OECD method No 236. After four days of exposure, our results show that tested drugs influenced hatching rate at all tested concentration, which suggests that these substances might have the potential to disrupt early development of fish. Moreover, heartbeat rate was found to be affected as well. qPCR analysis indicated significant changes in the expression of genes responsible for the early development of embryos.

3.13.P-We134 The Effect of Environmentally Relevant Concentrations of Diclofenac, Ciprofloxacin, and a Binary Mixture on *Mytilus edulis* Fertility Potential

***Shannen Keyser*[1]**, *Magnus Løkset[2], Leslie Petrik[3], Liana Maree[1] and Daniela Maria Pampanin[4], (1)Department of Medical Bioscience, University of the Western Cape, South Africa, (2)Department of Chemistry, University of Stavanger, Norway, (3)Department of Chemistry, University of the Western Cape, South Africa, (4)Chemstry, Bioscience and Environmental Engneering, University of Stavanger, Norway*

It has been extensively reported that pharmaceutical compounds are present on a global scale in the aquatic environment. It is of great importance that we do not to underestimate the potential environmental risk that these chemicals pose, despite the low concentrations detected in the environment. This is especially true when multiple pharmaceutical contaminants are combined. Both diclofenac and ciprofloxacin have been suggested to cause reproductive toxicity, although test concentrations are often higher than those measured in the aquatic environment. In addition, it is suggested that aquatic spermatozoa may be more sensitive to exposure of these chemicals than oocytes.

The present study investigates the effect of environmentally relevant concentrations (500, 1000 and 10000 ng/L) of diclofenac, ciprofloxacin and a binary mixture on the fertility potential and spermatozoa function of mussels (*Mytilus edulis*). To determine the effect on fertilizing potential, both *in vivo* and *in vitro* exposure are carried out and successful fertilization and normal larvae development assessed. Specifically, male gametes are investigated after a 60-minute *in vitro* exposure to the selected pharmaceuticals for presences of reactive oxygen species (ROS), intact mitochondria, viability and total motility, as their impairment predicts decrease reproduction and consequently an impact at population and ecosystem level.

In the *in vivo* experiment, the fertilization rate and larvae development are evaluated after the exposure of adult individuals to the same chemical used in the previous testing.

Results indicate that, after 60 minutes *in vitro* exposure to environmentally relevant concentrations of diclofenac, ciprofloxacin and a binary mixture of the two, no significant difference ($p=0{,}988$) in the percentage of positive ROS spermatozoa was observed, as compared to control. Despite showing no significant effects on ROS, previously mentioned assays may further elude into the possible mechanism behind the effect of the pharmaceuticals on reproductive function in male mussels and whether environmentally relevant concentrations decrease fertilization potential in marine invertebrates, especially when chronically exposed to the pharmaceuticals.

3.13.P-We135 Effects of Pharmaceuticals and Personal Care Products (PPCPs) on Plants, Soil Invertebrates and Ecosystem Service Delivery

Oluyemi Ojo, *Environment, Heslington, United Kingdom*

The occurrence of Pharmaceuticals and Personal Care Products(PPCPs) in the environment has spurred a quest for knowledge of the sources, pathways, occurrence, fate, and ecotoxicological effects on the ecosystems. Moreover, a corresponding increase in the effects of PPCPs is anticipated in the future since the demand and use of PPCPs keeps rising for obvious reasons such as existing and emerging diseases (for instance Covid and its mutants), economic & population growth, deteriorating climatic condition and a host of others. This research is focused on a deliberate attempt to link the effects of PPCPs on the terrestrial ecosystem and the corresponding impacts on ecosystem service delivery.

This study is considering the effects of some of the most frequently occurring pharmaceuticals (Antibiotics, Anti-epileptics and Non-steriodal anti-inflammatory Drugs and Personal Care Product) on terrestrial plants (wheat, rye, lettuce) and soil invertebrates using earthworm as a model organism. It starts with a systematic review of existing literature and published databases on the subject matter. This would be followed by pot experiments and determination of the effects of these chemicals on the test organisms/plants.

In the meantime, preliminary findings following a systematic review of previous publications and ecotoxicological database have revealed that PPCPs may have an inhibitory or lethal effect on the biochemistry, physiology, population and yield of plants, soil microbiota, soil invertebrates as well as disrupting the ecosystem service delivery. Several gaps were identified in the on-going systematic review such as missing data on the effect of metabolites, chemical cocktails or transformation products of PPCPs in soils and a need to elucidate microbiotic functions and their significant effects on the terrestrial ecosystem. As this project is still ongoing, the results will be revealed at the completion of the study. An ecosystem service assessment will be also conducted based on the result gotten from the study.

3.13.P-We136 Ecotoxicological Impact of Gentamicin, Streptomycin and Ampicillin on Soil and Water Bioindicators

Guillermo Lorca[1], ***M Rosa Pino*[1]**, *Natalia Ferrando Lázaro[1], Cristina Gan-Oria[1], Antonio Valenzuela[1], Elisa Langa[2] and Diego Ballestero[1], (1)Universidad San Jorge, Spain, (2)San Jorge University, Spain*

Antibiotics are a group of pharmaceuticals in widespread use worldwide. In recent decades, their detection in aquatic and terrestrial environments has generated the need to know their impacts on non-target organisms in these habitats. There are still many antibiotics whose impact on key terrestrial and aquatic organisms is unknown, so more research is needed to complete this knowledge and obtain conclusive results.

Three widely consumed antibiotics detected in water bodies and soils were chosen in this study: gentamicin, streptomycin, and ampicillin. To assess ecotoxicological effects, three key non-target organisms were analyzed over a wide range of concentrations: *Daphnia magna* for aquatic ecosystems, *Eisenia foetida* for terrestrial ecosystems, and *Allium cepa* for plant toxicity.
In the case of *D. magna*, the concentrations tested varied according to the sensitivity of the antibiotic to the organism. The LC_{50} (24 hours) value was the lowest for streptomycin 772.368 µg/mL, somewhat higher for gentamicin (LC_{50}=840.751) and high for ampicillin (LC_{50}=4324.134 µg/mL).
For *E. foetida*, tested concentrations were 0,1, 1, 10, 100 and 1000 mg/kg. No toxicity effects were observed even at the highest concentration.
For *A. cepa*, tested concentrations were 0,3, 3, 30, 300 and 3000 µg/mL. For gentamicin and streptomycin, LC_{50} values were 42.567 and 535,318 µg/mL, respectively. No toxicity was detected in the case of ampicillin.
Our results suggest that acute toxicity effects in the environment are unlikely, as it is difficult to reach concentrations that show toxicity in selected non-target organisms. However, the effects of long-term exposure to these drugs, as well as their synergies with other emerging contaminants also present in the environment, need further investigation.

3.13.P-We137 Changes in Soil Microbiome and Plant Metabolome Caused by Swine Wastewater Irrigation
*Wei-Ni Lyu[1], Sih-Yi Yu[2], Mong-Hsun Tsai[1], Shu-Yen Liu[2], Sheng-Chi Lin[3] and **Wen-Ling Chen**[2], (1)Institute of Biotechnology, National Taiwan University, Taiwan, (2)Institute of Food Safety and Health, National Taiwan University, Taiwan, (3)Hydrotech Research Institute, National Taiwan University, Taiwan*
The environmental and agricultural impact of livestock wastewater irrigation has not been concluded. This study investigated the changes in soil microbiome caused by swine wastewater irrigation and the effects on crops.
Pak choi was planted in three farm areas, each irrigated with groundwater (GW group), a reasonable amount of swine wastewater (RS group), and an excessive amount of swine wastewater (ES group). Topsoil and pak choi were sampled in each group (both n = 54). Homogenised soil samples were processed with Bacterial DNA isolation and purification and sequenced with 300 bp paired-end reads. The metagenomic analysis was carried out using QIIME2 pipeline. Univariate analyses and permutational multivariate analysis of variance were used to compare the differences among groups. Linear discriminant analysis Effect Size (LEfSe) was used to find microbial biomarkers. The metabolites in soil and pak choi were acquired by high-resolution mass spectrometry (HRMS) and analysed chemometrically. Partial least squares discriminant analysis (PLS-DA) was employed to compare the metabolite profiles among irrigation groups. The metabolites with higher scores of variable importance in projection were identified.
Irrigation with swine wastewater impacted the bacterial structure of the soil microbiome, resulting in the elevation of certain bacteria. Beta diversity showed that bacterial compositions in the RS and ES groups differed significantly from the GW (all pairwise $p < 0.01$). Compared to the GW, *Luteimonas arsenica,* an arsenic-tolerant bacterium, was enriched in the RS. In addition, *Novosphingobium arabidopsis* and *Chlorella sorokiniana*, both resistant to chemical contaminants, were abundant in the ES. These bacteria were found to survive under high nutrient salt and pharmaceutical contamination provided by wastewater. The metabolites in soil and pak choi differed among irrigation groups. Antibiotic substances, lincomycin, tiamulin, and 1-deoxynojirimycin, increased with the amount of swine wastewater, which may explain the microbiome findings in the soil. Significantly negative correlations ($p < 0.05$) were observed between the amount of swine wastewater and the abundance of cysteinyl-valyl-leucine and 7-methylguanine in pak choi.
This study discovered the microbiome shift in the soil irrigated with swine wastewater, likely resulting from the input of nutrients and antibiotics. The functions of microbial biomarkers on crop metabolism will be elucidated.

3.13.P-We138 Resistance of Cyanobacterium *Microcystis aeruginosa* to Diclofenac Measured by Various Markers
***Magda Caban**[1], Martyna Zalewska[2], Anna Aksmann[2], Justyna Kobos[3], Hanna Mazur-Marzec[3], Katarzyna Bethke[1] and Klaudia Kropidłowska[4], (1)University of Gdansk, Poland, (2)Faculty of Biology, University Gdański, Poland, (3)University Gdański, Poland, (4)Chemistry, University of Gdansk, Poland*
Microcystis aeruginosa is one the of unicellular cyanobacteria used in the ecotoxicology tests. It is cosmopolitan species with high adaptation abilities. The natural water contain the pollutants, which can cause the toxic effect to cyanobacteria and change in phytoplankton structure. The pharmaceuticals are among other new emerging pollutants. The ecotoxicology tests are often performed using green algae, but having in mind the increasing problem with blooms, there is a need to perform risk assessment of pharmaceutical using cyanobacteria. The diclofenac (DCF) is one the priority pharmaceuticals with proven high stability in waters and negative impact on organisms. Furthermore, the presence of DCF was noted in waters around world. In this study we aimed to check how the DCF impact *M. aeruginosa* biology. The research was scheduled to test the several biomarkers and physiological markers. The basis of the ecotoxicological test was the OECD 201 protocol with modification. The DCF concentration was 100 mg/L. The flow cytometry, the spectrophotometry and HPLC-DAD techniques were adapted. At the end of test other markers were tested: chlorophyll a fluorescence, pigments (carotenoids and chlorophyls, phicobilins), peptides and toxins (in buffer extract of cells, quantification by LC-MS). Stability of DCF in test conditions was proven by the HPLC-DAD quantification. The main metabolites of DCF were not noted in water. The growing of the *M. aeruginosa* was not impacted by the DCF, thereby can be stated that this pharmaceutical is not toxic for tested cyanobacteria. Generally, the stable DCF concentration in water mean that the penetration of this chemical into cell is limited. The main lipophilic pigments (carotenoids and chlorophylls) and the microcystins production was not changed by DCF. At the start of experiment (first hours) the photosynthetic processes was altered, but cyanobacteria acclimated to new conditions. Research show the *M. aeruginosa* resistance to the DCF toxic effects, most probably due to repulsion of the negatively charged cell of cyanobacteria and anion of DCF. This make this cyanobacterium win the interspecies competition in the environment impacted by DCF.

3.13.P-We139 Chronic Exposure to Diclofenac Produces Reproductive and Biochemical Effects on the Cladoceran *Daphnia curvirostris*

*Miriam Hernández Zamora[1], Laura Martínez-Jerónimo[2] and **Fernando Martínez-Jerónimo**[1], (1)Instituto Politécnico Nacional Escuela Nacional de Ciencias Biológicas, Mexico, (2)Escuela Nacional de Ciencias Biológicas-IPN, Mexico*

Diclofenac is a non-steroidal anti-inflammatory drug reported in waterbodies in concentrations ranging from ng L^{-1} to µg L^{-1}. Diclofenac is discharged in domestic and hospital wastewaters and persists in effluents after conventional wastewater treatments, causing toxic effects in aquatic biota in polluted environments. In particular, the zooplankton community can be affected by polluting pharmaceuticals even at low concentrations. In this study, we quantified the chronic effects of diclofenac on the reproduction and metabolic biomarkers (proteins, lipids, and carbohydrates) of the cladoceran *Daphnia curvirostris*. The acute toxicity (48 h) of diclofenac was determined. In the chronic studies, *D. curvirostris* was exposed to the sub-lethal diclofenac concentrations corresponding to LC_1, LC_5, LC_{10}, and LC_{20} (10.3, 14.4, 17.2 and 21.3 mg L^{-1}, respectively), during 21 d at 25°C, 16:08 photoperiod, feeding with $8x10^5$ cells mL^{-1} of the green microalgae *Pseudokirchneriella subcapitata*. Survival, accumulated progeny, and the number of clutches were quantified daily, and the proteins, carbohydrates, and lipids were determined at the end of the bioassays. The determined LC_{50} for diclofenac was 32.29 mg L^{-1} (limits 25.58 to 38.32 mg L^{-1}). The chronic assays indicated that accumulated progeny was significantly reduced in all concentrations of diclofenac; however, age to first reproduction significantly increased in all the concentrations of the drug compared with the control. The number of clutches was significantly affected at concentrations of 10.3, 14.4, and 21.3 mg L^{-1} of diclofenac. The neonates of *D. curvirostris* had increased protein content, but carbohydrates and lipids were significantly decreased in all concentrations of diclofenac; nevertheless, in the highest concentration of diclofenac, all the biomarkers content decreased significantly. The results indicated that diclofenac causes damage in *D. curvirostris*, warning about the toxic effects of pharmaceuticals on the aquatic biota.

3.13.P-We140 How Diclofenac Affects the Early Life Stages of *Danio rerio*

*Miriam Hernández Zamora[1], Laura Martínez-Jerónimo[2] and **Fernando Martínez-Jerónimo**[1], (1)Instituto Politécnico Nacional Escuela Nacional de Ciencias Biológicas, Mexico, (2)Escuela Nacional de Ciencias Biológicas-IPN, Mexico*

The presence of pharmaceutical products in the aquatic environment has become a global issue of increasing environmental concern. Diclofenac is a non-steroidal anti-inflammatory drug used worldwide in human and veterinary medicine and has an estimated production of 940 tons per year; for this reason, it was identified as one of the most important pharmaceutical active compounds detected in aquatic environments in various countries. This study aimed to evaluate the effects of diclofenac on the early life stages of the zebrafish *Danio rerio*. Fish embryos were exposed to concentrations of 1, 2, 4, 6, 8 and 10 mg L^{-1} of diclofenac following the protocol proposed by OECD Guideline 236 to evaluate toxic effects. Toxic effects were determined during 7 d at 25°C, 16:08 photoperiod. Effects on the early life stages were assessed daily up to 144 h post-fertilization. Lethal endpoints assessed were coagulation, no tail detachment, no somite formation, and no heartbeat. Sublethal endpoints to assess the effects of diclofenac on embryos included the presence of edema and curved tail. Results show that LC_{50} for diclofenac on embryos of *D. rerio* was 6.27 mg L^{-1} (limits 4.72 to 7.91 mg L^{-1}). The hatching rate of zebrafish embryos decreased by 40, 51.6, and 80% at concentrations of 6, 8, and 10 mg L^{-1} of diclofenac, respectively. Exposure to this drug produced lethal effects, such as coagulation, from 24 to 72 hpf. Sublethal effects such as edema and curved tailed were observed at all tested concentrations from 48 to 144 hpf, and the effects increased as the concentration of diclofenac increased. The obtained results indicated that diclofenac could be an environmentally toxic compound with the potential to provoke lethal and sublethal effects in the early life stages of *D. rerio*, so it is essential to establish safe levels of this kind of drug in the aquatic environment.

3.13.P-We141 Toxic Effects of Diclofenac on the Green Microalgae *Scenedesmus quadricauda*

*Laura Cruz-Castillo, Miriam Hernández Zamora and **Fernando Martínez-Jerónimo**, Instituto Politécnico Nacional Escuela Nacional de Ciencias Biológicas, Mexico*

Worldwide 940 tons of diclofenac are produced and consumed each year. The presence of this pharmaceutical in waterbodies is a risk for the plankton community. Moreover, when the microalgae are affected, significant effects could be expected in all the trophic structures in aquatic ecosystems. This study aimed to evaluate the effect of diclofenac on population growth in the concentration of photosynthetic pigments and in the main biomolecule composition in *Scenedesmus quadricauda*. Bioassays were performed starting with 50,000 cells mL^{-1} in PCG medium, with 0.01, 0.1, 1, 10, and 100 mg L^{-1} diclofenac, incubating with constant aeration and continuous illumination at 25°C for 96 hours. The population growth of *S. quadricauda* was not significantly modified at any concentration of the pharmaceutical. However, an increased frequency in atypical cells was observed as the concentration of diclofenac increased. The concentration of chlorophylls *a* and *b* for the microalgae exposed to diclofenac was similar to that assessed in the control. Nonetheless, carotenoid content decreased significantly in all concentrations of diclofenac. The protein concentration in the microalgae increased by 271, 338 and 339 %, respectively, for the drug concentrations of 1, 10, and 100 mg L^{-1}, while carbohydrates increased by 204 and 207% with 10 and 100 mg L^{-1} of diclofenac. The lipids concentration was significantly reduced at all diclofenac concentrations compared with the control. Although the population growth was not reduced for diclofenac, the algae were affected in their morphology and the main macromolecule content, modifying their composition that could affect the development of filter-feeding zooplankton in waterbodies. The results confirm the vulnerability of primary producers to pharmaceuticals such as diclofenac and allow us to conclude that its discharge to aquatic ecosystems must be regulated to avoid ecological impacts.

3.13.P-We142 Effects of Naproxen, Ibuprofen, and Diclofenac on Cyanobacterium Synechocystis Salina with Relation to Salinity of Medium

Klaudia Kropidłowska[1]*, Katarzyna Bethke*[2] *and Magda Caban*[2]*, (1)Chemistry, University of Gdansk, Poland, (2)University of Gdansk, Poland*
Cyanobacteria of the species *Synechocystis salina* are very widespread, living in different types of water bodies. The *S. salina* studied in this work was isolated from the Baltic Sea, which is heavily polluted by pharmaceuticals, among other pollutants. Pharmaceuticals are designated as emerging contaminants and their impact on the environment can be significant even at relatively low concentrations. The bioavailability of pharmaceuticals in salt water can differ from that in fresh water. Studies available in the literature indicate that microalgae can remove pharmaceuticals from water. However, most studies on the subject focus on green algae, and there are few papers on cyanobacteria. Cyanobacteria are mixotrophic organisms, so they can obtaining energy through photosynthesis, but also from chemosynthesis, theoretically taking pharmaceuticals residues as source of organic carbon. Therefore, the aim of the present study was to investigate the effects of several frequently used pharmaceuticals from the group of non-steroidal anti-inflammatory drugs - NSAIDs, i.e.: naproxen (NPX), ibuprofen (IBF) and diclofenac (DCF) on *S. salina* and the effect of salinity on the toxicity of the tested NSAIDs. In order to meet the growing problems of pharmaceutical contamination in water, another objective of this study was to investigate the potential of *S. salina* to degrade selected NSAIDs. In order to carry out this research, 96-h tests were conducted in which cyanobacteria were exposed to NSAIDs at concentrations of 0.1 - 100 mg L^{-1}, in basal culture medium and in medium with addition of sea salt (35‰). The study showed that IBF, NPX and DCF did not affect the growth of *S. salina*. In contrast, high salinity inhibited the growth of *S. salina*, but after some time the culture adapted. Salinity had no effect on the toxicity of the tested NSAIDs, and the cyanobacteria showed no potential to degrade the tested pharmaceuticals. The cyanobacteria's resistance to selected pharmaceuticals, as well as its inability to degrade them, may be due to the mutual repulsion of NSAID molecules with *S. salina* cells also carrying a negative charge. The high content of inorganic forms of carbon in the culture medium may also reduce the potential for degradation of NSAIDs.

3.13.P-We143 Psychoactive Drugs Alter Behavior in Non-target Species – Coiling Movements as a Sensitive Endpoint For Neurotoxicity In Zebrafish (*Danio rerio*) Embryos

Maria Fischer[1]*, Raoul Wolf*[2] *and Thomas Braunbeck*[3]*, (1)COS, Aquatic Ecology & Toxicology, Germany, (2)Norwegian Geotechnical Institute (NGI), Norway, (3)University of Heidelberg, Germany*
The permanent increase in prescription and consumption rates of pharmaceuticals in our society results in elevated concentrations in open water bodies. These contaminants, including antidepressants, are of special concern, since they are designed to be stable and act already at low doses. Psychoactive drugs interfere with neurotransmitter homeostasis in synaptic clefts and the brain and can, thus, manipulate neurobehavioral patterns. Given the high conservation of binding sites across vertebrate groups, fish are likely to also be affected by unintentional exposure to such psychoactive drugs. Since, at early stages of development, the nervous system is particularly vulnerable to external stressors such as chemicals, early life-stage exposure bears the risk of irreversible adverse effects in later stages of life. This, there is a need for sensitive and robust testing systems in early life-stages of fish to determine potential risk of neurotoxic compounds in non-target species.
As a non-protected vertebrate model, zebrafish embryos have also received increasing attention for testing of behavioral effects within developmental neurotoxicity. Spontaneous coiling of the tail is the earliest detectable motor behavior and can relatively easily be recorded. The purpose of this study was to compare the effects by different antidepressants on coiling activity of zebrafish embryos. Movements were recorded from 21 to 47 hours post fertilization and analyzed with respect to coil duration and frequency. A generalized additive model (GAM) was applied to describe the complex linear and non-linear relationships between coiling behavior and multiple factors including batch, time, light phases, and contaminant concentration. As a major advantage, this approach allows to distinguish between non-treatment related effects (random effects) resulting from natural variation within groups and replicates as well as fixed treatment effects of the chemical concentrations. Thus, time-dependent alterations in behavioral patterns by antidepressants can also be identified within a complex exposure setting characterized by intrinsic high variability.

3.13.P-We144 Physiological and Biochemical Alterations in Zebrafish Exposed to an Antineoplastic Drug

Diana Isabel Oliveira Carneiro[1]*, Daniel Alexandre Bruno*[2]*, Évila Pinheiro Damasceno*[1]*, André Borges*[3]*, Susana Loureiro*[1]*, Roberto Martins*[1] *and Maria D Pavlaki*[4]*, (1)CESAM & Department of Biology, University of Aveiro, Portugal, (2)University of Aveiro, Portugal, (3)University of Aveiro, Department of Biology, Aveiro, Portugal, (4)University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Portugal*
Antineoplastics agents (AAs) are applied in cancer therapy, and they can end up in environmental compartments through the hospital and domestic wastewater. They usually enter the wastewater partially transformed or even unchanged via human excretion. The growing use of AAs is an emerging issue in environmental safety, which represents a problem when regarding Environmental Risk Assessment approaches. They are considered micropollutants and one of the least studied groups of pharmaceuticals being inadequately or not regulated. They are mainly cytotoxic at low concentrations which may pose a threat to aquatic organisms. One of the most used antibiotic agents with antineoplastic properties used in cancer treatment are anthracyclines. Epirubicin (EPI) is a chemotherapeutic agent belonging to the anthracycline drug class that acts by supressing the DNA and RNA synthesis. It is indicated for treating several cancers. Approximately 11% of EPI is excreted unmetabolized via urine within 24 h.
The zebrafish *Danio rerio* is a well-established freshwater model organism that is widely used in both eco- and toxicological assessment of numerous contaminants. Zebrafish is a model which allows the evaluation of different apical and cellular/molecular endpoints (e.g., lethality, developmental, biochemical, and genotoxic alterations, locomotor behaviour) which will help to holistically understand the toxicity induced by a given contaminant. Thus, the present study aimed to assess the physiological and biochemical alterations of Epirubicin HCl (EPI HCl) in *Danio rerio* eggs.

The exposure followed the OECD 236 FET protocol and different endpoints were daily observed and documented during 96 h, such as mortality, hatching success, and malformations (e.g., pericardial oedema, incomplete yolk sac absorption, and tail deformities). Also, biomarkers for neurotoxicity and oxidative-stress and DNA damage (comet assay) were assessed. The behaviour assay occurred at the end of 120 h of exposure to EPI HCl using the Zebrabox (Viewpoint, Lyon, France) to track the locomotory activity of the larvae.
Results from the present study showed physiological, biochemical and genotoxic alterations at concentrations higher than the ones observed in wastewater effluents. Nonetheless, by integrating the endpoints at different levels of biological organization, we can establish adverse pathways and provide sound insight for regulatory proposes.

3.13.P-We145 Prediction of the Joint Toxicity of Anticancer Agents to the Zebrafish *Danio rerio*
Daniel Alexandre Bruno[1]*, Diana Isabel Oliveira Carneiro*[2]*, Évila Pinheiro Damasceno*[2]*, Susana Loureiro*[2] *and Maria D Pavlaki*[3]*, (1)University of Aveiro, Portugal, (2)CESAM & Department of Biology, University of Aveiro, Portugal, (3)University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Portugal*
Pharmaceuticals are considered emerging contaminants and concerns about their environmental impact have been raised in the last decades as they have been detected in the environment. One group of pharmaceuticals commonly found in the environment are the anticancer agents (AAs). AAs are one of the least studied groups with respect to environmental hazard and may present specific risks to aquatic species. Under a real scenario, AAs (as other substances) do not exist alone in the environment but rather in mixtures with other AAs and/or chemical substances simultaneously. It is thus of urgent need to assess the effects of eventual mixture exposures to non-target aquatic species.
Aiming at understanding the potential hazard of AAs mixtures, the single and joint effects of three AAs (the alkaloid Trabectedin, the anthracycline Doxorubicin and the platinum-based agent Oxaliplatin) were evaluated in zebrafish embryos using the OECD 236 Fish Embryo Acute Toxicity (FET) Test Briefly, fertilized eggs were exposed initially to a series of concentrations of each AA for 96h. Once the LC_{50} values were determined for each AA, they were transformed into Toxic Units (TU) and a full factorial design was used to predict their joint toxicity pattern. Additionally, the comet assay was performed using no-effect concentrations in order to evaluate DNA damage after 96h of exposure of embryos to the compounds. Embryos were exposed during 96h to a series of combinations of the three AAs (Trabectedin+Doxorubicin, Trabectedin+Oxaliplatin, and Doxorubicin+Oxaliplatin) along with control treatments. The MIXTOX model was used to predict their joint toxicity using as starting point the reference models for Concentration Addition and Independent Action.
The single acute toxicity tests showed that trabectedin, doxorubicin and oxaliplatin caused mortality and several malformations in zebrafish embryos/larvae, such as pericardial edema, yolk sac absorption and tail deformities, with values ranging from µg/L to mg/L. DNA damage was also promoted to larvae exposed to all three AAs after 96h at concentrations where no apical effects were observed. Preliminary results of the mixture exposure indicate interaction between the tested AAs.

3.13.P-We146 Isoxazoline Parasiticides: Should We Worry About Their Environmental Impact?
Philippe Berny[1]*, Dalil Belhadj*[2]*, Bernadette Espana*[2]*, Julie Auré*[2]*, Julia Cado*[2] *and Alexis Lecu*[3]*, (1)VETAGRO-SUP, France, (2)Vetagro-Sup, (3)MNHN, France*
Isoxazoline ectoparasiticides are a novel class of veterinary drugs. They are currently widely used thanks to their properties (broad spectrum, prolonged action, simple use).
Currently, these drugs are approved for use in dogs and cats but also used in poultry. Pharmacokinetic parameters indicate that these compounds are eliminated primarily in feces (90%) and have long half-lives in animals (5-13 days). I northerly carnivore species such as wild carnivores in captivity, external parasites can have deleterious effects and carry other pathogens. Therefore, zoo veterinarians are interested in using these effective and safe drugs. The purpose of our study was to determine some PK parameters in wild carnivore species (by means of fecal elimination) as well as in companion animals and to evaluate species differences as well as difference Émond the 4 different isoxazoline ectoparasiticides.
Our results indicate that some species like lions or mountain lions can eliminate significant residues of fluralaner in their feces for up to three months. Data regarding dogs and cats are still being analyzed.
Using published information on the susceptibility of insects, we conclude that dung beetle feeding on contaminated feces may be exposed to high (and potentially lethal) concentrations of isoxazoline ectoparasiticides for several weeks.
We suggest that Environmental Risk Assessment should be performed for these drugs, even though they are only used in companion animals and that the development of scorifier scenarios could help cover this approach. In the meantime, it is strongly recommended to pet owners to collect their animals' feces and eliminate them in the garbage, especially if wastes are incinerated, to avoid any environmental diffusion of these compounds.

3.13.P-We147 Overview on the Diversity of Ectoparasiticidal Veterinary Medicines Authorised for Cats and Dogs in the EU/EEA and the Related Insecticidal and Acaricidal Active Substances
Haru Kroneis[1]*, Benoit Courty*[2]*, John Jensen*[3]*, Boris Kolar*[4]*, Ludek Blaha*[5]*, Rene van Herwijnen*[6] *and Ricardo Carapeto-García*[7]*, (1)Austrian Medicines and Medical Devices Agency (AGES MEA), Austria, (2)French Agency for Veterinary Medicinal Products (ANMV), Fougères, France, (3)Department of Ecoscience, Aarhus University, Denmark, (4)National Laboratory of Health, Environment and Food, Slovenia, (5)RECETOX, RECETOX, Masaryk University, Czech Republic, (6)National Institute for Public Health and the Environment (RIVM), Netherlands, (7)Veterinary Medicines Department, Agencia Española De Medicamentos Y Productos Sanitarios (AEMPS), Spain*
Current research on the presence of ectoparasiticidal active substances used in veterinary medicinal products (VMPs) for companion animals in the environment predominantly focuses on the two active substances fipronil and imidacloprid. The actual

range of substances authorised in such VMPs, however, is much broader. The exposure pathways of these substances into the environment and their environmental concentrations are strongly determined by characteristics of the medicinal products such as the posology, the method of administration (e.g. spot-on, collar, tablet, spray, injection) as well as the mode of action (systemically or locally acting). Knowledge on the additional uses of some active substances for instance as biocide or pesticide ("multi-use substances") represents a hurdle in the interpretation of environmental concentrations. Such details are usually difficult to access for environmental researchers.
To provide an overview on the available knowledge on the types of ectoparasiticidal VMPs currently authorised for cats and dogs in the EU/EEA and on the specific active substances that are included in these products, a survey was carried out in 2021 among the Member States to retrieve information on these products from databases of the national competent authorities. Together with information from further databases on VMPs currently authorised via national, decentralised and centralised procedures, a dataset of more than 1200 ectoparasiticidal VMPs was obtained and evaluated. The evaluation showed that about 40 different ectoparasiticidal and endectocidal active substances are included in VMPs authorised for cats and dogs in the EU/EEA. In addition, a rough estimate of the extent of their use across the Member States, as well as information on the approval status of these active substances within the EU biocidal and pesticidal legal frameworks are given.
This overview provides environmental researches, regulators, and managers with a knowledge base on ectoparasiticidal medicinal products currently authorised in the EU/EEA for cats and dogs and their active substances. It also provides a status quo of these substances' uses in the different regulatory frameworks, which is essential for exposure modelling and interpretation of environmental concentrations and for planning future studies.

3.13.P-We148 Imidacloprid in SWTP and Watercourses in Spain: Are Veterinary Medicines a Significant Source of Emission?

*Irene de la Casa-Resino[1], Julia Villegas Grondona[2], Alejandra Puig Infante[2], Amparo Haro Castuera[1], Arancha Bartolomé Rodríguez[3], Eva Mª Herrera Hernández[3], Cintia Flores Rubio[3], Josep Caixach[3] and **Ricardo Carapeto-García**[4], (1)Spanish Agency of Medicines and Medical Devices, Spain, (2)Ministry for the Ecological Transition, Spain, (3)Institute of Environmental Diagnosis and Water Studies, IDAEA-CSIC, Spain, (4)Veterinary Medicines Department, Agencia Española De Medicamentos Y Productos Sanitarios (AEMPS), Spain*

Imidacloprid is a commonly used neonicotinoid insecticide that has been authorised as plant protection product (PPP), as biocide (BP) and as Veterinary Medicinal Product (VMP). However, strict regulations have been established in the European Union (EU) during the last two decades to control the concentration levels of imidacloprid (among other water contaminants) in the water environment. In Spain, monitoring of imidacloprid by following the indications reflected in the Water Framework Directive (WFD) have been performed since 2018 and have been extended until (at least) 2021. Within this framework, samples in Sewage Water Treatment Plants (SWTP) and watercourses were taken.
The main aim of this work is to summarize the results obtained from the monitoring of imidacloprid in Spain during the years 2018 and 2019. Furthermore, a reflection of the possible sources of emission of imidacloprid residues is performed.
Quantifiable levels of imidacloprid, that might suppose a risk for the aquatic environment, were detected in almost all SWTP and watercourses sampled in Spain in 2018 and 2019. Further water samples have been taken during the years 2020 and 2021 although the results are not available yet. It seems that PPP and VMPs might be the main sources of imidacloprid to the aquatic environment. However, as the uses of imidacloprid as PPP are no longer authorised, special attention should be paid to the residues detected in the following years to obtain a more reliable conclusion on which could be the main imidacloprid sources.

3.13.P-We149 Fur Used in Nest Building by Birds Potentially Contributes to Pesticide Exposure

***Cannelle Tassin de Montaigu**[1], Dave Goulson[2] and Gaetan Glauser[3], (1)University of Sussex, United Kingdom, (2)School of Life Sciences, University of Sussex, United Kingdom, (3)University of Neuchatel, Switzerland*

The fate and environmental impact of insecticides used as ectoparasitic treatment for companion animals is obscure. It has long been assumed that veterinary medicinal products used in pets are likely to be associated with fewer environmental concerns than those in food producing animals. However, there are an estimated 9.9 million dogs and 10.9 million cats in the UK alone (PDSA, 2019), and approximately 80% of dogs and 82% of cats are treated for fleas. Many cat and dog flea treatments contain either fipronil or imidacloprid, which have been banned from agricultural use since 2017 and 2018 respectively. Treatment is conducted as often as monthly and will remain on fur for a long period of time as they are mainly applied topically in the form of shampoos, spot-on, sprays, dips, foams, collars or even powders. We collected fur from the nest lining of 103 nests from blue tit (*Cyanistes caeruleus*) and great tit (*Parus major*) collected by volunteers both from rural (62% of nests) and urban (38%) habitat. Using Liquid Chromatography Mass Spectrometry methods, we screened the nests for 24 different pesticide compounds. Eighteen pesticides were detected, with the number of compounds found per nest ranging from 2 to 12. The insecticides fipronil, imidacloprid and permethrin were detected in 100%, 88.3% and 87.3% of samples, respectively. Across nest samples, the mean concentrations were: fipronil (115 ppb), imidacloprid (360 ppb) and permethrin (208 ppb). Additionally, the highest concentration found was for dinotefuran, in the single sample where it was detected, at 7,198 part per billion (ppb). We found that the concentration of clothianidin, imidacloprid, thiacloprid, and fipronil was positively linked to either chick survival and/or egg hatching rate, while permethrin and cypermethrin were negatively correlated. These findings suggest that dermal contamination and ingestion through preening behaviour from the nestlings could be a route of exposure. We argue for a re-evaluation of the environmental risk associated with dermal exposure of chicks to commonly used pesticides and parasiticides.

3.13.P-We150 Pet Dogs Transfer Veterinary Medicines to the Environment

*Noël Diepens[1], Dick Belgers[2], Laura Buijse[2] and **Ivo Roessink**[3], (1)Dept of Aquatic Ecology and Water Quality Management,*

Wageningen University & Research, Netherlands, (2)Team Environmental Risk Assessment, Wageningen Environmental Research (WUR), Netherlands, (3)Wageningen Environmental Research (WUR), Netherlands
Worldwide, the number of pet dogs increases yearly, and as a result so does the use of veterinary medicines for flea and tick control. We investigated the potential transfer of veterinary flea products from dogs to the environment in a 'proof of principle' experiment. For this purpose, samples of hair, urine, and water after swimming were investigated. Nine dogs were recruited for this study, eight of which had been recently treated with an ectoparasiticide product. Hair and urine samples were tested for afoxalaner, fluralaner, fipronil and imidacloprid. Interestingly, contamination with ectoparasiticides was frequently demonstrated in samples from dogs untreated with these particular substances, suggesting widespread secondary transfer.
In addition, hair retrieved from a bird's nest contained fipronil, fluralaner and imidacloprid, indicating a potential pathway for the exposure of juvenile birds. Three of the dogs also participated in a swimming experiment. One had been treated with oral fluralaner, whilst the remaining two had received other compounds not included in our study. However, in all three dogs, both fluralaner and imidacloprid were detected in hair samples. Fluralaner concentrations in the swimming water exceeded Dutch water quality standards, indicating a potential risk to the aquatic environment. Imidacloprid levels increased after each swimming dog but did not breach Dutch water quality standard levels. These findings all call for improvements in the current risk assessment and management for veterinary medicines, by including companion animals and their exposure pathways into ecosystems.

3.13.P-We151 The Consequences of Misinformation: Acute Effects of a Mixture Between Polystyrene Nanoplastic and Ivermectin on Invertebrates and Green Algae

***Vitor Pereira Vaz**[1], Philippe Juneau[2], Maria Elisa Magri[3], William Gerson Mathias[3] and David Dewez[4], (1)Sciences de l'Environnement, University of Quebec at Montréal, Canada, (2)Department of environmental Sciences, University of Québec à Montréal, Canada, (3)Departamento de Engenharia Sanitária e Ambiental, Universidade Federal de Santa Catarina, Brazil, (4)Departement de Chimie, University of Québec à Montréal, Canada*
Environmental pollution is becoming increasingly complex due to the number of compounds being discharged into the water bodies. Rivers will carry plastic and chemical pollution toward the ocean or lakes making plastic a pollutant that is considered ubiquitous in the environment even in regions without human occupation. In the environment species are concomitantly exposed to several chemicals such as medicines and plastics. Among the most used veterinary antiparasitic drugs is ivermectin (IVM), which has seen a surge in consumption due to its supposed effect on avoiding COVID-19 infections but has already been proven false. IVM is mostly excreted through feces, it can be present in the environment in concentrations that pose a risk to the biota. *Daphnia magna* is known for its sensibility to IVM, while the effects on algae are yet unknown. This work aims to help bridge the gap between laboratory and environmental conditions by testing the mixture between polystyrene nanoplastics (PSNP) and IVM. Both compounds are hydrophobic thus indicating a possible chemical interaction, that could alter the effect of the mixture. Acute toxicity tests were performed with Daphnia magna, following OECD 202 resulting in an EC50 of 126.4 ± 17.4 mg/L for the PSNP and 7.63 ± 17.4 ng/L for the IVM. While the algae growth inhibition was performed following the *Chlorella vulgaris*, *Raphidocelis subcapitata*, and *Chlamydomonas reinhardtii*. Their mixture was evaluated following the Abbott method to indicate whether the mixture was synergetic or antagonistic. A brief risk assessment of the mixture was also performed. The results from this evaluation can help regulatory bodies understand if their water quality standards are being too permissive by not including these emerging contaminants in their legislations. When including contaminants such as IVM, will help them verify if the established concentration is safe enough given the mixture scenario in the environment.

3.13.P-We152 Biological Effects of Simultaneous and Separated Exposure of Mussels to Citalopram/Bezafibrate and Polyethylene Microplastics in Seawater

***María del Mar García Pimentel**[1], Juan Antonio Campillo[1], Juliana Valdés[1], Jose Maria Castano-Ortiz[2], Sara Rodriguez-Mozaz[2], Marica Mezzelani[3], Stefania Gorbi[4], Michela Panni[4], Francesco Regoli[4] and Victor M. León[1], (1)Instituto Espanol de Oceanografía (IEO-CSIC), Spain, (2)Catalan Institute for Water Research (ICRA), Spain, (3)Università Politecnica delle Marche, Italy, (4)Polytechnic University of Marche (UNIVPM), Italy*
Pharmaceutical active compounds (PhACs) have been detected in the different marine environmental compartments and their occurrence in marine organisms raises concerns regarding toxic effects. Similarly, it is still little known the role of microplastics (MPs) as pollutant vectors in the marine environment, particularly for contaminants of emerging concern such as PhACs. MPs can sorb pollutants in their surface, including PhACs, so MPs could modulate the bioavailability of PhACs for aquatic organisms, impacting their associated effects. Mussels have been proposed as model organism in ecotoxicology studies, representing suitable bioindicators for environmental monitoring and toxicity test. In this study, the aim was to evaluate the effects of polyethylene MPs and selected PhACs, considering separated exposures of mussels (*Mytilus galloprovincialis*) to the antidepressant citalopram (CIT), the lipid regulator bezafibrate (BEZ), and polyethylene microplastics (MPs 4-6 µm (PE)), and the corresponding PE-PhAC mixtures, besides a control without contaminants. Individuals were sampled twice during exposure (10 and 21 days), and after depuration (28 days), to obtain the digestive glands and gills tissues for biomarker analyses. Mussel's gills were used for oxidative stress analysis (lipid peroxidation, acetyl cholinesterase, glutathione peroxidase, glutathione S-transferase and catalase activity. The analyses carried out in mussel gills showed results with greater sensitivity than those obtained in the digestive glands. Mussels accumulated PhACs over the experiment, with higher concentrations of CIT than BEZ, maintaining relatively constant levels during the exposure period (mean: 763 ng/g dw for CIT and 2 ng/g dw for BEZ). In the depuration period, a partial release of CIT, previously accumulated in the organisms, was observed in seawater and mussel tissue. The results suggest that PhACs can be significantly accumulated in mussels, especially CIT, and that they can be removed from organisms when the exposure to the PhACs ceases. On the other hand, it was observed in a first period of 10 days, the mussels increased their antioxidant activity in those treatments with PhACs, appearing increases in cell damage at 21 days exposure. After the exposure

to environmentally representative concentrations, it can be observed how the treatments that have contained MPs tend to have higher levels of cell damage than those that have PhACs dissolved.

3.13.P-We153 Bioaccumulation and Biological Effects of Triclosan, Polyethylene, and Polystyrene Microplastics on Mussels (*Mytilus galloprovincialis*) in Seawater

María del Mar García Pimentel, *Juliana Valdés, Beatriz Fernández-Galindo, Concepción Martínez-Gómez, Tatiana Oporto, Juan Antonio Campillo, Marina Albentosa and Victor M. León, Instituto Espanol de Oceanografía (IEO-CSIC), Spain*

Personal care products have been detected in the different marine environmental compartments and their occurrence in marine organisms raises concerns regarding toxic effects. Triclosan (TCS) is an antibacterial agent widely present in consumer products. TCS has a highly hydrophobic nature with high log Kow value as 4.76, that it is likely to be sorb in sediments and other particles present in the surrounding environment, such as microplastics (MPs). MPs can sorb pollutants on their surface, impacting their bioavailability and associated effects. The bioaccumulation and the adverse effects caused by the separate and co-exposure of microplastics (PE and PS) and TCS on mussels (*Mytilus galloprovincialis*) in seawater were evaluated. An initial period of exposure (3 days) of mussels to high concentrations of TCS was applied, followed by 10 days of low environmental realistic concentrations and 7 days of depuration period to assess their resilience capacity. Bioaccumulation in soft tissues was determined using QuEChERs extraction followed by stir bar sorptive extraction coupled to gas chromatography with mass spectrometry. Oxidative stress and neurotoxicity (acetylcholinesterase, lipid peroxidation, catalase activity, glutathione-S-transferase and glutathione reductase) were analyzed in gills. Total Oxidant Scavegning Capacity Assay (TOSCA) toward peroxyl and hydroxyl radicals using gas-chromatographic were analyzed in digestive gland. The accumulation of MPs in the digestive gland of the organisms was also analyzed. The results obtained showed similar bioaccumulation of TCS in mussels at the highest concentrations of exposure with and without MPs, producing an oxidative stress response on mussel tissues. The concentration of TCS was reduced in all cases when the exposure concentration decreased, specially after the depuration period, but the contaminant was still detectable. The detection of methyl-TCS, an anaerobic degradation intermediate of TCS, in mussel tissues was also relevant.

3.13.P-We154 Biological Responses in Digestive Gland of Mussels (*Mytilus galloprovincialis*) Exposed to Citalopram/Bezafibrate and Polyethylene Microplastics in Seawater

María del Mar García Pimentel[1], *Juan Antonio Campillo*[1], *Victor M. León*[1], *Juliana Valdés*[1], *Jose Maria Castano-Ortiz*[2], *Sara Rodriguez-Mozaz*[2], *Marica Mezzelani*[3], *Michela Panni*[4], *Stefania Gorbi*[4] *and Francesco Regoli*[4], *(1)Instituto Espanol de Oceanografía (IEO-CSIC), Spain, (2)Catalan Institute for Water Research (ICRA), Spain, (3)Università Politecnica delle Marche, Italy, (4)Polytechnic University of Marche (UNIVPM), Italy*

Pharmaceuticals (PhACs) have been detected at low concentrations (ng/L) in the marine environment, particularly in coastal areas and in several compartments, including biota. PhACs are very often found together with other contaminants of emerging concern, such as microplastics (MPs). MPs can sorb pollutants on their surface, impacting their bioavailability and associated effects. Antidepressants and lipid regulators, such as citalopram (CIT) and bezafibrate (BEZ), constitute good examples of relatively bioaccumulative PhAC classes (log $K_{ow} > 3$).The bioaccumulation and the adverse effects caused by the separate and co-exposure of microplastics (PE) and pharmaceuticals (PhACs) on mussels (*Mytilus galloprovincialis*) in seawater were evaluated. Mussels were exposed to polyethylene MPs 4-6 µm (PE), BEZ and CIT, and the corresponding PE-PhAC mixtures, besides a control without contaminants. Individuals were collected at 10 and 21 days followed by a depuration period of 7 days. Mussel's digestive glands were used for oxidative stress analyses: Total Oxidant Scavegning Capacity Assay (TOSCA) toward peroxyl and hydroxyl radicals using gas-chromatographic and *gene* expression analysis (*Cat, Se-GPx, SOD, Acox, GST-pi, abcb1*) using a Real time PCR. The results showed an increase in the *GST-pi* gene expression after 10 days of exposure for different treatments respect to the control, while *Se-GPx* gene expression showed an increasing trend for treatments containing BZ as well as a decreasing trend for TOSCA, in contrast to treatments containing CIT. Thus PE coexposure did not affect to the effects of the PhACs.

3.13.P-We155 Comparison of Environmental Impact of Five Pain-Relief Medicines

Melvin Faber, *Stan de Groot, Erwin Roex, Caroline Moermond and Mark Montforts, National Institute for Public Health and the Environment (RIVM), Netherlands*

In the Netherlands, there is a large market for self-care products, with a yearly revenue of over 800 million euros. A large share of this market consists of pain-relief (analgesic) medicines. Self-care pain-relief medicines like paracetamol and the NSAIDs aspirin, diclofenac, ibuprofen and naproxen of course benefit the user but may also impact the environment. Known negative effects of NSAIDs are tissue damage in aquatic organisms and secondary poisoning. Because of these concerns, diclofenac and ibuprofen are proposed as priority substances within the Water Framework Directive. From various stakeholders in the health care sector questions have been raised whether the impact of pain-relief medicines on the environment differs between compounds and which of these could be chosen if environmental impact is taken into account besides patient benefits and side effects. Therefore the Dutch National Institute of Public Health and the Environment was asked to compare the environmental impact of aspirin, diclofenac, ibuprofen, naproxen and paracetamol. This poster presents the preliminary results of this study, including a risk assessment based on recent monitoring data.

3.13.P-We156 Defining the Data Gap: What Do We Know About the Exposure and Risks of Pharmaceuticals into The European Aquatic Environment?

Francis David Spilsbury[1], *Pedro A. Inostroza*[2], *Patrik Svedberg*[3], *Cristiana Cannata*[4], *Ad M. J. Ragas*[4] *and Thomas Backhaus*[2], *(1)School of Molecular and Life Sciences, Curtin University, Bentley, Australia, (2)University of Gothenburg, Sweden,*

(3)Department of Biological & Environmental Sciences, University of Gothenburg, Sweden, (4)Radboud University Nijmegen, Netherlands
Identifying the potential risks from pharmaceutical residues in the environment is a goal and current strategic direction of environmental management described in the EU Strategic Approach to Pharmaceuticals in the Environment and the Green Deal. This is complicated by a paucity of high-quality monitoring and toxicity data to adequately describe risks posed to the riverine ecosystems by human and veterinary medicines - critical data gaps in the knowledge base needed to inform policy. The European Medicines Agency (EMA) advocates models in its environmental risk assessment (ERA) guidelines to fill data gaps, although the accuracy and efficacy of such methods vary.
In this study we analyze measured environmental concentrations (MECs) at 5933 sites in 25 European countries from EMPODAT and UBA monitoring program data from 1997 to 2020, and experimentally-derived toxicity data from the U.S. EPA ECOTOX database. Although 1764 uniquely identifiable active pharmaceutical ingredients are registered with the EMA for sale in the European Economic Area (EEA), only 312 (17.7%) of these are included in publicly available monitoring data, and only 36 (1.8%) compounds have sufficient ecotoxicological data to perform an EMA-compliant ERA.
Among the 27 compounds with sufficient empirical exposure and hazard data to conduct a single substance risk assessment according to EMA guidelines, four compounds (14.8%) had a median risk quotient (RQ) > 1. Endocrine disruptors have the highest median RQ, with 7.0 and 5.6 for 17a-ethinyl-estradiol and 17b-estradiol respectively. A comparison of modelled exposures vs empirical data for 72 APIs demonstrated the high level of protectiveness of the current EMA guidelines, showing predicted environmental concentrations (PECs) exceeding median MECs in 98.6% of cases, with a 100-fold median increase. A total of 70 (97.2%) of compounds exceeded the 10ng/L PEC threshold for phase 1 EMA risk assessment using *in-silico* methods, compared to 40 (55.6%) using median values from empirical monitoring data.
This study describes and summarizes the data shortfalls hindering an accurate assessment of the risk posed to European waterways by pharmaceuticals, and identifies APIs about which neither their ecotoxicity or occurrence is known. Mandatory, central reporting requirements for monitoring data, and targeted ecotoxicity testing may alleviate the paucity of empirical data available for effective and accurate characterization of API risks.

3.13.P-We157 An Updated Concordance Assessment of Predicted-No-Effect-Concentration (PNECs) Aquatic Toxicity Data for Pharmaceuticals
***Tim Verslycke** and Ifeoluwa Bamgbose, Gradient, Boston*
Environmental safety assessments are required for market approval of new Active Pharmaceutical Ingredients (APIs), however, such assessments are lacking for older drugs. To determine whether existing environmental toxicity data can be used to estimate predicted-no-effect-concentrations (PNECs) for APIs for which effect data is lacking, we analyzed publically available data from 197 APIs and presented our findings at the SETAC 2012 Berlin Meeting (Verslycke T, Mastrocco F, Lemay JC. 2012. poster number TU068).
Here, we present an update to our previous assessment by incorporating new PNECs that have been generated over the last decade and reported into the Swedish National Formulary (FASS.se) database. Following an outlier analysis, the updated dataset was used to evaluate statistical correlations between the PNEC and trophic level (algae, fish, and invertebrate), benchmark type (EC_{50}/NOEC), assessment factor, and Anatomical Therapeutic Chemical (ATC) Classification System group. Based on the findings of the statistical analyses, two potential approaches are presented for developing PNECs for APIs for which no effect data are available along with their strengths and weaknesses.

3.13.P-We158 Do New Generations of Active Pharmaceuticals for Human Use Require an Adaption of the Environmental Risk Assessment? Part II: Case Studies
***Karsten Schlich**[1], Mirco Weil[2], Jasmin Brueckner[3], Kathi Westphal Settele[4], Ute Kühnen[5], Marwin Jafari[1], Bernd Göckener[1], Anja Coors[2] and Elke Eilebrecht[1], (1)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Germany, (2)ECT Oekotoxikologie, Germany, (3)German Environment Agency (UBA), Germany, (4)Pharmaceuticals, German Environment Agency, Germany, (5)Federal Environment Agency Germany*
In 2006, the European Medicines Agency (EMA) adopted a guideline on the environmental risk assessment (ERA) of medicinal products for human use. Since then, a large number of active pharmaceutical ingredients (APIs) with specific Mode-of-Actions (MoAs) that are potentially effective in the aquatic environment in concentrations lower than 0.01 µg/L have been approved. This raised concern that the guideline does not allow a sufficiently protective environmental risk assessment for all of these new and very specific APIs and adaptations might be necessary.
A test strategy proposed after a previously conducted literature research should enable identification of effects specifically related to the MoA of the API and/or effects which occur at concentrations lower than the endpoints derived in the current standard long-term toxicity test set on fish, daphnia and algae. During the literature research, a number of test systems with potentially high sensitivity to these new APIs were identified. These tests included the *Lemna sp*. Growth Inhibition Test (OECD 221), the *Danio rerio* Fish Embryo Test (OECD 236) amended with sublethal endpoints, and the comet assay with environmentally relevant cell types derived from *Daphnia magna* and *D. rerio*.
Following 18 substances of the group oncologicals or cardiologicals and statins were assayed in these tests. The data generated according to the proposed new test strategy was compared to data from European public assessment reports (EPARs) to evaluate the level of protectiveness.
It was observed that the *Lemna sp.* growth inhibition test (OECD 221) is a suitable test system to be integrated into the environmental risk assessment (ERA) of specific classes of human pharmaceuticals (e.g. statins), while the other two short-term test systems (fish embryo toxicity test amended with sub-lethal endpoints and the comet assay) were in none of the cases

examined more sensitive than the currently employed apical endpoints from chronic aquatic toxicity tests (OECD 201, 211, 210) and can at best provide additional information. The test with *Lemna sp.* was more sensitive than the standard endpoints in the EPARs for one substance with a pharmacological MoA relating to the mevalonate pathway and to two tyrosine kinase inhibitors. Thus, the Lemna growth inhibition test might be a relevant additional test for the ERA of at least some APIs.

3.13.P-We159 Establishment of a Novel Public Database and Digital Assessment System (DAS) on Pharmaceuticals in the Environment (PIE) in the EU

Jan Wölz[1]*, Thomas Backhaus*[2]*, Anja Coors*[3]*, Gemma Janer*[4]*, Caroline Moermond*[5]*, Samuel K Maynard*[6]*, Ad M. J. Ragas*[7]*, Susanne Schwonbeck*[8]*, Joan G. Tell*[9] *and Rhys Whomsley*[10]*, (1)Research & Development, Pharmaceuticals, Bayer AG - Crop Science Division, Germany, (2)University of Gothenburg, Sweden, (3)ECT Oekotoxikologie, Germany, (4)Novartis Pharma, Spain, (5)National Institute for Public Health and the Environment (RIVM), Netherlands, (6)Global Sustainability, Astrazeneca UK, United Kingdom, (7)Radboud University Nijmegen, Netherlands, (8)Fraunhofer ITEM - Institute for Toxicology and Experimental Medicine, Hannover, Germany, (9)MSD, (10)European Medicines Agency, Netherlands*

A precondition for data-driven prioritization of active pharmaceutical ingredients (APIs) in the environment (PIE) is the availability and accessibility of relevant and reliable data.

However, today there is no database in the EU that could be used to inform data-driven prioritization or environmental risk assessments (ERA) of APIs. While relevant and reliable environmental data exists for many APIs, as ERAs are formally required as part of the marketing authorization procedure for medicinal products since 2006, these datasets are not consistently made public, findable by stakeholders, or organized in a systematic way. At the same time, there is growing interest from stakeholders to increase accessibility and transparency on available environmental data for APIs. For many of these issues, consolidation of all ERA data at one site would be a solution. It would also allow identification and prioritization of APIs with data gaps.

The public private partnership IMI PREMIER project (www.imi-premier.eu) is a consortium of academia, authorities, SMEs, and pharmaceutical industry partners, which aims to provide a solution and to establish a database on environmental data for APIs in the EU. This database will be provided together with a novel publicly accessible digital assessment system (DAS), which can be used by stakeholders to perform risk assessments for pharmaceuticals.

The database in the DAS will be populated by experimental fate and ecotoxicological data generated for marketing authorization and provided by the EFPIA industry partners in PREMIER. Furthermore, there will be data from other databases and literature. The DAS aims to provide a high level of details on the experimental data. Additional elements such as API identifiers will be provided. There will be tools to search the database, algorithms developed within the PREMIER project to assess and evaluate the data presented, and guidance. Stakeholders shall be enabled to identify and collate all the information they need for their purposes.

Sustainability of the DAS is a key goal in the PREMIER project and the plan is that it will be made accessible and navigable by stakeholders for free. Our ambition is that the DAS will be hosted and maintained beyond the PREMIER project by European authorities.

3.13.P-We160 The ZERDA Database – A Collection of Data from the Environmental Risk Assessment of Pharmaceuticals

Gunther Speichert[1]*, Fabian Reiser*[2]*, Yvonne Lehmann*[2]*, Arne Hein*[1] *and Robert Reiche*[2]*, (1)German Environment Agency, Germany, (2)CONET Solutions, Germany*

Since the mid-2000s, there have been EU-wide legal assessment concepts that allow a detailed and standardized investigation of the behavior and effects of active pharmaceutical ingredients (APIs) used in human and veterinary medicinal products (HMP/VMP) in the environment.

The results of these environmental risk assessments (ERAs) are partly published as endpoints (e.g. the adsorption coefficient normalized to the organic carbon content (K_{oc}), the half-life (DT_{50}), or the no observable effect concentration (NOEC)) in (European) Public Assessment Reports (EPARs/PARs) and are then, in contrast to the marketing authorization documents, in principle publicly accessible.

However, the EPARs/PARs are stored as PDF documents on sub-websites of various institutions and are therefore neither easy to find nor convenient to use. Up to now, no database exists in which all environmental information on APIs from EPARs/PARs is collected centrally.

The aim of this project was to collect all publicly available endpoints from ERAs of HMPs and VMPs marketed in Europe and to compile them in a database in a convenient and comprehensible way.

In the first step, all EPAR/PARs containing these data were compiled. For this purpose, a web crawler written in Python was developed to automatically find and download these reports. The endpoints were then extracted from the collected reports by another Python program and integrated into a database. Afterwards, a two-step quality assurance was performed.

This poster will show the detailed steps to harvest the (E)PAR documents and an overview on the ERA extraction results. Furthermore, we will provide characteristics about the created database. Currently, the database contains endpoints for 463 APIs used in HMPs and 65 APIs used in VMPs. The extent is very heterogenic, from only predicted environmental concentration (PEC) values to comprehensive data for the compartments water and soil. This data collection allows us to assess the quality of EPARs with a view to ERA results and gives an interesting overview on the data availability from APIs marketed in HMP and VMP in Europe.

3.13.P-We161 Extended Environmental Risk Assessment for Sitagliptin

Lisa Ziv[1] *and Joan G. Tell*[2]*, (1)Merck, (2)MSD*

This voluntary extended environmental risk assessment (eERA) considers the active pharmaceutical ingredient, sitagliptin, a

dipeptidyl peptidase 4 inhibitor indicated for treatment of type 2 diabetes mellitus. Sitagliptin was first approved in the United States in 2006 and has since been approved for use throughout most of the world.
The risk of an adverse environmental impact from use of sitagliptin was evaluated according to guidance provided by the United States Food and Drug Administration and by the European Medicines Agency. The results of the assessment concluded that sitagliptin is unlikely to pose a risk to the environment. Based on water solubility and log Kow, sitagliptin is not expected to bioaccumulate and is not considered to be a PBT (persistent, bioaccuumulative, and toxic) compound. PEC/PNEC (predicted environmental concentration/predicted no effect concentration) ratios with respect to water, groundwater, sediment and microorganisms are all less than regulatory thresholds.
This eERa, presented herein, serves to share the available environmental test data compiled to date, while supporting our company's product stewardship commitments to continue to focus on identifying and preventing or minimizing potential safety and environmental hazards throughout the product's life cycle. Based on recently available measured concentration data in the literature, sitagliptin was found in river waters on all continents except Antarctica. However, based upon the low concentrations observed and ongoing expected usage, sitagliptin will continue to be unlikely to pose a risk to the environment.

3.13.P-We162 Diclofenac in Recycled Fertilisers: Screening Risk Assessment Identifies Low Risk but There Are Various Uncertainties and Need for Monitoring
Nele Deleebeeck*, Michiel Claessens and Laura Lefèvre, Arcadis Belgium, Belgium*
The findings presented in this poster resulted from an assessment which was performed in view of a project for the European Commission, Directorate General Environment. In this project, the exposure and risk of contaminants/impurities of potential concern in fertilisers needed to be assessed, to identify contaminants/impurities or fertilisers for which additional regulatory measures may be required. Although various types of pharmaceuticals were considered eligible for risk assessment, diclofenac was the only pharmaceutical for which a case was set up within this project. The focus was on the potential risk from diclofenac in fertilisers based on/containing precipitated P salts derived from sewage sludge, and a screening level risk assessment was performed for the different environmental compartments, secondary poisoning, as well as humans exposed via the environment. Although there are indications of high removal efficiency of diclofenac during P salt precipitation, there is only limited experimental data available. Therefore, as a reasonable worst case, two scenarios with 1 and 10% transfer from sewage sludge to recycled material were included. Risk characterisation ratios (RCRs) were typically < 1 except for soil and secondary poisoning. However, when only considering the addition through the assessed use, RCRs would be below 1. Background concentrations (used as PECregional) were close to or even above the PNEC values for the environmental compartments under consideration and therefore determined the outcome of the assessment rather than the contribution via recycled fertilisers. Source contribution analysis learned that important contributors to emissions of diclofenac to the agricultural environment are likely the use of raw or anaerobically digested sewage sludge and irrigation water. Manure might be an additional source for diclofenac input into the agricultural environment, however, monitoring data were lacking to confirm this. High local/regional differences are expected but could not be assessed in detail. Although low risk was identified in this screening assessment, attention will be drawn to the main sources of uncertainty in this assessment and their potential impact on the outcome of the assessment.

3.13.P-We163 UV-Light Absorbance of Natural Water Regulates the Bioavailability of Ciprofloxacin to Cyanobacteria
Qiyun Zhang, Ph.D. candidate[1]*, Karel De Schamphelaere*[1] *and Kristof Demeestere*[2]*, (1)Ghent University - GhEnToxLab, Belgium, (2)Ghent University, Belgium*
Recently, dissolved organic carbon (DOC) was found to regulate the ecotoxicity of fluoroquinolone antibiotic ciprofloxacin (CIP). Through the various interactions, CIP molecules bound to DOC increase in molecular size and polarity, which inhibits them from traversing the membrane system of aquatic organisms and decreases the observed ecotoxicity of CIP. As the brownification of many freshwater ecosystems is predicted to rise due to climate change, the importance of DOC on the bioavailability of CIP in nature might increase consequently. In this study, we investigated how DOC of different origins affects CIP bioavailability to cyanobacteria using a cyanobacteria toxicity test performed with *Microcystis aeruginosa* PCC7806. The bioavailability was expressed by the ecotoxicity of CIP observed in test media dissolved with different DOC compounds: (1) freshwater DOC in the naturally occurring states, collected from six rivers and lakes in Europe, (2) processed DOC extracted from the river Schwarzbach, and (3) commercial DOC product Suwannee River organic matter. The impact of DOC wasquantified via describing the $CIP^{+/-}$-DOC interaction using a binding constant ($K_{d,CIP}{}^{+/-}$), which was related to the concentration of DOC and the ultraviolet (UV) light absorbance test media at 350 nm (A_{350}). Observations showed that the composition of DOC clearly affected the ecotoxicity of CIP. When around 11 mg L^{-1} different DOC compounds were present, the 50% effect concentration of CIP (EC50) varied by 10-fold, between 1.4 µg $L^{-1}$and 15.2 µg L^{-1}. Thus, DOC concentration alone is not sufficient to predict CIP bioavailability. Rather, the A_{350} of the test media demonstrated a significant positive correlation with the observed EC50, while the absorption coefficient (ε_{350}) correlated significantly with the $K_{,d,CIP}{}^{+/-}$. Our findings suggest that the light absorbance of natural water might be a better predictor for the impact of both processed and unprocessed DOC on CIP bioavailability.

3.13.P-We164 The Transmission Pathway of Multidrug Resistance Genes During Manure Application to Soil
Ewa Korzeniewska*, University of Warmia and Mazury in Olsztyn, Poland*
Antibiotics are growing environmental contaminants leading to public health concern due to enhancing the occurrence of antibiotic resistance genes (ARGs). In the world, antibiotics are frequently used as the growth promoters and commonly as the therapeutic agents in poultry feed. Unfortunately, they are not completely metabolized in the body of chicken and ultimately excreted as poultry droppings. Therefore, usage of droppings as manure in agriculture may result in the promotion of co-occurrence of ARGs in the soil and ultimately leads to their transfer to crops and surface water via groundwater. In the present

study metagenome of poultry and bovine manure, soil and crops (parsley) samples was analysed for multidrug resistance (MDR) genes presence using deep sequencing method. Metagenomic analysis indicated that MDR genes were the most abundant in resistome of all analysed samples: manure, soil, groundwater, crops (parsley root and leaves). The obtained data indicate the transfer of MDR genes to the crops in both: the control (0.12 ppm) and manure-fertilised (0.68 ppm) soil samples. Therefore, the use of poultry and bovine manure as a fertilizer may carries the risk of inducing the spread of ARGs and, at the same time, the resistance phenomenon in agriculture and natural environments. Conducted research stands for another step in enhancing knowledge of possible dissemination pathways of resistant determinants in the agriculture environment.

3.13.V Human and Veterinary Pharmaceuticals in the Environment – Risk, Prioritisation & New Insights

3.13.V-01 Microextraction and Chromatographic Determination of Diazepam and Clonezapam in Wastewater Samples

*Silumko Nzube and **Vernon S Somerset**, Cape Peninsula University of Technology, South Africa*

Pharmaceutical pollutants entering the aquatic environment have become a growing environmental concern. These pharmaceuticals are unique pollutants because of their special characteristics and behaviour that cannot be simulated with other organic pollutants. The untreated wastewater effluent that contains pharmaceuticals poses considerable threat to the aquatic ecosystem because of the negative effects of non-target organisms in the water. Recent years have seen a growing concern about the benzodiazepines, as emerging pollutants, and their effects on the aquatic environment. These compounds are nowadays widely detected in sewage wastewater. It is important to increase the emphasis on the characteristics of the benzodiazepines in order to differentiate them from industrial chemical compounds. In this study various solid phase extraction techniques have been employed focusing on isolation of benzodiazepines in wastewater matrices. Employing this methodology has shown improved detection and analysis of diazepam and clonezapam as benzodiazepines.

Preliminary results have shown the diazepam concentrations to range between 1 to 9 ppm in seasonal wastewater samples analysed, with higher concentrations during the winter season. In the case of clonezapam, concentrations ranged between 0.4 to 2 ppm. Seasonal characteristics of the benzodiazepines are discussed along the trends observed for the water quality characteristics of the final treated wastewater.

3.14 In Search of the Smoking Gun: Linking Environmental Contamination to its Source

3.14.T-01 A Bird in the Hand: A Sticky Death for Thousands of Seabirds Due to a Spill Of 'Highly Reactive' Polyisobutene (PIB).

***Steven Rowland**[1], Paul A Sutton[2], Andrew Tonkin[2] and Thomas A Brown[2], (1)University of Plymouth, United Kingdom, (2)SoGEES, University of Plymouth, United Kingdom*

Spills of complex mixtures of hydrocarbons other than crude oils can have detrimental effects on wildlife. In January and again in April, 2013, spills of a 'mystery' substance in UK coastal waters led to the deaths of thousands of seabirds. We identified the offending substance as a polyisobutene (PIB) by comparison of Fourier Transform infrared (FTIR) spectra with a library spectrum of a 'conventional' PIB. However, there were subtle differences between the library spectrum and spectra of the spilled PIB. Examination by high temperature gas chromatography-mass spectroscopy and nuclear magnetic resonance spectroscopy showed that the 2013 pollutant PIB mixture contained oligomers with a high proportion of terminal double bonds, referred to as 'highly reactive' PIB (HR-PIB). The identification of the pollutant was finally confirmed by comparison of FTIR and mass spectra with those of an authentic HR-PIB sample. The identification led to a legal re-classification of the potential hazards associated with PIB transport at sea.

3.14.T-02 Can the Source of Oil Pollution be Identified using Diamondoid Molecular Indicators Accumulated in Fish Tissue?

***Alan Scarlett**[1], Francis David Spilsbury[2], Steven Rowland[3], Kliti Grice[1] and Marthe Monique Gagnon[2], (1)Curtin University, Australia, (2)School of Molecular and Life Sciences, Curtin University, Australia, (3)University of Plymouth, United Kingdom*

Following an oil spill, the spilled oil becomes increasingly weathered and identification of its source becomes challenging but can often be achieved by comparing the relative abundances of chemical biomarker compounds known for their resistance to weathering processes, e.g. steranes and hopanes. This is sometimes referred to as oil 'fingerprinting'. Establishing the source of an oil to which organisms have been exposed is far more challenging, especially in motile species such as fish that also have the ability to metabolize many components of oils. In order to find the 'smoking gun', a forensic fingerprint of chemical biomarkers linking the oil components in fish tissues to the source oil is required. An initial step towards achieving this was accomplished using ratios of bicyclic sesquiterpane (bicyclane) isomers to provide aracteristic fingerprints of oils conserved in the adipose tissues of fish. However, a limitation of the method was that only six bicylane ratios were available for comparison and therefore additional forensic ratios are required.

Diamondoids are saturated hydrocarbons with cage-like structures that resemble diamonds. Tricyclic (adamantanes) and pentacyclic (diamantanes) diamondoids have been used as maturity and source rock indicators due to their high thermal stability and resistance to biodegradation. The molecular weight range of such diamondoids (150 – 202 Da for methyladamantanes to methyldiamantanes) are similar to that of the bicyclanes used in the initial study (194 – 222 Da for C_{14} – C_{16} bicyclanes), suggesting that they may have similar bioavailability and bioaccumulation potential.

In this study, we explore the use of diamondoid indices for their potential for forensic fingerprinting of oils bioaccumulated in fish. In order to enhance resolution of the diamondoids, comprehensive two-dimensional gas chromatography with time-of-flight mass spectrometry (GCxGC-TOFMS) was used to analyze the oils and the fish adipose extracts.

Preliminary results correlating indices derived from a crude oil and fish adipose extracts suggest an excellent linear fit close to the ideal 1:1. Additional work is ongoing to test fish exposed to a heavy fuel oil and to explore if the profiles of the indices are sufficiently different for forensic fingerprinting purposes, either in their own right or in conjunction with bicyclane ratios.

3.14.T-03 Investigation of Sources of Polychlorinated Biphenyls in Rivers of the Lake Geneva Basin
*Fabienne Pfeiffer[1], **Ines Tascon**[1], Céline Weyermann[1] and Nicolas Estoppey[2], (1)School of Criminal Justice, University of Lausanne, Switzerland, (2)Norwegian Geotechnical Institute (NGI), Norway*
In 2018 and 2019, two large-scale surveys of hydrophobic micropollutants were conducted in the Lake Geneva basin. Polychlorinated biphenyls (PCB), polybrominated diphenyl ethers (PBDE) and polycyclic aromatic hydrocarbons (PAH) were studied by deploying passive samplers on over 30 sites in Switzerland and France. Three relevant features (concentration, load and chemical signature of pollutants) were analysed. The results revealed the rivers presenting the highest risk for biota (i.e. highest concentration), as well as those contributing the most to the pollution of the basin (i.e. highest load). Information about the type of PCB source was obtained from the chemical signature.
Three of the rivers presenting a high load or concentration (Chamberonne, Rhône and Nant d'Avril) were chosen for further investigation of their pollution sources. The observed PCB profile (i.e. relative concentration of each sampled congener), combined with knowledge of the geographical and historical context of the river, was used to locate potential pollution sources. Silicone passive samplers were deployed up- and downstream of the river segment in which one or more potential sources were located. A passive sampling-based approach was used as it overcomes the limitations of current approaches targeting hydrophobic micropollutants: insufficient sensitivity, low temporal representativeness and poor data comparability. After identifying the river segment presenting a major increase in concentration and load, as well as a change in chemical profile, the investigation focused on the effluents present in the segment. An example of a relatively straightforward investigation will be given with the Chamberonne river. A river segment presenting a 12-fold increase in PCB concentration and a change in PCB profile was indeed rapidly identified in 2021. Two effluents of a potential source were located in this segment and samplers were deployed closely up- and downstream of the entry points in spring 2022. More complex investigations will be presented through the examples of the Nant d'Avril and the Rhône. In these cases, more sources contributed to the pollution and/or changes in rivers were less marked.
The presented investigative approach, guided by information obtained during large-scale monitoring, can be used to support authorities in the investigation and trial of current pollutant sources, ideally preventing current chemical releases from being continued.

3.14.T-04 Time Series Analysis to Elucidate Contamination Sources of Unknown Substances in the Rhine River
***Teofana Chonova**[1], Mark Honti[2], Martin Loos[3], Steffen Ruppe[4], Ingrid Langlois[4], Dorrit Griesshaber[4], Kathrin Fenner[1] and Heinz Singer[1], (1)Swiss Federal Institute of Aquatic Science and Technology, Switzerland, (2)Budapest University of Technology and Economics, Hungary, (3)enviBee, Switzerland, (4)Agency for Environment and Energy Canton Basel-City (AUE-BS), Switzerland*
More than 58 million people live along the river Rhine, and many depend on it for drinking water. However, the industrial activity in the Rhine catchment is among the highest in the world, which raises concerns about potential risks from unexpected releases of harmful substances. Aiming to ensure good water quality and to reduce contamination, the monitoring station of the Office for Environment and Energy in Basel is controlling daily intensities of known and unknown substances via liquid chromatography high-resolution mass spectrometry (LC-HRMS/MS), performing target and non-target analysis. This high-throughput, high-frequency monitoring makes it possible to inform downstream drinking water plants in a timely manner if sudden increases in measured signals are observed.
However, to efficiently reduce pollution, it is essential to better comprehend its origin and to trace the main contamination sources. To this end, we performed an in-depth analysis on the monitoring data. After extensive pre-processing, we obtained high-frequency time series containing daily measurements of over 50 000 compounds recorded from 2019 to 2022. In a first step, we identified priority substances of particular relevance for reducing contamination. Secondly, we used state-of-the-art modelling and clustering approaches to identify contaminants originating from similar sources.
The high diversity of time series pattern in the dataset enabled the identification of hundreds of clusters. Based on our models and on information obtained from known substances, we were able to identify multiple clusters with temporal patterns clearly pointing toward one of the possible contamination sources. We detected clusters of substances most probably originating from households, agricultural usage, from contaminated groundwaters or of industrial origin. The chemical structure of several unknown industrial priority substances was identified and those compounds were further monitored with increased vigilance. We observed an overall decreasing trend in contamination, suggesting that measures taken to reduce contaminant load at the watershed level are effective.
In conclusion, we were able to show that, despite the single measurement location, high-frequency monitoring in combination with the use of advanced data science tools allowed obtaining a comprehensive picture of anthropogenic contamination and its sources in the Rhine river, thus providing key information for river surveillance and management.

3.14.T-05 Behavioural Fingerprint Implementation for Sourcing Contamination at an Industrial Wastewater Treatment Plant
***George Ruck**[1], Alexandre Decamps[2], Jean-Baptiste Aubin[3], Jean-Luc Bertrand-Krajewski[4], Maxime Dauphin[2], Laura Garnero[5], Kassandra Montalbano[2], Hervé Quéau[6], Didier Neuzeret[2], Olivier Geffard[7] and Arnaud Chaumot[8], (1)UR RiverLy - Ecotox, National Research Institute for Agriculture, Food and Environment (INRAE), France, (2)ViewPoint, France, (3)INSA de Lyon,*

France, (4)INSA LYON, France, (5)UR RiverLy - ECOTOX, Laboratoire d'écotoxicologie INRAE, France, (6)INRAE, France, (7)UR RiverLy, Institut national de recherche pour l'agriculture, l'alimentation et l'environnement, France, (8)Institut National de la Recherche Agronomique, France
Industrial micro pollutants must pass by a wastewater treatment plants (WWTP) before eventual contamination of the environment. WWTPs therefore present a known network point for linking contamination to the source of pollution, which is essential not only from a legal perspective but also for environmental protection. ToxMate biomonitoring, whereby invertebrate locomotor behaviour is tracked in real-time, alerts operators to surges in micro pollutant contamination in effluents. Industrial sites have known upstream production lines that discharge into the dedicated on-site WWTP, which can narrow down the potential sources of contamination. One site, partnered for this study, has been equipped with ToxMate biomonitoring to tackle micro pollution since 2020, and further research was recently undertaken to implement behavioural fingerprinting in the ToxMate biological signal to identify the nature of contamination. The objective of the communication is to present 1/ the observation of micro pollution surges that occur 2/ the strategy used to implement behavioural fingerprinting to help identify types of contamination and thus narrow down potential sources of contamination.
In total, 8 suspected chemicals were targeted by the WWTP and sent to the laboratory for ToxMate testing. In order to implement behavioural fingerprinting at the WWTP effluent for the chemicals, multiple steps were taken: 1/ Organisms were exposed to low concentrations of the chemicals in closed circuit lab conditions 2/ The same exposure was carried out in the effluent bypass 3/ Data screening for the identified fingerprints was analysed for the long-term collected data. Results showed that naturally occurring spikes in micropollutants, that were in turn used for data screening, matched behavioural fingerprints observed during the controlled testing phase. Behavioural fingerprinting, used to assess the probability of a certain contamination nature, was formed using functional data analysis. The behavioural fingerprinting showed potential to provide solution in industrial WWTPs, whereby better understanding of the effluent contamination can point to known sources of contamination.

3.14.P In Search of the Smoking Gun: Linking Environmental Contamination to its Source

3.14.P-Th217 Fingerprinting Fish: Using Linear Discriminant Analysis (LDA) of Lipid Bicyclane Profiles to Identify Oil Contamination in Fish

Francis David Spilsbury[1]*, Alan Scarlett*[2]*, Steven Rowland*[3]*, Kliti Grice*[2]*, Marthe Monique Gagnon*[1] *and Gemma Spaak*[2]*, (1)School of Molecular and Life Sciences, Curtin University, Australia, (2)Curtin University, Australia, (3)University of Plymouth, United Kingdom*
In the event of an oil spill, identification of source oil(s) for assessment, or for litigation purposes, typically uses diagnostic ratios of chemical biomarkers to produce characteristic oil "fingerprints". Matching fingerprints from an environmental sample to that of a reference oil is to some extent subjective, and requires expert judgement.
Bicyclic sesquiterpanes (bicyclanes) are a class of petroleum hydrocarbons which have been used to forensically identify fuel oils and light crudes where more traditional biomarkers such as steranes and hopanes are not present. Bicyclanes are sufficiently lipophilic for passive cellular uptake, but are non-toxic, not metabolized by fish, and are resistant to the weathering processes that may alter characteristic fingerprinting ratios beyond use.
In this proof-of-concept study, we conducted a 35-day laboratory trial exposing *Lates calcarifer* (Asian seabass) via diet to either an Australian medium crude oil (Montara) or a heavy fuel oil (HFO). Adipose tissue extracts showed bioaccumulation of bicyclanes in fish lipid tissue with consistent bioaccumulation rates such that diagnostic fingerprinting ratios are preserved. Linear discriminant analysis (LDA) is a form of multivariate analysis similar to principal component analysis (PCA), often applied in facial recognition systems. We trained an LDA model using bicyclane profiles of Montara, HFO and seven other reference crudes, fuel oils and asphaltites. The model was subsequently able to correctly identify the respective exposure oil when challenged with bicyclane profiles from lipid tissue extracts from 18 exposed fish with a posterior probability exceeding 95%.

3.14.P-Th218 Fingerprinting 'IMO-2020' Compliant Low Sulphur Fuel Oils using Biomarkers and Heterocyclic Aromatic Compounds

Alan Scarlett[1]*, Robert K Nelson*[2]*, Marthe Monique Gagnon*[3]*, Alex I Holman*[4]*, Chris Reddy*[5] *and Kliti Grice*[1]*, (1)Curtin University, Australia, (2)Marine Chemistry & Geochemistry, Woods Hole Oceanographic Institution, (3)School of Molecular and Life Sciences, Curtin University, Australia, (4)School of Earth and Planetary Sciences, Curtin University, Australia, (5)Woods Hole Oceanographic Institution*
The International Maritime Organization (IMO), which is responsible for worldwide regulation of the marine sector, mandated that shippers transition to Low-Sulphur Fuels by January 1, 2020. Known as 'IMO-2020', its aim is to reduce air pollution, such as sulphur-oxide (SOx) and nitrous-oxide (NOx) compounds and particulates in Emission Control Areas (ECA's) caused by the burning of marine fossil fuels. IMO-2020 lowered the allowable weight percentage of sulphur from 3.5 wt% down to 0.5 wt%. Fuels compliant with the 0.5 wt% sulphur limit are referred to as Very Low Sulphur Fuel Oils (VLSFOs). In addition to IMO-2020 ECA's, a number of European Union countries together with the United States and Canada have implemented more stringent Sulphur ECAs (SECAs) requiring ships to utilize marine fuels containing a maximum of 0.1 wt% sulphur, referred to as Ultra Low Sulphur Fuel Oils (ULSFOs). Just eight months after IMO-2020 came into force, the first major spillage of VLSFO occurred when the MV *Wakashio* struck a reef off the southeast coast of Mauritius in August 2020. In order to understand if VLSFOs and ULSFOs can be forensically differentiated, a thorough analysis of their chemical composition is required. In particular, those compounds that are resistant to weathering processes that occur when oil is spilled into the environment. In our study we have examined the chemical characteristics of three VLSFOs and three ULSFOs using traditional GC-MS, comprehensive two-dimensional gas chromatography with high resolution time-of-flight spectrometry (GCxGC-HRT), GC×GC-

FID, and stable isotope analysis by GC-irMS. Comparisons of molecular biomarkers, such as steranes and hopanes, by both GC-MS and GC×GC-FID revealed that the two ULSFOs were near identical, but all other oils could be readily differentiated. Heterocyclic aromatic compounds were analysed by GCxGC-HRT to explore the possibility of developing forensically useful fingerprints using the profiles of their parent and alkylated homologues. Oils could also be differentiated by their $\delta^{13}C$ and $\delta^{2}H$ of *n*-alkanes and isoprenoids, adding to an overall fingerprint.
The *Wakashio* oil spill may have been the first release of VLSFO into the marine environment but it is unlikely to be the last. This study provides important forensic data that may prove invaluable in the event of future oil spills.

3.14.P-Th219 An Annual Resolution 600-year Record of Polycyclic Aromatic Hydrocarbons and Charcoal as Fire Proxies in Laminated Lake Sediments
*Kristin Haas[1], Sara Saeidi[2], **Thomas Schiedek**[1], Matthias Hinderer[3] and Elena Marinova[2], (1)Geosciences, Technical University Darmstadt, Germany, (2)Laboratory for Archaeobotany Baden-Württemberg, Germany, (3)Technical University Darmstadt, Germany*
Lakes adjacent to human settlements are storing the relationship between (long-term) environmental changes and human activities (land-use, urban emissions, fire events, etc.). Biogeochemical parameters and pollutant profiles can be associated with pre-industrial production. Such compounds are still eco-toxicologically detectable centuries later. However, publications on lake sediments usually focus on time scales from present to the last ca. 150 years. The multi-disciplinary research project Bad Waldsee (Germany) aims to evaluate the economic-demographic and socio-environmental development of the medieval city Bad Waldsee and its adjacent Stadtsee Lake during the late Medieval period to Modern Times. Here the impact of land-use intensity on the quality of the aquatic system and pollutant emissions archived in the lake sediments were studied systematically, using Polycyclic Aromatic Hydrocarbons (PAHs, 31 compounds) as well as micro- and macro-charcoal particles (as fire proxies) with annual resolution. Macro charcoal results showed 15 screened charcoal peaks, which group into two phases of biomass burning. The first phase in the late Medieval period (ca. 1297-1417 AD; 653-533 cal. yr BP) show high proportions of burned grass and monocot leaves. After more than 200 years probably without severe fire events, in the second phase (ca. 1637-1859 AD; 313 cal. yr BP onwards) wood was the main fire fuel. Indicative PAH concentrations were analyzed for the first burning phase. The obtained results from the geochemical fire indicators support the change in the fuel source. It is reflected by the Dimethyl-Phenantherene (DMP) isomers ratios and Perylene fluctuations. Moreover, high perylene values at the beginning of the record indicate a biogenic generation process under anoxic sediment conditions and suggests delivery of terrestrial organic material by water in this period. The retene pattern, as a marker of burned soft wood, indicate an increasing share of coniferous biomass along the grass-wood transition in fuel source. The pattern of typical PAH as combustion results (∑Fth, Pyr, BaA, Chry, BkF, BeP, BaP, Indeno, BghiP) confirms the low intensity but frequent burning events, showed by the micro-charcoal record. A ca. 10-fold increase of the 6-ring Benzo(ghi)perylene in ca. 1637 AD coincides with the detected high magnitude charcoal peak during the Thirty Years' war, most likely due to amplified macro charcoal input from regional burning events.

3.14.P-Th220 Identify a Possible Source Using an Oil Spill Model
***Jari Claassen**[1,2], Marlea H.A.B. Wagelmans[2] and Marcel Kotte[3], (1)RWS-WMCN, Netherlands, (2)Rijkswaterstaat, Netherlands, (3)Data and Information management, Ministry of Infrastructure and Water Management, Netherlands*
The Dutch part of the North Sea is one of the most intensively used seas in the world. There are international routes passing along the coast and shipping routes to and from Rotterdam, Antwerp, Zeebrugge, Amsterdam, Eemshaven/Delfzijl. Rijkswaterstaat (the Dutch maritime and marine management organization) is the national authority and is responsible for and activates counter-pollution measures in offshore and inland waters as well as on the shoreline.
In the beginning of 2022 oil tar balls beached over a large area along the coast of the Netherlands and even on beaches of Belgium. Due to weather conditions and technical problems the oil spill wasn't detected by EMSA CleanSeaNet satellite service. The beaches were cleaned and samples were taken from the different beaches for analysis. Oil fingerprinting by GC-FID-MS has identified that these oil tar balls came from the same source. With help of an oil spill model a back track was performed which identified a potential source of the spilled oil.

3.14.P-Th221 Low-Cost Passive Air Samplers for High Density Field Deployments in Population-based Studies
***Holly Mia Walder**, Environmental Research Group, Imperial College London, United Kingdom*
There is an urgent need to better understand population exposures to airborne chemical emissions, the indoor-outdoor continuum and in areas in close proximity to exposure sources, such as brownfield sites. Significant political motivation exists to develop these sites across Europe to meet housing demand and limit urban sprawl. Concerns of adverse health effects have been expressed by local communities during the remediation and redevelopment, due to potential fugitive emission exposures. The aim of this work was to design multi-functional and novel low-cost passive air samplers (PAS) that can be deployed at-scale in these areas to monitor volatile and semi-volatile organic compounds (VOC/SVOCs). These PAS were milled from PTFE (less than 3 cm in diameter) and contain up to five x 9 mm sorbent discs including (a) a liquid phenylene oxide-coated PALLFLEX® Emfab filter and (b) a polydimethylsiloxane (silicone) substrate. A proof-of-concept trial was performed involving deployment of PAS weekly for a month in the kitchen, bedroom and front garden (roadside) of an urban home. PAS sorbents were extracted and analysed by gas-chromatography-mass spectrometry with >135 identified SVOCs and VOCs tentatively identified using NIST17 libraries. The PAS demonstrated on average a 2-fold accumulation over the month with the most chemical residues found in the bedroom (>forty-five compounds). The chemical fingerprint between the indoor and outdoor environment was evident. The outdoor samplers shared eight common compounds with the indoor samplers, including human and plant metabolites (e.g., octadecane, tetradecane). Within the home, the bedroom and kitchen had nineteen common compounds including personal care products (e.g.

lauraldehyde) and fragrances (e.g. n-hexyl salicylate). These novel PAS show promise for VOC and SVOC monitoring discretely in both public spaces, inside homes and worn as badges. This will complement planned future biomonitoring work that will generate a *weight of evidence* towards an individual's exposome living near or on these brownfield sites.

3.14.P-Th222 The Use of Passive Samplers to Monitor Polar Organic Micropollutants in Surface Water and to Produce Knowledge on Contamination Sources

Naomi Reymond[1]*, Vick Glanzmann*[1]*, Sofie Huisman*[1]*, Nicolas Estoppey*[1,2] *and Céline Weyermann*[1]*, (1)School of Criminal Justice, University of Lausanne, Switzerland, (2)Norwegian Geotechnical Institute (NGI), Norway*

Environmental agencies have been addressing the problem of polar organic micropollutants (e.g. pesticides and pharmaceuticals) in surface water for some time now. However, the data collection is seldom systematic over time and space, mainly because of politics and budget restrictions, which makes it difficult to detect relevant patterns. This study proposes to use forensic science theory to design systematic and coordinated monitoring campaigns, and therefore better detect and track problematic situations. Intelligence-led processes aim at acquiring knowledge based on forensic traces to better understand spatial and temporal patterns of water pollution, and to identify chronic pollution sources. Intelligence can be produced from raw data to lead decision and policy makers design adequate actions to significantly reduce pollution problems.

Here, we present a practical low scale monitoring example based on Chemcatcher-like hydrophilic samplers (SDB-RPS extraction disks covered by PES microporous membranes) co-deployed with silicone disks spiked with performance reference compounds. The samplers were calibrated to follow the time-weighted average concentration of 44 hydrophilic contaminants in water. Each device was implemented in the field during 20 consecutive 14-day periods to measure the pollutants' concentrations at 5 different sampling sites. All acquired data (concentrations of pollutants) was added to a structured memory, that also included data from the local environmental agency collected with an autosampler (close to two of the five monitored sites). Sub-problems (trends, patterns) were studied using spatiotemporal visualisations and analyses. The data analysis is also used to guide further the sampling of future monitoring campaigns.

3.14.P-Th223 Reconstructing Temporal PFAS Trends from Sediment Cores with Multiple Approaches

Michaela Cashman[1]*, Anna Robuck*[1]*, Maya Morales-McDevitt*[2]*, Jeremy Koelmel*[3]*, Thomas Boving*[4] *and Mark Cantwell*[1]*, (1)U.S. Environmental Protection Agency, (2)ORISE c/o U.S. Environmental Protection Agency, (3)Yale University, (4)University of Rhode Island*

The use of Per- and polyfluoroalkyl substances (PFAS) in industrial applications predates analytical techniques for their identification in environmental matrices, leaving a gap in historical contamination records. One way to determine past PFAS contamination is through examining sediment cores. In this study, a sediment core was taken from an urban river in Rhode Island, USA. The sediment core was collected in a quiescent depositional area of a dammed mill pond near former mills that were suspected of using products containing PFAS. The core was radiometrically dated using 210-Pb and Cs-137 markers and analyzed for PFAS using multiple techniques including Targeted Analysis (TA), Total Oxidizable Precursor Assay (TOP), Extractable Organic Fluorine (EOF), and Nontarget Analysis (NTA). Results from NTA and radiometric dating were compared to determine co-occurrence of PFAS as a means of source identification.

A constant rate of supply (CRS) model of 0.99 cm/yr was determined from results of radiometric dating. The CRS model was applied to the sediment core sample depths to establish an age-depth model. Initial TA sediment concentrations showed temporal trends of PFAS preserved within the sediment record ranging from <1-55 ng/g sediment (d/w) in 18 unique PFAS compounds. A fluorine mass balance was performed pre- and post TOP assay to determine the presence of PFAS precursors. Results from the mass balance were compared with results from EOF. Certain parts of the core saw as little as 6% of the fluorine accounted for in fluorine mass balance. NTA data revealed the presence of additional PFAS including long chain PFCAs (C15-19), fluorotelomer carboxylic acids (PFCAs), and 6:2/8:2 FT diPAP. The majority of PFAS compounds detected in initial NTA results indicated peak PFAS inputs from 1970-1973.

This research highlights the utility of a multi-analysis approach to characterize temporal PFAS trends in sediments. This study highlights the utility of combining NTA with radiometric data and other proxies to elucidate temporal trends of environmental contaminants. Hierarchical clustering distinguished several notable time periods of PFAS deposition. Many detected PFAS compounds were released into the environment in the mid-1970s. There were also groupings of PFAS released more recently (2000s) and in the mid-1950s. Understanding the depositional history of environmental PFAS is important for understanding PFAS fate and long-term persistence in the environment.

3.14.P-Th224 Development of a Groundwater Toolbox to Support Site Conceptual Models

Derek Wallace*, Klaus Schnell and Matthias Piepenbrink, ERM Regulatory Services Limited, United Kingdom*

The Farm to Fork strategy and Chemical Strategy for Sustainability both identify a need to ensure that the production of food in EU agriculture needs to be conducted in a sustainable fashion to reduce pollution from pesticide use. In order to identify potential emerging contaminants of concern, groundwater monitoring plays an important role in clarifying and identifying potential pollutants to support sustainable use. Whilst being an incredibly powerful tool for driving our understanding of potential water pollutants, it must be recognised that there is a requirement for the development of a toolbox to ensure that groundwater observations are reliable and reflective of environmental processes.

As a starting point, a site visit is always recommended as it must be recognised that damage can, and will, occur for monitoring infrastructure *in situ*, especially when its location brings it into proximity with farming machinery. Therefore, a through site inspection, including an investigation down the monitoring well to look for potential root ingress, cracks or other damage which impacts well integrity. Such events manifest in the analytical data through very high concentrations of the active substance with

no or limited generation of metabolites, especially where these would be expected to form, demonstrating limited contact with the soil and thus potential for biotransformation.
It is also possible to investigate potential flow pathways and sources of water through the analysis of "chemical fingerprinting". By collecting water from various potential sources at a location (e.g., rainwater, surface water, etc.) it is possible to establish their individual chemical composition, which allows for the relative contribution of each source to a mixed water source to be determined. Further, through the use of aging techniques and flow mapping pathways, it is possible to evaluate potential sources of pollution for the observed observation at a given monitoring well, specifically by establishing water age, travel time and the theoretical zone of recharge.
Overall, groundwater monitoring is a hugely powerful tool for evaluating groundwater health and identifying residues of concern or emerging substances of concern. However, it must be acknowledged that false positives do occur and that a set of techniques for elucidations are required to support data interpretation and support conclusion making.

3.14.P-Th225 Impact of Wastewater Treatment Works' Effluent on Downstream Water Quality
Lucy Kennelly[1]*, Mike Gardner*[1] *and Sean Comber*[2]*, (1)wca environment Ltd., United Kingdom, (2)Stantec, United Kingdom*
The presence in wastewater treatment works' (WwTW) effluents of a range of trace substances is of increasing concern. It is often the default assumption that observed poor river water quality downstream of a particular WwTW discharge arises primarily as a consequence of that specific sewage effluent input. This leads to calls for the implementation of local remedial measures, when in fact the influence of the local discharge is often of limited importance because water quality upstream is already poor. This poster presents data on the influence of local WwTW effluent discharges on water quality. It shows that the sources of contamination in many cases might need to be addressed on a wider river catchment scale rather than on a local basis. Only by drawing this distinction can it be possible to prioritise remedial measures that are more likely to be successful in achieving environmental goals.
Investigations: This study uses data from the UK Water Industry Research Chemicals investigation (CIP) programme to examine local impact of effluent discharges. The CIP monitoring programme, gathered over a recent 5-year period, is a resource of water and effluent quality data for over 600 WwTW sites for a total of 50 different determinands.
Results: Initial correlation analysis of the CIP database of riverine contaminant concentrations upstream (u/s) and downstream (d/s) of WwTW discharges was carried out for each discharge. Higher correlation tends to indicate low impact i.e. no marked change in concentration from u/s to d/s concentration. Lower correlation indicates an impact by the local effluent such that d/s concentration values diverge from u/s ones. As expected, this divergence is evident for the principal effluent sanitary parameters (COD, BOD, phosphate, ammonia, suspended solids) and also less predictably for a limited number of trace contaminants. Further analysis will be provided for substances of particular interest of: 1) The change in observed concentrations for the main contaminants of regulatory interest under the Water Framework Directive from u/s to d/s locations, and, 2) The impact that this change in concentration has on compliance with relevant water quality standards downstream of the effluent discharge.

3.14.P-Th228 Understand How Distinct Seabird Foraging Strategies Can Influence Mercury Loads Along a Gradient of Exposure
Ivo Nobre Sarmento dos Santos[1,2]*, Joana Pais de Faria*[1]*, Jorge M. Pereira*[1]*, Lara Cerveira*[1]*, Maria I. Laranjeiro*[1,3,4]*, Nathalie Almeida*[1]*, Sara Nujo Veríssimo*[1]*, Vitor H. Paiva*[1]*, Jaime A. Ramos*[1] *and Paco Bustamante*[2,5]*, (1)MARE - Marine and Environmental Sciences Centre, University of Coimbra, Portugal, (2)LIENSs CNRS & Université de la Rochelle UMR 7266, France, (3)ESTM, Politécnico de Leiria, MARE – Marine and Environmental Sciences Centre, & ARNET – Aquatic Research Network, Portugal, (4)Department of Life Sciences, MARE - Marine and Environmental Sciences Centre, Portugal, (5)Institut Universitaire de France (IUF), France*
Mercury (Hg) is a non-essential trace element that can be easily transferred to marine food webs, bioaccumulates along time, and biomagnifies with increasing trophic level. As top predators, seabirds have been extensively used as bioindicators of Hg contamination in the marine environment. According to their foraging strategy, seabirds can be good models to assess the Hg contamination among habitats (*e.g.,* terrestrial, coastal, or oceanic), and they can be relevant to identify local sources of Hg and to biomonitoring the risk of Hg contamination, particularly during the breeding season. Thus, the main goal of the current study was to identify the influence of differential feeding ecology (proxied by δ^{13}C, δ^{15}N, δ^{34}S values) and spatial habitat use (proxied by tracking logger data) in explaining inter-specific and inter-colony variation of blood Hg concentrations along a gradient of exposure. For this, yellow-legged gulls (*Larus michahellis*) were used as bioindicators of the urban/terrestrial and coastal habitats, Audouin's gulls (*Ichthyaetus audouinii*) were used to assess contamination levels in coastal marine habitats, and Cory's shearwaters (*Calonectris borealis*) were used as indicators of oceanic habitats. Higher concentrations of Hg were associated to a higher trophic level (higher δ^{15}N) and to a higher reliance on marine resources (higher δ^{13}C and δ^{34}S), strongly supported by the habitat use strategy of yellow-legged gulls in different colonies, and to a lower extent by Audouin's gulls and Cory's shearwaters. Breeding Audouin's and yellow-legged gulls in natural colonies had Hg concentrations above the international defined toxicity thresholds, indicating a potential health risk to these gull populations. The higher reliance on fishery discards by yellow-legged and Audouin's gulls breeding in the natural colonies, together with the strong dependence on terrestrial resources by urban-dwelling yellow-legged gulls, should explain the Hg patterns found in this study. Although the habitat use strategy helped to understand the variations in Hg levels between yellow-legged gull breeding in different colonies, it failed to show the existence of a oceanic-coastal-terrestrial gradient of exposure to Hg contamination. Finally, we argue for the combined use of stable isotopes and GPS tracking in order to provide a more detailed picture on the characterisation of Hg sources and other contaminants in seabirds.

3.14.P-Th229 Using Pelagic and Coastal Seabirds to Compare Chemical Contamination Between the Northeast Atlantic Ocean and the Western Mediterranean Sea

Maria I. Laranjeiro[1], *Joan Navarro*[2], *Ivo Nobre Sarmento dos Santos*[1], *Lara Cerveira*[1], *Jorge M. Pereira*[1], *Albert Bertolero*[3], *Vitor H. Paiva*[1], *Marco F.L. Lemos*[4], *Jaime A. Ramos*[1], *Sara Novais*[5] *and Filipe R. Ceia*[1], *(1)MARE - Marine and Environmental Sciences Centre, University of Coimbra, Portugal, (2)Institut de Ciències del Mar (ICM), CSIC, Spain, (3)Associaciû Ornitolúgica Picampall De Les Terres De L'ebre, Spain, (4)Polytechnic of Leiria & MARE, Portugal, (5)Instituto Politécnico de Leiria, Portugal*

The continuous growth of anthropogenic activities makes chemical pollution a significant threat to marine environments worldwide, with increasing trends for the upcoming decades. However, the impact of marine pollutants on marine organisms may differ between oceanic basins, associated with differences in specific ecological or geographic features. Our objective was to investigate the differences in the concentrations of metals and metalloids (Arsenic, Bromine, Cadmium, Chromium, Mercury, Nickel, Lead, Strontium, Titanium, Copper, Iron, Selenium and Zinc) between two interconnected but very contrasting basins, the northern Atlantic Ocean and the western Mediterranean Sea. We analysed all these elements in feathers of four seabird species (Cory's shearwater *Calonectris borealis*, Scopoli's shearwater *Calonectris diomedea*, Audouin's gull *Icthyaetus audouinii* and yellow-legged gull *Larus michahellis*) inhabiting these basins during two consecutive breeding seasons (2020 and 2021). Moreover, stable isotope values were also analysed to infer about the trophic level and habitat use of these species, and relate with potential contamination in the two regions. Results showed differences in elements concentrations between the two environments and among species, with habitat use and trophic ecology of seabirds being the main possible cause for such variation. This study reveals the importance of biomonitoring marine environments using top predator species as sentinels to evaluate contamination patterns and dynamics in marine food webs and, ultimately, to maintain the quality of resources and ensure organisms well-being.

3.14.P-Th230 Sharing a Success Story: How Access to Reliable Data Is Central to Improved Environmental Performance

Alexandra Duguay, *Rio Tinto, Canada*

As environmental specialists, we are all very familiar with the paramount importance of reliable data. Not only can they support informed decision and adequate management to reduce footprint and environmental damage, but they can help us achieve our goal towards impeccable ESG credentials.

In Saguenay- Lac Saint Jean, Rio Tinto operates an important hub of aluminium assets. These include an alumina refinery, five smelters, six hydropower plants, a high-tech research and development center as well as an operational center. Also, a 300 km rail network connects our international port to the rest of this hub.

With the most stringent environmental protection commitment at heart, we have established a comprehensive surface and underground water monitoring network. It consists of more than 200 monitoring stations equipped with the latest technologies in terms of online telemetry. Every key parameter is monitored including pH, conductivity, organic and inorganic pollutants, as well as heavy metals. This management is done in collaboration with our long-lasting partner: SNC Lavalin.

Previously, and before we integrated with the ESRI suite: Survey 123 and Arc GIS, all environmental monitoring results were received by email via pdf and only after the completion of each campaign. All the results were then re-entered and re-processed manually by Rio Tinto's employees.

Now, using the current flexible cloud to cloud system from the ESRI ecosystem, we are directly connected to the SNC Lavalin database and are receiving our results instantaneously. We gain efficiency, keep ownership of our data as well as accessibility for all users pre-registered to the database. This adds a lot of value and reduces inefficiency because we are no longer spending hours to re-transcribe the data into our own system. We have replaced unreliable paper-based data collection with a trustworthy digital solution that fits the needs of our environmental commitment. This connection will now serve as a foundational element and accelerator for our digital transformation whereby we can envision seamless data integration with all our consultants and data providers, improving efficiency and quality.

With this case study, we will showcase how we have succeeded in creating a positive change taking on the challenge of better sharing environmental data directly form the source and how we were able to implement a sustainable solution to optimize environmental performance in nowadays digital world.

3.14.V In Search of the Smoking Gun: Linking Environmental Contamination to its Source

3.14.V-01 Contamination Sources Drive Hg Bioaccumulation in Arctic Marine Predators

Marianna Pinzone[1], *David Amouroux*[2], *Alexis Eric Adrien Trinquet*[3], *Liz Loutrage*[4], *Chester Gan*[5], *Julián Garcia*[5], *Davi Munhoz*[5], *Loïc Michel*[5], *Emmanuel Tessier*[2], *Rune Dietz*[6], *Frank Rigét*[6], *Igor Eulaers*[6,7], *Erling Nordøy*[8], *Haug Tore*[9], *Jean-Pierre Desforges*[10], *Gilles Lepoint*[5] *and Krishna Das*[5], *(1)FOCUS RU, University of Liege, Belgium, (2)LCABIE-IPREM UMR CNRS-UPPA, France, (3)Institut des Sciences de la Mer de Rimouski, Canada, (4)Institut Français de Recherche pour l'Exploitation de la Mer (Ifremer), France, (5)University of Liege, Belgium, (6)Aarhus University, Denmark, (7)Norwegian Polar Institute, Norway, (8)UiT - The Arctic University of Norway, Norway, (9)Institute of Marine Research, Norway, (10)Department of Environmental Studies and Science University of Winnipeg, Canada*

Poor understanding of mercury (Hg) sources and exposure pathways limits the effectiveness of prevention and mitigation of Hg marine pollution. In the Arctic, spatiotemporal variation in monomethyl-Hg (MMHg) production defines Hg bioavailability and trophic biomagnification, dictating Hg exposure in marine predators. Hg stable isotope analysis enhanced our understanding of environmental Hg dynamics. In this study, we aimed at assessing spatiotemporal variation in Hg sources to Arctic marine predators. We measured δ^{202}Hg, Δ^{199}Hg and Δ^{200}Hg values as well as THg, MMHg and iHg concentrations in muscle (n = 483) of hooded seal *Cystophora cristata,* harp seal *Pagophilus groenlandicus* and ringed seal *Pusa hispida* sampled in the Greenland Sea between 1985 and 2019. We identified Hg sources at a spatial scale, estimating Hg multi-isotopic niches in R (SIBER). We compared THg with δ^{202}Hg, Δ^{199}Hg and Δ^{200}Hg temporal trends to assess how shifting Hg sources affect Hg bioaccumulation over time. Ringed seals presented the highest THg concentrations (1190±488 ng.g^{-1} *dw*), followed by hooded (881±942 ng.g^{-1} *dw*) and harp seals (407±289 ng.g^{-1} *dw*). The proportion of MMHg did not differ among the three species (74 - 94%). The proportion of iHg was significantly higher in ringed seals (14±4.3%) than in harp (11±2.7%) and in hooded seals (10±2.9%). This was related to ringed seals residing in fjords, where MMHg production and inputs are enhanced by bacterial activity and freshwater run-off. Hg multi-isotopic niches confirmed that ringed seals were exposed to a mixture of terrestrial and local Arctic Hg sources, while harp and hooded seals were more exposed to oceanic and long-range Hg sources. Ringed seal THg varied strongly in time following δ^{202}Hg, Δ^{199}Hg and Δ^{200}Hg trends, suggesting that Hg bioaccumulation in this species is governed by the complex environmental changes in Arctic coastal marine ecosystems. In hooded seals, THg showed a significant decrease (1.5%.y^{-1}) over time, following the trends in Atlantic cod and Greenland halibut biomass. This suggests that Hg bioaccumulation in this species is governed by shifts in prey availability. No temporal trends were found for δ^{202}Hg, Δ^{199}Hg and Δ^{200}Hg values in hooded seals, indicating no shift in Hg sources over time. We conclude that in Arctic seals contamination sources drive Hg bioaccumulation and temporal trends at a species-specific and local scale resolution.

3.15.A Innovations in Analytical Methods Used for Monitoring Emerging Contaminants in Marine and Freshwater Aquatic Environments

3.15.A.T-01 A Novel Chemcatcher-Based Method for the Integrative Passive Sampling of Hydrophilic Micropollutants in Surface Water

Naomi Reymond[1]*, Vick Glanzmann*[1]*, Sofie Huisman*[1]*, Cécile Plagellat*[2]*, Céline Weyermann*[1] *and Nicolas Estoppey*[1,3]*, (1)School of Criminal Justice, University of Lausanne, Switzerland, (2)Chimie des Eaux, Direction Générale de l'Environnement, Switzerland, (3)Norwegian Geotechnical Institute (NGI), Norway*

Integrative passive sampling is a particularly useful alternative or complementary method to automated active sampling for the monitoring of multiple sites. However, the uptake on the samplers – and thus the sampling rates R_S – is influenced by environmental factors such as the hydrodynamic conditions. As R_S are used to calculate the concentration of contaminants in water, it is necessary to have a robust method that accounts for the influence of hydrodynamics. In this study, a novel method relying on the determination of the mass transfer coefficient of the water boundary layer k_w is proposed using Chemcatcher-like hydrophilic passive samplers.

Chemcatcher-like samplers (SDB-RPS extraction disks with PES membranes) were calibrated at 4 water velocities (5– 40 cm s^{-1}) in a channel system for 44 hydrophilic micropollutants. The R_S were modelised as a function of k_w to establish relationships between the two parameters. Then, the deployment of a device consisting of a Chemcatcher-like hydrophilic sampler and a silicone disk spiked with performance reference compounds (PRC) was tested in a river during 11 consecutive 14-day periods. The dissipation of the PRC from the silicone disk allowed the measurement of in-situ k_w, and to determine the most appropriate (site-specific) R_S from the R_S–k_w relationships. The obtained time-weighted average (TWA) concentrations were compared with concentrations obtained by automated active sampling (14-day composite samples).

The same compounds were generally detected and quantified using both sampling approaches, though passive sampling achieved lower LOQs because analytes were pre-concentrated in the sorbent. Most measured concentrations (76%) showed no major difference between the two methods. The added value of the PRC-spiked silicone disk was assessed by comparing results with concentrations calculated from fixed R_S (e.g., $R_{S,max}$). The errors on TWA concentrations due to the use of fixed R_S (instead of site-specific R_S) were determined to provide – for each compound – the approximate values of water velocity below which the added value of the method is significant. This showed that the added value was relatively limited in the studied hydrodynamic conditions (24 cm s^{-1} on average) and that the use of a fixed R_S is acceptable when working above a given water velocity (>20 cm s^{-1} for 33 compounds). These findings would allow practitioners to assess the best strategy to adopt when monitoring campaigns need to be implemented.

3.15.A.T-02 Water-Soluble Plastics: An Emerging Concern in Freshwater Environments

Eve Tarring[1]*, Charlotte Robison-Smith*[2]*, Robert Lucas*[3]*, Isabelle Durance*[4]*, Daniel Read*[5]*, Ben Ward*[4] *and Michael Harbottle*[4]*, (1)Chemistry, Cardiff University, United Kingdom, (2)Biosciences, Cardiff University, United Kingdom, (3)GlaxoSmithKline, United Kingdom, (4)Cardiff University, United Kingdom, (5)Centre for Ecology and Hydrology, United Kingdom*

In the field of plastic pollution, water-insoluble plastics such as micro and nanoplastics have moved to the forefront of polymer research. Over the last decade, numerous studies have highlighted their detrimental environmental impact, with interest in this field only growing. However, in the wider conversation regarding plastic pollution, water-soluble plastics (WSPs) have been excluded from the conversation.

With a large variety of properties, the applications for WSPs are increasing. Their use in industry as well as household products, often as thickeners, stabilisers and flocculants, demonstrate their prevalence in high-use products and, therefore, their likelihood to end up in freshwater environments, particularly through the route of wastewater treatment.

However, the gap in sensitive analytical techniques to detect WSPs represents one of the greatest challenges to research. Mass spectrometry, such as matrix-assisted laser desorption/ionisation (MALDI), is one of the most explored techniques for polymer research due to the small amount of analyte needed. However, it requires complex sample preparation and is not quantitative. Size-exclusion chromatography (SEC) such as gel-permeation chromatography (GPC), on the other hand, can quantify polymer in the sample but is less sensitive.

As well as difficulties detecting WSPs in the environment, very little is reported on their effects on freshwater organisms. As the major path for WSPs entering the environment is wastewater treatment, a large recipient of this waste is expected to be rivers. Despite this, and due to assumptions made about removal and degradation, there has been little investigation into toxicity and environmental impact to date.
Our research has focussed on developing MALDI-TOF mass spectrometry methods to detect a range of WSPs at a low concentration in samples such as cosmetic products and their degradation in wastewater. As well as this, we have been developing a tandem MALDI-TOF/GPC method to identify, separate and quantify polymers in cosmetic samples and environmental media. Combining these analytical methods with toxicity studies allows sublethal effects to be measured and polymer chemistry and degradation to be measured at the same time, opening up a new avenue in WSP research. This will further our understanding into the scope of these plastics in the environment, as well as their potential threats.

3.15.A.T-03 Passive Sampler Design Determines Polar Micropollutant Adsorption and Subsequent Bioassay Responses
Milo Leon de Baat[1]*, Dominique Narain-Ford*[2]*, Jasperien de Weert*[3]*, Daniel Giesen*[3]*, Henry Beeltje*[4]*, Timo Hamers*[5]*, Rick Helmus*[6]*, Pim de Voogt*[6] *and Michiel Kraak*[7]*, (1)KWR Water Research Institute, Netherlands, (2)FAME, University of Amsterdam, Institute for Biodiversity and Ecosystem Dynamics, Netherlands, (3)Deltares, Netherlands, (4)Netherlands Organisation for Applied Scientific Research (TNO), Netherlands, (5)Amsterdam Institute for Life and Environment (A-LIFE), Section Environment & Health, Vrije University Amsterdam, Netherlands, (6)University of Amsterdam, Netherlands, (7)University of Amsterdam, Institute for Biodiversity and Ecosystem Dynamics, Netherlands*
The combination of integrative passive sampling and bioassays is a promising approach for monitoring the toxicity of polar organic contaminants in aquatic environments. However, the design of integrative passive samplers can affect the accumulation of compounds and therewith the bioassay responses. The present study aimed to determine the effects of sampler housing and sorbent type on the number of chemical features accumulated in polar passive samplers and the subsequent bioassay responses to extracts of these samplers. To this end, four integrative passive sampler configurations, resulting from the combination of polar organic chemical integrative sampler (POCIS) and Speedisk housings with hydrophilic-lipophilic balance and hydrophilic divinylbenzene sorbents, were simultaneously exposed at reference and contaminated surface water locations. The passive sampler extracts were subjected to chemical non-target screening and a battery of five bioassays. Extracts from POCIS contained a higher number of chemical features and caused higher bioassay responses in 91% of cases, while the two sorbents accumulated similar numbers of features and caused equally frequent but different bioassay responses. Hence, the passive sampler design critically affected the number of accumulated polar organic contaminants as well as their toxicity, highlighting the importance of passive sampler design for effect-based water quality assessment.

3.15.A.T-04 Occurrence of Wastewater-borne Contaminants in Wild River Fish Tissues by ULPC-HRMS/MS
Diana Manjarrés[1]*, Nicola Montemurro*[2] *and Sandra Pérez*[2]*, (1)IDAEA-CSIC, Spain, (2)Department of Environmental Chemistry, IDAEA-CSIC, Spain*
Contamination of surface water sources by wastewater-borne contaminants has recently been evaluated. Aquatic biota, such as wild river fish, are constantly exposed to these compounds and can uptake and accumulate them in their tissues through the skin, gills or diet. Some wastewater-borne contaminants have been previously reported in fish muscle or whole homogenized fish, but few studies have evaluated their distribution in fish tissues. Among the main reasons, muscle analysis is of particular interest in studies investigating the risk assessment of human exposure through the consumption of contaminated fillets. Furthermore, it is easier to obtain a sufficient sample than other tissues that could provide more information. Under this scenario, we analyzed tissues from 4 wild river fish species: liver, kidney, skin, brain, muscle, plasma, heart, and bile to evaluate the distribution of 1556 wastewater-borne contaminants. The extraction method was ultrasound-assisted solvent followed by a clean-up step with Z-sep C18 sorbent. A suspect screening of 1556 analytes was performed. Chromatographic separation and data acquisition were performed via UPLC coupled to a hybrid Q-TOF-MS system and SWATH data acquisition was performed. Thirty-two compounds were detected, of which the majority were PhACs. Of these, 16 were detected at confidence level 2. a (amantadine, bisoprolol, citalopram, clozapine, desmethylcitalopram, fempromimorph, o-desmethylvenlafaxine, ondansetron, quetiapine, tiamulin, tramadol, trazodone, Terbutryn, terazosin, triphenyl phosphate, and telmisartan) according to the Schymanski scale, and 16 (clarithromycin, codeine, diltiazem, fluoxetine, metoprolol, sertraline, sotalol, venlafaxine, acetaminophen, acridone, caffeine, carbamazepine, diazepam, loratadine, trimethoprim, and ketoprofen) with confidence level 1 with genuine standards. Of the latter, concentrations were calculated. The presence of sertraline in all tissues was highlighted (C. max 1165 ng g^{-1} pancreas).
Finally, since most of the confirmed compounds were PhACs, an extraction method was validated to include 83 PhACs in routine analysis. The method was validated at two concentration levels, obtaining recoveries between 40%-120% and RSD <30% for most analytes. In future studies, the validated method will be used to evaluate the bioaccumulation and PhACs distribution in the tissues of 10 common carp, one of the species in which the highest average concentrations were reported.

3.15.A.T-05 Application of Compound-Specific Isotope Analysis (Csia) In Identifying Sources and Transformation Mechanisms of the Main Synthetic Musk Compound (Galaxolide)
Hatice Turan[1]*, Mathieu Sebilo*[2]*, Thierry Pigot*[1]*, Bahia Khalfaoui-Hassani*[1]*, Rémy Guyoneaud*[1]*, Gwenaël Imfeld*[3] *and Mathilde Monperrus*[1]*, (1)Université de Pau et des Pays de l'Adour, France, (2)Sorbonne University, Institute of Ecology and Environmental Sciences, France, (3)University of Strasbourg, France*
The knowledge of isotopic fingerprints of the environmental organic compounds is of paramount importance in evaluating the fate of organic compounds allowing to trace the source and address transformation processes. Galaxolide (HHCB) is the most frequently used synthetic musk compound, which is attributed to the chemicals of the highest concern. However, despite being

life-threatening, its environmental fate not yet fully known. In this study, we investigated the degradation potential of HHCB and its isotopic fractionation using compound-specific isotope analysis (CSIA) during photodegradation and biodegradation in the aquatic ecosystem. Photodegradation experiments were carried out to investigate direct and indirect photolysis under natural (solar irradiation) and treatment process (UVC irradiation) in synthetic and riverine water including nitrate (NO_3^-), carbonate (CO_3^{2-}), humic substances associated with different experimental conditions, and hydrogen peroxide (H_2O_2) in relation to the treatment process. Pure bacterial strain that has been previously isolated from marine canyon sediment was cultivated to test HHCB microbial degradation. Concentrations and carbon isotopic signatures were determined by GC-MS and GC-C-IRMS, respectively. The results have demonstrated that HHCB was quickly photodegraded by direct and indirect photolysis in a range from 40±4 to 202±29 minutes half-life time. Enhanced degradation was observed in the presence of H_2O_2 under UVC irradiation due to hydroxyl radicals. Up to 90% of the HHCB depletion driven by a bacterial strain which belongs to genus *Bacillus* sp. was recorded with 368±95 min half-life time. Although a high degradation of HHCB was obtained, no significant isotopic fractionation was determined neither due to photodegradation nor biodegradation. These results reveal that carbon isotopic composition in HHCB is stable against different degradation processes. Isotopic fingerprinting of HHCB can thus be used as novel approach to distinguish the source of HHCB directly from the commercial products and environmental samples.

3.15.B Innovations in Analytical Methods Used for Monitoring Emerging Contaminants in Marine and Freshwater Aquatic Environments

3.15.B.T-01 Monitoring Pollution Pathways in River Water by Predictive Path Modelling Using Untargeted GC-MS Measurements

Maria Cairoli[1]*, André Van den Doel*[1]*, Berber Postma*[1]*, Tim Offermans*[1]*, Gerard Stroomberg*[2]*, Henk Zemmelink*[3]*, Lutgarde Buydens*[1]*, Geert Van Kollenburg*[4] *and Jeroen Jansen*[1]*, (1)Radboud University Nijmegen, Netherlands, (2)RIWA Rijn, (3)Rijkswaterstaat, Netherlands, (4)Technical University Eindhoven, Netherlands*

A comprehensive approach to protect river water quality is needed within the European Water Framework Directive: this requires a paradigm shift from the monitoring of individual target chemicals toward a complete understanding of the aquatic ecosystem. Non-target screening is essential toward this approach, as it provides a complete chemical fingerprint of the aquatic ecosystem, detecting known and yet-unknown chemicals of emerging concern and revealing their suspicious dynamic patterns in river water. Statistic spatiotemporal tools are complementary to track and model such dynamics. A new combination of two measurement paradigms is therefore required: the path of potential pollution should be traced through the river network, while there may be many compounds that make up this chemical composition—both known and unknown. In this work, we combine dedicated data processing of ongoing GC-MS measurements at 9 sites along the Rhine using PARAFAC2 for non-target screening with spatiotemporal modelling of these sites within the river network using path modelling (Process PLS). This new integrated approach allows to track chemicals through the Rhine catchment, to tentatively identify known and as-yet-unknown potential pollutants based on non-target screening and spatiotemporal behaviour, and even to hint toward the source of their contamination. Such an approach utilizes data that has already been collected, allowing water authorities to take effective decisions without adding to the already costly monitoring efforts.

3.15.B.T-02 Unknown PFAS Revealed by the Total Oxidizable Precursor Assay: Towards a Better Understanding of Their Occurrence and Transfers in Marine Biota

Yann Aminot*, Caroline Chauvet, Nadège Bely, Charles Pollono and Catherine Munschy, IFREMER, France*

Per- and polyfluoroalkyl substances (PFAS) are thousands of anthropogenic chemicals reported for their ubiquitous presence in the environment. Because of the analytical challenges of the target monitoring of thousands of molecules, scientists have focused on a limited set of PFAS, although an extensive number of overlooked PFAS - including perfluoroalkyl acid precursors - remain unaccounted for. Global understanding of the cycling of PFAS can only be approached through the inclusion of such precursors, for their key role as intermediate compounds of environmental relevance. To better capture this “dark matter”, environmental analytical chemists now have in their toolbox the Total Oxidizable Precursor (TOP) assay, an alternative technique where an additional simple oxidation step turns all the compounds that can generate the stable PFCAs into such easily analyzable final products. With limited marine applications found to date, our goal here is to present how the TOP assay assists our understanding of the cycling of PFAS in marine ecosystems. Two applications will be discussed: their screening in a national marine bivalve biomonitoring programme and the investigation of the trophic transfer of PFAS across coastal foodwebs. First, the occurrence and levels of precursors were assessed in filter-feeding bivalves from the French biomonitoring programme for contaminants, collected annually in 20 sites from 2017 to 2021. In the second application, several species of the European seabass and common sole trophic networks from the Seine estuary, including plankton, polychaetes, bivalves, crustaceans and forage fish, were investigated. PFAS were analysed on one hand via targeted analysis of selected carboxylates, suflonates and precursors and on the other through a protocol including the oxidative conversion of precursors. Both studies evidenced that PFCA precursors were by far the major contributors to the total PFAS burden in most species, with as little as 10% of the total PFAS concentration being explained by targeted analyses in mussels of the Seine estuary. This presentation will discuss how the post-oxidation levels and profiles assist in gaining insight into the global PFAS contamination of biota. We conclude that conventional PFAS surveys likely miss a large part of the overall PFAS contamination, demonstrating that there is a crucial need to identify the specific compounds responsible for this contamination by means of non-targeted screening approaches.

3.15.B.T-03 Novel Antibody-based Methods for Emerging Contaminant Sensing

Caroline Murphy[1]*, Weili Guo*[2]*, Louis Free*[3]*, Sean Power*[3]*, Ciprian Briciu-Burghina*[3]*, Anne Parle-McDermott*[4] *and Fiona Regan*[5]*,*

(1)School of Biotechnology, Dublin City University, Ireland, (2)School of Biotechnology, DCU Water Institute, Dublin City University, Ireland, (3)Water Institute, DCU Water Institute, Dublin City University, Ireland, (4)Dublin City University, Ireland, (5)Water Institute, Dublin City University, Ireland
Under the European Union's Water Framework Directive (WFD) (2000/60/EC) all members of the EU are required to protect and improve water quality. The WFD applies to rivers, lakes, groundwater and transitional coastal waters. Traditional detection methodologies involve the use of high performance liquid chromatography (HPLC) and enzyme-linked immunosorbent assays (ELISAs).
This project involves the development of a multiplex lab-on-chip (LOC) *in-situ* monitoring system for the detection of harmful algal toxins saxitoxin (paralytic shellfish poisoning toxin) and domoic acid (amnesic shellfish poisoning toxin) and emerging anthropogenic contaminants non-steroidal anti-inflammatory drug (NSAID) diclofenac, the hormone estrone and a member of the pyrethroid insecticide bifenthrin. Competitive immunoassays were generated for each contaminant using 'off-the-shelf' antibodies and in-house generated conjugated contaminants. The immunoassays were then transferred to a lab-on-chip (LOC) detection system for *in-situ* monitoring.
Antibody-based assays were developed to detect each contaminant at or near their required concentrations. Following the development of antibody-based immunosorbent assays, the tests were transferred to the lab-on-chip surface and assay optimisation was performed on-chip. The lab-on-chip surface was composed of poly methyl methacrylate (PMMA) and chip layers were bonded using pressure sensitive adhesive (PSA). Free bifenthrin and diclofenac were tested on plasma treated silanized chips and FITC fluorescence was viewed on a fluorescent microscope, fluorescence intensity was analysed using FIJI software. Assays to detect bifenthrin and diclofenac were performed on the PMMA material. The reduction of fluorescent intensity revealed both free bifenthrin and diclofenac could be detected on the LOCs.
This project is currently on-going and further work is underway to optimise assays for the detection of harmful algal toxins saxitoxin and domoic acid, and the hormone estrone. The work shown herein demonstrates the development of antibody-based immunoassays for the detection of marine emerging contaminants on a novel lab-on-chip platform.

3.15.B.T-04 Comprehensive Coverage of Both Known and Unknown PFAS in Ocean, Leachate, and Lake Foam using Non-Targeted Analysis and FluoroMatch 3.0
Jeremy Koelmel[1], Emma Rennie[2], Michael Kummer[3], Bernard Brooks[3], Sheng Liu[1], Carrie McDonough[4], Emily Parry[2], David Godri, Jacqueline Bangma[6], John A Bowden[7], Nandarani Abril[3], ***Stephan Baumann***[8] *and Krystal Pollitt[1], (1)Yale University, (2)Agilent Technologies, (3)Innovative Omics, (4)Chemistry, Carnegie Mellon University, (5)U.S. Environmental Protection Agency, (6)University of Florida, (7)Academic and Government Applied Marketing, Agilent Technologies*
Perfluoroalkyl and Polyfluoroalkyl Substances (PFAS) span across thousands to tens of thousands of possible substances. Certain PFAS are persistent, bioaccumulate, and have been linked to various health effects including specific cancers, changes in liver enzymes, reduced immune response, increased cholesterol levels and risk of high blood pressure, slightly lower birth weight, and preeclampsia. These toxicities along with the fate and transport in the environment depend on structure, and only a small portion (< 50%) of PFAS by concentration are generally covered by commonly used analytical approaches.
Therefore, we have developed a non-targeted analysis (NTA) PFAS user-friendly software for comprehensive coverage. FluoroMatch Suite 3.0 performs all NTA data-processing steps: file conversion, peak picking, annotation, scoring, homologous series grouping, and visualization. Recently we have expanded the visualization component for aiding the researcher in discovering unknowns and confirming FluoroMatch annotations as part of our new release. This visualizer shows EICs, annotated MS1 spectra (including isotopic peaks), annotated MS2 spectra, normalized mass defect plots (e.g., CF_2), tables of annotation evidence and peak areas, and statistical visualizations (PCA, ANOVA, Volcano Plots, Violin Plots, etc.). We have also added new libraries containing MS/MS rules for certain biotransformation products and biotransformation product fragment screening.
We applied this software to dried blood spots, aqueous firefighting foams (AFFF), and mice spiked with AFFF. Furthermore, for water bodies, we have found that PFAS concentrate in foams, and have discovered hundreds of PFAS in leachate, lake, and ocean foam samples. Data was acquired on an Agilent 6546 or Agilent 6545, with reverse phase liquid chromatography in negative ion mode. A 5% or less false positive (annotations scored A) and false negative rate was determined for these datasets. PFAS which are uncommonly screened or previously unreported were also discovered including unsaturated pentafluorosulfonic acids and glucoronate PFAS conjugates. PFAS were an order of magnitude or higher in foam compared to representative water samples, with higher chain species being more concentrated in the foam. Foaming water could be a form of remediation of PFAS.

3.15.B.T-05 Study of the Influence of Seasonal Conditions on the Occurrence of Pharmaceuticals in Irish Surface Waters
Dylan O'Flynn[1]*, Blanaid White[2], Imogen Rose Hands[1], Anne Parle-McDermott[2], Denise Harold[2], Thomas McCloughlin[2], Linda Holland[2], Stefania Scurtu[3], Jenny Lawler[2], Kristyna Mrstna[2] and Fiona Regan[1], (1)Water Institute, Dublin City University, Ireland, (2)Dublin City University, Ireland, (3)School of Chemical Sciences, Dublin City University, Ireland*
Small-molecule pharmaceuticals play an increasingly important role in both human and animal health. The ever-growing use and availability of pharmaceuticals in the last decade have led to the contamination of global surface water ecosystems from ng/L to µg/L concentrations. Additionally, the continuous release, stability and biological activity of these "micro-pollutants" can lead to a "pseudo persistence" in the environment, with ensuing behavioural and health-related effects. However, the occurrence and fate of these pseudo-persistent pharmaceuticals and their residues remain generally unknown. The analysis of 17 pharmaceutical APIs has been accomplished using LC-MS/MS. Eight pharmaceuticals (17 α- ethinylestradiol, 17 β-estradiol, estrone, erythromycin, clarithromycin, azithromycin, amoxicillin, ciprofloxacin) were chosen from the updated surface water "Watch List" (Decision (EU) 2018/840), followed by five pharmaceuticals which are commonly found in European surface water and pharmaceuticals which have a low removal efficiency in conventional activated sludge type wastewater treatment plants (trimethoprim,

sulfamethoxazole, carbamazepine, gemfibrozil and diclofenac). Furthermore, these pharmaceuticals are ubiquitous within the Irish healthcare system (OTC and prescription drugs), are recognised as potentially harmful substances for aquatic organisms and lack Irish data on their presence and concentrations. Surface water grab samples were collected from EPA-recommended sampling locations from September 2020 to March 2022 to provide valuable evidence establishing their presence and identification of their simultaneous occurrence of pharmaceuticals in surface water catchments.

3.15.P Innovations in Analytical Methods Used for Monitoring Emerging Contaminants in Marine and Freshwater Aquatic Environments

3.15.P-We165 Analytical Strategies for Nanoplastics Detection in Complex Biomatrices

*Gabriella Schirinzi[1], **Andrea Valsesia**[2], Andrea Masseroni[3], Jessica Ponti[2] and Douglas Gilliland[2], (1)European Commission, Italy, (2)European Commission Joint Research Centre, Italy, (3)Department of Earth and Environmental Sciences, University of Milano-Bicocca, Italy*

Micro(nano)plastics are now present throughout the environment, and there is growing concern that their accumulation may, in the future, present serious risks to the environment, including aquatic organisms, and to human health. Although it is a well-recognized problem in the scientific community, the lack of methods to detect the smallest plastic particles (typically < 5 μm) continues to leave huge gaps in knowledge of their distribution and possible harmful effects.

Taking into account the results of previously developed methods on organisms exposed to micro- and nanoplastics, an attempt was made to develop an innovative and cost-effective analytical strategy for the detection of nanoplastic pollution in complex biomass to be applied to routine biomonitoring activities.

In this work, freshwater mussels were used as model organisms, as they are already widely used as bioindicators of plastic contamination. After validating the enzymatic digestion process using metal-doped nanoplastics (recovery greater than 65%), the detection capability of microscopic and spectroscopic techniques was explored. The results obtained indicate that the applied protocol allows the identification and quantification of nanoplastics in the pellet after digestion. In particular, an analytical strategy based on the hydrophobicity of nanoplastics was pursued to adapt routine spectroscopic techniques, such as (μ)Raman, to the detection of plastic particles in complex biomatrices.

3.15.P-We166 Identification of Mid-polar and Polar Aryl Hydrocarbon Receptor Agonists in Gamcheon Harbor of Busan Bay Using Effect-directed Analysis Combined with Full-scan Screening

***Jiyun Gwak**[1], Jihyun Cha[1], Junghyun Lee[2], seong-Ah An[1], Hyo-Bang Moon[3], Jong Seong Khim[2] and Seongjin Hong[1], (1)Department of Marine Environmental Science, Chungnam National University, Daejeon, Korea, (2)School of Earth and Environmental Sciences & Research Institute of Oceanography, Seoul National University of Science and Technology, Korea, (3)Department of Marine Science and Convergence Engineering, Hanyang University, Korea*

In this study, unmonitored aryl hydrocarbon receptors (AhR) agonists in sediments from Gamcheon Harbor of Busan Bay (S1–S12, *n*=12) were identified using effect-directed analysis (EDA) combined with full-scan screening analysis (FSA). The AhR-mediated potencies were measured in organic extracts, silica gel fractions, and RP-HPLC fractions in sediments using H4IIE-*luc* recombinant cells. Results showed that all sediment extracts showed significant AhR-mediated potencies. Among the silica gel and RP-HPLC fractions, great AhR-mediated potencies were shown in F2.6–F2.8 (mid-polar, log K_{OW} 5–8) and F3.6–F3.7 (polar, log K_{OW} 5–7) in stations S3 and S10. Targeted compounds, including traditional and emerging AhR agonists, could not fully explained the bioassay results (except for the F2.6 of S3 and S10). It is indicated that unknown AhR agonists occurred in the sediments. FSA was performed for F2.7–F2.8 and F3.6–F3.7 of S3 using GC-QTOFMS and LC-QTOFMS, respectively, which showed the great AhR-mediated potencies. Through four-step selection criteria, such as 1) NIST library, 2) library matching score (≥70), 3) presence of aromatic ring, and 4) number of aromatic rings (≥4), one (triphenylbenzene) and two (daphnoretin and ishomnetin) tentative AhR agonist candidates were selected in F2.7 and F3.6, respectively. Among the three candidates, daphnoretin and ishomnetin showed significant AhR-mediated potencies, and the relative potency values compared to benzo[*a*]pyrene were 0.4×10^{-3} and 6.5×10^{-5}, respectively. The results of VEGA QSAR, these compounds were confirmed to cause genotoxicity, carcinogenicity, and developmental toxicity. These newly identified AhR agonists have been used for pharmaceuticals. We compared the major AhR agonists in sediments of the highly polluted coastal areas of South Korea. The major AhR agonists in each area differed by region (e.g., chrysene in Ulsan Bay, Lake Sihwa, and Busan Bay; benzo[*b*]fluoranthene in Masan Bay; and benzo[*j*]fluoranthene in Yeongil Bay), which can be attributed to the influence of surrounding activities. The results of this study are significant that provide useful information for the selection and management of the priority substances in the coastal environments.

3.15.P-We167 Integration of Multidisciplinary Techniques to Achieve a Global Diagnosis of a Freshwater Aquatic Ecosystem

*Marina Barbudo-Lunar[1], Gema Arjona[2], Chiara Trombini[3], Ana Maria Herruzo-Ruiz[1], Julian Blasco[3], Arturo Francisco Chica[2], José Ángel Siles[2], Jose Alhama[1] and **Carmen Michan**[1], (1)Dpt. Biochemistry and Molecular Biology, ceiA3, Universidad de Córdoba, Spain, (2)Dpt. Chemical Engineering, IQUEMA, Universidad de Córdoba, Spain, (3)Dpt. Ecology and Coastal Management, Instituto de Ciencias Marinas de Andalucía, Spain*

Freshwater ecosystems are at particular risk because they are continuously exposed to multiple-stressors effects. In addition to pollution and conflicts in the water use, climate change is emerging as a new and increasingly worrisome challenge. At Southern Spain, the Guadalquivir River is the main hydrographic basin of Andalusian region that supports the impact of numerous socioeconomic activities (*e.g.*: urban centers, and agricultural/industrial/mining activities). With a transversal team made up of researchers from different areas, we have carried out a global diagnosis of the river by using different multidisciplinary techniques to evaluate biochemical, cellular, physiological and behavioral changes along its course. Significant changes have been found in the concentration of total soluble organic carbon, suspended solids, and in some metals (*e.g.*: iron), as well as high turbidity in the final stretch of the river. Agricultural activities carried out around the river are responsible for the presence of nitrates and ammonia in certain sections of the river. From the integration of physicochemical and microbiological analysis, a water quality index was evaluated. This index, which was the highest at the source, decreased along the course of the river. Poor water quality values were related to anthropogenic activities carried out in tributaries of the Guadalquivir River (high levels of Fe and Cu and proliferation of coliform bacteria, such as *E. coli*, from the Guadaira and Genil rivers, respectively) or in the final stretch of the river (agricultural activities). Since microorganisms are in almost every environment in the biosphere playing unique essential roles, we have also assessed the utility of water metaomics for environmental diagnosis. The taxonomic identification through genomic analysis of 16S rRNA made it possible to assess changes in the global structure of the microbiome in terms of bacterial distribution, abundance, and diversity along the riverbed, alterations that were associated to variations in physicochemical variables and to environmental stress sources. This multidisciplinary study can be used as a model to prepare risk maps, with the identification of "hot-spots" on which to act, to improve the management of fundamental water resources.

3.15.P-We168 Cytotoxicity of Anti-androgenic Endocrine Disrupting Compounds Occurring in the Brackish Baltic Waters

Paulina Goździk[1]*, Katarzyna Smolarz*[2] *and Anna Hallmann*[3]*, (1)Medical University of Gdansk, Poland, (2)Division of Marine Ecosystems Functioning, University of Gdansk, Poland, (3)Department of Pharmaceutical Biochemistry, Medical University of Gdansk, Poland*

The anthropogenic pressure causes a constantly increasing problem of toxic compounds influx to the marine waters. These chemicals include endocrine disruptors (EDs), chemicals affecting multiple endocrine pathways and disturbing the physiological reproductive functions of various species, including molluscs. They include a heterogeneous group of chemicals and are divided in two main categories, the estrogenic (xenoestrogens) and anti-androgenic EDs. The exposure to these chemicals has been associated with reproduction disorders impairing fertility and fecundity, intersex and imposex formation, developmental disorders, but also affecting various metabolic pathways etc.

The aim of our study was to assess the seasonal changes in the presence and concentration of chemicals acting as potential EDs occurring in the brackish water and to analyze the possible impact of these compounds using various biological models, including GMM organisms, cancer cell line and *Mytilus trossulus*. The water and bivalves samples were collected seasonally during one-year period in the vicinity of the sewage treatment plant Dębogórze (the Gulf of Gdańsk). The assessment of androgenotoxicity and estrogenotoxicity of sub-bottom water was conducted using the system of genetically modified yeast XenoScreen YES/YAS and the cancer cell line BT-474. Additionally, the transcriptomic analyses were performed based on *M. trossulus* samples to test the effect of EDs using the RNA-seq method.

The obtained results highlighted the presence of EDs compounds characterized by a high anti-androgenic activities. The highest concentrations of the anti-androgen equivalents were noted in the samples collected in the autumn 2021 (36,47 µM aAEQ) and winter 2022 (23,57 µM aAEQ). No substances with androgenic activity were detected. Studies conducted on the cell line BT-474 showed that administration of the water samples induces cytotoxic effects, decreasing cell viability. At the same time the water samples demonstrated no estrogenic or anti-estrogenic activity. Further research concerning the analysis of the transcriptome changes of *M. trossulus* will contribute to the assessment of the potential impact of EDs on the sea bivalves.

3.15.P-We169 Industry Related Wastewater of Dialysis Membrane Production Containing N,N-Dimethylacetamid and N,N-Dimethylamin: Screening Combined Toxicity Using *Daphnia magna* and *Raphidocelis subcapitata*

Katrin Weise[1]*, Juliane Isler*[1]*, Thomas Schalk*[2]*, Anja Rollberg*[3]*, Dirk Freitag-Stechl*[4]*, Cornelia Kienle*[5]*, Etienne Vermeirssen*[5]*, Stefan Stolte*[6]*, Thomas U. Berendonk*[7]*, Dirk Jungmann*[7] *and* ***Sara Schubert***[1,8]*, (1)Institute of Hydrobiology, Technical University Dresden, Germany, (2)Institute of Urban Water Management, Technical University Dresden, Germany, (3)B. Braun Avitum Saxonia, Germany, (4)CUP Laboratorien Dr. Freitag, Germany, (5)Ecotox Centre, Switzerland, (6)Institute of Water Chemistry, Technical University Dresden, Germany, (7)Institute of Hydrobiology, Technical University Dresden, Germany, (8)Technical University Dresden, Germany*

Dialysis is one of the most important forms of kidney replacement therapy. Wastewater generated during the production of dialysis membranes contains the solvent N,N-dimethylacetamide (DMAc) and its primary degradation product N,N-Dimethylamin (DMA) both known as critical substances for aquatic organism. The project Med-zeroSolvent [1] aims to 1) prevent transfer of these substances via process water to wastewater treatment plants and then the aquatic environment, and 2) the development of an adequate on-site treatment for a wastewater-free production process. Effect-based methods (EBM), such as ecotoxicological bioassays [2], can be applied to evaluate a potential toxicity of DMAc and DMA.

To analyze the ecotoxicity of solvent containing process water, an acute toxicity test using *Daphnia magna* (immobilization) and the combined algae test using *Raphidocelis subcapitata* (inhibition of photosystem II (PSII) and growth) were applied [3,4,5,6]. DMAc and DMA were tested as single compounds, in mixture after concentration addition was calculated and, finally, process water was evaluated.

Assessing individual compounds resulted in an $EC50_{DaphniaDMAc}$ of 575 mg/L, $EC50_{DaphniaDMA}$ of 34 mg/L and for the mixture in an $EC50_{DaphniaMix}$ of 288 mg/L DMAc and 17 mg/L DMA. Therefore, mixture testing in daphnids showed an additive toxicity compared to the single compounds. Testing process water resulted in $EC50_{DaphniaPW}$ between a dilution of 1.56% and 3.13%. Preliminary results of the combined algae assay showed low inhibition of growth and PS-II for DMAc and process water. In contrast, high inhibition of PSII and growth was observed for DMA and the mixture. To check the actual concentrations during the experiments DMAc and DMA were analyzed by HPLC or IC methods in exposure media incl. process water.

Generally, it is useful to assess mixtures with EBM [1,7,8]. In this case we detected an additive toxicity when testing the mixture of DMAc and DMA. Contribution of further environmentally critical substances to the toxicity of process water should clarify in future since e.g., bisphenols, polysulfone and N-methyl-2-pyrrolidinone [9] could be found in membrane process water. In Med-zeroSolvent, scalable treatment modules will be developed for process water. Nevertheless, these modules may help to reduce freshwater demand and emissions from comparable industrial processes and wastewaters.

3.15.P-We172 Multi-Residue Determination of Pharmaceuticals in Daphnia magna and Danio rerio Using Solid Phase Extraction and Liquid Chromatography-Tandem Mass Spectrometry
Jasmin Uhlhorn[1]*, Luigi Margiotta-Casaluci*[2]*, Samuel K Maynard*[3] *and Thomas Miller*[1]*, (1)Brunel University, United Kingdom, (2)King's College London, United Kingdom, (3)Global Sustainability, Astrazeneca UK Ltd, United Kingdom*
The influx of pharmaceutical mixtures into the aquatic environment poses a significant risk to the aquatic biota. Better understanding of the potential for pharmaceutical compounds to bioconcentrate in biota and determination of the toxicokinetics requires development of reliable analytical methods that can quantitatively measure a wide range of pharmaceuticals with varying physico-chemical properties at trace-levels. We developed, optimized, and validated an analytical method using liquid-chromatography-tandem mass spectrometry (LC-MS/MS) for multi-residue determination and quantification for over 100 pharmaceuticals covering a wide range of therapeutic classes such as antidepressants, NSAIDS, calcium channel blockers, lipid regulators, etc. The method was developed to determine pharmaceutical concentrations in both *Daphnia magna* and *Danio rerio* to enable cross-species comparison of toxicokinetics. The method used solid phase extraction (SPE) for pre-treatment and clean-up followed by LC-MS/MS analysis. Sample clean-up was investigated using different approaches that included freezing-lipid precipitation and tandem SPE with varying sorbents. Additionally, a high-throughput clean-up method was studied using a 96-well micro-elution plate. Overall, the method showed good performance with method detection limits at single figure ng g^{-1} range. Quantitatively the method showed acceptable linearity ($R^2 \geq 0.98$) and method repeatability (<15% RSD) across the ng to µg g^{-1} range. The method was successfully applied to determine the internal concentration of analytes in *Daphnia magna* exposed to selected pharmaceuticals.

3.15.P-We173 Historic Landfills as a Source of Emerging Contaminants to Aquatic Systems
Abdullah M Almehmadi[1]*, John Wilkinson*[1] *and Alistair B.A. Boxall*[2]*, (1)Environment and Geography, University of York, United Kingdom, (2)University of York, United Kingdom*
Many chemicals used by society ultimately end up in landfill sites. It is being increasingly recognised that legacy landfill sites or sites with insufficient management are an important source of contaminants into aquatic systems. However, work to date on the chemical characteristics of landfill leachate has focused on only a handful of chemicals. This study was therefore performed to characterise the chemical signature of landfill leachate from cells of different ages. Monthly leachate samples were obtained from cells of different ages from a large landfill site between March 2020 to February 2021. Leachate samples were analysed using a High Resolution Mass Spectrometry (HRMS) Orbitrap. The resulting data files were searched for 5871 compounds, including current use and banned pesticides, pharmaceuticals, biocides and home-use products, that would be expected to be disposed to landfills. So far, data have been obtained for two sampling timepoints (September and January). A total of 128 chemicals has been identified with the highest number (83) of compounds being detected in a leachate from a cell that was closed in 2016. Only six chemicals were detected in leachate from the oldest cells (closed in 1988) namely DEET (an insect repellant), Selenium Sulfide (an antidandruff treatment), DEHP (a plasticizer), profenofos (an insecticide), N,N'-diphenulguanadine (a rubber vulcanizing agent) and EDTA (a chelating agent used in personal care products). The data analysis is ongoing and will be used to construct a chemical history of the landfill.

3.15.P-We174 Targeting Metal Impurities for the Detection and Quantification of Carbon Black Particles in Water via spICP-MS
Kenneth Flores[1] *and Jorge Gardea-Torresdey*[2]*, (1)Chemistry, University of Texas at El Paso, (2)Chemistry and Biochemiistry, University of Texas El Paso*
Carbon black (CB) is a nanomaterial with numerous industrial applications and increasing use, prompting concern for potential environmental release and accumulation. In order to improve detection capabilities for this and other graphitic materials, particularly in water systems, this study investigated the metal impurities contained within these materials as potential analytical tracers. The analysis of eighteen different metal impurities was conducted on six commercial varieties of CB materials. Of the metals identified in these characteristic metal fingerprints, La impurity was chosen as a tracer for single particle inductively coupled mass spectrometry (spICP-MS) based on the apparent concentration, low detection limits, and lack of polyatomic interferences. Following optimization efforts, a limit of detection of 63.9 µg/L and quantification limit of 122.2 µg/L of CB exemplified the sensitivity of this novel detection/quantification technique. When compared to UV-visible absorption spectroscopy, and gravimetric analysis, this spICP-MS approach exhibited similar quantification sensitivity in the mg/L concentration range, with the ability to detect CB particles an entire order of magnitude lower. The particle sizing capability of the spICP-MS technique allowed for consistent sizing of the most frequent La particle diameter contained in CB, which could act as a characteristic signal for detection of these particles in environmental waters. The sensitivity of this detection method was unaffected when dissolved lanthanum was added to sample matrices at concentrations typical of environmental waters. In comparison to existing technologies, this high throughput method of detection has achieved competitive sensitivity, a wide dynamic working range for quantification, and high selectivity for managing complex matrices.

3.15.P-We175 Method Validation for 260 Pesticides Quantitation at ng/L Level in Water samples with LC – ESI Laminar Flow MS/MS and Direct Injection

Floriane Queiroga[1], *Philippe Boniteau*[2], *Sebastien DI Mayo*[1] *and Félix Massat*[1], *(1)Laboratoire Départemental D'Analyses de la Drôme, France, (2)PerkinElmer, France*

European Union water polices are continuously being reevaluated to determine safe levels of many contaminants in water sources, resulting in the lowering of detection limits by various governments to meet more stringent regulatory requirements. The aim of this study was to develop and validate a LCMSMS method with direct injection in order to analyze a large polarity range of pesticides in water samples. Results needed to meet the protocol (EU reference ISO/TS 13530:2009), based on the French regulations NF-TO-90210. They should also include statistical tests on calibration, robustness and inaccuracy studies.

3.15.P-We176 Identification of Contamination Sources in Undergroundwater at Hanlim, Jeju Island by Target/Suspect/Non-target Analysis with LC/Orbitrap-MS

Moon Haeran[1], ***Jeong-Eun Oh***[1], *Won-Jin Sim*[2] *and Seong-Taek Yun*[3], *(1)Department of Civil and Environmental Engineering, Pusan National University, Korea, (2)Institute for Environmental and Energy, Pusan National University, Korea, (3)Department of Earth and Environmental Sciences, Korea University, Korea*

Groundwater and subsurface environment pollution from anthropogenic sources has been a serious problem owing to the long-term recovery period and not judging defaulters immediately. To identify the contamination sources, Environmental forensics technology has recently received a lot of attention for identifying contamination sources. In this aspect, target, suspect, and non-target analysis with high-resolution mass spectrometry (HRMS) is regarded as a new tool to decipher the diverse and specific chemical molecular formulas of compounds occurring at trace levels in matrices without reference standards. In addition, related previous research has suggested the use of chemical compounds as indicators or tracers to represent specific major contaminant sources, such as pesticides, livestock wastewater, and industrial activities. This study aimed to screen unrevealed organic contaminants and identify indicator chemicals for agriculture and livestock contamination sources by suspected and non-target screening using LC/Orbitrap-MS. Hanlim in Jeju, which had a pig manure accident history in 2017, was selected as our sampling site to evaluate our technology scheme. In brief, 35 compounds were detected through targeted and suspected screening at Hanlim, and some antibiotics were only detected in major manure-contaminated sites. We are also suggesting certain new indicators for livestock origin by statistical analysis. Detailed information will be provided during the presentation at the conference.

3.15.P-We177 Pilot Large Scale Testing of UV LED Technologies for Reuse of Wastewaters: Anti-microbial Efficiency and Effects on Micropollutant Concentrations

Lucie Blahova[1], *Michal Bittner*[1], *Kumiko Oguma*[2], *Jutta Eggers*[3], *Tim Schwarzenberger*[3], *Jaroslav Lev*[4], *Lucie Baborska*[4] *and Ludek Blaha*[5], *(1)RECETOX, Masaryk University, Czech Republic, (2)University of Tokyo, Japan, (3)TZW DVGW (German Water Centre), Germany, (4)ASIO TECH s.r.o., Czech Republic, (5)RECETOX, RECETOX, Masaryk University, Czech Republic*

In the present study, we report results of one of the first large scale pilot study that tested innovative LED reactors emitting UV (UV LED) for disinfection of pre-treated wastewater effluents. Two different UV LED systems were installed in parallel with conventional low pressure Hg-based UV lamp (repeated 7 day-long pilots) at the municipal wastewater treatment plant (WWTP). The investigation showed that UV LED was efficient in reducing numbers of microorganisms in WWTP effluent waters that might be recycled and used for various technological or irrigation purposes. At the same time UV irradiation was observed to affect concentrations of some micropollutants in the final effluents. Pharmaceuticals and other xenobiotics enter the environment through excretion either in their original parental form or as metabolites formed during detoxification in vivo. Most importantly, glucuronide or sulfate conjugates with variable chemical properties may reach receiving waters at concentrations that are comparable or even higher than those of parent compounds. Deconjugation of the metabolites in the environment including WWTPs may release original biologically active pharmaceuticals. This phenomenon was confirmed by LC-MS/MS in the present study, where UV irradiation triggered deconjugation of metabolites followed by unexpected increases in concentrations of parent pharmaceuticals. These observations indicate potential risks for water quality, which needs further investigation.

3.15.P-We178 Application of Passive Sampling to Monitor Melamine and Its Derivatives in Water Environment

Yoonah Jeong, *Korea Institute of Civil Engineering and Building Technology (KICT), Korea* Melamine is one of the emerging contaminants with persistent, mobile, and toxic (PMT) properties. Due to the release of large quantities for various uses, the widespread occurrence of melamine in the environmental matrix has been reported. Once discharged, melamine can be transformed into cyanuric acid, ammeline, and ammelide. In this study, passive sampling was applied to identify the efficient monitoring method to monitor melamine and its three derivatives in the water environment. Based on existing passive samplers, polar organic chemical integrative sampler, and chemcatcher, various sorbents and membranes were applied for sampler materials. As a receiving phase, SDB-RPS disk, SDB-XC, Oasis HLB, and Oasis MCX were employed. In addition, PTFE and PES membranes were prepared. Sampling rates and sampler-water partition coefficients for four target compounds were determined for various passive sampling combinations. The results of this study contribute in situ monitoring of melamine and its derivatives in surface water.

3.15.P-We179 Parameter-Free Extracted Ion Chromatography Builder for Non-Target Screening

Gerrit Renner[1], *Max Reuschenbach*[1] *and Torsten C. Schmidt*[2], *(1)University of Duisburg-Essen, Instrumental Analytical Chemistry (IAC), Germany, (2)Instrumental Analytical Chemistry, University of Duisburg-Essen, Germany*

The non-target screening (NTS) is a promising method for aquatic system monitoring and risk mitigation. NTS is mainly a

qualifying method for liquid chromatography coupled with high-resolution mass spectrometry. It does not require reference standards by design and is used for samples with unknown substance compositions like waste waters or rivers. Unfortunately, there is a lack of standardized algorithms for evaluating NTS data, which then provide hardly comparable results. Besides, many NTS algorithms require user-input parameters. Therefore, we are developing a new generation of NTS algorithms that (1) do not require any user-input parameters, (2) provide uncertainties for all intermediate results, and (3) consider uncertainties from former steps for calculations. We have already published a centroiding method for HRMS data that follows our abovementioned concept. We will now present a modern method for extracting ion chromatograms (XIC). Thereby, the new algorithm will work user-independent and considers and provides the process uncertainties.
The algorithm's main principle is considering each data point's m/z distance to its right neighbour when the dataset has been sorted. If two m/z belong to the same XIC, their distance will follow a characteristic distribution (Null Hypothesis H0). However, the Alternative Hypothesis (H1) will be accepted if a critical value is exceeded.
The algorithm was applied to various data sets and compared to other XIC building concepts. We calculated the silhouette score for each XIC that describes its data quality. Moreover, we used automatic peak detection to distinguish between XICs containing chromatographic peaks (True Positives TP) and only noise (False Positives FP). We obtain that our new method reaches the highest silhouette scores, i.e., the classification quality was best. Using peak detection, it can be deduced that all methods detect a significant number of FP XICs. However, our approach provides more TPs as well.
The new algorithm presented in this work is a suitable parameter-free alternative to existing XIC builders for NTS. The method uses information from the data and an iterative process to find the best XIC composition for any NTS data set, which fits the urgent demand for harmonized data evaluation. Moreover, the silhouette score is suitable for describing XICs' qualities to improve removing FP from NTS results.

3.15.P-We180 Influence of the Sample Pretreatment Method on the Suspect Screening Output of Pollutants Identified in Treated Wastewaters from an Urban/Industrial WWTP

Dana Orlando Véliz[1]*, Rocío Inés Inés Bonansea*[2]*, Manuel Garcia-Vara*[3] *and Miren López de Alda*[3]*, (1)Enviromental Chemistry, Spanish Research Council (CSIC), Institute of Environmental Assessment and Water Research (IDAEA), Spain, (2)Universidad Nacional de Cordoba, Córdoba, Argentina, (3)Spanish Research Council (CSIC), Institute of Environmental Assessment and Water Research (IDAEA), Spain*

In the current global/climate change context, the circular economy as a sustainable model has been applied in the water sector as a solution to mitigate the water scarcity, mainly, in arid and semi-arid areas such as the Mediterranean. However, among other reasons, industrial pollution appears as an obstacle due to the contribution of organic pollutants to the water networks as a consequence of their incomplete removal in wastewater treatment plants (WWTPs). This is the case of a wide variety of pollutants, such as industrial chemicals or pharmaceuticals, which could represent a risk for the environmental and human health. For the identification of these pollutants, the application of suspect screening (SS) methodologies is emerging as a practical, convenient approach. However, the kind of sample treatment applied before the SS analysis can have a large impact on the outcome, leaving out in some cases relevant pollutants. In order to investigate this issue, in the present study, three different pretreatment methods were applied to a series of treated wastewater samples collected daily during one week from an urban/industrial WWTP located in an industrial area: (i) direct injection (100 µL), (ii) lyophilization of 250 mL of sample, reconstitution in a final volume of 1 mL of methanol:water 25:75 and injection of 5 µL of the solution, and (iii) on-line solid phase extraction (SPE) of 1 mL of water using a polymeric cartridge. The subsequent analysis of the samples was performed in all cases by LC-HRMS using a hybrid Q-ToF analyzer and in positive and negative ionization. Then the SS workflow for identification of the compounds present in the samples considered different parameters such as exact mass, isotopic pattern and fragmentation, as well as the contrast of the data obtained with MS libraries. From the different sample pretreatment methods tested, the lyophilization allowed the identification of the largest number of compounds, probably because in the online SPE procedure some compounds are lost, and in the direct injection method the comparatively lower sensitivity achieved together with the existence of relevant matrix effects do not allow the detection of compounds present at low concentrations or exhibiting low ionization efficiencies. The results of this study also showed the predominant presence of pharmaceuticals and industrial chemicals followed by some personal care products and other categories of substances, such as caffeine or pesticides.

3.15.P-We181 Environmental and Multisource Monitoring – Strategies and Approaches in PARC

Nicole Bandow[1]*, Anja Duffek*[1]*, Valeria Dulio*[2] *and Katrin Vorkamp*[3]*, (1)German Environment Agency, Germany, (2)Institut National de l'Environnement Industriel et des Risques (INERIS), France, (3)Department of Environmental Science, Aarhus University, Denmark*

The European Partnership for the Assessment of Risks from Chemicals (PARC) was launched in May 2022 and aims to advance current risk assessment practices, for a better protection of the environment and human health. The monitoring of chemicals in the environment is an important component of risk assessment, also including matrices directly related to exposure, e.g. food and dust. An appropriate design of monitoring studies is a challenging task, which should also consider the high number of potentially harmful chemicals. The aim of the task "Environmental and multisource monitoring" in PARC is to develop an overall framework for a science-based selection of chemicals for environmental monitoring and to design monitoring schemes closely linked to activities to establish an early warning system. This overall framework includes a prioritization mechanism, the review of existing knowledge, the design and implementation of monitoring studies, data analysis and a feedback step. It is based on the two main prerequisites of responding to regulatory needs and of building on existing knowledge and infrastructure. Depending on the questions to be answered, it will include target methods and non-target/suspect screening approaches as well as effect-based methods. An ongoing pilot project addresses the regulatory relevant compounds classes of endocrine disrupting chemicals (ECD) and per- and polyfluoralkyl substances.

3.15.P-We182 Sorption Kinetics of Psychoactive Compounds on Active-Passive Sampling (APS) Sorbent Gels
Allen Anies[1]*, Adrian Covaci*[2]*, Ronny Blust*[1] *and Raewyn M. Town*[1]*, (1)ECOSPHERE, University of Antwerpen, Belgium, (2)University of Antwerp, Belgium*
The novel environmental pollutant monitoring approach, active-passive sampling (APS), is being optimized for use in wastewater-based epidemiology (WBE). APS provides *in situ* pre-concentration of pollutants in water independent of the hydrodynamic conditions. The APS device incorporates a pump to control the laminar flow of the sampled medium into a diffusion cell which houses sorbent gels that selectively sorb pollutants. In this study, sorption kinetics on sorbent gels of commonly detected antidepressants, opioids, and illicit drugs in WBE was investigated by laboratory exposure experiments in tap water. Agarose- and polymer-based HLB (hydrophilic-lipophilic balanced) and MCX (mixed-mode cation exchanger) sorbent gels were evaluated by exposure to spiked tap water at different exposure times. Results showed that O-desmethylvenlafaxine, morphine, tramadol, and benzoylecgonine sorbed preferentially on HLB while N-desmethylcitalopram and amphetamine sorbed to a greater extent on MCX; benzoylecgonine was sorbed the least by both sorbents. Sorbent-water partitioning coefficients (K_{SW}) were significantly higher on polymer-based sorbent gels compared to the agarose-based counterparts. Accumulation rate constants (k_x) varied significantly between MCX gels but not between HLB gels. Exposure at different water conditions (pH and salinity) was undertaken to explore the interplay between the hydrophilic and electrostatic binding properties of the sorbent gels and the physicochemical properties of the target compounds. For HLB, sorption was greatest at pH 8-9 for most compounds while sorption on MCX increased as the pH was decreased. At increasing ionic strength of water (0-3 g/L NaCl), more abrupt decrease in sorption was observed for MCX as compared to HLB. Findings demonstrate that sorption kinetics of psychoactive compounds on sorbent gels depend on chemical interactions in the sampling medium. The complementary use of HLB and MCX sorbent gels is proposed for a wider coverage of different psychoactive drugs in WBE.

3.15.P-We183 Screening Of Organic Pollutants In Clam And Fish Samples By Matrix Solid-phase Dispersion Combined To Liquid And Gas Chromatography With High Resolution Mass Spectrometry
Sandra Mendez[1]*, Javier Lopez-Vazquez*[1]*, Daylin Lopez-Castillo*[1]*, Rosa Montes*[2]*, Joana Raimundo*[3]*, Miguel Caetano*[3]*, Clara Lopes*[3]*, Cátia Figueiredo*[4]*, Teresa Neuparth*[5]*, Bárbara Marlene Pinheiro*[6]*, Nélson Alves*[5]*, Ricardo Capela*[5]*, Susana Barros*[5]*, Hugo Morais*[5]*, Miguel M. Santos*[5]*, José Benito Quintana*[1] *and* ***Rosario Rodil***[1]*, (1)Universidade de Santiago de Compostela, Spain, (2)University of Santiago de Compostela, Spain, (3)Portuguese Institute for Sea and Atmosphere (IPMA), Portugal, (4)MARE - Marine and Environmental Sciences Centre, Portugal, (5)University of Porto, Interdisciplinary Centre of Marine and Environmental Research, Portugal, (6)Porto University, Portugal*
The presence of organic micropollutants (OMPs), such as persistent organic pollutants (POPs) and contaminants of emerging concern (CECs) has been documented in several aquatic environments. The bioaccumulation of these compounds has become a matter of concern for its possible transfer to the food chain and impact on several wildlife species of the marine environment and human consumers of seafood. Thus, the aim of this work was to apply a wide screening strategy in order to detect different types of OMPs in fish and clam samples from the Portuguese coast.

Liver and muscle *of Trachurus trachurus, Solea solea, Microchirus azevia, Microchirus variegatus, Trisopterus luscus* and the whole body of *Spisula solida* were collected from different areas of the Portuguese coast within the project *CEIC* (Contaminants in commercial species from the Portuguese coast). Sample treatment was performed by three matrix solid-phase dispersion (MSPD) methods and then the extracts were analyzed by both liquid and gas chromatography coupled to high-resolution mass spectrometry (LC-HRMS and GC-HRMS).

In this way, a total of 120 OMPs were identified by using two high-resolution and one low-resolution (NIST) spectral libraries. From the substances detected, 58% of them derived from industrial activity, 22% were pharmaceuticals and drugs, 12% cosmetic products and 8% pesticides. Moreover, the number of OMPs identified using the three different MSPD methods was compared. The method that allowed the detection of the highest number of OMPs was the one incorporating silica impregnated with sulfuric acid, likely because of its capacity to remove lipids and other interfering substances.

Among the surveyed samples, clams and fish muscle showed a similar contamination profile regardless of the collection area and the number of OMPs detected compared to fish liver, which exhibited a different profile.

3.15.P-We184 Complex Investigation of the Potential Environmental Risk of UV-filtering Compounds in Cosmetics for Lake Balaton
Zoltan Nemeth[1,2]*, Zsolt Pirger*[3]*, István Fodor*[3]*, Mihály Óvári*[4] *and András Komáromy*[3]*, (1)Doctoral School of Environmental Sciences, ELTE Eötvös Loránd University, Hungary, (2)Ecophysiologycal and Environmental Toxicologycal Research Group, Balaton Limnological Research Institute, Hungary, (3)Balaton Limnological Research Institute, Hungary, (4)Nuclear Security Department, Centre for Energy Research, Hungary*
Our research group investigates the presence of different chemicals in surface waters, performs risk assessment, and investigates the effects on aquatic species. Nowadays, the presence of synthetic UV-filtering compounds in the global ecosystem is a hot topic in ecotoxicology. It has been shown, mostly by recently published studies, that these chemicals can cause acute and chronic toxicity to aquatic invertebrate and fish species.

Lake Balaton (Hungary) is the largest shallow lake of Central Europe and an important summer holiday destination visited by millions of tourist every year. Hence, the preservation of its good water quality and biodiversity is of strategic importance from an ecological and economic point of view. Based on our calculations, about 2.5 tons of UV-filtering substances can dissolve in Lake

Balaton on an average summer day. Importantly, surveys aiming at the investigation of the presence of these compounds in Hungary have not yet been performed. Hence, the aims of my research are to determine what type of UV-filtering compounds are present in Lake Balaton, to investigate their spatio-temporal variations, and to investigate their potential effects on the widely used ecotoxicological model species, the water flea (*Daphnia magna*).
During my experiments, I focus on five UV-filtering compounds, avobenzone, octinoxate, octocrylene, octisalate, and homosalate. After the appropriate sample preparation (e.g., lyophilisation, microwave-assisted, and solid phase extraction), the compounds are analyzed with UHPLC-MS in water, sediment, biofilm, and biota samples. Besides, we performed photostability and, for the first time, freeze-thaw stability experiments under different temperature and pH conditions in both aqueous and non-aqueous solutions with UV-Vis spectrophotometry to ensure a more realistic environmental measurement. Moreover, in preliminary experiments, we exposed *D. magna* specimens to avobenzone, octocrylene, octinoxate at an environmentally relevant concentration (200 ng/L) for 21 days. During the treatments, changes in the heart rate, body size, and reproduction (time of the first egg production, egg number in the first production, and maximum egg number per individual) were investigated. All of the compounds significantly increased all of the behavioral parameters investigated. Our results show that the release of sunscreen agents into aquatic ecosystems poses an environmental risk.

3.15.P-We185 Analytical Monitoring of Organic Contaminants Treated by an Industrial Waste Water Treatment Plant for a Deeper Understanding of Removal Rates
*Valerie Held[1], **Thomas Dutriez**[2], Gordon Sanders[2], Diane Petermann[2], Anny Dabaghian[2], Josiane Gallay[1], Honey Peteut[1], Luis Linares[1], Marc Molliet[1], Neil Owen[3] and Karen Jenner[3], (1)Givaudan Suisse SA, Switzerland, (2)Givaudan International SA, Switzerland, (3)Givaudan UK, United Kingdom*
Wastewater treatment is a key step for minimizing the release of organic molecules into the environment. Through a multistep process, e.g. physico-chemical and biological processes, molecules are removed from waste water effluents and degraded through bioactivity of inoculum. Although routine analyses are frequently performed to monitor WWTP efficiency (e.g. TOC, BOD, pH…), specific analyses at a substance specific level are needed for in-depth understanding of removal processes and to further minimize the release of potential micro-pollutants into surface water.
As a proactive initiative, an inventory of organic molecules in waste water, being treated by an industrial WWTP has been established, with an emphasis on potential micro-pollutants. The industrial WWTP studied represents an on-site treatment plant at a fragrance manufacturing / formulation site. A list of molecules of interest was selected for method development, based on production and consumption rates, their persistency (low biodegradation) and hydrophilic behaviour (low log Kow). Appropriate sample preparation (e.g. LLE or SPE) and analytical technique (e.g. LC-HRMS or GC-MS) were optimized in order to cover a concentration range from 0.01 to 10 ppm.
For the initial study, incoming and outflow effluents of the biological step were sampled on a weekly basis for 14 weeks and analysed by headspace GC-MS for volatiles and SPE-GC-MS for semi-volatiles. This initial assessment highlights the most recurring organic molecules in the incoming & outlet flows and provides qualitative removal rates.
In a second study, quantitative monitoring of selected molecules was carried out through a daily sampling point approach. Quantitative data can be extracted using a targeted analysis approach such as determination of removal and release rates. With daily data collected on a substance specific basis, root cause investigations can be implemented for identifying which specific industrial process(es) mostly contribute to the level of organic compounds found at WWTP.
The data generated by the present study allows more detailed understanding of an industrial WWTP at a substance specific level. It provides novel data which enables the optimization of industrial processes and the development of additional treatment regimes for the more ecotoxic molecules. Finally, it provides a real world case study for potentially refining environmental risk assessment at a fragrance manufacturing and/or formulation site.

3.15.P-We187 Development of a Multiresidue Method for the Determination of Pharmaceutical Products in Seawater
***Jorge Lejo Lejo-Santiago**[1], Estefanía Concha-Graña[2], Purificación López-Mahía[2] and Soledad Muniategui-Lorenzo[2], (1)University Institute of Research in Environmental Studies (IUMA), University of A Coruña, Spain, (2)Universidade da Coruña, Spain*
The increase of population and industrial development have produced an increase on the presence of potentially toxic compounds. These compounds are known as contaminants of emerging concern (CEC), among them the pharmaceutical compounds and their metabolites are highly spread. The main sources of their presence in the environment are, firstly wastes from laboratories, hospitals and agriculture, and secondly their excretion after their consumption, which appears in wastewaters. Some of them are not removed in wastewater treatment plants and consequently they could contaminate seawaters. The aim of this work is to develop a rapid and sensitive multi-residue method using liquid chromatography coupled to mass spectrometry of triple quadrupole LC-MS/MS (QqQ) with SPE on-line extraction for the determination of pharmaceutical compounds in seawaters. 56 pharmaceutical compounds including antibiotics, analgesics, cardiovascular drugs and psychiatric drugs among others were determinated. The proposed method injects only 100 µl of water sample as alternative to the pre-concentration phase allowing to quantify the majority of analytes in the range of <10 ng/L in a short period of time, due to these characteristics it is appropriate for the monitorization of environmental samples.

3.15.P-We188 An Automated Toxicity Based Prioritization Framework for Fast Chemical Characterization in Non-Targeted Analysis and Its Validation in Sludge Water
***Claudia Rathmann**[1], Yongjun Xiao[2] and Junjie Yang[3], (1)Waters Corporation, Germany, (2)International Food and Water Research Centre, Singapore, (3)School of Civil and Environmental Engineering, Singapore*

The identification of environmental pollutants with harmful effects is usually performed by non-targeted analysis (NTA) using liquid chromatography coupled with high resolution mass spectrometry. However, the prioritization of possible candidates is challenging due to the large number of candidates from MS acquisitions. Therefore, we have developed an R package application, "NTAprioritization.R", for fast prioritization of suspect lists, where candidates with potential exposure are prioritized based on their toxicity and identification evidence in the matrix. In this workflow, candidates were first rated for their identification levels based on spectral matching and retention time prediction. The level of toxicity levels was rated according to candidates' toxicity of different endpoints or ToxPi score. Finally, the candidates' level of exposure was ranked from Tier 1-5, in order of priority from highest to lowest. For validation of this workflow, it has been used to identify pollutants in a sludge water sample spiked with 28 environmental pollutants. The workflow reduced the number of potential candidates from 6,982 candidates to a final list of 2,779 compounds with 21 out of 28 spiked standards ranked in 5 tiers (Tier 1 to 5). Overall, this study shows the added value of an automated prioritization R package based on the NTA method for the fast screening of environmental pollutants.

3.15.P-We189 Assessing Pharmaceuticals In Red Seaweed through Ultra-High Performance Liquid Chromatography with Time-of-Flight Mass Spectrometry (UHPLC-TOF-MS) Multi-Residue Strategy
***Sara Leston**[1], Márcia Dias[2], Miguel A. Pardal[2], Jorge Barbosa[3], Fernando Ramos[3] and Andreia Freitas[4], (1)University of Coimbra, Centre for Functional Ecology, Portugal, (2)University of Coimbra, Portugal, (3)REQUIMTE/LAQV, (4)INIAV-LNIV, Instituto Nacional de Investigação Agrária e Veterinária, Portugal*
Red macroalgae have quickly become a valuable commodity worldwide, representing over 46% share of the major commercial seaweed market. Although their production is mainly directed for human consumption, many other purposes have been listed including food and feed industries, water treatment and remediation, medicine, cosmetics, and as biofuels (FAO, 2020). In 2018, *Gracilaria* species aquaculture accounted for over 3400 thousand tonnes, being the third most farmed genus. Another important use for these seaweeds is their role as bioindicators in ecosystem monitoring, given their proven ability to take up and bioaccumulate contaminants from the water and sediments. Therefore, it becomes paramount to have reliable analytical tools to their detection and quantification. Thus, the present work describes the development and validation of an ultra-high performance liquid chromatography with time-of-flight mass spectrometry (UHPLC-TOF-MS) multi-residue method for the quantification of 74 pharmaceuticals in *Gracilaria multipartita*. Since currently there is a gap on regulation and guidelines concerning the validation criteria specifically for seaweed, validation was performed following Commission Decision 2002/657/EC.

3.15.P-We190 Strategies for Monitoring Coastal Environments using Liquid Chromatography with High-Resolution Mass Spectrometry
***Fiona Regan**[1] and Chloe Richards[2], (1)Water Institute, Dublin City University, Ireland, (2)School of Chemical Sciences, DCU Water Institute, Dublin City University, Ireland*
Coastal environments present interesting challenges in environmental monitoring. Sewage outfalls, personal care products (PCPs), which may be partly attributed to the increasing popularity of open-water swimming, and the ubiquitous per-/polyfluorinated alkyl substances (PFAS) all contribute towards a cocktail of contaminants to which marine environments may be exposed. Challenges with sampling and the chemical composition of sea water present additional complications for analysis. Liquid chromatography coupled with high-resolution mass spectrometry (LC-HRMS) is emerging as a key analytical technique in environmental monitoring, offering the benefits of non-targeted data acquisition and yielding data that can be flexibly interrogated by suspect screening and discovery workflows, as well as retrospectively analysed for novel contaminants of concern.
This talk will present workflows for the analysis of emerging environmental contaminants in Irish coastal samples using liquid chromatography coupled with quadrupole-time of flight mass spectrometry (LC-QTOF-MS), covering experimental design, instrumental set-up and data handling.

3.15.P-We191 Identification of Tidal-Related Pollution Patterns in the Elbe River by Non-target Screening and Statistical Analysis
***Jonas Richard Leonhard Schneider**[1,2] and Michael Radke[1], (1)Labor für Umweltuntersuchungen, Institut für Hygiene und Umwelt, Freie und Hansestadt Hamburg, Germany, (2)Institute of Sustainable Chemistry, Leuphana University Lüneburg, Germany*
Tidal rivers are a vital and insufficiently studied nexus between freshwater and marine ecosystems where river-tide-interactions alter a river's hydrology and geomorphology, but also the composition of the water. Constantly changing water level, flow rate and even flow direction can impact the behavior and fate of organic micropollutants (OMPs). By means of highly time-resolved sampling in combination with non-target screening and multivariate statistical methods, this study aimed at unravelling tidal-related pollution patterns in a large river and at identifying relevant sources and entry pathways.
In three sampling campaigns, hourly composite water samples were simultaneously collected at two monitoring stations. The stations were located along the tidal influenced section of the Elbe River, upstream and downstream of the urban area of Hamburg, Germany. Chemical analysis was performed by liquid chromatography coupled to an Orbitrap mass spectrometer. The software Compound Discoverer including an extensive in-house spectral library was used to perform peak picking, alignment, blank correction, and annotation of known OMPs. A self-programmed R workflow was employed to statistically analyze the resulting peak lists in order to unravel tide-related patterns.
Comparing annotated OMPs with water level data, up to now three different pollution patterns could be identified: a) features which are characterized by increasing intensities at the upstream station and decreasing intensities at the downstream station during high tide, and vice versa. Their main sources are obviously located between the two monitoring stations in the Hamburg area, b) features with increasing intensities during flood tide at both stations, supposedly introduced downstream of the Hamburg

area, and c) features with relatively constant intensities or patterns not related to water levels or direction of flow, likely originating from the upper reaches of the river.
This study confirmed that tidal dynamics substantially influence the behavior and composition of OMPs. Further, it was successfully shown that the applied sampling design allowed for an approximate localization of the sources. To gain a deeper understanding, monitoring is currently continued and the patterns are going to be analyzed further, i.e., by including additional physiochemical parameters in the statistical models. Moreover, unknown features in the dataset will be ranked and prioritized for subsequent identification.

3.15.P-We192 Dynamic Passive Sampling Methods for Marine Monitoring of Emerging Contaminants
***Chloe Richards**[1], Caroline Murphy[2], Weili Guo[3], Louis Free[4], Sean Power[4] and Fiona Regan[5], (1)School of Chemical Sciences, DCU Water Institute, Dublin City University, Ireland, (2)School of Biotechnology, Dublin City University, Ireland, (3)School of Biotechnology, DCU Water Institute, Dublin City University, Ireland, (4)Water Institute, DCU Water Institute, Dublin City University, Ireland, (5)Water Institute, Dublin City University, Ireland*
Marine ecosystems are subject to a multitude of direct human pressures, such as overexploitation, eutrophication, pollution and species introductions[1–3], including the effects of global impacts, namely ocean acidification and climate change[4]. These stressors can have synergistic effects on marine ecosystems[5,6], altering their functioning and ability to provide goods and services[7,8]. Their impact is expected to be even stronger in enclosed and semi-enclosed basins with high population density, tourism flow and maritime activities[9]. Improved knowledge on the consequences of the effects of multiple stressors on marine biodiversity and ecosystem functioning is urgently required. The aim of this work is to develop a robust, sensitive and reliable method for the preconcentration of diclofenac in seawater using a dynamic passive sampling process.

3.15.V Innovations in Analytical Methods Used for Monitoring Emerging Contaminants in Marine and Freshwater Aquatic Environments

3.15.V-01 Quality Assessment of the Source Identification Applied to Different Spilled Oils and Performed by Distinct Methods
***Ana Catarina Carvalho da Rocha**[1], Carla Palma[2] and Ricardo Bettencourt da Silva[3], (1)Division of Chemistry and Marine Pollution, Hydrographic Institute, Portugal, (2)Division of Chemistry and Pollution of the Marine Environment, Hydrographic Institute, Portugal, (3)Centre for Structural Chemistry - Institute of Molecular Sciences, University of Lisbon, Portugal*
Chemical analysis performed on samples collected in the spill and suspected source(s) of its origin has been a valuable support for judicial investigations. The Gas Chromatography-Mass Spectrometry are used to obtain the sample fingerprint defined by a set of abundance ratios between chromatographic signals of specific components, *i.e.*, diagnostic ratios (DR). The DR observed in two samples are compared using statistical methods and the equivalence between all DR in the set indicates sample composition equivalence, which allows identify the spill origin. The most common approaches to compare DR are based on Student's *t* statistics (S-t) (Nordtest method), and on a maximum relative difference of 14% (SC) (EN 15522-2 standard). However, the S-t approach assumes that the probability distributions of DR follow the normal distribution, while the 14% criterion relies on empirical knowledge that experts have acquired over the years, assuming a most expectable dispersion. Therefore, if inadequate assumptions or approximations are considered, erroneous assessments can be made about the equivalence of DR and fingerprints. The development of DR comparison approaches that better describe the reality of the variables under study is essential to ensure identification quality. This work compares the St and SC approaches with a developed alternative approach based on the accurate simulation of correlated chromatographic signals using the Monte Carlo Method. The study was carried out on International Round Robin test samples, made available by Oil Spill Identification Network of Experts, that represent spills of different petroleum products, allowing evaluate the impact of different DR sets on confidence intervals for DR comparison and on the probability (total risk) of true acceptance of compositional equivalence between samples.

3.15.V-02 Assessment of Emerging Contaminants in an Anthropogenic-impacted Watershed: Application Using Targeted, Non-targeted, and In Vitro Bioassay Techniques
***Theodora Lee**[1], Caixia Li[2], Mauricius Marques dos Santos[3], Suan Yong Tan[4], Mithusha Sureshkumar[4], Khajornkiat Srinuansom[5], Alan Ziegler[5] and Shane Allen Snyder[4], (1)NEWRI, Singapore, Singapore, (2)Nanyang Environmental & Water Research Institute, Singapore, (3)Nanyang Environment & Water Research Institute (NEWRI), Nanyang Technological University, Singapore, (4)Nanyang Environmental & Water Research Institute, Singapore, (5)Faculty of Fisheries Technology & Aquatic Resources, Mae Jo University, Thailand*
Monitoring the prevalence of emerging contaminants (ECs) in mixed-use watersheds is crucial for managing water resources effectively, particularly in light of growing population densities in cities worldwide. Restricted to a predefined set of target compounds, suspect screening by target analysis alone for water quality monitoring is insufficient to truly comprehend the impact of anthropogenic activities on aquatic ecosystems. Non-targeted screening (NTS) and biological risk assessments such as the use of *in vitro* bioassays (BSY), used in tandem with target screening (TS), are pivotal in ensuring a comprehensive assessment and data transferability to aid decision making processes in water quality management.
In this study, we investigated the presence of ECs in a mixed use Ping river catchment, Chiang Mai, Thailand, from remote, rural, agriculture, urban and subsurface sources from July 2021 to August 2022. The main objective of this study was to evaluate the use of three screening methods, TS using online solid phase extraction coupled to high-resolution liquid chromatography mass spectrometry (LC-MS/MS), NTS using liquid chromatography quadrupole time-of-flight mass spectrometry (LC-QToF-MS) and *in vitro* BSY (cytotoxicity and reporter assays), to identify potential sources of pollution across a rural-urban gradient.

All three screening methods highlighted urban sites as the most polluted and toxic while remote sites were the cleanest and least toxic as expected. However, our NTS results further suggests that the contaminant profile across a rural to urban gradient is not simply linear, but the contamination profile of each land use type may vary for various reasons including the nature of contaminant use, and prevalent use of septic tanks in this region.
The results of this study also presented both the benefits and limitations of each screening technique, demonstrating how each technique can be used strategically in specific goal-oriented situations, or used in tandem synergistically to ensure high quality and well-informed water quality analysis.

3.15.V-03 Paper Microfluidic Device for Rapid Detection of Pathogens and Antimicrobial Resistance in Water
*Yuwei Pan[1] and **Zhugen Yang**[2], (1)Cranfield University, United Kingdom, (2)School of Water, Energy and Environment, Cranfield University, United Kingdom*
Pathogen detection in wastewater is critical for early warning of pandemic, contributing to public health surveillance. We have demonstrated the application of paper-based microfluidic devices for veterinary diagnosis in India and malaria testing in Uganda, Africa. The severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) causes respiratory illness and gastrointestinal infections, with viral material being excreted in feces (and surviving within sewage for several days). Here, we propose a low-cost and user-friendly paper-based microfluidic device incorporating reverse transcription loop-mediated isothermal amplification (RT-LAMP) for the detection of SARS-CoV-2 and influenza. Qualitative results were displayed by a UV torch, observed with naked eyes or recorded using a mobile phone camera. The paper-based platform could complete the concentration, extraction, amplification and detection of viruses in wastewater within 1.5 hours, with a detection limit as low as 10 copies μL^{-1}. The device was used for on-site detection of SARS-CoV-2 in wastewater samples from four quarantined hotels at London Heathrow Airport, showing results comparable to those obtained using reverse transcription quantitative polymerase chain reaction (RT-qPCR) assays. The N gene presented the highest detection rate in wastewater samples, followed by the S and ORF1ab genes. ORF1ab gene shows less sensitivity than N, and S genes due to shorter sequence which is likely be degraded in the wastewater system. Our platform enables rapid detection of viruses without the need to send wastewater samples to centralized laboratories. Compared to gold-standard PCR assay, our platform provides similar or higher specificity and sensitivity for pathogen detection at a much cheaper and faster way, providing a high-resolution data set for highly responsive measurement during the pandemic. It has a clear potential that the platform can be used as a public health early warning tool for various applications in community settings and shows great potential for rapid and on-site wastewater surveillance at community settings in both developing and developed countries.

3.16.A Legacy, Emerging and Novel Per- and Polyfluoroalkyl Substances (PFASs): Latest Findings and Future Research Needs

3.16.A.T-01 Polar and Nonpolar Interactions That Determine the Partition Properties of Neutral PFAS
***Satoshi Endo**, Jort Hammer, Yoko Katakura and Sadao Matsuzawa, National Institute for Environmental Studies (NIES), Japan*
Per- and polyfluoroalkyl substances (PFAS) are a large group of substances with diverse molecular structures. To capture the emissions, transport, exposure, and risks of PFAS, their partition properties need to be understood. However, past studies were limited to a small number of PFAS of highest environmental concern. In this study, we measured isothermal gas-chromatographic (GC) retention times of 64 neutral PFAS on capillary columns with varying polarity to investigate the polar and nonpolar interaction properties of PFAS. The measured GC data were combined with partition coefficient data from the literature and our own lab and used to determine polyparameter linear free energy relationship (PP-LFER) solute descriptors, which quantitatively characterize the interaction properties of PFAS and can be used to predict various partition coefficients.
Retention data for the nonpolar columns were used to determine the log of the hexadecane/air partition coefficient (*L*) as an indicator of nonpolar interactions, which was described in a previously published article. Measured log retention factors (*k*') obtained with the low polarity HP-5ms column exhibited a high correlation with *L* values, confirming the predominance of nonpolar interactions. Still, minor but significant difference was found in the trend of *k*' between nonpolar PFAS (e.g., perfluoroalkyl iodides, fluorotelomer olefins) and polar PFAS (e.g., fluorotelomer alcohols (FTOHs) and perfluoroalkane sulfonamides (PFASAs)). High polarity columns such as DB-225ms resulted in high scatter in the log *k*' vs *L* plot. (*N*-substituted) PFASAs deviated most strongly from the nonpolar PFAS baseline, indicating high polarity of these chemicals. FTOHs exhibited intermediate polarity, while fluorotelomer iodides, acrylates, and methacrylates demonstrated weak polarity.
PP-LFER solute descriptors (e.g., *S*, dipolarity/polarizability parameter; *A*, H-bond donor property; *B*, H-bond acceptor property) were determined using the data for *k*' and partition coefficients (*K*) and the calibrated PP-LFER equations. Preliminary results for FTOHs suggest that the *A* descriptor decreases with increasing $-CH_2-$ spacer length. Also, it was indicated that *N*-substitution of PFASAs decreases the *A* property. These results are reasonable considering the structure of these PFAS. Currently, more *k*' and *K* data are being measured, which will yield new descriptor values and refine those that exist.

3.16.A.T-02 Finding a Way Out? Biotransformation Study of Novel Fluorinated Surfactants
***Viktória Licul-Kucera**[1,2], Annemarie van Wezel[3], Tobias Frömel[1] and Thomas P. Knepper[1], (1)Institute for Analytical Research, Hochschulen Fresenius gem. Trägergesellschaft mbH, Germany, (2)Institute for Biodiversity and Ecosystem Dynamics, University of Amsterdam, Netherlands, (3)University of Amsterdam, Institute for Biodiversity and Ecosystem Dynamics, Netherlands*
Per- and polyfluorinated substances (PFAS) are a diverse group of anthropogenic chemicals with unique chemical and thermal stability. Stability made PFAS favorable for the industry, at the same time, caused concerns from the environmental point of view.

A new approach by the European Commission suggests a large-scale ban of PFAS and at the same time, highly supports the design of potentially safer alternatives. The goal of this study is to investigate the environmental fate of novel fluorinated surfactants designed with green chemistry sight.
Two trifluoromethoxy-substituted surfactants with either an ether or a thioether linkage were designed and synthesized. Microbial transformation studies under aerobic conditions in activated sludge-wastewater medium were performed for 126 days. A semi-closed experimental system with a trapping sorbent was selected to avoid any loss of volatile transformation products (TPs). The changes in the concentration of the initially added surfactants and the expected TPs were monitored by target analysis using liquid chromatography–tandem mass spectrometry. High resolution mass spectrometry (HRMS) was also used to identify other unquantifiable TPs.
Results and Discussion: Significant decrease in the concentration of the surfactants was observed over the incubation period. The main TPs were carboxylic acids (CAs), moreover, a shorter-chained CA representing the last product prior mineralization, was also detectable. Two additonal TPs were identified by HRMS in the case of the thioether surfactant. The three CAs stayed quite stable during the incubation time and no final mineralization could be observed with our method. The total amount of the substances achieved only about 30-45% of the total expected concentration at the end of the incubation time. It was linked to the irreversible sorption of the surfactant molecules to the sludge.
Although mineralization of the surfactants was not obeserved based on the concentration monitoring of the TPs, it can be not excluded. When the use of any PFAS is essential, these prototype chemicals could be a compromise as their terminal products are less fluorinated and likely have less bioaccumulation potential compared to the conventionally used PFAS.

3.16.A.T-03 Development of Protein-Water and Membrane Water Partition Coefficients for Target and Suspect PFAS
Derek Muensterman[1]*, Jennifer Field*[1]*, Carla A. Ng*[2]*, Ruiwen Chen*[2] *and Mark J Benotti*[3]*, (1)Oregon State University, (2)University of Pittsburgh, (3)NewFields*
The unique chemical properties of per- and polyfluoroalkyl substances (PFASs) present a challenge for developing regulatory guidelines to protect organisms in the environment, and there is a need to establish protein-water and membrane-water partition coefficients to better characterize and model bioavailability in support of regulatory development. This poster/talk describes ongoing work to empirically-measure protein-water and membrane-water partition coefficients of 1) approximately fifty target PFAS using dialysis and the TRANSIL assay and 2) of approximately fifty target PFAS and additional suspect PFAS using biomimetic chromatography (BC) with detection by high resolution mass spectrometry (HRMS).
Membrane lipid-water partition coefficients (K_{mw}) in variable pH for traditional and emerging PFAS were obtained by the TRANSIL Membrane Affinity assay. The K_{mw} for each PFAS is evaluated by the linear regression of log PFAS concentrations in the aqueous phase and the membrane lipid phase. The binding affinity of these PFAS for human serum albumin (HSA), the major carrier of PFAS in human blood, is also being evaluated and validated using equilibrium dialysis, the gold standard for protein-water partition coefficients. For these experiments, the rapid equilibrium dialysis (RED) assay provides a higher-throughput format using 96-well plates. Dissociation constants (K_D) and PFAS-albumin partition coefficients (K_{PW}) are evaluated by non-linear regression analysis.
Biomimetic chromatography has the benefit of directly simulating a biological environment using commercially available high-performance liquid chromatography (HPLC) columns containing immobilized artificial membrane (IAM) and human serum albumin (HSA) which act as bio-relevant stationary phases. Furthermore, protein binding of PFAS will be measured using HSA stationary phases whereas phospholipid binding will be measured using the IAM stationary phase[1]. The rapid-gradient approach allows for the determination of partition coefficients (k) for a wide variety of compounds in a single, gradient-based HPLC run. Findings from the empirical measurements conducted at Oregon State University and University of Pittsburgh will be reported. Combination of the techniques will help further understanding of PFAS protein and membrane binding for future research needs.

3.16.A.T-04 Characterizing the Flow of Perfluoroalkyl Substances in an Avian Aquatic-Terrestrial Food Web
Kailee Hopkins[1]*, Melissa A. McKinney*[1]*, Robert J. Letcher*[2]*, Amandeep Saini*[3]*, Natalie K. Karouna-Renier*[4] *and* ***Kim J. Fernie***[5]*, (1)McGill University, Canada, (2)Science and Technology Branch, Environment and Climate Change Canada, Canada, (3)Environment and Climate Change Canada, Canada, (4)U.S. Geological Survey, (5)Environment and Climate Change Canada, Science & Technology Branch, Canada*
Per- and polyfluoroalkyl substances (PFAS) are a group of emerging contaminants found ubiquitously in the environment. Limited research has been conducted on the flow of PFAS, including perfluoroalkyl sulfonates (PFSAs), perfluoroalkyl carboxylates (PFCAs), their precursor compounds, and newer alternative PFAS, through aquatic and terrestrial food webs. As a species that forages on terrestrial and aquatic invertebrates, tree swallows (*Tachycineta bicolor*) potentially transfer and accumulate PFAS from both aquatic and terrestrial ecosystems. Our objectives were to assess the flow of PFAS in the aquatic-terrestrial food web of tree swallows, by: 1) determining food web structure using fatty acid (FA) signatures; 2) investigating PFAS patterns across abiotic and biotic food web compartments; 3) modelling PFAS contributions of food web compartments to PFAS burdens of tree swallows; 4) estimating bioaccumulation of target PFAS in this food web. We characterized 46 PFAS compounds in air, surface water, aquatic sediment, aquatic and terrestrial invertebrates, and gastrointestinal tracts (GIT) and livers of nestling tree swallows. The FA signatures of aquatic invertebrates had greater proportions of the FA 20:5n3, a FA typical of aquatic environs, vs. the terrestrial invertebrates, whicht had higher proportions of 18:2n6, a FA common to terrestrial biota. Tree swallow FAs were intermediate between aquatic and terrestrial invertebrates, although closer to the latter, consistent with aquatic and terrestrial feeding, but somewhat more terrestrial-based. Distinct patterns were evident in the PFAS profiles among ecosystem compartments: PFAS profiles of air, terrestrial invertebrates, and tree swallow tissues had higher proportions of PFOS than the aquatic compartments. The fluorotelomer carboxylate (FTCA) precursor, 5:3 FTCA, was a major component of the PFAS profiles

of aquatic sediment, aquatic invertebrates, and tree swallows (GIT, livers). Nonetheless, concentrations of most PFAS precursors were greater in aquatic samples than tree swallow tissues. Nestling tissues had greater concentrations of most long-chain PFSAs and PFCAs than the other environmental compartments. These patterns are consistent with dietary uptake of PFAS by tree swallows via aquatic and terrestrial pathways and demonstrate the complexity of the flow of PFAS in this avian aquatic-terrestrial food web.

3.16.A.T-05 Multigenerational Toxicity of Per- And Polyfluoroalkyl Substances (PFAS) To *Daphnia Magna* and *Folsomia Candida*

Ge Xie[1]*, Michiel Kraak*[2]*, Arie J. Vonk*[2]*, Thomas L. ter Laak*[2,3]*, Annemarie van Wezel*[2] *and Cornelis A.M. van Gestel*[4]*, (1)A-LIFE, Vrije University Amsterdam, Netherlands, (2)University of Amsterdam, Institute for Biodiversity and Ecosystem Dynamics, Netherlands, (3)KWR Water Research Institute, Netherlands, (4)VU Amsterdam, Amsterdam Institute for Life and Environment (A-LIFE), Netherlands*

Per- and polyfluoroalkyl substances (PFAS) are a diverse group of man-made chemicals that have been widely applied and have raised environmental concerns across the globe due to their high persistence and ubiquitous presence in the environment. Short-chained PFAS have been used to replace long-chained PFAS, but they remain largely unregulated, such as perfluorobutanesulfonic acid (PFBS) and its precursor perfluorobutane sulfonamide (FBSA). These compounds have been detected in the environment near 3M Zwijndrecht, a PFAS hotspot in Belgium. The persistent and bio-accumulative features of these compounds call for chronic and multigeneration ecotoxicity tests, which are, however, virtually lacking. The aim of the present study was therefore to assess the multigenerational toxicity of PFBS and FBSA to the reproduction of an aquatic (*Daphnia magna*) and a soil-dwelling (*Folsomia candida*) arthropod species exposed for 6 and 5 generations, respectively. The toxicity tests followed OECD guidelines 211 and 232, respectively. The results of the single-generation tests showed that FBSA is much more toxic than PFBS to *D. magna* (EC_{50}s of 5.48 and 856 mg L^{-1}, respectively) and *F. candida* (EC_{50}s of 1.21 and >1000 mg kg^{-1} $soil_{wd}$, respectively). Although the multigeneration toxicity tests with *F. candida* are still ongoing, we already showed that the EC_{50} values of PFBS for the reproduction of *D. magna* decreased significantly from 856 to 376 mg L^{-1} in the first four generations (F0 to F3), while the EC_{50} value of FBSA decreased significantly from 5.48 to 1.19 mg L^{-1} in the first three generations (F0 to F2). These results demonstrate an increasing sensitivity of *D. magna* towards continuous exposure to PFAS over multiple generations, which could be related to increasing internal exposure concentrations due to PFAS accumulation. Therefore, we plan to analyze the PFAS concentrations within *D. magna* and *F. candida* from the different generations. It is concluded that conventional single-generation toxicity tests underestimate long term PFAS toxicity.

3.16.B Legacy, Emerging and Novel Per- and Polyfluoroalkyl Substances (PFASs): Latest Findings and Future Research Needs

3.16.B.T-01 Applications of Non-Targeted Analysis in PFAS Investigations

James McCord*, Mark Strynar and Jacqueline Bangma, U.S. Environmental Protection Agency*

Historically, industrial producers and users of legacy per- and polyfluorinated alkyl substances (PFAS) have been a major source of chemical contamination to nearby communities. Following the general phase-out of legacy PFAS such as PFOA/PFOS, it has been the domain of non-targeted analysis (NTA) to identify replacement PFAS species introduced by industry. Environmental and public health organizations have a significant interest in identifying emerging chemical contaminants such as PFAS due to concerns for potential widespread release and the persistence and bioaccumulation of PFAS species. As such, over the last several years the US Environmental Protection Agency's Office of Research and Development (USEPA ORD) has applied non-targeted analytical approaches alongside traditional targeted PFAS quantitation techniques to expand the coverage of PFAS information in uniquely impacted locations. USEPA partnerships with state and regional governments have examined novel PFAS classes including novel PFAS fluoroether species such as chlorinated perfluoropolyethers (ClPFPECAs), polyfluorinated side products of polyfluorovinylidine (PVDF) and further compounds containing unique head group moeties and ether linkages; identified specific replacement chemicals used in applications such as metal plating and PFOS-free AFFF; identified the presence of these replacement PFAS in local media, including biota; and supported evaluation of the effectiveness of various PFAS remediation techniques on legacy and novel PFAS. This presentation will discuss case studies of recent work by USEPA ORD in NTA investigations of PFAS sources. Source examination reveals both intentionally added chemical species and production byproducts as common origins for emerging PFAS. Non-targeted interrogation of treatment approaches for emerging contaminants indicates that existing treatment technologies can be effective controls for many undescribed species. The talk will additionally discuss efforts to ensure the consistent application of NTA approaches in partner laboratories, reporting of NTA results to interested parties, and decision making using non-targeted analysis as a data source.

3.16.B.T-02 Closing the Organofluorine Mass Balance in Marine Mammals with Suspect Screening and Machine Learning-Based Semi-Quantification

Melanie Lauria[1]*, Thomas Ledbetter*[1]*, Helen Sepman*[1]*, Merle Plassmann*[1]*, Malene Simon*[2]*, Anna Roos*[3]*, Anneli Kruve*[1] *and Jonathan Benskin*[1]*, (1)Stockholm University, Sweden, (2)Greenland Climate Research Centre, Greenland Institute of Natural Resources, Greenland, (3)Swedish Museum of Natural History, Sweden*

A recent survey estimated that more than 6 million per and polyfluoroalkylsubstances (PFAS) exist on the database PubChem, yet only a fraction of these substances are routinely monitored. This discrepency has led to concerns that targeted analysis may understimate the extent of PFAS contamination in the environment. To address this, fluorine mass balance experiments aim to quantify unidentified PFAS through a combination of targeted anaylsis and total fluorine-based measurements. High resolution

mass spectrometry-based non-target and suspect screening is vital for identification of novel organofluorine substances. However, assessing the contribution of newly identified substances towards the fluorine mass balance is hampered by the availability of analytical standards. To address this, machine learning models that predict ionisation efficiency (IE) in LC-ESI-HRMS can be useful for estimating concentrations.
In this work, liver from marine mammals collected from Greenland and Sweden were subjected to a fluorine mass balance and HRMS-based suspect screening. Thereafter, a machine learning-based semi-quantification approach was validated and applied to suspects in an effort to close the fluorine mass balance.
EOF concentrations were lowest in west Greenland dolphins, and were entirely accounted for by known PFAS (∑PFAS of 53 ± 10 ng F/g). In comparison, the highest EOF concentrations were observed in Swedish dolphins (1222 ± 600 ng F/g) with only 46% accounted for by known PFAS (411 ± 148 ng F/g). In wet Greenland Pilot whales, two individuals displayed a closed fluorine mass balance while three contained an average of 31% unknown EOF.
Suspect screening revealed several novel PFAS not captured by targeted analysis, which were confirmed at CL2. This included e.g. fluorotelomer sulfonic and carboxylic acids, perfluorinated sulfonamides, which collectively accounted for significant portions of the EOF following semi-quantification.
This study represents the first time machine learning-based semi quantification was applied to suspect PFAS in an effort to close the organofluorine mass balance. This in silico approach can be useful for estimating the contribution of newly identified PFAS towards overall PFAS exposure; and (2) identifying which standards should be prioritized for development.

3.16.B.T-03 Fluorine Mass-balance in Pooled Serum Samples from Northern Norwegian Men and Women Between 1986 and 2015

Lara Cioni[1,2]*, Merle Plassmann*[3]*, Jonathan Benskin*[3]*, Ana Carolina Coelho*[2]*, Therese Nøst*[2]*, Charlotta Rylander*[2]*, Vladimir Nikiforov*[1]*, Dorte Herzke*[1] *and Torkjel Sandanger*[2]*, (1)Norwegian Institute for Air Research (NILU), Norway, (2)UiT - The Arctic University of Norway, Norway, (3)Stockholm University, Sweden*
Per- and polyfluoroalkyl substances (PFAS) are a class of synthetic chemicals used in numerous industrial and consumer product applications. Due to their widespread use, PFAS are ubiquitous in the environment and humans and wildlife are exposed globally. While regulation of two of the most well-studied PFAS, PFOS and PFOA, has contributed to declining concentrations in human blood, production of other PFAS continues unabated. Considering that only ~1 % of the over 4700 PFAS on the global market are routinely monitored, there is increasing concern that human exposure to these chemicals might be underestimated.
In this study, human serum samples from the Tromsø (Norway) population, collected in 1986, 2007 and 2015, were pooled based on sampling year, sex, age and type 2-diabetes diagnosis. Each of the 46 pools contained 8-15 individuals and was analyzed for total fluorine (TF), extractable organic fluorine (EOF), total oxidizable precursors (TOP) and 54 target PFAS. The aim was to evaluate the concentrations of TF and EOF in human serum, the portion of unidentified EOF, the contribution of oxidizable precursors and the impact of sex and age on all these fractions.
TF concentrations ranged from <25 to 1330 ng F/mL and EOF concentrations ranged from 13.3 to 45.3 ng F/mL No significant differences between sampling years were observed for TF while for EOF a significant decrease was observed between 1986 and 2007 (-1.20 ng F/ml) and no differences were observed between 2007 and 2015. There were no associations with sex and age for TF and EOF. In 25 µL of pooled serum, 10 of the 54 target PFAS were detected: PFOA, PFNA, PFDA, PFUnDA, PFHxS, PFHpS, PFOS, FOSAA, Me-FOSAA, Et-FOSAA. The sum of target PFAS concentrations was lowest in 1986 and highest in 2007. Known PFAS accounted for 23-100% of the EOF. The unidentified EOF fraction was largest in 1986 (22-77 %; median: 46 %), significantly lower in 2007 (0-40 %, median: 11 %) compared to 1986 and significantly higher in 2015 (0-56 %; median: 37 %) compared to 2007. Women had significantly higher concentrations of unidentified EOF than men, opposite to what is observed for known legacy PFAS. Oxidizable precursors ranged from 0.00 to 1.85 ng/mL and accounted only for a small portion of the EOF (0-4%), meaning that additional analytical tools are required to close the organofluorine mass balance in human serum.

3.16.B.T-04 Dermal Bioaccessibility of Per- And Polyfluoroalkyl Substances (PFAS) From House Dust; Influence of Topically Applied Cosmetics

Oddný Ragnarsdóttir*, Mohamed Abou-Elwafa Abdallah and Stuart Harrad, University of Birmingham, United Kingdom*
Human exposure to per- and polyfluoroalkyl substances (PFAS) has been shown to negatively impact human health, e.g. by decreasing immune response after vaccinations. Their stability as well as their hydrophobic and lipophobic properties make PFAS suitable for use in a broad range of products, such as: textiles and personal care products. Many of these PFAS-containing products come in contact with the skin. Still, very little is known about the possible human exposure to PFAS via the dermal pathway.
This study investigates, *for the first time*, the dermal bioaccessibility of PFAS from household dust. Physiologically-based *in-vitro* tests were performed to evaluate the bioaccessibility of 17 PFAS from indoor dust to different synthetic sweat sebum mixtures (SSSM). Additionally, the impact of commonly used personal care products (foundation, sunscreen, moisturiser and deodorant) on PFAS bioaccessibility in the most physiologically-relevant SSSM composition (1:1 sweat:sebum) was examined.
The composition of the SSSM greatly impacted the bioaccessibility of the target compounds. PFAS bioaccessibility in the 1:1 sweat:sebum mixture ranged from 54-92% for perfluorocarboxylic acids (PFCAs) and 61-77% for perfluorosulfonic acids (PFSAs). Of the selected personal care products, sunscreen and moisturiser significantly decreased the sum PFCAs bioaccessibility. Similarly, foundation and moisturiser significantly decreased sum PFSAs bioaccessibility while the presence of deodorant significantly increased their bioaccessibility.

Finally, preliminary estimates of human exposure to PFAS via dermal contact with indoor dust were calculated based on our bioaccessibility data. These estimates show that for some PFAS (e.g. PFOS and PFOA), dermal uptake could contribute as much to an adult's overall daily exposure as other well-characterised pathways, such as drinking water and dust ingestion. While further research is needed to more accurately determine the human dermal uptake of PFAS, the current study shows that dermal exposure could contribute significantly to total human body burdens of PFAS and should not be neglected in PFAS risk assessment studies.

3.16.C Legacy, Emerging and Novel Per- and Polyfluoroalkyl Substances (PFASs): Latest Findings and Future Research Needs

3.16.C.T-01 Enrichment and Emission of Perfluoroalkyl Acids on Nascent Sea Spray Aerosol from the Oceans

Bo Sha[1]*, Jana Helena Johansson*[2]*, Matthew Salter*[3,4]*, Ian Cousins*[3] *and Sara Blichner*[1]*, (1)Environmental Science, Stockholm University, Sweden, (2)Thematic Studies - Environmental Change, Linköping University, Sweden, (3)Stockholm University, Sweden, (4)Bolin Centre for Climate Research, Sweden*

The ubiquitous presence of perfluoroalkyl acids (PFAAs) in the environment has raised global concern. Oceans used to be considered as the final sink of PFAAs, where they would stay and be diluted into the deep ocean over decades. Recent laboratory studies demonstrated that PFAAs in seawater can be enriched hundreds of thousands of times on sea spray aerosols (SSA) and re-emitted from oceans to the atmosphere. Field evidence has shown that PFAAs transported on SSA significantly contributed to observed concentrations of PFAAs in air in coastal regions. However, the magnitudes of the PFAA emission via SSA from global oceans is not well quantified. One of the reasons is that it is uncertain whether the laboratory derived enrichment factor (EF) used in the estimation is environmentally relevant. In this study, field experiments were conducted along a north-south transect of the Atlantic Ocean to study the enrichment of PFAAs in SSA. Strong linear relationships were observed between the concentration of PFAAs in seawater and in supermicrometer SSA (both normalized to Na^+ concentration), which indicates the EF of PFAAs on supermicrometer SSA varied little along the cruise. The field-derived EFs were higher than previously observed in the laboratory, which may be due to the difference between artificial seawater and natural seawater. Based on the field-derived EFs, concentration of PFAAs in seawater measured in the field experiments and modelled global inorganic SSA production flux modeled by the Norwegian Earth System Model version 2 (NorESM2), we estimate that the emission of perfluorooctanoic acid (PFOA) and perfluorooctanesulfonic acid (PFOS) from the Atlantic and from the global oceans via SSA is comparable to or greater than estimates for the other known global emission sources. The spatial variation of the concentration of PFAAs in global oceans is likely a greater source of uncertainty than the variation in the EFs when estimating PFAAs emitted with SSA globally.

3.16.C.T-02 Environmental Distribution and Bioaccumulation of Understudied PFAS Surrounding Two Fluoropolymer Manufacturing Sites in Italy and the United States

Anna Robuck[1]*, Sara Valsecchi*[2]*, James McCord*[1]*, Mark Strynar*[1]*, Mark Cantwell*[1]*, Michaela Cashman*[1]*, Stefano Polesello*[2]*, Marianna Rusconi*[2]*, Beatrice De Felice*[3] *and Rainer Lohmann*[4]*, (1)U.S. Environmental Protection Agency, (2)Water Research Institute - Italian National Research Council IRSA-CNR, Italy, (3)University of Milan, Italy, (4)Graduate School of Oceanography, University of Rhode Island*

With the phase-out of some per- and polyfluoroalkyl substances (PFAS) like perfluorooctanesulfonic acid (PFOS), replacement PFAS have been introduced in consumer and industrial applications across the globe. Little is known about the occurrence, biological accumulation, or potential impacts of some of these replacement PFAS, even though some of them have been in use for years or decades. Here we used tandem mass spectrometry (MS/MS) and high-resolution mass spectrometry (HRMS) to evaluate emerging PFAS in surface water, sediment, and fish tissue from the Delaware River (USA) and the Bormida River (Italy). These river systems are adjacent to similar fluoropolymer manufacturing activities, with known overlap of specific PFAS processing aids in production at both sites. Previous work in both regions has demonstrated the presence of understudied PFAS incorporating at least one chlorine atom and one or multiple ether linkages, called chloroperfluoropolyether carboxylates, or Cl-PFPECAs. Environmental samples from both locations demonstrate an abundance of Cl-PFPECAs in surface water, sediment, and fish from the sampling region, with the highest levels observed adjacent to and downstream from each suspected point source, respectively. Surface water concentrations of Cl-PFPECAs were on the same order of magnitude in both locations, with maximum sum concentrations totaling ~1780 ng/L in Italy and ~750 ng/L from the Delaware River in the USA. C6O4, a novel ether-based PFAS, was found abundantly in samples from Italy, but this compound was not apparent in any environmental matrix from the US. Bioaccumulation factors (BAF) were calculated for ten chlorinated homologs in fish tissue compared to surface water concentrations. BAF estimates from both Italy and the USA were in good agreement and suggest that the larger molecular weight Cl-PFPECAs demonstrate bioaccumulative behavior equal to or surpassing PFOS (log BAF $\approx$ 3-4), with calculated logBAFs ranging from approximately 2 – 7. This work highlights the continuing evolution of PFAS occurrence in the environment and underscores the importance of non-targeted methods to screen for PFAS beyond limited targeted lists. These data also suggest Cl-PFPECAs may be equally or substantially more bioaccumulative compared to legacy PFAS. This work also underscores the importance of international collaboration to advance our understanding of novel PFAS in the environment.

3.16.C.T-03 The Decomposition and Emission Factors of a Wide Range of Per and Polyfluorinated Alkyl substances (PFAS) in the Dry Pyrolysis of Various Contaminated Organic Waste Fractions

Erlend Sørmo[1]*, Gabriela Castro Varela*[2]*, Michel Hubert*[3]*, Viktória Licul-Kucera*[4]*, Marjorie Quintanilla*[5]*, Alexandros G. Asimakopoulos*[2]*, Gerard Cornelissen*[1] *and Hans Peter Arp*[1]*, (1)Norwegian Geotechnical Institute (NGI), Norway, (2)Norwegian University of Science & Technology (NTNU), Norway, (3)Norwegian Geotechnical Institute and Norwegian University of Science*

and Technology (NTNU), Norway, (4)Institute for Analytical Research, Hochschulen Fresenius gem. Trägergesellschaft mbH, Germany, (5)Department of Chemistry, Norwegian University of Science & Technology (NTNU), Norway
General treatment options for organic waste contaminated with poly- and perfluoroalkyl substances (PFAS) are currently limited to incineration, composting or landfilling, all leading to eventual emissions to the environment. Dry pyrolysis is emerging as a promising new waste handling alternative for contaminated organic wastes, as it recycles waste to biochar, condensate and syngas products that can have various useful applications. However, the fate of organic contaminants like PFAS during dry pyrolysis is still uncertain. In the present work, a mass balance for 56 different PFAS was established during the pyrolysis of sewage sludges, food waste reject, garden waste and waste timber. Pyrolysis was done in a medium-scale unit (500-800 °C) with syngas combustion. All wastes contained PFAS (56 to 3651 ng g^{-1}), but pyrolysis led to a ≥98% removal. PFAS residuals (0.1-3.4 ng g^{-1}) were detected in biochars produced at temperatures up to 750 °C. Loads of emitted PFAS increased with temperature in a range from 3 to 268 µg $tonne^{-1}$ of biochar produced and were mainly associated with aerosols. Emissions only accounted for <0.1% of the total mass of PFAS in the wastes. The presence and potential environmental impact of thermal degradation products are the main remaining uncertainties.

3.16.C.T-04 Forever legacies? Profiling Historical PFAS Contamination Sources and their Current Influence on a Groundwater Source for Drinking Water
***Mohammad Sadia**, University of Amsterdam, Netherlands*
A wide range of PFAS residues was studied in an aquifer affected by historical PFAS contamination from a landfill and military airport. Samples were taken at two monitoring and four pumping wells at different depths ranging from 33 to 147 m. Comparison of results with previous research from 2013 with a more limited range of PFAS, showed decreasing in the concentrations and migration of PFAS both in depth and in distance over decade.
Using the PFAS profile and branched isomer contribution pattern as a source characterization tool, the landfill was confirmed to contaminate the groundwater in both monitoring wells, while the former airport was found to be the potential source for contaminating the deep water in the first monitoring well. Only deeper sections of one of the monitoring wells were affected by the airport. Pumping wells used to produce drinking water were not yet affected by both PFAS sources, however a new and yet unidentified contamination source with a different PFSA profile and isomer pattern influenced one out of the four sampled pumping wells. This work shows the necessity of implementing screening of potential historical PFAS sources for identification and prevention of future contaminant migration in groundwater nearby drinking water extraction wells.

3.16.P-Tu209 Perfluoroalkyl Substances in the Atlantic and Southern Oceans: Forever Around Us?
***Núria Trilla**[1,2], Jordi Dachs[1], Jon Iriarte[3], Naiara Berrojalbiz[1], Gemma Casas[4], Pere Colomer-Vidal[5], Odei Garcia-Garin[6], Maria vila-Costa[1] and Begona Jimenez[7], (1)Environmental Chemistry, Spanish Research Council (CSIC), Institute of Environmental Assessment and Water Research (IDAEA), Spain, (2)Global Change And Genomics Biogeochemistry Research Group, Spanish Research Council (CSIC), Institute of Environmental Assessment and Water Research (IDAEA), Spain, (3)Environmental Chemistry, IDAEA-CSIC, Spain, (4)Spanish Research Council (CSIC), Institute of Environmental Assessment and Water Research (IDAEA), Spain, (5)IQAG-CSIC, Spain, (6)University of Barcelona, Spain, (7)Institute of Organic Chemistry - Spanish National Research Council (IQOG-CSIC), Spain*
Perfluoroalkyl Substances (PFAS) are persistent synthetic organic chemicals widely used either as surface-active chemicals in the industry, in household consumer products, and a myriad of other applications. The high-water solubility and extraordinary persistence of perfluorooctanesulfonic acid (PFOS), perfluorooctanoic acid (PFOA), and other perfluoroalkylsulfonates (PFSAs) and perfluorocarboxylates (PFCAs) results in their ubiquity in the oceans, but with very slow removal in the marine environment, with only one report of PFOS degradation in seawaters. Furthermore, individual PFAS show a wide range of physicochemical properties, thus their transport, and interactions with organic matter and oceanic sinks may show significant differences among them, and remain unexplored. Among all the compounds, PFOS and PFOA have been the most extensively studied as they have been determined to be abundant, ubiquitous, and some reports suggest decreasing concentrations. Oceans are a major sink and reservoir of PFAS, eventually driving the global occurrence and trends of PFAS. Therefore, the objective of this work was to assess the spatial and vertical distribution of PFAS by sampling and analyzing samples taken during latitudinal transects in the Atlantic Ocean (from 40N to 55S) and in the Southern Ocean (from 61S to 71S). On the other hand, concentrations for PFOA and PFOS will be contrasted with temporal datasets to assess their potential decrease in the environment.
This study shows how ubiquitous PFAS are, being found not only in the Atlantic but also in remote areas such as the Southern Ocean. PFAS surface concentrations ranged from 62 to 1425 pg L-1 in the Atlantic transect, and from 13 to 516 pg L-1 in the Southern Ocean.
No statistically significant differences were found between Atlantic and Southern Ocean surface samples, nor between samples from the surface and the depth of the chlorophyll maximum. Vertical profiles showed surface enrichment and depth depletion profiles, consistent with the introduction of these chemicals on the surface by rivers, wet/sea-spray deposition, and slow transport to deep waters. Compared to previous studies, we found variable temporal trends. Both biogeochemical processes and different regulations, can explain the different profiles of PFOS, PFOA and other PFAS. A number of transport and biogeochemical processes will be explored to provide further evidence of the controls on the occurrence of PFAS.

3.16.P-Tu210 Indoor Exposure to Per- And Polyfluoroalkyl Substances in the Faroe Islands
***Melissa Woodward**[1], Jitka Becanova[1], Simon Vojta[1], Pál Weihe[2] and Rainer Lohmann[3], (1)University of Rhode Island, (2)The Faroese Hospital System, Faroe Islands, (3)Graduate School of Oceanography, University of Rhode Island*
Due to their environmental ubiquity and toxicity to life, per- and polyfluoroalkyl substances (PFAS), have been classified as a

group of emerging persistent organic pollutants. Given that humans typically spend 90% of their time indoors, main sources of exposure to PFAS include indoor air and dust alongside food and water. Developing reliable detection tools to quantify PFAS present in indoor matrices and evaluating the significance of different exposure pathways are therefore critical to understanding the potential threat to human health. Passive air sampler tubes were deployed in 40 homes on the Faroe Islands and dust samples collected from the same homes. Several targeted PFAS were detected in the indoor matrices: Most notably, fluorotelomer alcohols (FTOHs), which are precursors to the more stable perfluorinated alkyl acids (PFAAs), were present in all 40 homes, while both volatile and ionic PFAS were present in dust. For example, 6:2 FTOH dominated with concentrations ranging from 0.1 to 2.6 ng/m3 in air, and 17.6 to 94.3 ng/g in dust. Concentrations of ionic PFAS in dust were dominated by perfluorohexanoic acid (PFHxA), perfluorooctanoic acid (PFOA), perfluorooctanesulfonic acid (PFOS), and perfluorodecanesulfonic acid (PFDS) with concentrations ranging from 0.5 to 14.3 ng/g, 0.5 to 29.0 ng/g, 0.3 to 24.2 ng/g, and 0.9 to 20.1 ng/g respectively. Concentrations in air and dust were compared to those found in the drinking water and traditional diet consumed by the Faroese population to estimate the overall exposure and assess the importance of the various pathways. Alternatively, reported concentrations for PFAAs in pilot whales, a traditional part of the Faroese diet, range from below detection limits to 7.4 ng/g wet weight. Yearly exposure to PFOS and perfluoroalkyl carboxylic acids (PFCAs) via air and dust pathways is estimated to be equivalent to 9g of pilot whale. Nevertheless, this research highlights the potential of indoor air and dust to be possible routes of exposure to PFAS, even in remote locations.

3.16.P Legacy, Emerging and Novel Per- and Polyfluoroalkyl Substances (PFASs): Latest Findings and Future Research Needs

3.16.P-Tu211 FluoroMatch Flow and Visualizers are New Tools for Streamlined PFAS Annotation and Visualization
*Jeremy Koelmel[1], Paul Stelben[1], Krystal Pollitt[1], **Stephan Baumann**[2], Emma Rennie[3], Carrie McDonough[4] and Marcus James Chadha, PhD[5], (1)Yale University, (2)Academic and Government Applied Marketing, Agilent Technologies, Inc., (3)Agilent Technologies, Inc., (4)Chemistry, Carnegie Mellon University, (5)Agilent Technologies, Inc., United Kingdom*
Suspect and nontarget screening with liquid chromatography based high-resolution tandem mass spectrometry can be used for comprehensive characterization of PFAS. Many structure elucidation algorithms are focused on the six main chemical elements necessary for life, namely carbon (C), hydrogen (H), nitrogen (N), oxygen (O), phosphorus (P), and sulfur (S). This means that they tend to perform poorly when confronted with anthropogenic compounds such as PFAS.
FluoroMatch Flow and Visualizer were designed as an open-source solution for PFAS Annotation that is freely available from innovativeomics.com/software. FluoroMatch Flow directly processes vendor files and includes a systematic scoring framework to communicate confidence for every feature, alongside reporting confidence levels via the Schymanski schema.
FluoroMatch automates file conversion, chromatographic peak picking, blank feature filtering, PFAS annotation based on precursor and fragment masses, and annotation ranking. The software library contains ~7,000 PFAS fragmentation patterns based on rules derived from standards and literature, and the software automates a process to add more compounds.
To aid interpretation, we added a Visualizer tool to the FluoroMatch suite of software based on Microsoft PowerBI. It provides interactive mass defect plots, accurate mass vs. retention time plots, MS/MS fragmentation plots, and annotation tables. Selecting a feature in one graph will adjust what is displayed in other views. This interactive cross filtering allows simplified evaluation of a feature, PFAS series, or other groups of features.
Validating the percent coverage and accuracy of annotations in real-world samples was challenging due to the case of known unknowns and unknown-unknowns. In this experiment, we used all-ion fragmentation to estimate that FluoroMatch covered 71% of CF_2 containing PFAS compounds. Alternatively, with CF_2 normalized mass defect plots, we estimate 56% coverage of compounds with the remaining being false negatives.

3.16.P-Tu212 Predictability of perfluoroalkylated substances (PFAS) in homegrown eggs using local environmental and biotic variables
***Robin Lasters**[1], Marcel Eens[2], Thimo Groffen[2] and Lieven Bervoets[2], (1)Systemic Physiological and Ecotoxicological Research (SPHERE), University of Antwerp, Belgium, (2)University of Antwerp, Belgium*
The housing of free-ranging chickens has gained worldwide popularity over recent years due to its economic, nutritional and ecological benefits. However, homegrown eggs in private backyards have been associated with elevated pollutant concentrations, including perfluoroalkylated substances (PFAS). Within this exposure context, very little is known about the contribution of local environmental and biotic variables in explaining potential variation of egg concentrations. While experimental studies have demonstrated that PFAS concentrations in the soil are largely influenced by soil characteristics, very little is known about its implications on the bioavailability of PFAS in laying hens. Furthermore, the contribution to the egg PFAS burden of potentially important biotic matrices, which may serve as feed source to laying hens, has not been evaluated to the best of our knowledge. The main objectives of this study are to examine the (in)direct influence of multiple soil characteristics, soil and biota (vegetables, earthworms) concentrations on the egg PFAS concentrations in free-ranging laying hens and to evaluate the usefulness of empirical models to predict PFAS egg concentrations, taking into account these environmental and biotic variables.
Soil, egg, vegetable, worm and water samples were collected from 91 private gardens across Flanders. These matrices were analyzed for 32 target PFAS and the following soil characteristics were measured: total organic carbon (TOC) content, cation-exchange capacity (CEC), pH, electrical conductivity and clay content.
Results showed that egg concentrations of all PFAS were positively and negatively related with, respectively, soil concentrations and soil exchangeable potassium. For PFOS, clay content showed a strong and negative association with egg concentrations, while the reverse relationship was true for C11-C14 perfluoroalkyl carboxylates (PFCAs). Moreover, the effect size of clay

content increased with increasing chain length for the PFCAs. Apart from PFBA, the most suitable predictive and explanatory models were obtained with soil concentrations, clay content, pH and exchangeable potassium as sole predictors in the regression models (R^2 range: 49.9 - 69.8).
Cross-validation of the final regression models indicated that egg concentrations could be predicted with good accuracy, especially for PFOS and PFNA. However, training the model with additional field data is necessary to validate the models' predictability.

3.16.P-Tu213 Analysis of PFAS in food and food packaging by targeted and non-targeted approaches
Yelena Sapozhnikova *and Raegyn B Taylor, U.S. Department of Agriculture*
Per- and polyfluoroalkyl substances (PFAS) are wide-spread, persistent environmental contaminants. Their grease repelling, non-stick properties make them ideal for food-contact materials. However, the same resistant qualities that are beneficial for industry have made PFAS a major concern for environmental contamination due to limited degradation. Because of their ubiquity, longer-chain PFAS have recently been banned in several countries, but alternatives continue to emerge despite a limited understanding of potential health risks. Environmental contamination has ultimately led to several reports of contaminated food, through irrigation or uptake in animals. Thus, monitoring food and food packaging for PFAS continues to be imperative for understanding human exposure. Analytical efforts on PFAS analysis have largely focused on water, but analysis of food samples, and consequently the development of efficient analytical protocols for food, has recently gained more attention. This study aimed to investigate PFAS in food and food packaging using targeted liquid chromatography tandem mass spectrometry (LC-MS/MS) to monitor 33 PFAS and LC-high resolution mass spectrometry (LC-HRMS-Orbitrap) for non-targeted screening. We have developed and validated a simple and efficient analytical method for analysis of PFAS in fish, meat and eggs, which provided satisfactory recoveries in these foods with matrix effects below 20%. Using this method, several PFAS compounds were found in fish samples, including perfluorodecanoic acid (PFDA), perfluoroundecanoic acid (PfUdA), perfluorotridecanoic acid (PFTrDA), perfluorododecanoic acid (PfDoA), perfluorotridecanoic acid (PFTrDA), perfluorotetradecanoic acid (PFTeA), perfluorodecanesulfonic acid (PFDS), perfluorohexanesulfonic acid (PFHxS) and perfluoro-1-octanesulfonamide (FOSA) at low ng/g levels. Even fewer methods have been published for PFAS monitoring in food packaging, especially when coupled with non-targeted analysis. We have developed and evaluated an efficient sample extraction protocol for targeted and non-targeted analysis of PFAS in food packaging samples. Analysis of various food packaging samples of different geographical origin revealed frequent detection of PFHxS, perfluorohexanoic acid (PFHxA), perfluorooctanoic acid (PFOA), perfluorononanoic acid (PFNA) and perfluorooctanesulfonic acid (PFOS) at ng/g levels. Food packaging for dry meats had the highest frequency of PFAS detection.

3.16.P-Tu214 Target and suspect screening of 4,777 per- and polyfluoroalkyl substances (PFAS) in river water, wastewater, groundwater and biota samples in the Danube River Basin
Kelsey Ng[1,2]*, Nikiforos A Alygizakis*[1,3]*, Andreas Androulakakis*[3]*, Aikaterini Galani*[3]*, Reza Aalizadeh*[3]*, Nikolaos Thomaidis*[3] *and Jaroslav Slobodnik*[1]*, (1)Environmental Institute, Koš, Slovakia, (2)RECETOX, Masaryk University, Czech Republic, (3)National and Kapodistrian University of Athens, Greece*
Per-and polyfluoroalkyl substances (PFAS) have been scrutinized in the regulatory context as some of them are persistent, bioaccumulative, and toxic. In this study, the state-of-the-art computational and analytical tools were employed for the target and suspect screening of 4,777 PFAS in the Danube River Basin (DRB; 11 countries). Target screening covered 56 commercially available reference standards of PFAS. Suspect screening covered all the PFAS suspect lists submitted to the NORMAN Suspect List Exchange, including 4,777 PFAS in total. Chemical screening of the PFAS was performed in liquid chromatography – high resolution mass spectrometry using NORMAN Digital Sample Freezing Platform (DSFP). In total, 82 PFAS were detected in the studied 95 samples of river water, wastewater, groundwater, biota and sediments. Among them 10 PFAS were detected by target screening, 72 additional ones were revealed by suspect screening. Utilizing a quantitative structure-toxicity relationship (QSTR)-based approach, predicted no effect concentrations (PNECs) were derived for each PFAS and used for ecotoxicological risk assessment. Eighteen PFAS of environmental concern were prioritized in at least one environmental compartment. Seventeen of the 18 ranked PFAS are not monitored under the current legislative framework. The presence of PFAS across the DRB indicates a potentially widespread occurrence of PFAS in Europe, which requires systematic regulatory monitoring with special focus on the prioritized PFAS.

3.16.P-Tu215 The universe of fluorinated polymers and polymeric substances and potential environmental impacts and concerns
Robert J. Letcher[1] *and Rainer Lohmann*[2]*, (1)Science and Technology Branch, Environment and Climate Change Canada, Canada, (2)Graduate School of Oceanography, University of Rhode Island*
Per-/Poly-fluoroalkyl substances (PFAS) are a diverse group of surface treatment chemicals, although less than 6 % of the estimated 4,730 PFAS are reported to be of global commercial relevance, and can be divided into non-polymeric and polymeric categories. PFAS have been produced and used for several decades including in electric and electronic devices, fire-fighting foams, and textiles. Glüge *et al.* recently concluded there are more than 200 use categories and sub-categories for more than 1400 individual PFAS. To date, research has primarily focused on the identity, life cycle, hazard, and environmental occurrence, monitoring, biotic exposure and health risks of non-polymeric PFAS particularly perfluoroalkylcarboxylic acids (PFCAs), perfluoroalkanesulfonic acids (PFSAs), and some of their precursors. PFOS, PFHxS, PFOA and long-chain (>C7) and their related chemistries, have been increasingly phased-out of production and regulated in global jurisdictions. Those PFAS classified as polymeric can be further sub-divided into fluoropolymers, perfluoropolyethers (PFPEs) and side-chain fluorinated polymers (SCFPs), but environmental studies are far less prevalent than for non-polymeric PFAS. The present review summarizes

fluorinated polymers and polymeric substances and discusses the potential environmental concerns based on the current state of knowledge. Fluoropolymer producers are interested in having fluoropolymers treated as “polymers of low concern (PLC)”, due to their stability and seemingly low environmental impact; it is the use of fluorinated polymer processing aids that has caused widespread contamination at the production and manufacturing sites. Regardless, compared to many non-polymeric PFAS, fluoropolymers, PFPEs and SCFPs have received comparatively little attention from environmental scientists and regulators, despite their manifold industrial uses and high volumes. The current information demonstrates that there is already a considerable environmental burden of fluorinated polymers and polymeric substances and potential reservoir of more bioaccumulative degradation products. Concerted action is needed to address the dearth of environment-associated information and understanding on polymeric PFAS. Conducting research on those critical knowledge and data gaps that are most relevant for soundly regulating/managing polymeric PFAS and starting with reduction of emissions and release into the environment.

3.16.P-Tu216 Defluorination of 14C-Trifluoromethoxy Benzoic Acid in Soil

Doris Ebert[1]*, Brianna Scherffius*[2]*, Christopher Dobe*[3]*, Dieter Schaefer*[4]*, Emilie Charlier*[5]*, Gianna Braun*[6]*, Luis Paniagua*[7] *and Ron Vanpeer*[8]*, (1)BASF SE, Germany, (2)Corteva, (3)Syngenta, United Kingdom, (4)Bayer AG - Crop Science Division, Germany, (5)ISK, (6)Nufarm Europe GmbH, Germany, (7)Nichino, (8)FMC Agricultural Solutions*

During the last decades the introduction of CF_3 or CF_2 groups in the chemical structure of active ingredients (e.g. plant protection chemicals or pharmaceuticals) was found to be a very useful tool for increasing the target accessibility and thus the overall efficiency. Without the fluorinated group, the potency of molecules is often reduced (e.g. due to less cell membrane permeability) with the consequence that a much higher application or dose rate may be needed to reach similar protective or curative effects. Sometimes the molecule even becomes ineffective.

It is therefore of high interest if potentially degradable fluorinated groups (in the sense of being mineralized) can be introduced into active ingredients so that the high potency can be kept but without the risk of forming persistent "arrow head" substances (degradates).

HO-CF_3 was identified from the literature as a substance meeting the OECD PFAS definition, but that is also known to be hydrolytically unstable. The goal of this investigation was to confirm the potential degradability in soil of a model compound after the introduction of an O-CF_3 group, on the basis that the hypothetical “arrow head” is not a stable molecule.

Trifluoromethoxy benzoic acid was selected and radiolabelled directly at the CF_3-group to be able to directly follow the fate of the fluorinated carbon atom during soil degradation.

Results from incubations of ^{14}C-trifluoromethoxy benzoic acid in three soil types according to OECD guideline 307 are presented, showing that the C-F bond is cleaved and the carbon atom finally oxidized to CO_2.

After an incubation period of 28 days, trifluoromethoxy benzoic acid was completely degraded (<1% of total applied radioactivity recovered in soil extracts). For all three soils, the major degradation product was CO_2 accounting for 62 - 73% of the total applied radioactivity.

The presented results show that a single CF_3-group does not per se make a molecule or its transformation products persistent.

3.16.P-Tu217 "Perfluoroalkyl substances (PFASs) in food webs: a state-of-the-art review and future research agenda"

Maria Teresa Guerra *and Giorgio Mancinelli, Department of Biological and Environmental Sciences and Technologies, University of Salento, Italy*

This review work aims to analyse the current literature knowledge on Perfluoroalkyl substances (PFASs), their presence in the environment and accumulation and behaviour in food webs. PFASs can be subdivided in short-chained and long-chain chemical structures, the latter received scientific attention in the last years, since they accumulate along trophic structures. The available literature focusing on PFASs dynamics in trophic networks was scrutinized using Publish or Perish software. Several PFAS congeners were compared and among them, congeners with higher bioaccumulation rate have been identified. The results of the collected studies are generally consistent, showing that long-chained PFASs have a higher rate of bioaccumulation and biomagnification in organisms along food chains. Above all, the research mainly covered polar and temperate regions, while little is known for tropical regions, on which different environmental factors might play a role in the kinetics of these substances along the food web. Most of the studies were aquatic (marine and freshwater), while only a minor aliquot were carried out in terrestrial systems, for which information on PFAS dynamics on the food web is limited. Within the PFAS congeners studies in the last decades, for some of them regulatory actions were taken, and replaced with some short-PFAS alternatives. Short-chain PFAS did not show bioaccumulation in aquatic ecosystems. Nevertheless, also for short-chained PFASs data from terrestrial environments are still negligible. In the future, systematic research about the effects of the new emerging short-chain PFAS on the environment and their bioaccumulation or biodilution in the food web must be addressed. It would be appropriate to include multiple trophic-interactions along the food-web, to compare literature, and to apply a meta-analytical approach to quantitatively verify biotic (e.g., species identity and trophic habits) and abiotic (e.g., temperature) effects on PFASs bioaccumulation patterns.

3.16.P-Tu218 Distribution and Bioaccumulation of Per-and Polyfluoroalkyl Substances in the Aquatic Environment: A Mesocosm Study on PFAS Uptake from Sediment by an Aquatic Plant

Ioanna Spyridoula Gkika[1]*, Michiel Kraak*[1]*, Cornelis A.M. van Gestel*[2]*, Thomas L. ter Laak*[3]*, Annemarie van Wezel*[1]*, Robert Hardy*[4] *and Arie J. Vonk*[4]*, (1)University of Amsterdam, Institute for Biodiversity and Ecosystem Dynamics, Netherlands, (2)Amsterdam Institute for Life and Environment (A-LIFE), Vrije University Amsterdam, Netherlands, (3)KWR Water Research Institute, Nieuwegein, Netherlands, (4)University of Amsterdam, Netherlands*

Per- and Poly Fluorinated Substances (PFAS) are a widely used group of anthropogenic compounds, with a multitude of industrial and consumer applications. The widespread use of PFAS together with their persistence and bioaccumulation potential has led to global contamination of the abiotic and biotic environment. Nevertheless, their distribution across environmental compartments, including the potential uptake by aquatic plants, remains largely understudied. The aim of the present study was therefore to investigate the distribution and bioaccumulation of PFAS in the aquatic environment. To this end, we analysed the PFAS uptake from sediment by an aquatic plant. Sediment cores originating from a heavily PFAS-contaminated pond (Blokkersdijk, Antwerp) and a reference site (lake Gaasperplas, Amsterdam) were sampled. In Laboratory mesocosms, shoots from the rooting macrophyte *Myriophyllum spicatum* were planted and left to grow in these sediments, overlayed with Dutch Standard Water (DSW). At the start and the end of the 56 days experiment, the distribution and bioaccumulation of 10 PFAS with different molecular structures, including 3 isomer pairs (L-PFOS, Br-PFOS, L-PFOA, Br-PFOA, L-PFHxS, Br-PFHxS, PFBS, FBSA, 6:2 FTS, PFECHS) were determined in all matrices. All selected PFAS were detected in the contaminated sediment, while 6 out of 10 were also present in the reference sediment. All but one compounds were detected in the roots and shoots of the plants that grew on the contaminated sediment, while 5 PFAS were present in the roots and shoots of the plants that grew on the reference sediment. The calculated Biota-to-Sediment Accumulation Factors (BSAFs) for the 3 isomer pairs showed that linear isomers had a higher bioaccumulation potential from the sediment to the roots of the plants compared to the branched ones. It is concluded that PFAS are widely present in aquatic environments and that their bioaccumulation potential is driven by their molecular structure.

3.16.P-Tu219 Per-and Polyfluoroalkyl Substances Research Priorities for Environmental Risk Assessment

Ioanna Spyridoula Gkika[1], *Ge Xie*[2], *Cornelis A.M. van Gestel*[2], *Thomas L. ter Laak*[3], *Arie J. Vonk*[4], *Annemarie van Wezel*[1] *and Michiel Kraak*[1], *(1)University of Amsterdam, Institute for Biodiversity and Ecosystem Dynamics, Netherlands, (2)Amsterdam Institute for Life and Environment (A-LIFE), Vrije University Amsterdam, Netherlands, (3)KWR Water Research Institute, Nieuwegein, Netherlands, (4)University of Amsterdam, Netherlands*

Per- and polyfluorinated substances (PFAS) are a group of > 6000 ubiquitously applied persistent industrial chemicals. The field of PFAS research is developing rapidly, but suffers from substantial biases towards specific compounds, environmental compartments and organisms. The aim of this perspective was therefore to highlight current developments, and to identify knowledge gaps and subsequent research needs that would contribute to a comprehensive environmental risk assessment for PFAS. To this end, we consulted the open literature and databases, revealing that the environmental fate of PFAS is based on the analysis of less than 1.0% of the compounds that are categorized as PFAS. Moreover, soils and solid particulate matter (SPM) remain largely understudied. To determine the bioavailability of PFAS, the capacity of different passive sampler types to reliably take up the wide variety of bioavailable PFAS from the environment has yet to be determined. Furthermore, PFAS bioaccumulation and food web transfer studies focus on a very limited number of compounds and are biased towards aquatic biota. Fish are predominantly studied, with aquatic invertebrates and macrophytes being included less frequently. The available ecotoxicity data revealed that only a few PFAS have been well-studied for their environmental hazards, and that PFAS ecotoxicity data are strongly biased toward aquatic organisms, emphasizing the need to catch up in the terrestrial environment. Considering the persistency and bioaccumulation of PFAS, more chronic studies, but also multigeneration studies on ecologically relevant test species are needed. Finally, we identified the urgent need to unravel the relationship between sorption, bioaccumulation and toxicity on the one hand and molecular descriptors of PFAS chemical structures and physicochemical properties on the other. The present perspective ends by systematically listing the presently identified research needs to contribute to a comprehensive environmental risk assessment for PFAS.

3.16.P-Tu220 Chronic Toxicity of PFOS to Aquatic Macroinvertebrates

Ayesha Siddiqa[1], *Anna Huang*[2] *and Paul van den Brink*[3], *(1)Aquatic Ecology and Water Quality Management, Wageningen University & Research, Netherlands, (2)Wageningen Environmental Research (WUR), Netherlands, (3)Wageningen University & Research, Netherlands*

Perfluorooctane sulfonic acid (PFOS) is of high concern because of its wide application in consumer products and its toxic effects on human and animal health. PFOS has been known to be extremely environmentally persistent, bioaccumulative toxic, and capable of long-distance transport. Previous studies assessed the acute effects of PFOS on the traditional endpoints mortality and immobilization for crustaceans while chronic effects on insects and crustaceans were assessed including also different endpoints like reproduction, body length, and growth. Previous studies have found that insects are more sensitive than crustaceans so we decided to perform not only chronic test using two model crustaceans macroinvertebrates (*Gammarus pulex* and *Asellus aquaticus*), but also evaluate insect species at least till their emergence. For this we also performed tests with *Cloeon dipterum* while tests with *Chaoborus obscuripes*, Zygoptera and *Chironomus riparius* are currently running. During the chronic toxicity, mortality, immobilization, emergence, and food consumption were evaluated. Each species' juvenile was exposed to 5 different concentrations ranging from 0 to 1000 ug/L for all three test systems.

The NOECmortality was 1000 ug/L for *G. pulex*. *C. dipterum* exhibited a greater sensitivity than *G. pulex* and *A. aquaticus*. *G. pulex* and *A. aquaticus* showed a 14 and 28 days control mortality of 11%. *C. dipterum* showed a 13% control mortality at the end of the experiment. The EC50 of *G. pulex* was 13,859 µg/L and 3,247 µg/L after 7 and 14 days, respectively. *A. aquaticus* showed no effects up to a concentration of 10,000 µg/L. The NOEC value of 100 µg/L based on mortality suggests that *C. dipterum* is among the most sensitive freshwater organisms tested. *C. dipterum* showed EC50 of 317 and 131 µg/L for 7 and 28 days, respectively. The present study indicates that insects are more sensitive than crustaceans, so the follow-up chronic tests using insect species are currently running to observe the effects of PFOS on the emergence of insects. Further experiments will be performed on the toxicokinetics with the same freshwater macroinvertebrates to evaluate the bioaccumulation and biomagnification of PFOS.

3.16.P-Tu221 Hydrogen Carrier Gas for GC/MS and GC/MS/MS analysis with a Novel EI Source

Rich Davis, *Agilent Technologies, Inc., United Kingdom*

Concerns around helium price and availability are increasing the demand for alternatives to this traditional mobile phase in gas chromatography mass spectrometry systems (GC/MS, GC/MS/MS). Hydrogen is the best alternative for GC/MS analysis as chromatographic resolution is superior when compared to alternatives, leading to faster analysis times. Hydrogen however is a reactive gas, hydrogenation and dechlorination reactions can and do occur in the mass spectrometer electron ionization (EI) source. Consequences when hydrogen is used with traditional ion sources are variances to mass spectral ion ratios, spectral infidelity, and peak tailing. Therefore, a novel EI source for GC/MS and GC/MS/MS was developed and optimized for use with hydrogen carrier gas.

3.16.P-Tu222 Development of Suitable Methods for PFAS Sample Preparation in Different Matrices

*Angelika Köpf[1], **Thomas Gersthagen**[2], Sebastian Wierer[2] and Suman Kharel[2], (1)LCTech GmbH, Germany, (2)RnD, LCTech GmbH, Germany*

Per- and polyfluorinated alkyl substances (PFAS) get into the environment during their manufacturing process and further also during their use and disposal. Analyzing these PFAS compounds is challenging and dedicated lab equipment helps to avoid blind values and standardizes the processes in sample preparation. Currently, there are existing SPE cartridge solutions for extractions of PFAS from drinking water. However, solid samples (especially soil samples) have often the ability to strongly bind neutral and long chain PFAS. Further, more demanding sample matrices, for instance, environmental and food/feed matrices are handled with a more elaborate dual SPE or a combination of SPE and dispersive clean-up to remove matrix intereferences. In spite of the tedious process, all of them lack the ability to enrich some specific PFAS in a sufficient way e.g. neutral sulfonamides or long chain PFAS. The challenge is to develop a SPE solution that is not cost intensive and at the same time effective for the clean-up and enrichment for all types of PFAS analytes. Additionally, some of the PFAS analytes are volatile and an appropriate method for sample concentration is needed. Analyte extraction of solid samples via manual shaking was compared with a pressurized liquid extraction. For the enrichment and/or purification of PFAS compounds solid phase extraction (SPE) was applied. SPE cartridge solutions of different compositions were used. For the critical evaporation step a vacuum centrifuge with cold trap was used. The samples were subsequently analysed by LC-MS/MS. A pressurized liquid extraction method was successfully developed especially to extract neutral and long chain PFAS from soil. An important point in the development of the method was the establishment of the blind value free PLE system. SPE cartridge solutions of different compositions show high recoveries, low standard variations and reliable clean-up of PFAS analytes in different matrices. An evaporation method where no volatile PFAS compounds were lost has been successfully devloped using a vacuum centrifuge in combination with a cold trap. The presented workflow shows a streamlined sample preparation process for the PFAS analysis, which can be used for different kinds of PFAS including neutral sulfonamides and long chain analytes in various matrices. Further, SPE cartridges with a superior performance for enrichment and clean-up of PFAS molecules from water, soil and food matrices were developed.

3.16.P-Tu223 AN ULTRA-HIGH SENSITIVITY ANALYSIS OF PFAS COMPOUNDS IN MULTIPLE WATER SOURCES

***Jianru Stahl-Zeng**[1], Jack Steed[2], Bertram Nieland[3], Kay Hup[4] and Abdessamad Chahbouni[4], (1)SCIEX, Germany, (2)SCIEX, United Kingdom, (3)SCIEX, Netherlands, (4)Het Waterlaboratorium, Netherlands*

PFAS compounds are ubiquitous in our environment due to overuse and their lack of breakdown, ensuring that this will be a challenge for decades to come. Therefore, it is imperative to provide rigorous and sensitive analytical testing to regulate these compounds and try to limit their possible effects on human health.

In December 2020, the European Parliament and Council of the European Union released a new directive that sets the limit of PFAS in drinking water to 0.5 µg/L for all PFAS compounds identified, and 0.1 µg/L for a subset of PFAS compounds that are particularly concerning for humans. The 0.5 µg/L limit applies to all PFAS compounds in total. This method is suitable for drinking water, surface water and groundwater.

Mixed standards were prepared at a ratio of 2.5 mL LC-MS water to 2 mL 50:50 acetonitrile/methanol +0.22% formic acid to construct a calibration curve between 0.2-1000 ng/L. Samples were prepared with 2.5 mL of seawater from the Irish Sea added to 2 mL of 50:50 acetonitrile/methanol + 0.22% formic acid solution prior to analysis.

Chromatographic separation was performed using a Phenomenex Luna Omega PS C18, 100 Å, 100 x 2.1 mm, 3 µm , and a Phenomenex Gemini C18, 110 Å, 100 x 2.0 mm, 3 µm delay column. The injection volume was 50 µL. Mobile phase A was 20 mM ammonium acetate in water and mobile phase B was methanol. The analysis was performed using a SCIEX 7500 system, operated in electrospray ionization in negative ion mode.

This analytical method presented shows ultra-high levels of sensitivity with LOQ values ranging between 0.2 ng/L and 2.0 ng/L for 26 relevant PFAS compounds analyzed in LC-MS grade, drinking, ground and surface water. In addition to the sensitivity of the method, excellent levels of precision, linearity and accuracy were achieved; all within typical validation criteria. Three water matrices were spiked at either 0.2 or 0.8 ng/L depending on their LOQs. From this, the detection limits were calculated between 0.06 ng/L to 1.12 ng/L in three different water matrices. With contamination being a challenge for successful PFAS analysis, recommended steps are documented in this method to reduce both contamination and interference.

Testing of surface and ground water is important to ensure that these water sources are not contaminated and that drinking water sources are not affected.

3.16.P-Tu224 Critical Insights in the detection of PFAS in our environment: A deeper look at various methods in water samples

***Derek Mattern**[1], Philippe Boniteau[2] and Roberto Bozic[3], (1)PerkinElmer, Germany, (2)PerkinElmer, France, (3)PerkinElmer, Italy*

Per- and polyfluoroalkyl substances (PFAS) represent a diverse group of synthetic fluorinated organic compounds that have been produced and widely used in industrial applications and consumer products since the 1930s. Common applications where PFAS are used include surfactants, fire-fighting foams, nonstick cookware coatings, lubricants, and coatings for food packaging. Because of their wide use, testing is of great importance to mitigate potential risks to our health and the environment.
The work presented will demonstrate various PFAS methods accommodating the different global regulations while at the same time offering high-performance solutions to optimize your laboratory workflows, e.g. sample preparation. Global regulations and sometimes their standardized methods require various sample preparation steps to reach the required detection limits. In the work presented we will show various regulation specific methods (EPA, ISO and EU) accommodating exactly this feat including offline SPE, direct injection and online SPE. We will delve into some key methods that are turnkey and ready to implement in various testing lab.

3.16.P-Tu225 Validation of a weak-anion exchange solid phase method for determination of extractable organic fluorine including trifluoroacetic acid in water samples

***Zongzhe He**, Ian Cousins, Jonathan Benskin and Merle Plassmann, Stockholm University, Sweden*

Per- and polyfluoroalkyl substances (PFAS) are widespread contaminants of the aquatic environment, including surface waters and groundwater. As these natural waters are important drinking water sources and drinking water treatment methods are ineffective for many PFAS, drinking water also contains PFAS. Given the large number and diversity of PFAS, there are growing concerns that targeted methods underestimate the extent of PFAS contamination in natural waters and drinking water. To address this concern, a growing number of studies have paired targeted analyses with determination of extractable organic fluorine (EOF) in an effort to capture substances that would be otherwise overlooked by targeted methods alone. However, when applied to water samples, such experiments require additional rinse steps to remove inorganic fluorine, which inadvertently removes ultra-short chain perfluoroalkyl acids such as trifluoroacetic acid (TFA). With this in mind, the present work aimed to develop a new extraction method for determination of extractable organic fluorine (EOF) as well as ~50 PFAS, including ultra-short chain substances, in different types of water samples. A suite of spike/recovery experiments involving fluoride and TFA were performed in order to determine exactly where each component eluted from the cartridge. Thereafter, careful adjustment of rinse and elution steps was performed to remove fluoride while maximizing retention of TFA. The performance of the method was benchmarked against two published methods. Overall, our developed method showed a satisfactory removal efficiency of high concentrations of fluoride with improved recovery of TFA.

3.16.P-Tu226 PFAS Analysis to Address the New EU Regulations for 24 Compounds

***Day Powell**, Agilent Technologies, Inc., United Kingdom*

Environmental challenges have never been greater, whether analyzing the purity of drinking water or contaminants in wastewater, measuring indoor air quality, responding to natural or man-made disasters, or identifying emerging contaminants. Environmental analysis must be done more reliably, more efficiently, and with even higher quality results than ever before. Agilent's solutions enable our customers to answer new questions at the leading edge of life science, diagnostics, and the applied markets.   is poster details the latest Agilent analytical method to address the latest directive from the European Commission for 24 PFAS compounds in waters.

3.16.P-Tu227 Ultimate Sensitivity for the Detection of Per- and Polyfluorinated Alkyl Substances in Environmental Water Samples

***Claudia Rathmann**[1] and Janitha De Alwis[2], (1)Waters Corporation, Germany, (2)Food and evironment, Waters Corporation, United Kingdom*

Sensitivity limits are constantly being challenged with the continued evolution in regulations and guidelines for per- and polyfluorinated alkyl substances (PFAS). It is still unknown what the official regulations from the US EPA will become, but if they follow similar guidance to the European Drinking Water Directive, individual PFAS could be regulated around 1 ng/L (parts per trillion). Direct injection approaches have become popular for PFAS analysis since they reduce the sample preparation time, and more importantly limit the risk of introducing contamination. Generally, this approach requires large injection volumes of 30 µL or more. With the introduction of the enhanced sensitivity of a new tandem quadrupole, large volume injections are no longer necessary to reach the required sensitivity in the ng/L range.
To be successful with a direct injection approach for PFAS analysis, instrument sensitivity is extremely important. Initial evaluation was performed using solvent standards to understand instrument sensitivity. Peak area, peak height, and signal to noise were used to make this evaluation. Enhancements were experienced in all three parameters, indicating a true sensitivity increase without a detriment to signal to noise. Previous applications of the direct injection approach required a 30 µL injection volume, but with the increased sensitivity, injection volume was reduced to 10 µL. Even using the reduced injection volume, limit of detection (LOD), determined using a S:N of 3, for most compounds was near or below 1 ng/L.
Additionally, the mixed mode C18 AX column had excellent retention for the short chain PFAS, especially ≤ C5 chain length carboxylates that have poor retention on C18 columns. This also makes this chemistry a great candidate as an isolator column. For the C4 carboxylate (PFBA), contamination in the mobile phase was successfully resolved 8 minutes from the eluting analytical peak.
As studies on PFAS continue to advance, the analytical technology used to support research need to continue advancing as well. Improvements in both the analytical and isolator column technologies demonstrated in this work, as well as enhancements in negative ion sensitivity from the Xevo TQ Absolute Mass Spectrometer are helping to support ongoing efforts in PFAS analysis. This allows for easier, more robust, and accurate options as PFAS analysis continues into the future.

3.16.P-Tu228 Investigating the Impact of the Liquid Chromatography Method on NTA Identification of Short-Chain PFAS in Industrial Samples

Jacqueline Bangma[1]*, Mark Strynar*[1]*, James McCord*[1] *and Jeremy Koelmel*[2]*, (1)U.S. Environmental Protection Agency, (2)Yale University*

Per- and polyfluorinated substances (PFAS) are a class of thousands of unique chemicals containing carbon-fluorine bonds. Due to their widespread and decades-long usage, many PFAS are globally detectable in environmental media, wildlife, and humans. The most investigated PFAS to date are long-chain PFOS and PFOA. Yet, in recent decades, many applications of PFAS have transitioned to using shorter-chain replacement compounds. While some short-chain compounds have been identified (e.g., PFBA), emerging short-chain PFAS are still a concern and often require the use of high-resolution mass spectrometry (HRMS) and non-target analysis (NTA) techniques for identification. Many current reversed-phase liquid chromatography (LC) methods used to investigate PFAS result in short-chain PFAS eluting from columns within or close to the column's dead volume. This results in a variety of drawbacks including little to no chromatographic separation of isomers, ion suppression from matrix effects, and an increase in in-source artifacts. As the industrial production and application of short-chain PFAS are on the rise, it is important to optimize LC methods for the identification of emerging short-chain PFAS. In this study, industrially contaminated water samples from across the US were isolated using a weak anion exchange (WAX) extraction method and analyzed in triplicate with either a standard reversed-phase C18 column with a ramping gradient (25:75 aqueous: organic starting gradient) or a dual-phase column with an isocratic gradient (60:40 acetonitrile: methanol) in line with a high-resolution quadrupole time-of-flight instrument. Agilent Profinder was used for feature finding and FluoroMatch was used for visualization, grouping (via homologous series detection), annotation (via accurate mass and diagnostic fragment ion matching), and scoring. All data processing steps and FluoroMatch settings were maintained across experiments, and results were manually confirmed whenever possible. Results revealed that the dual-phase column resulted in increased retention of short chain compounds, improved compound separation, and improved identification of emerging short chain PFAS.

3.16.P-Tu229 Adaptation of large panels of Per- and Polyfluoronated Alkyl Substances (PFAS) for routine analysis in Drinking and Environmental Waters by Direct Injection Using UPLC-MS/MS

Jenny Louise Davies[1]*,* ***Janitha De Alwis***[2] *and Claudia Rathmann*[3]*, (1)Waters Corporation, United Kingdom, (2)Food and evironment, Waters Corporation, United Kingdom, (3)Waters Corporation, Germany*

Per- and Polyfluoroalkyl Substances(PFAS), are extremely persistent in the environment. Their production and use have resulted in severe contamination of soil, water and food. To protect public health, advisory and regulatory limits continue to be created and updated. Consequently, routine PFAS analysis has become challenging as not only low detection limits are required, but extensive compound coverage is a prerequisite nowadays.

The purpose of this work was to demonstrate a direct injection UPLC-MS/MS method for the ultra-low level determination of multiple PFAS compounds in drinking and environmental waters. The method performance study was completed on an ACQUITY Premier™ System with a Xevo TQ Absolute™ and UniSpray™ ion source. Samples were prepared by dilution with an acidified organic solution containing internal standards directly into an autosampler vial.

A method validation study was carried out on 2 common drinking water and 2 surface water matrices. The method performance was assessed using 3 spike levels at 1, 5, and 10 ng/L for all analytes, with 6 replicates at each level. Average method performance for trueness, repeatability, linearity, and sensitivity was assessed through inter and intra-laboratory studies. Improvements in both the analytical and isolator column technologies demonstrated in this work, as well as enhancements in negative ion sensitivity from the Xevo TQ Absolute Mass Spectrometer are helping to support ongoing efforts in PFAS analysis. This allows for easier, more robust, and accurate options as PFAS analysis continues into the future.

3.16.P-Tu230 How to investigate potential emission sources of PFAS in consumer product materials? Comparative extraction approaches and sum parameter analysis by combustion ion chromatography analysis

Philipp Roesch*, Christian Vogel, Ute Kalbe and Franz-Georg Simon, Division 4.3, Bundesanstalt für Materialforschung und – prüfung (BAM), Germany*

Besides classical per- and polyfluorinated alkylated substances (PFAS), side-chain fluorinated polymers (SFPs) are widely applied as efficient anti-wetting and anti-greasing coatings in various daily applicated consumer products such as outdoor apparel, carpetry or paper-based food contact materials. Although the fluorinated sidechains are chemically bound to a base polymer, their release can be triggered by environmental influences or wear-off, thus contribute as significant sources of PFAS in the environment. Since only little knowledge of PFAS and SFP composition in consumer products is available, a comprehensive analytical approach might be beneficial.

Herein, we investigate the comparison between full combustion analysis, classical extraction methods and a hydrolysis-based extraction process for PFAS containing consumer product samples, resulting in the distinct sum parameter values total fluorine (TF), extractable organically bound fluorine (EOF) and hydrolyzable organically bound fluorine (HOF), determined via combustion ion chromatography (CIC). As reported previously, basic hydrolytic extraction can be applied to convert chemically bound PFAS into soluble precursors (e. g. as fluorotelomer alcohols). Consequently, a lot more sources of PFAS can be made accessible for analysis, while conventional methods can only comprise soluble PFAS with low chemical interaction within the sample material. Depending on the investigated consumer product sample, we found that the hydrolysis-based sum values (HOF) were larger compared to when conventional extraction protocols were applied. Differences in the measured sum parameter values might be attributed to the presence of SFC's at the material surface. Alongside, gas chromatography coupled mass spectrometry (GC-MS) analysis was applied to validate the hydrolysis reaction and formation of respective fluorinated reaction products. In

order to evaluate the fluorine mass balance of all extracted samples, our studies were complemented with targeted analysis investigation via liquid chromatography coupled tandem mass spectrometry (LC-MS/MS) based on state-of-the-art extraction and measurement protocols.
Overall, we have shown that sum parameter analysis in combination with different extraction approaches allows a comprehensive investigation of PFAS-containing product materials and can be used to assess the PFAS content of a wide range of consumer products.

3.16.P-Tu231 Towards a systematic workflow for screening and identification of polymeric per- and polyfluoroalkyl substances (PFAS) in consumer products
*Lisa Skedung[1], **Eleni Savvidou**[2], Steffen Schellenberger[1], Anders Reimann[1], Ian Cousins[2] and Jonathan Benskin[2], (1)RISE Research Institute of Sweden, Sweden, (2)Stockholm University, Sweden*
Within the class of per- and polyfluoroalkyl substances (PFAS), fluorinated polymers — including side-chain fluorinated polymers, fluoropolymers and perfluoropolyethers — pose a significant analytical challenge. In this work we systematically compare the performance of a wide range of analytical methods for determination of polymeric PFAS in consumer products, including cookware, textiles, electronics equipment, and hygiene consumables. The methods included two portable and non-destructive screening techniques (Fourier-transform infrared spectroscopy (FTIR) and handheld laser induced breakdown spectroscopy (HH-LIBS)), two total fluorine approaches (particle-induced gamma-ray emission spectroscopy (PIGE) and combustion ion chromatography (CIC)), and an approach for structural elucidation (pyrolysis-gas chromatography/mass spectrometry (pyr-GC/MS)). Overall, FTIR displayed good potential as a rapid screening method for coatings of cookware while HH-LIBS was not sensitive enough to detect fluorine in any matrix. Quantification of total fluorine (TF) using PIGE and CIC demonstrated an overall good agreement between these two methods for most of the consumer products, with concentrations ranging from 70-550 000 ppm TF in cookware, 10-6100 ppm TF in textiles, 20-2100 ppm TF in electronic equipment and 10-630 000 ppm TF in hygiene consumables. The highest concentrations were observed in products containing polytetrafluoroethylene (PTFE). Finally, pyr-GC/MS was used to confirm that the fluorine was indeed organic in nature, and in some cases structural information about the substance was obtained. This is one of the few studies to quantify fluorine in a wide range of polymeric consumer products, and highlights key knowledge gaps and future directions for standardization of a systematic workflow for the screening and identification of PFAS in plastics.

3.16.P-Tu232 Understanding Side-Chain Fluorinated Polymers and Their Life Cycle
***Zhanyun Wang**[1], Marie-Ange Baucher[2] and Eeva Leinala[2], (1)Swiss Federal Laboratories for Materials Science and Technology (EMPA), Switzerland, (2)Environmental, Health and Safety, Environment Directorate, Organisation for Economic Co-operation and Development, Paris, France*
Per- and polyfluoroalkyl substances (PFASs) comprise a class of synthetic chemicals that have attracted much public attention since the early 2000s. Over time, research and risk management measures have expanded to a wide range of PFASs, but mostly focused on non-polymeric PFASs. To ensure the sound management of the entire class of PFASs, it is equally important to understand polymeric PFASs, which include side-chain fluorinated polymers (SCFPs), fluoropolymers and perfluoropolyethers. This poster presents a report by the OECD/UNEP Global PFC Group, synthesizing scientific and technical information on the life cycle of SCFPs, which are polymers with a non-fluorinated polymer backbone and with PFAS moieties on the side chains. The report starts with a comprehensive overview on the chemical identities of SCFPs that have been on the global market, including a non-exhaustive list of 103 SCFPs and 42 monomers. Then it includes life-cycle information on different SCFPs separated according to structural repeating units in the polymer backbone, specifically: acrylates and urethanes, oxetanes, silicones, and ethoxylates. For each group, the analysis focuses on the production and use of respective SCFPs, presence of other PFASs in the commercial formulations, degradation of SCFPs during use and end-of-life treatment, environmental releases of SCFPs, and other PFASs present in the commercial formulations. This is followed by a summary of critical knowledge and data gaps and options for a way forward. Compared to many non-polymeric PFAS, SCFPs and their known and unknown degradation products have received comparatively little attention from scientists and regulators, despite their manifold industrial uses and high volumes, their propensity to release non-polymeric PFAS, and their potential environmental and health impacts. Concerted action by all stakeholders is needed to address SCFPs in an efficient and effective manner, including making funding available and conducting research on those critical knowledge and data gaps that are most relevant for soundly regulating/managing SCFPs in different jurisdictions, building on the gaps identified in the report.

3.16.P-Tu233 Directly Fluorinated Containers as a Source of Perfluoroakyl Carboxylic Acids
***Heather D. Whitehead**[1] and Graham F. Peaslee[2], (1)Department of Chemistry and Biochemistry, University of Notre Dame, (2)Department of Physics and Astronomy, University of Notre Dame*
Direct fluorination of plastics is performed to impart chemical resistance via exposure of polyethylene to fluorine gas to produce a thin, fluorine-modified surface layer. Leaching experiments were performed on directly fluorinated containers under various conditions and with different matrices, including foodstuffs. The average sum of PFAS concentrations measured from extraction of the fluorinated containers alone was 63.75 ± 13.2 ng/g plastic. 7-day leaching experiments of fluorinated containers with water, methanol, and acetone produced sum of PFAS concentrations that ranged from 0.99-66.92 ng/g plastic. Leaching experiments of fluorinated containers with food matrices produced sum of PFAS concentrations ranging from 2.74-5.50 ng/g plastic. For both solvent and food leaching experiments, a subset of samples was subjected to leaching at elevated temperatures, generating sum of PFAS concentrations up to 1,300% higher. In all experiments, short chain perfluoroalkyl carboxylic acids were detected in the highest frequencies and at the greatest concentrations, with analyte concentration decreasing as chain length increased. An

estimate for PFAS released from these containers into food was determined to be 0.35-3.23 ng/kg body weight per week, showing ingestion of food from these containers could be a significant source of PFAS exposure. Based on the large number of applications where directly fluorinated containers may be used, the observation of PFAS leaching into products suggest regulations on the use of fluorinated containers are warranted for where these products provide direct routes of human exposure to PFAS, and further studies should explore the fate and exposure pathways when fluorinated containers are disposed or recycled.

3.16.P-Tu234 How much and which PFAS are in North American Food Packaging?

Heather D. Whitehead[1]*, Heather Schwartz-Narbonne*[2]*, Chunjie Xia, PhD*[3]*, Laura Minet*[4]*, Anna Shalin*[5]*, Arlene Blum*[6]*, Graham F. Peaslee*[7]*, Marta Venier*[3]*, Zhanyun Wang*[8]*, Hui Peng*[2] *and Miriam L. Diamond*[9]*, (1)Department of Chemistry and Biochemistry, University of Notre Dame, (2)University of Toronto, Canada, (3)Paul H. O'Neill School of Public and Environmental Affairs, Indiana University, Bloomington, (4)University of Victoria, Canada, (5)ETH Zürich, Zürich, Switzerland, (6)Green Science Policy Institute, (7)Department of Physics and Astronomy, University of Notre Dame, (8)Swiss Federal Laboratories for Materials Science and Technology (EMPA), Switzerland, (9)Department of Earth Sciences, University of Toronto, Canada*

Considerable and well-deserved attention has been directed towards the use of PFAS in food contact materials because of the potential for direct human exposure and for indirect exposures through contamination of waste streams. In this work, we estimated that only ~2% of food contact materials in the U.S. and Canada have PFAS intentionally added to confer water- and grease-repellency. At this low intentional usage, and when accounting for an estimated 50% of food contact materials containing PFAS at "non-functional" levels, an estimated 10,000 and at least 11 tonnes per year of polymeric and non-polymeric PFAS move from production to end-of-life, respectively. Of this flow, we estimate that about 7000 tonnes/year of PFAS are landfilled or enter compost facilities and from there have the potential to enter the environment. Next, we analyzed samples of fast food contact materials from Canada. We found that of 42 samples, 43% contained elevated total fluorine concentrations measured via particle-induced gamma-ray emission spectroscopy. Of these samples, bagasse cardboard bowls consistently had the highest levels of total fluorine. The 8 contact materials with higher levels of total fluorine were found to contain 5-14 individual PFAS, dominated by 6:2 fluorotelomer methacrylate (FTMAc) and alcohol (FTOH). After hydrolysis, the concentration of 6:2 FTOH increased by an average of 220 times, and up to 33.7% of total fluorine was released from samples, indicating hydrolysis is a useful tool to assess the amount of unknown precursors. n-target analysis detected fluorotelomer carboxylic acids (FTCAs/FTUCAs) which is consistent with the use of side-chain fluoropolymers in food packaging materials, suggesting their continued use in the US and Canada, including in fast food packaging. Their use has the potential to release monomeric PFAS that are mobile in the environment and could be of toxicological concern. However, our estimates of low intentional use of PFAS to confer water- and grease-repellency in these materials suggests that the food packaging industry is moving away from this non-essential use of PFAS.

3.16.P-Tu235 Presence and concentrations of replacement fluorosurfactant processing aids and other PFAS in the air downwind of fluoropolymer production plants

Joost Dalmijn[1]*, Ian Cousins*[2]*, Jonathan Benskin*[2]*, Matthew Salter*[2] *and Jana Johansson*[2]*, (1)Department of Environmental Science, Stockholm University, Sweden, (2)Stockholm University, Sweden*

Fluoropolymer processing aid (FPA) emissions have contributed significantly to global environmental levels of per- and polyfluoroalkyl substances (PFAS) as fluoropolymer production plants act as a point source of these substances to water and air. With the phaseout of the FPAs based on salts of perfluorooctanoic acid (PFOA) and perfluorononanoic acid (PFNA) in multiple countries, various replacement FPAs have been introduced that are based on the salts of perfluoroether carboxylic acids (PFECAs). Additionally, efforts have been made by industry to reduce the emissions of PFAS from fluoropolymer production to the environment. This study aims to investigate the presence and concentration of replacement FPAs and other PFAS in the air downwind of fluoropolymer production plants in the Netherlands and the United Kingdom and the impact of the installation of an emission abatement system during the study at the former site. The particulate phase is collected using high-volume air samplers equipped with quartz fibre filters and after extraction analysed using liquid chromatography coupled with high resolution mass spectrometry (LC-HRMS). e dissociated FPAs hexafluoropropylene oxide dimer acid (HFPO-DA) and perfluoro-3,6-dioxaoctanoic acid (EEA) were found in samples taken downwind of the production sites in the Netherlands and UK respectively. These results imply that, although emissions have been reduced, these fluoropolymer production plants continue to act as a point source of atmospheric PFAS.

3.16.P-Tu236 Investigations of PFAS around industrial manufacturing sites

Mark Strynar*, Jacqueline Bangma and James McCord, U.S. Environmental Protection Agency*

PFAS have gone from environmental obscurity two decades ago, to one of the most common representations of environmental contaminants at present. A long use history from global sources is evident in the environmental literature. Compounding the issue is the cooccurrence of historical PFAS, with contemporary produced/emitted PFAS in collected samples. rgeted analysis of environmental samples with low resolution MS/MS is the method of choice for known contaminants. U ortunately, only a select species (<100) of 1000s of PFAS are sufficiently known and amenable to targeted analysis. A series of industrial site investigations within and outside of the United States at active production facilities have provided new insights into current and future PFAS. Therefore, high-resolution mass spectrometry and non-targeted analysis (NTA) methods are more appropriate for novel compound discovery. Parsing and annotation of 100s to 1000s of mass spectral features from these investigations is time consuming and quite often leads to PFAS of unknown or suspect identification. Appl ation of mass spectral feature alignment (*m/z*, retention time abundance) coupled with application of the aftermarket FluoroMatch software packet has helped to make recent advancement in many of these site investigations. Such M application can simultaneously rule out legacy PFAS not requiring further exploration (e.g. M-H, CO_2 loss, gas phase dimers) while identifying features demanding further scrutiny (e.g. CF_2 Kendrick mass defect homologous series). Water sa les collected near and distant from production sites aid in source apportionment. This talk will focus on the procedures used to identify suspected and novel PFAS at these facilities while offering insight into future PFAS for consideration on a broader scale. Contempora production and use facility emissions are a strong indication of future environmental contaminants. Even in unk wn compound identification, having knowledge of homologous series grouping (e.g. CF_2, CF_2O, CF_2CH_2, others) and characteristic negative mass defect alone help in sifting through scores of data needing more intensive analyst follow-up. Examples of unknown compounds within a known homologous series, and well as novel one-off and homologs will be presented. The natural pr ression of methods from novel compound discovery to robust targeted methods hinges on this critical identification first step and is often at industrial production and use facilities.

3.16.P-Tu237 Identification of PFAS Hotspots in German Rivers: Target Analysis vs. the Direct Total Oxidizable Precursor Assay

Bernd Göckener[1]*, Annette Fliedner*[1]*, Heinz Ruedel*[1]*, Alexander Badry*[2] *and Jan Koschorreck*[2]*, (1)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Schmallenberg, Germany, (2)German Environment Agency (UBA), Dessau-Rosslau, Germany*

The group of per- and polyfluoroalkyl substances (PFAS) comprises several thousand substances. The ever growing number is a major challenge for their chemical analysis. One analytical approach to overcome the complexity of PFAS are sum parameters, such as the total oxidizable precursor (TOP) assay. In this study, we conducted a spatial monitoring study with more than 210 suspended particulate matter (SPM) and sediment samples from rivers and lakes from Germany and the Netherlands to analyse spatial differences and identify contamination hotspots. All samples were analyzed by target analysis and a modified TOP assay (‘direct’ TOP (dTOP) assay, in which a small amount of sample is completely digested, converting previously unmeasurable precursors to measurable perfluorinated compounds.

The analysis revealed substantial differences between the different water bodies in both, the level and type of contamination. The ∑PFAS concentrations ranged from <0.5 to 53.1 µg/kg dry weight (dw) in the target analysis and from <1.0 to 336.8 µg/kg in the dTOP assay. The levels of perfluoroalkyl acids (PFAA) were substantially higher in the dTOP assay compared to the target analysis demonstrating the significant presence of unidentifed precursors in the samples.

As a simplistic approach to identify hotspots of PFAS contamination the 90th percentiles (P90) for target analysis ($P90_{Target}$: 7.11 µg/kg dw) and dTOP assay ($P90_{dTOP}$: 67.6 µg/kg dw), respectively, were used as thresholds. Both methods identified 17 hotspots, but only five of the sampling sites were consistently identified as hotspots by both methods. Thus, the majority of hotspots identified with the dTOP assay was overlooked by the classical target analysis.

The results of this study demonstrate the ubiquitous burden of PFAS in German rivers especially by unknown precursors. Only some of the hotspots identified in this study were (publicly) known before. At many of the hotspots and other sampling sites, however, the source of the PFAS contamination remains unknown and must be elucidated in the future to prevent further discharge into the environment.

3.16.P-Tu238 Identification of Local Sources of Perfluorinated Compounds - Case Study in the River Vantaanjoki Region

Ville Aimo Eemeli Junttila[1]*, Heli Vahtera*[2]*, Jari Männynsalo*[2]*, Henri Virkkunen*[3]*, Noora Perkola*[3]*, Pia Högmander*[3] *and Jukka Mehtonen*[3]*, (1)Suomen ympäristökeskus (SYKE), Finland, (2)Water Protection Association of the River Vantaa and Helsinki Region, (3)Finnish Environmental Institute (SYKE), Helsinki, Finland*

The Vantaanjoki River is the most urban waterbody in Finland; almost 10% of the Finnish population lives within its catchment area. The Vantaanjoki acts as a spare raw water resource and the riverside is an important recreation zone for local citizens. Chemical quality of the surface water of the Vantaanjoki fails to fulfil the criteria set by the Water Framework Directive of the EU. This is caused by high concentrations of perfluorooctanesulfonic acid in fish. Also, the highest surface water concentrations of other per- and polyfluoroalkyl substances (PFASs) ever detected in Finland have been measured in samples from the Vantaanjoki. High concentrations may cause risk for both human health and the environment. One source of PFASs has been identified to be the Helsinki-Vantaa airport located on the downstream of the river, but high PFAS concentrations occur also at the upstream sampling sites. This alludes, that unknown sources of PFASs to the Vantaanjoki exist.

We approached the PFAS source identification by conducting a PFAS screening campaign for surface waters, municipal waste waters and storm waters. Based on produced data, PFAS loads to the Vantaanjoki from the tributaries and wastewater treatment plants (WWTP) were calculated. In that way, we could identify the regions, which produced highest absolute and proportional PFAS loads.

We found that WWTPs have substantial impact on PFAS concentration in river water. However, their share of the total PFAS load carried by the river decreased to the downstream indicating other notable PFAS sources within the drainage area. PFAS load estimations for sub-basins highlighted the role of the airport and industrial areas as sources of PFASs. Due to their high PFAS concentrations, stormwaters were also recognized as potential PFAS sources to the Vantaanjoki both directly and via WWTPs. The PFAS profile at the upstream of the river was remarkably different comparing to the downstream. At the upstream, perfluoroalkyl carboxylic acids were the dominant group, whereas perfluorosulfonic acids dominated at the downstream. There were also differences in PFAS profiles between tributaries. These results indicate qualitative difference in PFASs sources located in different parts of the drainage basin.

Our approach proved to be an efficient way to identify significant PFAS source areas for which more detailed examinations should be directed. It is also easy to reproduce at other areas, which are affected by PFAS pollution.

3.16.P-Tu239 Insight in PFAS concentration within the Nethertlands

***Marcel Kotte**, Data and Information management, Ministry of Infrastructure and Water Management, Netherlands*

Since the early 2000's Rijkswaterstaat (RWS), as part of the Ministry of Infrastructure and Watermanagement has measured over 30 PFAS in its surface waters.

The current abstract is the follow-up to an earlier work (Jonker, 2017), in which a data analysis was presented of PFAS concentrations in national waters, as measured between 2008 and 2016. The current abstract gives an update. Information on trends is provided.
PFAS concentrations and loads over the years and, in addition, current concentrations can be
can be tested against the standards for PFOA and GenX that have since come into force. In addition,
The current abstract will go into a modified set of substances and, in addition to concentrations in water concentrations in biota measured between 2017 and 2019 are also included in the data analysis. This makes it possible to test against the PFOS biota standard and to link water and biota and thus gain more insight into bioaccumulation of PFAS in Dutch waters.

PFAS are ubiquitous in national waters. Already since the beginning of measurements by RWS in 2008 they are found at all selected sampling locations in the water phase; also at locations
at sea. The highest concentrations are generally found in the Scheldt and the Canal from Ghent to Terneuzen, but at the other inland sites the concentrations of specific PFAS are remarkably close to each other.

Some 10 PFAS have been detected in biota sampled in national waters between 2017 and 2019 at 15 locations, including locations in the open sea. Measured concentrations ranged from 0.1 to 140 µg/kg wet weight, with the highest concentrations measured in fish from the Western Scheldt, can be considered particularly PFAS-contaminated. At all sites, the relatively highest concentrations measured for PFOS, which are above the applicable standard for biota.
The poster will visualize the various trends in the Netherlands.

3.16.P-Tu240 Occurrence of PFAS in sea-spray aerosol from the Dutch coast

***Elvio D Amato**[1] and Frederic Magnus Béen[2], (1)KWR Water Research Institute, Nieuwegein, Netherlands, (2)A-Life, Vrije University Amsterdam, Netherlands*

Per- and polyfluoroalkyl substances (PFASs) are a diverse group of persistent chemicals that are widely found in environmental samples. Recent studies have shown that sea-spray aerosol (SSA) may contribute to atmospheric transport and spreading of PFAS across the globe. SSA is a suspension of particles in air generated by bubble bursting at the interface between air and seawater, which has been shown to contain PFAS concentrations order of magnitude higher than those measured in seawater. In this study, we investigated the occurrence of PFAS in SSA in two coastal locations in the Netherlands (L1 and L2). SSA was collected using a high-volume air sampler (equipped with a PM10 head) during winter and summer in L1, and in spring in L2, respectively. Results indicated that both perfluoroalkyl carboxylic acids (PFCAs) and perfluoroalkyl sulfonic acids (PFSA) occurred in air samples collected in winter and summer in L1. During winter sampling, also one precursor (i.e., 6:2 fluorotelomer sulfonic acid) and hexafluoropropylene oxide dimer acid (HFPO-DA) were measured. PFAS precursors were also detected by means of non-targeted screening analysis. Concentrations in samples collected in winter (0.04~4.95 pg/m^3) were consistently higher than those measured in summer (0.04~1.37 pg/m^3), suggesting that seasonal variation may be expected at this location. In L2, PFAS concentrations (0.04~0.64 pg/m^3) were similar, but lower, than those measured in L1 in summer. A positive correlation between concentrations of PFAS and Na^+ (typically used as a tracer ion) in air samples indicated that SSA may be an imporant source of PFAS in the atmosphere. These results show that SSA may contribute to the transport of PFAS in the atmosphere and potentially act as a source of contamination in coastal areas.

3.16.P-Tu241 A study of the SOURCE-TO-SEA occurrence of Poly- and perfluoroalkyl substances (PFASs) of emerging concern in Ireland

***Chloe Richards**[1], Brendan McHugh[2], Evin McGovern Dr[2], Ciprian Briciu-Burghina Dr.[3], Belinda Huerta[4], Kristyna Mrstna[5] and Fiona Regan[6], (1)School of Chemical Sciences, DCU Water Institute, Dublin City University, Ireland, (2)Marine Institute, Ireland, (3)Water Institute, DCU Water Institute, Dublin City University, Ireland, (4)Chemistry, Southern Conneticut State University, New Haven, (5)Dublin City University, Dublin, Ireland, (6)Water Institute, Dublin City University, Dublin, Ireland*

Poly- and perfluoroalkyl substances (PFASs) are a group of synthetic organic surfactants that have become a global concern because of the toxicity and widespread presence in the aquatic environment and organisms globally. In this study, a new analytical method has been developed and validated for the analysis of 15 perfluorinated compounds in different water matrices [1]: river water, drinking water and seawater. Water extraction was performed in anion exchange solid phase extraction cartridges, and extracts were analysed by liquid chromatography in tandem with mass spectrometry. Recoveries for target analytes were between 35–120%, depending on the water matrix. Method detection limits were in the range of 0.5–17 ng/L. The validated method was applied to the determination of perfluorinated compounds in water samples around Ireland. Eight compounds out of fifteen were detected at least in one sample. Measured concentrations were higher in river water than seawater, and drinking water had the lowest levels, although still detectable for a considerable amount of compounds. The most prevalent compounds were PFPeA, PFOA and PFHxA, present in all types of water, and they had the highest concentrations. This work will demonstrate the variability in chemical type in a sampling campaign from source to sea in the river Liffey, Dublin Ireland.

3.16.P-Tu242 A Detailed Assessment of Per- and Polyfluoroalkyl Substances (PFAS) in San Francisco Bay Sport Fish

Miguel Alexander Mendez*, Ezra Miller, PhD, Martin Duong Trinh, Diana Lin, Rebecca Sutton and Jay Davis, San Francisco Estuary Institute*

As a class of thermally stable and non-reactive contaminants, per- and polyfluoroalkyl substances (PFAS) are widespread in the environment. The high persistence of PFAS, along with the bioaccumulation risks of some compounds, have raised concerns of adverse effects on human and wildlife health. Beginning in 2009, the Regional Monitoring Program for Water Quality in San Francisco Bay (RMP) has monitored PFAS in sport fish. At present, no human health or regulatory thresholds have yet been established for PFAS in California fish. Previous analyses of Bay sport fish have identified PFAS, particularly in the southern portion of the Bay, as persisting over time at levels exceeding thresholds that have been established by other US states for the development of consumption advisories.

To better understand spatial patterns and temporal trends of PFAS in San Francisco Bay sport fish, this study examined 58 archived skinless fillet composite samples from four fish species collected at 10 locations in three sampling rounds in 2009, 2014, and 2019. Fish species were selected based on a number of criteria, including species that are: popular for consumption, sensitive indicators of problems (accumulating relatively high concentrations of contaminants), widely distributed, representative of different exposure pathways (benthic versus pelagic), and included in past monitoring. Of 58 archived samples analyzed, PFAS were detected in all samples, with a total 17 of 40 PFAS observed. Perfluorooctanesulfonic acid (PFOS) was the dominant PFAS detected followed by perfluorooctanesulfonamide (PFOSA), similar to previous analyses of Bay sport fish. In general, perfluorooctanoic acid (PFOA), short-chain perfluoroalkyl substances (e.g., perfluorobutanoic acid or PFBA, perfluorobutanesulfonic acid or PFBS), most precursors, and newer PFAS (such as Gen X and ADONA) were rarely detected, with concentrations generally close to detection limits when found.

The expanded breadth of available data from this study provides the means for a comprehensive assessment of spatial variation in PFAS in Bay fish, and a robust baseline for evaluating long-term trends. Retrospective assessment of temporal trends is possible, though changes in analytical methods over time limit rigorous analysis. Overall, findings from this study will further inform PFAS management actions to protect the health of humans and aquatic life.

3.16.P-Tu243 Per- and Polyfluoroalkyl Substances (PFAS) In Sunfish From North Carolina's Haw River and Jordan Lake

***Anna Boatman**[1], Jessie Chappel[2], James Dodds[1], Scott Belcher[2] and Erin Baker[1], (1)University of North Carolina at Chapel Hill, (2)North Carolina State University*

Per- and polyfluoroalkyl substances (PFAS) are emerging contaminants gaining global attention due to their persistence, bioaccumulation, and toxicity. Use and disposal of PFAS-containing products, such as nonstick pans and firefighting foams, has ultimately led to human exposure though food and drinking water consumption. Thus, understanding PFAS accumulation in different matrices and geographical locations is critical for setting meaningful regulatory and advisory limits. However, to date there are no fish consumption advisories for PFAS in the state of North Carolina. In this study, we evaluated PFAS accumulation in fish fillets for fish caught in Jordan Lake and the Haw River. Because Jordan Lake is the primary drinking water source for 700,000 North Carolina residents and is fed by the Haw River which has known PFAS, its potential as a source for human dietary exposure from both the fish and water is high. Therefore, to perform this study, we characterized PFAS in fillets from 38 individual sunfish (genus *Lepomis*) caught at five different locations in this watershed. For the evaluations, the PFAS were extracted from the fillets and analyzed with nontargeted measurements combining liquid chromatography, ion mobility spectrometry, and mass spectrometry (LC-IMS-MS) separations. Data analysis was then performed using the open-source software Skyline and our in-house library containing over 100 PFAS. Our findings showcased a total of 22 different PFAS detected in the fillets with 21 unique PFAS in the most contaminated fish fillet and at least 8 PFAS in every fillet sample. Several legacy PFAS that had previously been phased out of production were detected in all samples, including perfluorocarboxylic acids with carbon chain lengths between 10 and 14 and linear and branched perfluorosulfonic acids of 8 and 10 carbons. Additionally, the fish upstream of Jordan Lake in the Haw River had more PFAS species (median = 16 analytes detected) and higher PFAS abundances than the fish from Jordan Lake (median = 10 analytes). Finally, the comparisons of PFAS abundances in fish and water also illustrated different PFAS accumulation in the two different matrices, suggesting that effective PFAS monitoring should include both fish and water sampling.

3.16.P-Tu244 Target, non-target and suspect screening of Per-and PolyFluoroalkyl Substances (PFAS) in stranded dolphins, sea turtles and sharks (Tuscany coast, Mediterranean Sea)

***Sara Valsecchi**[1], Cecilia Mancusi[2], Claudio Roscioli[1], Letizia Marsili[3], Stefano Polesello[1], Paolo Altemura[2], Romano T. Baino[2], Marco Parolini[4], Beatrice De Felice[4] and Michele Mazzetti[2], (1)Water Research Institute - Italian National Research Council IRSA-CNR, Italy, (2)Environmental Protection Agency of Tuscany Region, Italy, (3)University of Siena, Italy, (4)University of Milan, Italy*

In this study, we investigated the PFAS occurrence in tissues of striped dolphins (*Stenella coeruleoalba*), sea turtles (*Caretta caretta*) and different shark species (*Prionace glauca*, *Carcharinus plumbeus* and *Isurus oxhyrinchus*) stranded or accidentally caught along Tuscany coast between 2020 and 2022.

Diverse PFAS were measured at high concentration in the tissues of dolphins (blood, brain, liver and muscle), whereas only PFOS was detected above detection limits in blood, liver and muscle samples of sea turtles and sharks. Liver tissue showed the highest PFAS levels, whereby PFOS was the dominat compound of the fingerprint. PFOS levels in dolphin liver (148 ± 104 ng/g ww; N = 23) were 10 fold higher than in the liver of the other marine species (1.12 ± 1.09 ng/g ww; N=9 and 1.22 ng/g ww; N=2 for sharks and sea turtles, respectively).

Suspect screening analysis allowed identifying 2 novel perfluorosulfonamides (FBSA(C4) and FHxSA(C6)) in all the analysed tissues of dolphin, as well as a series of n:3 fluorotelomer carboxylic acid (FTCA) in liver tissue only.
Lacking of accumulation pattern and elevate levels of PFCA in the liver suggested a high level of metabolisation of PFCA precursor compounds. This hypothesis was supported by the presence in liver of high levels of n:3 FTCA - stable intermediates of the metabolisation of perfluorotelomers. In contrast, the striped dolphin probably lacks, totally or partially, the ability of transforming perfluorosulphonamides to PFSA within the liver.
Our findings demonstrated that PFAA and perfluorosulphonamides accumulate in the marine cetacean species, whereas in sea turtles and sharks living in the same area accumulation does not occur. Metabolisation in liver of fluorotelomer precursors seems to be the main source of PFCA in dolphins. Further studies should be necessary to disentangle if the main pathway of exposure to precursors is the breathing or the diet.

3.16.P-Tu245 Evaluation of per- and polyfluoroalkyl substances (PFAS) level in Parus major eggs from Nord Eastern Italy

*Laura Giovanetti[1], Silvia Casini[1], **Sara Valsecchi**[2], Michele Mazzetti[3], Marianna Rusconi[2], Matteo Beccardi[4], Matteo Schiavinato[5], Tommaso Campani[1] and Ilaria Caliani[1], (1)University of Siena, Italy, (2)Water Research Institute - Italian National Research Council IRSA-CNR, Italy, (3)Environmental Protection Agency of Tuscany Region, Italy, (4)Institute of Avian Research "Vogelwarte Helgoland", Germany, (5)Wageningen University & Research, Netherlands*
Per- and polyfluoroalkyl substances (PFAS) are anthropogenic pollutants globally distributed. PFAS have raised increasing concerns in recent decades due to their persistence in the environment and toxicity to human and wildlife, birds included. Although some PFAS are regulated, the presence of their precursors and alternatives in the environment requires frequent monitoring. Wild birds are considered efficient sentinels of environmental contamination and bird eggs have been proven to be a good monitoring tool for assessing the presence and exposure to PFAS.
The aim of this study was to evaluate the PFAS levels in great tit (*Parus major*) eggs from areas characterized by different anthropogenic impacts. Therefore, during 2021 and 2022, great tit eggs were sampled from nest boxes installed in agricultural, urban and wooded areas of Nord Eastern Italy far from known contaminated sites. Eggs were freeze-dried and the extraction was performed by sonication with ACN/water mixture enhanced by salting out and acidification; extracts were purified on HybridSPE-Phospholipid to remove matrix suppression effects by phospholipids. Legacy and emerging PFAS were analysed by ultra-high performance liquid chromatography coupled with high resolution mass spectrometry (UHPLC-Q-Orbitrap).
The results allow matching anthropogenic impacts and levels of contamination, as well as to determine anthropogenic background levels due to diffusive pollution.

3.16.P-Tu246 Unravelling the complexity of per- and polyfluoroalkyl substances (PFAS) contamination in marine organisms

***Ninon Serre**[1], Randolph Singh[2], Catherine Munschy[3], Aurore Zalouk-Vergnoux[4] and Yann Aminot[3], (1)IFREMER - French Institute for Ocean Science, France, (2)University of Luxembourg, Luxembourg, (3)IFREMER, France, (4)Nantes University, France*
Per- and polyfluoroalkyl substances (PFAS) are a family of thousands of synthetic organofluorine compounds of high environmental concern. Some of these compounds have proven to be persistent, mobile, bioaccumulative and able to biomagnify. The stability and mobility of PFAS in waters make the oceans the largest environmental reservoir of PFAS and as a result, marine ecosystems are widely contaminated with these compounds. The combined evidence of their ubiquitous distribution and toxic properties has led to the ban of some of them (*e.g.* perfluorooctanesulfonic acid and long chain perfluorocarboxylic acids called PFOS and PFCA respectively). However, many alternative compounds and precursors of unknown environmental fate or effect on living organisms remain in use. By applying a non-specific method for PFAS analysis in biota (the Total Oxidizable Precursor or TOP assay), we evidenced that unknown PFCA precursors were by far the major contributors to the total PFAS burden of bivalves of the French coasts. Thus, beyond the ~20 PFAS traditionally studied and monitored in the environment, a large number of PFAS are overlooked. In this context, there is now a crucial need to identify the compounds responsible for this contamination. It is also necessary to further our knowledge of their environmental behavior, including bioaccumulation potential and toxicokinetics. The objective of this work is to go beyond the traditionally investigated PFAS in order to obtain a more exhaustive vision of the contamination of French coastlines by PFAS. Our specific objectives are i) to provide a definitive identification of these substances using a non-targeted approach, ii) to determine if they are accumulated by marine organisms from contrasting ecosystems, such as bivalves of the French coasts from a biomonitoring program, organisms from sea bass and sole trophic networks of the Seine estuary, and top predators such as marine mammals from the Bay of Biscay. Finally, the last objective is iii), to assess the biomagnification capacity of newly identified compounds from zooplankton to sea bass and sole. This presentation describes both the samples we investigate and the methods used to achieve the aforementioned objectives. A detailed example of the annotation of putative PFAS found in real samples is also provided.

3.16.P-Tu247 Narrowing Down the Identity of Extractable Organofluorine in Blubber

***Melanie Lauria**[1], Faiz Haque[2], Anna Roos[3], Malene Simon[4], Thanh Wang[5], Cecilia Persson[6], Merle Plassmann[1] and Jonathan Benskin[1], (1)Stockholm University, Sweden, (2)Department of Environmental Science, Stockholm University, Sweden, (3)Swedish Museum of Natural History, Sweden, (4)Greenland Climate Research Centre, Greenland Institute of Natural Resources, Greenland, (5)Orebro University, MTM Research Centre, Sweden, (6)Swedish NMR centre, University of Gothenburg, Sweden*
Unlike many other persistent organic pollutants that accumulate in lipid rich tissues, most known per and polyfluoroalkyl substances (PFAS) accumulate in protein rich tissues such as liver and blood. The recent discovery of elevated concentrations of

unidentified extractable organofluorine (EOF) in killer whale blubber shows this rule might not be applicable to all PFAS. The aim of this study was to narrow down the possible nature of the unknown lipophilic organofluorine.
Analysis of a second Greenlandic killer whale confirmed the original findings from Schultes et al. (2020), which showed that >90% of unexplained EOF and very similar target PFAS profiles. Thereafter, extracts were subjected to the total oxidizable precursor (TOP) assay, which revealed low to negligible perfluoroalkyl carboxylic acid (PFCA) formation, indicating the organofluorine substance(s) were not PFAA-precursors. Solvent extraction using hexane improved extraction efficiency compared to acetonitrile, suggesting a neutral/non-polar organofluorine substance. This observation was further supported by a lack of sorption to strong anion and cation exchange resins. Overall, these experiments point towards a neutral/non-polar non-PFAA forming organofluorine substance.
Efforts to characterize the purified extracts by ^{19}F NMR were unsuccessful, possibly due to the relatively high detection limits of this technique. A negative result might also indicate that the organofluorine is comprised of several neutral substances and not just one or a few substances in high concentration. Finally, a suspect screen for fluorinated liquid crystal monomers (LCMs) was carried out by GC-HRMS. While these substances display physical-chemical properties which align with those of our unidentified organofluorine, no fluorinated LCMs were detected from this analysis. Future work will apply a broader GC-HRMS-based non-targeted screening in an effort to further narrow down the identified of this unknown organofluorine.

3.16.P-Tu248 Detection and quantification of thyroid transporter interference in European water effluents using TTR-TRß CALUX

Laura Loewe[1]*, Sarah Johann*[2]*, Melis Muz*[3]*, Loic Maurer*[4]*, Werner Brack*[5] *and Henner Hollert*[6]*, (1)Evolutionary Ecology and Environmental Toxicology, Goethe University Frankfurt, Frankfurt am Main, Germany, (2)Department Evolutionary Ecology & Environmental Toxicology, Goethe University Frankfurt, Frankfurt am Main, Germany, (3)Helmholtz Centre for Environmental Research (UFZ), Germany, (4)Wirkungsorientierte Analytik, Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany, (5)Department of Effect-Directed Analysis, Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany, (6)Evolutionary Ecology & Environmental Toxicology, Goethe University Frankfurt, Frankfurt am Main, Germany*

Chemical pollution of ecosystems, partly and increasingly due to human activities, is intensifying in the present time. A potentially harmful and still not well understood group of chemicals for human and environmental health are per- and polyfluoroalkyl substances (PFAS), which represent a range of synthetic chemicals containing carbon-fluorine bonds. This highly stable bond makes PFASs difficult to degrade and easy to transport. PFAS contamination has already been detected in groundwaters, surface waters and soils. PFAS have been shown to bind to the thyroid transport protein transthyretin (TTR) and hence interact with the hormone system. Impairment of the binding of thyroid hormones to their plasma carrier proteins (TTR, TBG, albumin) by PFAS and related compounds may have implications for the availability of free T4 to thyroid cells. The concentration of free T4 in plasma is crucial for the maintenance of thyroid hormone homeostasis. Hence, binding defect of T4 to TTR is of particular importance because TTR is the only carrier protein capable of transporting T4 across the blood-brain barrier and the placental barrier and is therefore of particular significance.
The present study is incorporated in the NORMAN joint program activity on "sources related effluents". It addresses the identification of chemical fingerprints and toxicity profiles in different source-related effluents across Europe to characterize and prioritize source-related footprints. The present study focuses on the detection and quantification of adverse effects potentially caused by PFAS compounds within water sample extracts via receptor mediated bioassays. A set of 105 samples of several sources such as industry, agricultural areas, or wastewater treatment effluents was analysed using two thyroid-related bioassays (TRß- and TTR-TRß CALUX). Resulting bioequivalent concentrations were linked to a chemical profile which has been revealed within the project. In this respect, 7 PFAS components were quantified in a variety of samples. First results showed cytotoxic effects as well as TRß-activation within the samples in environmentally relevant concentrations. The impact of the TTR binding on TRß-activity will be discussed as well as the potential identification of toxicity drivers. Furthermore, the study aims to enable a larger scale application and evaluation of TTR-TRß-CALUX for biomonitoring of surface water quality in future.

3.16.P-Tu249 Per- and Polyfluoroalkyl Substances (PFAS) in Soil and Wild Boar Samples from a PFAS Hot Spot Area – a Comparative Chemical Fingerprinting Exercise

Tobias Frische[1]*, Annegret Biegel-Engler*[2]*, Marc Guckert*[3]*, Jan Koschorreck*[2]*, Raphaela Osterauer*[4]*, Jana Rupp*[5]*, Christina Riemenschneider*[6] *and Reiner Söhlmann*[7]*, (1)Section II 2.6 "Soil Protection Measures", German Environment Agency (UBA), Dessau-Rosslau, Germany, (2)German Environment Agency (UBA), Dessau-Rosslau, Germany, (3)DVGW-Technologiezentrum Wasser (German Water Centre), Germany, (4)State Institute for Environment Baden-Wuerttemberg (LUBW), Karlsruhe, Germany, (5)Helmholtz Center for Environmental Research (UFZ), Leipzig, Germany, (6)State Institute for Chemical and Veterinary Analysis of Food (CVUA), Freiburg, Germany, (7)Landratsamt Rastatt - Amt für Umwelt und Gewerbeaufsicht, Germany*

Per- and polyfluoroalkyl substances (PFAS) have been manufactured for decades for a broad range of technical uses in industrial processes and products. Intentional or non-intentional release of these highly persistent organic compounds resulted in diffuse contamination of the environment across the globe. Moreover, local point contaminations (PFAS hot spots) are identified in increasing numbers in industrialised countries. Large-scale PFAS hot spots might stretch over several kilometres and are typically located near the facilities of fluorochemical industry or sites where PFAS have been used in production processes or PFAS-containing waste was disposed-off. Soil, groundwater and surface water are often severely PFAS-contaminated in these areas and subsequent accumulation in biota and food-chain transfer is causing concern regarding long-term adverse effects on local human and wildlife populations. Against this background, a data analysis was conducted to explore the transfer of PFAS from contaminated soils into wild boar (*Sus scrofa L.*). This omnivorous terrestrial mammalian is known for intensely digging soils in search for food, and consequently, soil ingestion by wild boar is rather high. Surface soil samples were collected from a well-described PFAS hot spot in south-western Germany and underwent extraction and subsequent chemical target analysis by a multi method covering 41 PFAS compounds. Similarly, PFAS contents of liver tissue samples taken from wild boar individuals that have been culled in the hot spot area were determined as an indicator of internal exposure. The presentation will highlight the results of a comparative chemical fingerprinting exercise, i.e. PFAS soil contamination patterns are compared to PFAS contamination patterns in wild boar liver tissue. The results will be discussed regarding their general significance, considering potential exposure pathways and the biology of wild boars as well as knowledge on the bio-accumulative behaviour of the PFAS compounds detected.

3.16.P-Tu250 Legacy perfluoroalkyl acids and their oxidizable precursors in plasma samples of Norwegian women

Ana Carolina Coelho[1]*, Lara Cioni*[2]*, Vivian Berg*[1]*, Charlotta Rylander*[1]*, Ilona Urbarova*[1]*, Dorte Herzke*[3] *and Torkjel Sandanger*[1]*, (1)UiT - The Arctic University of Norway, Norway, (2)Norwegian Institute of Air Research, Norway, (3)Norwegian Institute for Air Research (NILU), Norway*

1. Introduction

Per- and polyfluoroalkyl substances (PFAS) are a large class of persistent chemicals extensively used in industrial and consumer products. Perfluoroalkyl acids (PFAA) are the most well studied PFAS family and have been recognized to pose risks to the health of humans. Exposure to PFAA may occur from the ingestion of food and drinks, but also upon the breakdown of its precursors, which might form stable PFAA. Nevertheless, limited data about these precursors is available, raising concerns about their contribution to the total PFAS burden. In this study, plasma samples from the participants of the Norwegian Women and Cancer (NOWAC) postgenome cohort were analyzed to estimate the concentrations of PFAA precursors and assess the associations between selected lifestyle and dietary factors and these precursors.

2. Materials and Methods

The present study included plasma samples from cancer-free women (n=302) from the Norwegian Women and Cancer (NOWAC) postgenome cohort, who completed questionnaires regarding their lifestyle, and a semi-quantitative food frequency questionnaire (FFQ). The samples were analyzed for 20 PFAS, including PFAA and known PFAA precursors, by using target analysis and an optimized TOP assay for human blood. Associations between post-TOP PFAA concentrations and selected lifestyle and dietary factors were assessed by logistic regression.

3. Results and Discussion

A total of seven PFAA were detected in more than 70% of the study participants in pre-TOP PFAS analysis. In post-TOP analysis, seven PFAA showed increased concentrations in at least 30% of the study participants, indicating the presence of oxidizable PFAA precursors within these samples. The biggest increases in concentrations were observed for PFHxA, br-PFOA, and PFDA. Few significant associations between the changes in PFAA concentrations post-TOP assay and lifestyle and dietary factors were observed. These associations were not consistent across the compounds, and considering the small increase in the PFAA concentrations, the statistical power of the analysis was limited.

4. Conclusions

More than 90% of the study participants had detectable amounts of PFAA precursors, and more than 30% of participants showed increased concentrations of seven PFAA after the TOP assay. Thus, estimating the oxidizable PFAA precursors is a complementary approach to estimate the total PFAS burden in humans.

3.16.P-Tu251 Effective Treatment Of PFAS Contaminated Waste And Process Water Using Coagulation And Flocculation – Implications For Soil Washing

Michel Hubert[1]*, Hans Peter Arp*[1]*, Sarah Elizabeth Hale*[2]*, Mona C. Hansen*[2] *and Thomas Meyn*[3]*, (1)Norwegian Geotechnical Institute and Norwegian University of Science and Technology (NTNU), Norway, (2)Norwegian Geotechnical Institute (NGI), Norway, (3)Department of Civil and Environmental Engineering, Norwegian University of Science & Technology (NTNU), Norway*

High concentrations of per- and polyfluoroalkyl substances (PFAS) are found in different types of wastewaters, including landfill leachate, domestic and industrial wastewater and in process water from soil washing facilities. The treatment of wastewater commonly includes a coagulation and flocculation step, where particles and parts of dissolved substances are separated from the liquid phase. For an environmental sustainable use of soil washing as a remediation method the treatment and reuse of washing water is crucial.

To evaluate the effectiveness of different coagulants and flocculants, six products that are commercially available were tested for their PFAS reduction efficiency. They were selected to represent the range of typical coagulants used in soil washing and wastewater treatment facilities. They consisted of metalloxides, polyacrylamides, activated carbon products, as well as one material specially designed for PFAS removal. To obtain a wastewater that could be considered typical to that produced by soil washing, a silt-clay-water mixture, spiked with PFAS in concentrations typically found at Aqueous Film-Forming Foam (AFFF) contaminated sites was used.

Preliminary results show reduction efficiencies for standard flocculants as high as 50% for long chain PFAS and up to 30% for short chain PFAS. Maximum reduction efficiencies for long chain PFAS can be reached using a lower coagulant concentration than that needed to remove shorter chain PFAS. The use of specially designed flocculant, as expected, led to the highest reduction of PFAS. Reduction efficiencies of long chain PFAS exceeded 98% and for short chain PFAS the reduction was over 85%.

The results of this study indicate that by choosing the right coagulant and flocculant in the wastewater treatment process, PFAS can be substantially removed from the water phase. This may facilitate further clean-up steps in a treatment train, such as increasing the life of activated carbon filters or reverse osmosis filters downstream of where the flocculation occurred. This is important as the change of a coagulant or flocculant can be made while operating these facilities and without bigger investments in additional treatment infrastructure, which makes this approach fast and easy to implement.

3.16.P-Tu252 Removal Of Persistent And Mobile Perfluoroalkylated Substances (C1-C13 PFAS) From Real Water Matrices Using A Boron-Doped Diamond Electrode

*Javier Lopez-Vazquez[1], Francisca C. Moreira[2], Carla S. Santos[2], **Rosario Rodil**[1], José Benito Quintana[1], Vitor J.P. Vilar[2] and Rosa Montes[3], (1)Universidade de Santiago de Compostela, Spain, (2)Porto University, Laboratory of Separation and Reaction Engineering (LSRE), Laboratory of Catalysis and Materials (LCM), Portugal, (3)University of Santiago de Compostela, Spain*

Poly- and per-fluoroalkyl substances (PFAS) are persistent organic chemicals that affect both aquatic organisms and humans. Hence, the European Union (EU) limited the presence of 20 PFAS (C4-C13) in water intended for human consumption by the 2020/2184/EU Directive. Besides, the recent proposal of revision of the EU Water Framework Directive (Directive 2008/105/EC) proposed to stablish environmental quality standards for up to 24 PFAS.

Given the fact that conventional (and several advanced) treatments are ineffective in removing PFAS, new technologies shall be developed to cope with this global threat. The present work aimed at assessing the performance of the anodic oxidation (AO) process using a boron-doped diamond (BDD) anode for the removal of PFAS from different aqueous matrices. Both the several regulated PFAS (C4-C13) and the ultrashort-chain, very mobile, PFAS (C1-C3) were investigated (24 carboxylates and sulfonates, in total) at realistic concentrations (down to 0.2 µg/L). The effect of the five following matrixes was assessed: ultrapure water, drinking water, urban wastewater after secondary treatment, reverse osmosis and nanofiltration concentrates from urban wastewater tertiary treatment. Experiments were carried out at different current densities, either in the presence of a mixture or just one single PFAS. PFAS with carboxylic moieties proved to be more easily degraded than those with sulfonic ones. Whereas the former PFAS were (almost) completely removed, the removal of the latter ones greatly varied with the carbon-chain length, from less than 10% for C1 to complete (<LOD) removal from C8 on. The presence of other species in real matrices affected the efficiency of PFAS removal, but not hindered the use of the AO process.

3.16.P-Tu253 Pilot testing and economic analysis of PFAS removal from groundwater using granulated activated carbon and Sorbix™ ion exchange resin at a Swedish airport

*Jeffrey Lewis[1], Jörgen Lindahl[2], Daniel Eriksson[2], **Meseret Tesfameskel**[3] and Carol Jarpa de Emilson[4], (1)Emerging Compounds Treatment Technologies (ECT2), Sweden, (2)ECT2, (3)Emerging Compounds Treatment Technologies (ECT2), Munich, Germany, (4)Skövde Municipality*

Skövde airport is located in south-central Sweden. It was inaugurated in 1989 and was used for regional commercial flights from the ealry 1990's until the early 2000's. A series of environmental studies revealed substantial PFAS contamination in surface soils, surface water and groundwater. e municipality engaged ECT2 to run pilot tests to evaluate the most economically beneficial technology to remediate the groundwater at the site. PF concentrations in the groundwater were shown to be as high as 17 000 ng/L for the sum of eleven PFAS species that are used in Sweden to assess PFAS contamination. Thes pilot tests were performed in 2022 and compared granulated activated carbon with ion exchange resin. The ai of the remediation is to bring PFAS levels down to under 90 ng/L for the sum of eleven PFAS. The pilot testing showed that the ion exchange resin was more than twelve times more effective on a per volume basis at treating the groundwater to under 90 ng/L and three times less expensive than a GAC solution.

3.16.P-Tu254 Life CAPTURE, a Project for the Sustainable Management of Contaminated Sites by Per- and Polyfluoroalkyl Substances (PFAS)

***Sara Villa**[1], Andrea Franzetti Prof[2], Valeria Mezzanotte Prof[2] and Life CAPTURE Consortium[3], (1)Dept Earth and Environmental Sciences, University of Milano-Bicocca, Italy, (2)University of Milano-Bicocca, Italy, (3)ABO*

LIFE CAPTURE is a project that has been funded by the European LIFE ENVIRONMENT programme to the tune of approximately EUR 5 million. The project is coordinated by ABO and involves 8 European institutions including research institutes and public and private companies.

The overall objective of LIFE CAPTURE is to develop sustainable management methods for the treatment of per- and polyfluoroalkyl substances (PFAS) in soil and groundwater.

The aim is to develop a robust protocol for the analysis of PFAS, which is currently lacking, and to broaden the spectrum of the PFAS family that can be analysed. LIFE CAPTURE proposes a robust protocol that follows a step-by-step approach: to quantify the presence of different types of PFASs; to quantify the concentrations of a predetermined group of well-studied PFASs; to determine whether other PFASs are present; and to quantify and qualify their concentrations.

During the investigation of a contaminated site, it is currently considered good practice to only observe concentrations. The use of flow measurements would be a valuable addition, allowing a more direct measurement of exposure and risk. It can also be used to drastically improve the efficiency of mitigation measures such as remediation. In this project, passive flow samplers will be used, which can be integrated into the new analytical protocol.

Due to the chemical properties of PFAS, most existing remediation technologies do not provide adequate sustainable treatment solutions. We propose a toolkit of promising innovative remediation technologies for PFAS (e.g. foam fractionation for soil treatment and AOP for groundwater remediation). Technology trains will be identified and tested at the laboratory level to optimise remediation approaches to remove contaminants from the environment. The technology trains will then be tested in representative environments through pilot tests at four contaminated sites in Belgium and Italy. The assessment of whether a given PFAS contamination is harmful is generally governed by a regulatory framework. It is proposed to develop a pragmatic approach to risk and effect assessment. This will be based on existing standardised ecotoxicity tests. Particular attention will be given to risk assessment for mixtures of different known or unknown PFAS.

3.16.P-Tu255 Connecting the Dots: PFAS Risk Framework and Communication Hub

***Mark Ballentine**, David W. Moore, Alan Kennedy, Manoj Shukla, Bill Gardiner and Jodi Ryder, U.S. Army Corps of Engineers*

Per- and Polyfluoroalkyl substances (PFAS) in the environment continues to evolve and grow in complexity with no obvious risk management strategy to protect citizens worldwide. The growing number of PFAS compounds (more than 10,000) and the ever-changing and large amount of scientific data being generated increases risk-management uncertainty; this uncertainty slows timely, science-based risk-informed decision-making for military installations and site managers. e U.S. Army Engineer Research and Development Center is developing a science-based, rapid risk characterization framework for PFAS across a broad range of environmental media (water, soils, sediments) to enable better informed and cost-effective management solutions. Th framework and communication hub will connect users to requisite resources and subject matter experts facilitating more timely decisions. Expe mental case studies (from micro- to mesocosm) are planned to bridge the gap between high fidelity laboratory generated data and field observations improving understanding of key mechanistic drivers required for derivation of risk estimates and reduce uncertainty. The data generated will be utilized in computational models to characterize fate and effect of PFAS in the environment. These mputational models will ultimately be used to optimize an existing multi-media fate and transport modeling framework for field scale PFAS concentration screening. The mult year effort's goal is to create a working PFAS risk framework prototype and communication hub to direct users to needed scientific data, tools, and standards.

3.16.P-Tu256 Luminescence Lifetime-Based Sensing Platform Based on Cyclometalated Iridium (III) Complexes for the Detection of Perfluorooctanoic Acid in Aqueous Samples

***Kun Zhang**, Stuart Harrad Prof and Zoe Pikramenou, University of Birmingham, United Kingdom*

The EU has listed perfluorooctanoic acid (PFOA) as a substance of very high concern. Given the high cost and time-consuming nature of current LC-MS methods for measuring PFOA and other perfluoroalkyl carboxylic acids (PFCAs); less expensive, rapid methods for the quantification of PFCAs and other perfluoroalkyl substances (PFAS) are urgently required. Luminescence lifetime is an attractive analytical technique for detection due to its high sensitivity and window of detection which varies based on the choice of the luminescent probe. Iridium probes exhibit luminescence with long lifetimes which are sensitive to the local environment. Herein, a novel and facile lifetime-based luminescence sensor for PFOA was prepared based on gold surfaces modified with lipophilic iridium complexes bearing alkyl chains, namely, IrC6bpySS and IrC12bpySS. Upon addition of PFOA, the luminescence lifetime of the iridium complex decreases allowing monitoring of PFOA in aqueous solutions. The platform was tested for measurement of PFOA in drinking water samples spiked with known concentrations of PFOA and demonstrated determination of PFOA for concentrations >100 μg/L (240 nM).

3.17 Measuring, Modelling, and Monitoring the Environmental Fate and Exposure of Pesticides

3.17.T-01 Determining the Fraction of Global Freshwater Ecosystem Carrying Capacities Exceeded by Pesticide Use

*Peter Fantke[1], Michael Z. Hauschild[1], Olivier Jolliet[1], Farshad Soheilifard[1] and **Marissa B Kosnik**[2], (1)Technical University of Denmark, Denmark, (2)Swiss Federal Institute of Aquatic Science and Technology, Switzerland*

Pesticide use nearly doubled from 1990 to 2018, and is projected to increase further with population growth. To determine whether current pesticide use practices exceed the limits for an ecosystem to withstand pesticide pressure, protective thresholds for environmental compartments must be identified across ecosystems at relevant spatial scales. Therefore, methods are needed to both calculate and link the actual pesticide pressure on ecosystems (as a result of pesticide usage) and the capacity for ecosystems to withstand that pressure. Challenges in developing these methods include variability in where pesticides are used, and spatial differences in features of ecosystems (e.g., climate, location of water bodies). Additionally, regions with seemingly distinct carrying capacities may be interconnected as pesticides emitted into one region may occupy the carrying capacity in other (e.g., downstream) regions. To address this gap, we introduce a spatially explicit framework to relate pesticide pressure to region-specific carrying capacities. We then assess current pesticide use against freshwater ecosystem boundaries globally and quantify the fraction of freshwater ecosystem carrying capacities that is occupied (and potentially exceeded) by toxicity-related pressure from pesticides. Pesticide application data for 865 chemicals was translated to emission mass to air, soil, and water. These data were integrated into the Pangea spatial multi-scale model to determine the concentration of each chemical in 87,063 freshwater catchments globally. Pesticide pressure and carrying capacity were combined, so the output for each chemical in a region is the fraction of a freshwater ecosystem's carrying capacity occupied by that pesticide, Fcc,o (considering both direct and indirect contributions into that region). For each region, the Fcc,o was analysed per pesticide and cumulatively (across pesticides). We found that most pesticides do not exceed any carrying capacities individually, but some frequently used pesticides do in a subset of catchments (e.g., atrazine and imidacloprid in the eastern United States). Further, up to 15% of global freshwater ecosystems have cumulative pesticide pressure exceeding their carrying capacities (based on the sum of individual pesticide F,ccos per catchment). This framework can help identify chemicals dominating cumulative chemical pressure in order to guide environmental remediation and inform more sustainable pesticide use practices.

3.17.T-02 Leveraging SWAT+' New Landscape Routing, Conditional Management, and Pesticide Functionalities

*Hendrik Rathjens[1], **Jens Kiesel**[1], Bettina Miguez[1], Michael F Winchell[1] and Robin Sur[2], (1)Stone Environmental, (2)Environmental Safety, Bayer AG - Crop Science Division, Germany*

The Soil and Water Assessment Tool (SWAT) has been an internationally leading model for predicting the fate and transport of non-point source agrochemicals at the watershed scale for nearly two decades. SWAT is a semi-distributed model based on a hydrologic response unit (HRU), a conceptual component that aggregates areas with similar landscape characteristics within a watershed, including land use and soils, to simplify the calculation of water fluxes, as well as sediment and chemical loading to a channel system. Strengths of SWAT for the simulation of agrochemicals include the comprehensive hydrologic model, channel routing and in-stream chemical transport processes, and extensive customization of agronomic management practices. A recently released enhanced version of SWAT, SWAT+, provides three main advantages over the historically used SWAT model for pesticide risks assessments of flowing water bodies: (1) the ability to directly simulate pesticide metabolite formation and environmental fate, (2) flexible spatial representation of landscape features and their interactions, and (3) advanced agricultural management practices, including rule-based probabilistic pesticide applications. This research was conducted to evaluate these new SWAT+ features and to assess its ability to predict observed pesticide and metabolite concentrations. The evaluation was conducted based upon a comparison of the results from six different model configurations with high-resolution monitoring data. The results showed that (1) SWAT+ is able to simulate the formation of degradate compounds and predict resulting concentrations in surface water, (2) an accurate representation of both surface and subsurface transport processes for pesticide exposure assessments is important, and (3) an appropriate degree of realism can be achieved with rule-based probabilistic pesticide application timing if information about the annual percent crop treated, a typical application rate, and a typical application window is available.

3.17.T-03 The Effect of Alternative Synthetic Hydrographs when Quantifying Pesticide Mitigation Efficiencies with VFSMOD in Exposure Assessments

***Rafael Muñoz-Carpena**[1], Robin Sur[2], Stefan Reichenberger[3], Stephan Sittig[4] and Amy Ritter[5], (1)University of Florida, (2)Environmental Safety, Bayer AG - Crop Science Division, Germany, (3)knoell France SAS, France, (4)knoell Germany, Germany, (5)Waterborne Environmental*

The higher-tier regulatory pesticide risk assessments (EU FOCUS, US-EPA, Canada PMRA, etc.) use the model PRZM to calculate edge of the field surface flow, sediment and pesticide runoff mass in daily time steps within long-term simulations. VFSMOD is currently available for the calculation of vegetative filter strip (VFS) pesticide mitigation within these regulatory frameworks. Critical to this analysis is that the inputs required to run VFSMOD for each daily event simulation in long-term assessments are those already available within the regulatory risk analysis framework. For the case of rainfall data, in some instances, hourly rainfall records exist for regulatory agroecological scenarios, where in other cases only daily totals are available. Quantifying VFS efficiency requires consideration of the flow and transport dynamics within the filter during the storm. For this, VFSMOD operates at the sub-hourly time step so PRZM daily field outputs used as VFSMOD inputs must be distributed during the storm. Different alternatives could be considered but these can affect the realism and accuracy of the calculations and the results of the regulatory assessment. This study compares 3 approaches for distributing daily rainfall and field runoff based on standard storm durations for the specific regulatory scenario: two simplified (rectangular and triangular shapes) and a more physical approach used as benchmark for comparison. A previous VFSMOD application case study is used to analyze the relative effect of the choice of hydrograph and rainfall distribution for a wide range of VFS sizes, 2 soil types dominant in the study area, storms magnitude (return periods) and duration, and pesticide characteristics (Koc). Statistical and global sensitivity analyses show that the triangular distribution is a good compromise in terms of simplicity of implementation, computational time and accuracy of calculated values for reductions of runoff, sediment and pesticide in the VFS. This supports its use in the regularly pesticide mitigation assessments with VFSMOD.

3.17.T-04 Harmonised Framework for the Spatially Distributed Leaching Modelling of Pesticides Initiative: A 2023 update

***Aaldrik Tiktak**[1], Anton Poot[2], Bernhard Jene[3], Gerco Hoogeweg[4], Maarten Braakhekke[5], Louise Wipfler[5], Abdul Ghafoor[6], Judith Klein[7], Michael Stemmer[8], Paul Sweeney[9], Robin Sur[10], Jutta Agert[11], Marnik van Clooster[12], Gerard Heuvelink[13], Gregory Hughes[14], Stephan Marahrens[15], Stefan Reichenberger[16] and Nicoleta Suciu[17], (1)PBL Netherlands Environmental Assessment Agency, Netherlands, (2)Board for the Authorisation of Plant Protection Products and Biocides, Netherlands, (3)BASF SE, Germany, (4)Waterborne Environmental, (5)Environmental Risk Assessment, Wageningen Environmental Research (WUR), Netherlands, (6)KEMI, Sweden, (7)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Germany, (8)Austrian Agency for Health and Food Safety (AGES), Austria, (9)Syngenta, United Kingdom, (10)Environmental Safety, Bayer AG - Crop Science Division, Germany, (11)Bayer AG - Crop Science Division, Germany, (12)Université Catholique de Louvain, Belgium, (13)ISRIC, Netherlands, (14)GeoSpatial Analytics, United Kingdom, (15)German Environment Agency, Germany, (16)knoell France SAS, France, (17)Università Cattolica del Sacro Cuore, Piacenza, Italy*

Spatially distributed leaching modelling (SDLM) of pesticides is a methodology to estimate leaching potential over a large spatial extent such as national or European. SDLM can help setting groundwater monitoring programs in context. It is described in the FOCUS groundwater report and foreseen to be used as higher tier leaching risk assessment as well as supporting monitoring studies. SDLM is already used as a higher tier assessment in the national authorization procedure in some EU countries and will probably become more important in future.

At the SETAC Europe 2020 online meeting, the initiative was officially formalised as a SETAC working group, consisting of a triad of members from regulatory agencies, academia, and the private sector. A steering committee manages the effort to develop a harmonized framework for spatially distributed leaching modelling across Europe. They published a problem definition document describing the aim and scope of the work. In 2021 subgroups for Geodata and Modelling were established each with a specific focus. As the SDLM teams continue to work, this presentation provides an update to interested parties.
The Geodata subgroup is evaluating datasets that can be used to generate a spatial modelling scheme and associated scenarios. Data reviewed fall in several established EU INSPIRE knowledge base metadata categories such as Agricultural, Meteorological, Land Cover, Hydrography, Soil, and many other categories. The Geodata group primarily focusses on pan-European datasets that cover the EU27 and the UK. Data has now been selected in each of these categories, and the presentation will highlight some important decisions, including the use of a new organic matter map.
The modelling subgroup is evaluating the models to be used in the SDLM context. Specific attention is paid to runoff processes. The subgroup showed that it is possible to describe runoff in a harmonised way using the runoff curve number approach. The modelling subgroup is further investigating if it is necessary to incorporate artificial tile drainage as well as preferential flow into the framework. However, in contrast to runoff processes, there is currently no agreed method available for the simulation of these two processes.

3.17.T-05 Contextualisation of Groundwater Monitoring Detections of Plant Protection Products: Observations from Site Elucidations
***Andrew C Newcombe**, Virginia Houck, Katherine Brutscher and Leah Martineau, Arcadis*
To support re-registration and environmental stewardship objectives, Arcadis has collected public monitoring data on more than 200 active substances and metabolites from many sources across Europe. More than 13 million analytical records have been identified by conducting database searches or contacting regulatory agencies and organisations that collect these data. For certain active substances and metabolites, elevated groundwater detections or exceedances of regulatory thresholds have been observed in the identified data. To better understand groundwater detections for select active substances, Arcadis has performed more than 140 detailed site elucidations across 12 European countries. Site elucidation activities included: 1) Determination of the sampling location type, quality and integrity, and protection measures. 2) Identification of nearby surface water and groundwater features, estimation of slope and direction, identification of any erosion or runoff channels, drainage features, and potential conduits to groundwater. 3) Documentation of karstic features, rock outcrops, and springs. 4) Interviews with farmers to collect historical product usage data on agricultural fields within the groundwater catchment area or 1,000-m radius of the sampling location. 5) Delineation of the treated field boundaries and locations of pesticide mixer/load, chemical storage, and farm machinery storage areas.
Data collected from each site elucidation was evaluated to determine if the potential cause of the groundwater detection or exceedance could be attributed to i) conventional leaching processes ii) point source contamination or iii) shortcut leaching pathways. From observations and data recorded during these site elucidations, a significant number of monitoring locations with groundwater detections or exceedances were classified as having a high possibility of a shortcut leaching pathway or potential point source contamination that contributed to the detections observed. Findings from the site elucidations demonstrate the need to assess the utility and quality of public monitoring data generated. Publicly available monitoring data for active substances and their metabolites provide important insight and knowledge about their leaching potential under actual use conditions and valuable information for use in assessing risk to groundwater. However, the quality of these monitoring data can vary greatly, which needs to be considered when used for regulatory risk assessment purposes.

3.17.P Measuring, Modelling, and Monitoring the Environmental Fate and Exposure of Pesticides

3.17.P-Tu257 Long-range atmospheric transport of currently-used pesticides over Europe

Currently-used pesticides (CUPs) are semi-volatile organic compounds that have been widely used in agriculture over the last 30 years at the global scale. Several CUPs were detected in air at remote locations such as the Arctic, showcasing their potential for long-range atmospheric transport. However, for most CUPs, their potential for long-range atmospheric transport has never been investigated. The aims of this study are (i) to report on the atmospheric levels of CUPs on the regional European scale and (ii) to identify the CUPs prone to long-range atmospheric transport.
To this end, a sampling campaign took place simultaneously at 29 sites in 17 European countries in spring 2020. The sampling sites were defined as rural (n=16), coastal (4), mountain (6) and polar (3) based on their geographical location and land use. About 120 samples were collected using a low or high-volume air sampler and were extracted and analysed by chromatographic methods coupled to mass spectrometry. In total, 76 CUPs were analysed in these samples including 35 herbicides, 22 insecticides and 19 fungicides.
Among the 76 CUPs targeted, 58 were quantified in the European atmosphere. In particular, six fungicides, six herbicides and one insecticide, which are all, except one, authorized for agricultural use in Europe, were found in more than 50% of the sampling sites. Overall, 22 out of the 76 CUPs investigated in this study were identified as prone to long-range atmospheric transport. Indeed, at the polar sites, 19 CUPs were present in the air. In addition, in the five samples collected within the free troposphere of the mountain sites, 14 CUPs were quantified, of which 11 that were also found at the polar sites.
Out of the 22 CUPs identified as prone to long-range atmospheric transport, 15 are currently authorized for agricultural use in Europe, suggesting a need to revise the registration criteria in terms of long-range atmospheric transport.

3.17.P-Tu258 The Use of Chemical Plant Protection Products In Industrial Scale Vegetable Production in Finland: A Longitudinal Study
Kati Räsänen[1]*, Asko Hannukkala*[2]*, Sirpa Kurppa*[2]*, Marja Aaltonen*[2]*, Anne Rahkonen*[2]*, Jussi Kukkonen*[3] *and Irene Vänninen*[2]*, (1)Bioeconomy and environment / Sustainability science and indicators, Natural Resources Institute Finland (Luke), Finland, (2)Natural resources / Plant health, Natural Resources Institute Finland (Luke), Finland, (3)University of Eastern Finland, Finland*
Pesticide usage data in the EU member states must be collected in accordance with the Community legislation concerning statistics on plant protection products (PPPs). However, the EU's public pesticide data still concerns only sales data. Our longitudinal study (17 years) utilizes a database that contains records of the use of PPPs on vegetable farms in southwestern Finland. The data was obtained from the local long-established food processing company which gave confidential rights to use the data to the Natural Resources Institute Finland (Luke). Here, we report, for the first time, the exact quantities of PPPs used in carrot, potato, swede, and fresh pea production in southwestern Finland from 2003 to 2019. Fresh peas and swede represent very low or decreasing use of PPPs, respectively. The number of fungicide treatments per field showed an increasing trend in potato, despite per unit area fungicide treatments having not increased. In carrots, insecticide and herbicide spray frequencies increased more than treatment volumes. The results of this study form a basis for analyzing ecotoxicological risks of PPP use in the studied crops because usage and spray frequencies alone do not convey the risk levels accurately.

3.17.P-Tu259 Spatial and Temporal Patterns of Pesticides Among Other Organic Pollutants in Seasonal Pools
Daniela Abramov[1]*, Tom Topaz*[2] *and Sarig Gafny*[3]*, (1)The School of Marine Sciences, Ruppin Academic Center, Israel, (2)The Faculty of Marine Science, Ruppin Academic Center, Israel, (3)Ruppin Academic Center, Israel*
Seasonal pools are defined as ephemeral wetlands that fill with water during the rainy season and dry out completely or mostly during the dry season. These water bodies support distinctive biodiversity and have great importance in conserving endemic species. Yet, due to anthropogenic stress, their occurrence has dramatically declined around the globe. In addition, surface water and runoff are increasingly contaminated with pollutants including microplastics, pesticides, pharmaceuticals etc. This may strongly impact the pools, which function as sinks for compounds washed with surface runoff and shallow underground flows. Although seasonal pools are gaining attention in the research literature, there is very limited information on the transport and dynamic of organic pollutants in them. This contrasts with their potential to serve as an efficient representative environmental model system for understanding pollutant mixtures transport mechanisms, dynamics and fate in aquatic environments. This study aims to shed light on the spatial and temporal dynamics of pollutant mixtures, mainly pesticides, and examine the parameters controlling these dynamics in seasonal pools located in Israel. Therefore, sediment, water and plant tissue samples were collected from 12 pools across Israel throughout one year. Preliminary results indicate that pollutant residues are present in the sediments and the water of all the pools, even those that seem separated from direct human influence. Plant protection products constituted the largest functional group of organic pollutants found in sediment and water during wintertime (47% and 38% respectively). A total of 25 different plant protection products were found in the sediments, ranging from zero in an isolated pool to 8-10 in pools adjacent to agricultural areas. On the other hand, 44 plant protection products were found in the winter sampling water, ranging between 6 to 30 different pollutants in each pool. The incompatibility in pools' ranking by plant protection products variety

between sediment and water requires further consideration. Additional data from the spring sampling will allow us to examine and discuss the temporal changes and the effect of other pools' characteristics such as vegetation presence. The presentation will discuss the spatial and temporal dynamics of pesticides with the aim to shed light on mechanisms that may provide authorities with science-based tools for managing runoff and seasonal pools.

3.17.P-Tu260 Water and Pesticide Transfers in Undisturbed Soil Columns Sampled From a Stagnic Luvisol and a Vermic Umbrisol Both Cultivated Under Conventional And Conservation Agriculture

Sixtine Cueff[1], *Lionel Alletto*[2], *Marjolaine Bourdat-Deschamps*[3], *Pierre Benoit*[3] *and Valérie Pot*[3], *(1)Plant Protection Products – Impact and Assessment, Agroscope, Switzerland, (2)University of Toulouse, France, (3)Université Paris-Saclay, INRAE, AgroParisTech, France*

Conservation agriculture consists of a combination of (i) a strong reduction of tillage, (ii) the diversification of crop rotations, and (iii) a permanent soil cover by living plants or residues. Under such practices, mechanical disturbances are minimised and the water and organic pollutant dynamics are deeply modified. In particular, a "vertical dominant" functioning is favoured, thus limiting erosion and runoff (behind surface water contamination). The risk of groundwater contamination is, however, generally favoured and even more problematic when the increase in weed pressure, due to reduced tillage, can lead to a greater use of herbicides.

The objective of our study was to characterise water and pesticide transfers in two soils from the South West of France (Pyrénées-Atlantique and Gers regions) managed under contrasted agricultural practices (regularly tilled vs. conservation agriculture). To do so, we performed percolation experiment on undisturbed soil columns sampled from the surface horizon. A molluscicide (metaldehyde) and two herbicides (nicosulfuron and mesotrione) frequently detected in the rivers of the studied fields catchment area were used. They were applied all together with a conservative water tracer. Columns were submitted to a series of two rainfall events (high and low intensities) separated by a two-days flow interruption, while maintained under unsaturated conditions (- 80 cm).

Preferential flows were evidenced at both sites and for both agricultural managements, but breakthrough curves showed a clearly different transport pattern between sites. At the Pyrénées-Atlantique site, behaviours were partly related to the pesticide sorption properties. Nicosulfuron and mesotrione were delayed compared to the tracer and slightly more under conservation agriculture. At the Gers site, we observed an early and simultaneous breakthrough of all substances under both management (independently of their sorption properties), suggesting a strong degree of preferential flow. At this site, experiments were carried out on shorter columns for the regularly tilled plot since a low conductive plow pan (evidenced by X-ray tomography) prevented flow beyond 20 cm. Due to this plow plan, surface and sub-surface runoff (observed in the field) are likely to be induced. Conservation agriculture practices performed for almost two decades seem, however, to have restored transfers to a 30 cm depth (at least), favouring the risk of groundwater contamination.

3.17.P-Tu261 Evidence for Aged Sorption to Be Used in Combination with Field Degradation Studies in Regulatory Assessments

Ian Hardy, *Battelle UK, United Kingdom*

In the EU Aged Sorption Guidance (SANTE/12586/2020) the use of field DegT50 values in combination with aged sorption parameters is only possible to a very limited extent. If the leaching assessment for a PPP is based on field DegT50 values only, it is not recommended by the current guidance to derive a $DegT50_{equilibrium}$ (rescaling of DegT50) for input in exposure models in combination with aged sorption parameters (f_{NE}, k_{des}) as described for laboratory DegT50 values. This virtually prevents the mitigating effect of aged sorption on leaching and limits the applicability of the aged sorption guidance in combination with field DegT50 to very few cases.

However, the guidance mentions that "Industry is preparing evidence for aged sorption in field studies and this option should replace the current recommendations as soon as appropriate guidance has been developed and tested".

Therefore, additional field studies were evaluated to show the relevance of aged sorption in the field. The evaluation was mainly based on the comparison of observed concentration depth profiles versus FOCUS-PEARL simulations with and without consideration of aged sorption. Where possible, site-specific aged sorption parameters from laboratory studies with the respective field soils were used. The depth to which 95% of the residues are found was defined as metric for comparison. It was found that in all studies and sites the simulated soil profiles without aged sorption significantly overpredict the leaching of the substances. When considering aged sorption in the simulation the leaching was mostly still overpredicted but to a lesser extent which confirms the relevance of aged sorption in the field. In addition, the increase of apparent K_d-values from field and laboratory aged sorption studies with the same soils were compared with the result that the effects of aged sorption in field soils are similar to what is observed in laboratory studies.

3.17.P-Tu262 Temporal Trends of Legacy Chlorinated Pollutants in Various Fish Species From Norwegian Marine Areas

Stepan Boitsov[1], *Sylvia Frantzen*[2] *and Bjørn Einar Grøsvik*[1], *(1)Havforskningsinstituttet/Institute of Marine Research, Norway, (2)Institute of Marine Research, Norway*

Fish stocks in Norwegian marine areas have been heavily impacted by various human activities in the recent decades and may be vulnerable to impacts of chemical contaminants even at relatively low levels. Several chlorinated persistent organic pollutants (POPs) as polychlorinated biphenyls (PCBs), dichlorodiphenyltrichloroethane (DDT), hexachlorocyclohexanes (HCH), hexachlorobenzene (HCB), *trans*-nonachlor (TNC) have been included in the monitoring program of the Institute of Marine Research (IMR) carried out in Norwegian marine areas since the 1990-s. Sampling of various marine species was carried out with IMR's own research vessels during the summer-autumn period every 3rd year in the North Sea or the Barents Sea. Approximately

25 fish of each species were collected at a single or several locations in the same area and analysed at IMR using an accredited analytical method.
Liver of Atlantic cod (*Gadus morhua*), haddock (*Melanogrammus aeglefinus*) and saithe (*Pollachius virens*) from the studied marine areas was found to have low to moderate levels of POPs, on average lower or slightly exceeding the established threshold values. The time trends have demonstrated a significant decrease with time for all the POPs (based on lipid weight) in the Barents Sea samples, where the levels in the 1990-s were considerably higher than in the later years. On the contrary, no significant decreasing trends were as a rule found in the North Sea for most POPs excluding HCH. The time series for the North Sea is from 2005 onwards, which may explain the absence of the decrease. It seems that the decrease has mainly occurred in 1990s and the levels have somewhat stabilized in the later years.
Sediment samples from the Barents Sea mostly show trace levels of the chlorinated POPs. The levels are correspondingly low in deepwater prawn (*Pandalus borealis*), capelin (*Mallotus villosus*), Atlantic herring (*Clupea harengus*), and are somewhat higher in polar cod (*Boreogadus saida*). There is however a significant decrease in POPs levels with time since the 1990-s also in these species. The levels are considerably higher in haddock and are the highest in Atlantic cod among all the studied species.
The observed time trends demonstrate a difficulty with removing these highly persistent pollutants from the enviornment once they have entered it. Biomagnification through different trophic levels is apparent and represents a danger for species occupying higher trophic levels.

3.17.P-Tu263 Occurrence and Distribution of Pesticides in Air at Two Agricultural Areas in Europe
Freya Debler[1]*, Juergen Gandrass*[1]*, Nelson Abrantes*[2]*, Isabel Campos*[3] *and Marjan Toren*[4]*, (1)Helmholtz Center Hereon, Germany, (2)Department of Biology, University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Portugal, (3)Environment and planning, University of Aveiro, Portugal, (4)Wageningen University & Research, Netherlands*
The ever-increasing problem of pesticide resistances and the inclusion of some pesticides in the Stockholm Convention due to their PBT (persistence, bioaccumulation and toxicity) properties and their potential to undergo long-range atmospheric transport has led to the application of newly discovered pesticides. These so-called currently-used pesticides (CUPs) can reach the atmosphere during their application due to spray drift or through post-application emissions such as volatilization. Some of these pesticides also occur in the air far from their application sites, even in such remote areas as the arctic. Information on the occurrence and distribution of these CUPs and their transport behavior are still limited.
This study was conducted within the framework of the EU project SPRINT. It investigates the occurrence and distribution of a wide range of pesticides in air at two agricultural areas in Europe (Portugal and the Netherlands) during a time period of one year (April 2021 until June 2022).
100 air samples were taken using high-volume air samplers. For the sampling of pesticides in the gasesous phase, PUF/XAD-2 cartridges were used, for the sampling of pesticides in the particle phase, glass-fibre filters (GFFs) were used.
The analytical method included 340 different pesticides, among them organochlorine pesticides, CUPs and 45 metabolites. PUF/XAD-2 cartridges were extracted by cold-column extraction with dichloromethane. GFFs were extracted using the QuEChERS approach. For GC analysis, a clean-up step using a dispersive SPE was performed. Instrumental analysis was performed by liquid chromatography coupled to a time-of-flight mass spectrometer and gas chromatography coupled to a tandem mass-spectrometer.
This study adds experimental data on the occurrence and fate of a wide range of pesticides in air. For pesticides found in both air phases, their distribution between the gaseous and particle phase can be determined by calculating gas-particle partitioning coefficients. Results show concentrations for several pesticides in the low pg/m^3 to ng/m^3 range. Highest concentrations of pesticides were found during the pesticide application period in spring and summer. Seasonal variations in pesticide concentrations and composition can be identified.
The results contribute to identifying pesticides to be considered in future work when investigating potential health impacts resulting from the exposure of humans to pesticides in the environment.

3.17.P-Tu264 Adaptive Neuro-Fuzzy Inference System Modelling of Pesticides and Heavy Metals Adsorption Coefficients in Soils
Babatunde Kazeem Agbaogun[1]*, Henning Buddenbaum*[2] *and Klaus Fischer*[1]*, (1)Analytical/Ecological Chemistry, University of Trier, Germany, (2)Environmental Remote Sensing and Geoinformatics, University of Trier, Germany*
Soil plays host to a multitude of chemicals, either applied on purpose or accidentally deposited from a variety of sources. Once on the soil surface, these contaminants are subject to vagaries of processes. Their persistence in soil, and migration to surface and groundwater, in particular, are problems of environmental concerns which require the knowledge of their sorption characteristics. Many mathematical models and/ or screening tools are described in the literature for evaluating the migration and leaching potentials of chemical contaminants in soils, using their distribution coefficients (K_d and K_{oc}). These parameters are usually obtained from classical laboratory or field experiments. Not only is this approach rigorous and expensive, it could also be fraught with many errors. Thus, developing an accurate expert system for in-silico quantitation of these distribution coefficients is much desirable. Though the concept of linear solvation energy (i.e., polyparameter linear free energy relationships, pp-LFERS) presents accurate method, it suffers some limitations. Our literature search has shown that artificial intelligence (AI) techniques such as the adaptive neuro-fuzzy inference systems (ANFIS) have proven to be very accurate for prediction of partition coefficients of chemicals in near fields but have not been used for soils. Hence why we chose this method. We obtained experimental data from adsorption of five (5) substituted urea herbicides (linuron, diuron, monuron, isoproturon and chlorotoluron) and three toxic metals (Pb, Cd and Cu) in several differently composed natural topsoils. Based on the established correlations, nine variables were selected as input vectors with the adsorption quantity (Q_e) as output vector. For each organic and inorganic systems as well as for

the integrated organic-metals systems, 255 ANFIS models were developed, using 10-fold cross-validation. These models were compared with similarly developed multiple linear regressions (MLRs), using three error metrics – mean average error (MAE), root mean square error (RMSE), and coefficient of determination (R^2). ANFIS delivered models that satisfied our search not only for the most accurate prediction but also for the smallest combinations of input vectors to construct the models, with high accuracy and interpretability trade-off. These models have been proposed for in-silico predictions of distribution coefficients of a variety of environmentally relevant chemicals in soils.

3.17.P-Tu265 Technical Challenges In Soil Photolysis Studies Using SETAC 1995 And/Or Draft OECD Guideline
Prasit Shrestha[1]*, Kari Moshenberg*[2]*, Thomas Hennecke*[1]*, Mike Kruse*[1]*, Michael Huben*[1]*, Andreas Häusler*[2] *and Dieter Hennecke*[1]*, (1)Ecological Chemistry, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Germany, (2)Environmental Fate and Modelling, GAB Consulting, Germany*
Data on photolysis of chemicals in soil are required by Commission Regulation EU 283/2013 for the registration of plant protection products. The SETAC (1995) guideline is the regulatory relevant guideline, while the OECD draft guideline on soil photolysis (2002) has never been implemented. A key difference between the two guidelines is that the SETAC guideline uses air-dried soils, while the OECD draft guideline recommends air dried or moist soils (75% of the field capacity). Based on both guidelines, a thin layer (2mm) of soil is prepared in a quartz glass tray and applied with the test item. The applied soil is incubated in an irradiation unit with continuous irradiation of $75 W/m^2$ for a period of 10-15d. While performing this test, specific technical challenges have been identified that can influence the test validity. One of the issues is maintenance of the temperature of 20±2°C in the soil layer. Normally, a cooling unit (cryostat) is placed under the test vessel to cool the soil layer which is heated by the irradiation from top. This leads to a very high temperature gradient in the 2 mm soil layer (>> 10°C) and only the position and geometry of the temperature sensor decides on the temperature measured. Thus, the temperature recorded is no reliable validity criterium. Another concern is the drying of the moist soil under flow through conditions, which is a rapid and not reproducible process. This is due to the extreme high energy input by irradiation and cannot be avoided.The aim of this study is 1) to optimize the study setup used in the soil photolysis study and to investigate on a robust and reliable validity criterion instead of defining a temperature that cannot be measured properly. 2) to perform a literature review followed by lab experiments comparing the extent of photodegradation when dry or moist soil is used.

3.17.P-Tu266 Derivation of Active Substance Content in Heubach Dust from the Seed Dressing Rate for the Assessment of the Exposure to Abraded Dust when Sowing Treated Seeds
Michael Hess[1]*, Thomas Gräff*[2]*, Johanna Hemetzberger*[2]*, Mirjam Diesner*[2]*, Christina Mordziol*[2]*, Dirk Suessenbach*[3] *and Silvia Pieper*[2]*, (1)German Environment Agency (UBA), Germany, (2)German Environment Agency, Germany, (3)German Environment Agency (UBA), Section IV 1.3 - Plant Protection Products, Germany*
The EFSA PPR Panel made already in 2004 explicit reference to the relevance of the exposure route "abraded dust drift deposition" in non-target areas when sowing treated seeds. However, the data available at that time were not sufficient to propose a calculation of the predicted exposure in the environment due to drift and deposition of abraded dust from seeds treated with plant protection products. After incidences with bees dying from abraded dust from treated maize seed in Germany 2008, exposure studies were conducted and guidance documents (GD) to assess and manage the risks were drafted (SANCO Working Group).
The current draft GD for Seed Treatment (Part Risk Assessment, version 17 from September 2021) includes a broad data basis on seed quality, especially for cereals. The exposure route by dust drift deposition on the ground and in vertical structures in non-target areas is dependent on crop, sowing density and seed quality can be expressed as amount of abraded dust (in the so-called "Heubach value") and the active substance (a.s.) content in Heubach dust released from treated seeds (so called "Heubach a.s.").
To identify and characterize the possible relationship between the seed dressing rate and the content of a.s. in the dust, comparable data sets from cereal tests of 2011 and 2019 were combined and analyzed.
The target variable "% a.s. in dust" is binomially distributed in this dataset. A generalised linear model was used on logit transformed data. The data set showed a relationship between the concentration of a.s. in dust, the amount of abraded Heubach dust and the seed dressing rate. Previously defined reference values for professional seed treatment facilities regarding the concentration of the active substance is 10%. Following the regression model, seed dressing rates below 22 g a.s./180 kg seeds benefit from the refinement option. For these seed dressing rates, the estimation can be used to reference the quality control to dust abrasion, in cases when only a limited number of data on the content of a.s. in abraded dust are available.
So far, a sufficient data set exists for cereals. With the provision of similar data sets for other seeds types, more crop specific approaches and an extension to other crop seeds and granules are possible. This could facilitate the quality management in seed treatment while keeping the same level of protection for the environment.

3.17.P-Tu267 On the use of sCience-based Thresholds for the Interpretation of Environmental Monitoring Data: Demonstrating that Glyphosate Residues in European Water Pose No Risk to Ecosystems or Human Health
Simon Mayer[1]*, Adrian Simon Terry*[2]*, Gregory Hughes*[3]*, Liz Whitworth*[4]*, Philip Manson*[5]*,* ***Mahmood Al Ramahi***[6] *and David Saltmiras*[1]*, (1)Bayer AG - Crop Science Division, Germany, (2)Cambridge Environmental Assessments (CEA), United Kingdom, (3)GeoSpatial Analytics, United Kingdom, (4)RSK ADAS, United Kingdom, (5)Bayer AG - Crop Science Division, (6)Crop Science Division, Bayer AG - Crop Science Division, Germany*
Pesticide authorization in Europe requires an overview and assessment of environmental monitoring data, typically compiled from publicly accessible online data repositories and reports. Such information provides valuable insight into the state of the environment, emerging issues, and possible impacts. However, caution is required in the collation and interpretation of such data.

In order to determine whether remedial actions are necessary to ensure protection of human and environmental health, the underpinning basis for threshold limits should be considered in light of whether arbitrarily established, or science-based and data-derived. Environmental and human health endpoints to establish such levels for glyphosate (GLY) will be discussed and compared with current regulatory values in Europe and the United States.
A GLY Annex I renewal dossier was recently submitted in Europe. Public monitoring data collection/analysis for all Member States across environmental compartments included: 1) Surface Water (SW): comprehensive dataset (>300K samples from >15K sites) versus the regulatory acceptable concentration (RAC) of 400 µg/L, shows very high regulatory compliance (>99.99%). No official environmental quality standard (EQS) threshold has been set at the European level so far. 2) Groundwater: comprehensive dataset (>251K samples from >40K sites) versus the EU arbitrary regulatory threshold (0.1 µg/L) shows very high regulatory compliance rates (>99.4%). Excluding a small number of high outlier concentrations indicated maximum concentrations well below the SW RAC (for groundwater fed ecosystems) and the lifetime health-based Acceptable Daily Intake (LTHBADI) concentration (1500 µg/L). 3) Drinking Water: smaller dataset (>9.5K samples from >3.7K sites) versus the EU regulatory arbitrary threshold (0.1 µg/L) shows very high regulatory compliance (>99.9%) and is in good agreement with a large number of aggregated data summaries in published reports. Where threshold exceedances occur, the maximum concentrations are low and well below the LTHBADI concentration. This is unsurprising as GLY is readily removed by conventional water treatment processes already in place to ensure microbiological safety.
Analysis of a comprehensive database of GLY residue analyses within the public monitoring of national and regional environment agencies in Europe with robust science-based thresholds suggest no issues for the state of the environment, nor to human health *via* drinking water.

3.17.P-Tu268 Pesticides Screening on Water and Soils along Mekong River in Cambodia

***Putheary Ngin**, Chemistry, Umea University, Sweden*

The massive use of pesticides has been causing great concern mainly regarding environmental contamination especially aquatic ecosystems including water, soil ect (1). Pesticides are detected in surface waters, close to agricultural sites, in concentrations from low ng l^{-1} to high µ l^{-1} (2). Pesticide usage in Cambodia is high, reflecting the importance of agriculture. There is no pesticide manufacturing in Cambodia and so the pesticide in Cambodia is entirely based on the importing from Vietnam, Thai, and China. All pesticides that are legally imported must follow the Cambodian legislation regarding quality assurance and labelling in Khmer language, a practice that results in lowering risk of misuse. However, it has been shown that illegally pesticides are used, which pose higher risk because the farmers don't understand the instruction written in the language of the origin of the pesticide. Nevertheless, the pesticides composition and prevalence, and the spread of pesticides in the environment have a few studied in Cambodia, severely limiting the possibility of targeted public health interventions.
This study aims to assess pesticide residue prevalence and composition in Cambodia. Water and soil samples along the Mekong River in Cambodia were analyzed for 65 pesticide residues by using liquid chromatography coupled with mass spectrometry methods. In total, 288 samples of water and soil (16 sampling sites within the four provinces along) were extracted by using solid-phase extraction and a modified Quick Easy Cheap Effective Rugged Safe protocol in combination with Ultrasonic-Assisted Extraction. The ecological risk assessment was also performed by calculating the risk quotient (RQ).
We plan to present the average concentration of detected pesticide residues in water and soil, and the value of risk quotient of detected pesticide residues in water and soil.

3.17.P-Tu269 Seasonal Monitoring of the Presence of Glyphosate and its Metabolite AMPA in Surface Water Bodies of the Pulia Region (Italy)

***Mariangela Triozzi**[1], Carmine Massarelli[2], Vito Felice Uricchio[2] and Claudia Campanale[2], (1)National Research Council - Water Research Institute, Italy, (2)Italian National Research Council - Water Research Institute (CNR-IRSA), Italy*

Glyphosate is the active ingredient in several commercial products, and is currently the most widely used herbicide on the planet with an estimated worldwide use of 750.000 tons. Since 2015, it has been classified as a "probably carcinogenic to humans" by IARC. As for other pesticides, also for glyphosate and its main metabolite AMPA, the Puglia Region carries out the monitoring of surface water bodies in the implementation of Directive 2000/60/EC and D.Lgs. n.152/2006. These standards include the obligation to monitor and classify water according to environmental quality objectives. Monitoring of surface water bodies is linked to the six-year duration of the Management Plans and Water Protection Plans. This study presents the results of the Glyphosate and AMPA analytical activities provided by the seasonal monitoring program for the years 2019-2021. Approximately 98 surface water samples of Puglia Region were analysed for each campaign. The physicochemical properties of the herbicide and the consequent analytical difficulties led to the development of a better retention and separation method. A pre-column derivatization with FMOC-Cl was applied and coupled to UHPLC-MS/MS. In 2019, Glyphosate and AMPA were present seasonally in 44 sampling stations with a maximum value of 4 µg/L for Glyphosate detected at the Cervaro river and 38 µg/L for AMPA found at the Canal of Contessa site. Both compounds were recorded in the spring season. Average annual values were 0.2 µg/L for Glyphosate and 1.2 µg/L for AMPA. In 2020, Glyphosate and AMPA were investigated in 98 stations with a maximum value of 17.85 µg/L for Glyphosate in the Triolo stream and 105 µg/L for AMPA in Cervaro river. Both were recorded in the summer season. Average annual values were 0.2 µg/L for Glyphosate and 1.3 µg/L for AMPA. In 2021, Glyphosate and its metabolite were analysed in 103 stations with a maximum value of 0.9 µg/L for Glyphosate in the Asso stream and 11 µg/L for AMPA in the Contessa canal. Both were recorded in the spring season. Average annual values were 0.1 µg/L for Glyphosate and 0.7 µg/L for AMPA. Overall, the results show a widespread presence of the herbicide and its metabolite throughout the region with minors differences among seasons over the years. This surely reflects a consistent use of the pesticide. More in-depth studies will be undertaken to identify the most significant sources in order to implement proper management of environmental resources.

3.17.P-Tu270 Sourcing and Interpretation of Water Monitoring Data for Crop Protection Substances, Biocides, and Pharmaceuticals in Europe

Clare Lane[1] *and Linda Maguire*[2]*, (1)ERM Regulatory Services, United Kingdom, (2)ERM, Belgium*

For the registration of active substances for use in Plant Protection Products within the European Union, the current data requirements (EC 283/2013) state that;

"Available monitoring data concerning fate and behaviour of the active substance and relevant metabolites, breakdown and reaction products in soil, groundwater, surface water, sediment and air shall be reported."

However, little to no guidance has been provided on how to support this request. In recent years, a number of member states have begun to request these data as part of the renewal of approval process for active substances under the crop protection legislation. While, overall databases exist that provide data for a number of crop protection, biocides and pharmaceutical substances (for both European and non-European countries), the amount of data available in these databases has been found to be lacking for a number of substances.

In this poster we will compare the availability of national water monitoring data across the EU (including the United Kingdom and Norway) and comment on the quality and usefulness of the available data.

We will discuss how we have compiled this information into useable format and how best to visualise the information.

3.17.P-Tu271 Occurrence of Plant Protection Products in Spanish surface water

*Irene Navarro, **Silvia Royano**, Adrián de la Torre and María de los Ángeles Martínez, CIEMAT, Spain*

A wide variety of plant protection products (PPPs) have been used in agriculture and landscape maintenance for controlling weeds (herbicides), insects (insecticides) or fungi (fungicides) and other pests, and for reducing competition from weeds since the middle of the 20th century.

Water pollution due to the use of PPPs in agriculture is a priority environmental issue and a cause of major global concern. The main objective of the European Water Framework Directive 2000/60/EC is to protect the water quality in order to prevent environmental and human health damage. Some PPPs present Environmental Quality Standards (AA-EQS) values and others have been included in the surface water watch list in 2022. Thus, this study evaluates the current trends of PPPs in river water to reflect the ecological status in an area of high representativeness such as the Tagus River watershed in its Spanish section.

A total of 25 river water samples were collected during 2020 and 2021 at 13 sampling sites in the Tagus river basin to determine the presence of 172 PPPs. The sampling locations were selected to represent different typologies of the Tagus River watershed and the target compounds (herbicides, fungicides, insecticides and some of their degradation products) included a wide range of physicochemical characteristics, uses and toxicity.

PPPs were detected in all water samples with a large dispersion in concentrations, from 0.2 ng/L to 47 ng/L (median). A total of 109 PPPs were found in the surface water. The range of compounds detected in a single sample was from 2 to 90 (median: 70), corresponding the highest value to a sampling point located in an urban and industrial area. PPPs with higher incidence (detection frequency > 90%) were carbendazim (20.2 ng/L, median), fluopyram (1.3), imidacloprid (47.1), 2,4-D (20.9), acetamiprid (12.3), azoxystrobin (7.5), azoxystrobin-O-desmethyl (37.9), diuron (27.6), metolachlor (6.7), tebuconazole (5.4) and terbuthylazine-desethyl (4.3).

The reported concentrations are of interest since these surface waters may be treated by water treatment plants to generate tap water, where the presence of PPPs could have human health implications.

3.17.P-Tu272 Pesticides in Aquatic Ecosystems in the Andean Region of South America: Occurrence and Ecological Risk Assessment in the Uco Valley (Mendoza, Argentina).

Fernando Gastón Iturburu[1]*, Lidwina Bertrand*[2]*, Vasiliki Soursou*[3]*, Erica Scheibler*[4]*, Gabriela Calderon*[5,6]*, María Valeria Amé*[2]*, Jorgelina Altamirano*[7]*, Mirta Luján Menone*[1] *and Yolanda Pico*[3]*, (1)Instituto de Investigaciones Marinas y Costeras, Argentina, (2)Centro de Investigaciones en Bioquímica Clínica e Inmunología, Argentina, (3)Centro de Investigaciones sobre Desertificación, Universidad de Valencia, Moncada, Spain, (4)Instituto Argentino de Investigaciones de Zonas Áridas, Argentina, (5)Instituto del Hábitat y del Ambiente, Argentina, (6)Consejo Nacional de Investigaciones Científicas y Técnicas, (7)Instituto Argentino de Nivología, Glaciología y Ciencias Ambientales, Argentina*

Chemical pollution constitutes one of the major drivers of biodiversity loss in freshwater ecosystems. It has been widely demonstrated that pesticides can reach aquatic ecosystems and affect the species that inhabit them. In Argentina, the major agriculture production is related to extensive crops (e.g. soybean, corn, wheat) and the pesticides monitoring efforts are mostly focused on water bodies related to agroecosystems located in the plains of Pampas region. However, there are other regional crops with economic relevance that include different management strategies and occur in ecosystems with differential climatic and hydrogeological characteristics. This is the case of the Uco Valley (Mendoza province, Argentina) in the Andean mountains, with highly technified production of vine, fruits and vegetables, but with scarce information on its environmental effects on water bodies. In this context, this study aimed on quantify pesticides in aquatic ecosystems of the Uco Valley and on develop an ecological risk assessment (ERA). For this purpose, two sampling campaigns (spring/ summer) in five sites with different land uses were carried out. Surface water samples were obtained (by triplicate) and current use pesticides were extracted with SPE columns and quantified with UPLC-MS/MS. A total of 72 analytes (pesticides and metabolites) were studied, and risk quotients (RQs) were calculated for each site/season. Several herbicides, fungicides and insecticides were detected in the different sites, with different patterns likely related to land use and hydrological conditions of water courses. A total of 16 analytes were detected, being atrazine and atrazine-deisopropyl, carbendazim, DMA, imidacloprid, tebuconazole, terbuthylazine-2-hydroxy and terbutryn the most ubiquitous. The RQs calculation showed that the pesticides reported in the Uco Valley could implicate medium/ high risk on organisms inhabiting in its aquatic ecosystems. Particularly, the herbicide terbutryn and the fungicide carbendazim were the major contributors to risk and, in some cases, also the fungicides tebuconazole and difenoconazole and the insecticide diazinon. These results constitute, for the author's knowledge, the first report of ERA for pesticides present in aquatic ecosystems of Uco Valley. The ecological risk assessment would be complemented with higher tier analysis, including different methodological approaches that include the evaluation of *in situ* effects on biological communities.

3.17.P-Tu273 Aquatic Risk Assessment at Catchment Scale – Case Study on Herbicide Exposure From Spray Drift and Drainage in Arable Crops in Belgium

Héloïse Thouément[1], *Wim Beltman*[2], *Hans Baveco*[3], *Louise Wipfler*[1], *Maarten Braakhekke*[1], *Bas Buddendorf*[1], *Sascha Bub*[4] *and Thorsten Schad*[5], *(1)Environmental Risk Assessment, Wageningen Environmental Research (WUR), Netherlands, (2)Environmental Risk Assessment, Wageningen University & Research, Netherlands, (3)Wageningen Environmental Research (WUR), Netherlands, (4)University of Kaiserslautern-Landau (RPTU), Germany, (5)Bayer AG - Crop Science Division, Germany*

Landscape scale modelling is considered to be important for future environmental risk assessment of plant protection products (PPP). Through assessing the risk at landscape levels and accounting for spatial and/or temporal variability, the realism of environmental risk assessment can be improved. A previous study quantified spatial and temporal risks for a strongly sorbing insecticide, for which entry via spray drift could be assumed as the only entry route. Yet, for mobile compounds, like most herbicides, drainage and runoff are potentially relevant entry routes to nearby surface water. The present study will evaluate spatially and temporally distributed surface water concentrations, due to spray drift deposition and drainage entries from application of a herbicide in arable crops within a meso scale river basin in Belgium. To this end a PEARL component will be added to the (previously developed) landscape model to calculate the emission via the soil and the drains to surface water (runoff is incorporated at later stage).

This landscape model integrates hydrology, PPP use, PPP drift deposition, pesticide fate, and effect components. A component incorporating the PEARL model is added to calculate pesticide drainage leaching to the nearby reach for each field in which PPP is applied. In the landscape model the water flows and depths calculated by the hydrological programming library 'Catchment Modelling Framework (CMF) are used by modules for spray drift (xDrift) e-fate (Cascade_TOXSWA) and drainage (PEARL). The fate of the pesticide is simulated with an hourly timestep for all reaches in the catchment.

Spatial and temporal surface water concentrations are calculated on the catchment scale. By including the drainage entry route in the landscape model the fate of mobile compounds and estimation of effects can be done more realistically. The emission from drain pipes is associated with lower concentrations than spray drift deposition, but the total mass emitted is much considered to be higher. The impact of chronic exposure to aquatic organisms of these substances may therefore be of relevance. The modifications make the modular framework for landscape risk assessment, suitable for a broader range of pesticides and allows for simulation of effects to aquatic macro-invertebrates, as well as e.g., macrophytes.

3.17.P-Tu274 Glyphosate Concentrations in Groundwater in Southern Spain – Causes and Stewardship Measures

Debora Boaventura[1], *Dado Srkalovic*[2], *Simon Mayer*[3], *Carlos Vicente*[4] *and Dirk Liss*[2], *(1)Bayer AG - Crop Science Division, Spain, (2)SGS Institut Fresenius, Germany, (3)Bayer AG - Crop Science Division, Germany, (4)Bayer AG - Crop Science Division, Spain*

Glyphosate (GLY) public groundwater monitoring data from EU member states show high compliance rate (> 99 %) with the regulatory groundwater concentration threshold of 0.1 µg/L. For Spain this compliance rate is lower (93.6 %). Available data from the heterogenous monitoring programs of the River Basins show exceedances in the region of Andalusia, southern Spain. To address the situation locally, the Glyphosate Renewal Group (GRG) initiated an investigation to assess the reason for this lower compliance rate.

As part of the study, 45 monitoring sites that showed the most exceedances, were subject to an elucidation. The results for Andalusia showed that most monitoring wells are located in rural areas, dominated by agriculture and that many of the wells are not adequate to assess the leaching behaviour of plant protection products (PPPs). Most of the monitoring sites assessed were not dedicated groundwater monitoring wells and used by farmers for irrigation, abstraction and in parts for mixing and loading of PPPs. Apart from the wells' deficiencies the elucidation identified likely reasons for the elevated GLY concentrations in groundwater in Andalusia. For most sites specific farming practices are likely cause for the GLY detections in groundwater. Also, for few uses additional label indications will be an improvement to avoid potential contributions as sources of GLY in groundwater.

Farmer surveys in Andalusia were performed to obtain information on GLY usage and application practices considering different agronomic settings (crop, farm sizes and management practices). Although in Spain all farmers before using crop protection products have received compulsory official training, the GRG findings show that there is opportunity for improvement in training skills related to handling, application, and documentation of plant production products. Particular on smaller farms it is relevant to train how to calculate and document the correct application rate; increase awareness about the different water contamination sources and improve the product label interpretation.

The elucidation and farmer surveys indicate that responsible stewardship program and farmer involvement can have a significant positive effect and thus increase environmental compliance at local level. Therefore, the GRG, Spanish industry association and local authority are committed to continue supporting, developing advocacy activities and training on water protection and safe use of PPPs.

3.17.P-Tu275 PERSAM Tier 3a with PELMO: What Happens to the Metabolite PECs if Parent Defaults are not Adapted?

Mareike Albrecht, *Sarah Becker, Nils Lange, Inga Schreiter and Steffen Schubert, RIFCON, Germany*

Following the tiered approach described in the new EFSA Soil Guidance (2017), PECsoil values need to be calculated using the software tool PERSAM (at Tier 1 and 2) and the models FOCUS PELMO and FOCUS PEARL at Tier 3a of the risk assessment. At Tier 3a, the output generated by PERSAM is transferred to the higher tier models PELMO and PEARL via a transfer file. Thereby, additional substance specific parameters, e.g. the Freundlich exponent and plant uptake factor, must be specified by the user. In case of PELMO, this can be done via its graphical user interface (GUI) before the psm-file is generated.
However, for the metabolite's run, the GUI does not provide the option to put in the necessary parameters for the parent substance but only for the respective metabolite. Instead, these parameters for the parent are set to default and need to be adapted in each individual psm-file, which is a laborious and error-prone task.
Interestingly, the guideline does not specify that the parameters of a parent substance need to be adapted when running a metabolite, which leads to the question whether this manual step is necessary at all, and, if yes, to which extend the parent parameters affect the resulting PECsoil values of the metabolite.
Thus, we studied a selection of pesticides using EFSA agreed endpoints and compared the output between manually changed parameters and defaults. From this comparison we can learn whether or not this time-consuming manual adaption of psm-files is scientifically needed or if this step can just be skipped in future risk assessments.

3.17.P-Tu276 Differences between the EFSA OM Map and the SoilGrids OM Map for Arable Land Europe and Potential Implications for Soil Risk Assessment

***Gregor Spickermann*[1], *Magnus Wang*[2], *Su Yeong Park*[2], *Jutta Agert*[3], *Olivier de Cirugeda Helle*[4], *Paul Sweeney*[5] *and Sebastian Gebler*[6], *(1)ADAMA Deutschland, Germany, (2)WSC Scientific, Germany, (3)Bayer AG - Crop Science Division, Germany, (4)Corteva Agrisience, (5)Syngenta, United Kingdom, (6)BASF SE, Germany*

In 2017, the European Food Safety Authority (EFSA) published a new guidance with four tiers for the exposure assessment of plant protection products (PPPs) in soil (EFSA, 2017) together with the PERSAM (Persistence in Soil Analytical Model) tool. To be able to calculate the 95th spatial percentile of the estimated soil concentration distribution in PERSAM, spatial data for crop growing, climate parameters and soil properties in Europe are considered. For the organic matter content in soil the EFSA (2012) OM map is used which is based on the organic carbon content information available in the ESDB (European Soil Data Base). The OC content of the ESDB map was converted to organic matter using a fixed constant (OC content x 1.724 = OM content) assuming that soil organic matter contains 58% carbon. In a final step a pedotransfer function (Tiktak et al. 2002) was used to estimate the bulk density (BD) of the soil exclusively based on the OM content. That means finally that OM and BD are based on estimations and not on measurements. It is already stated in the soil guidance document (EFSA 2017) that a true alternative for that OM data set was not available at this point in time. However, it was also stated, that once a better alternative is available, this new data set should be used to update PERSAM. Better alternative spatial data in the EU are becoming available (for example the SoilGrids OM map published in 2022 by De Sousa et al. 2022). In a GIS (GeoInformation System) analysis, the BD content given in EFSA (2012) and SoilGrids (BD calculated based on the same pedotransfer function as for EFSA) is compared with the measured BD data (LUCAS 2018) from 9000 sampling points across Europe. The comparison was done for arable land only. While overall estimated BD from EFSA and measured BD from LUCAS (2018) were mostly comparable, except for some outliers, regionally some differences were present. In comparison, calculated BD from SoilGrids (2018) different more from measured values from LUCAS (2018). As for the comparison between BD from EFSA (2012) and LUCAS (2018) there were notable regional differences. In general, the estimated BD data from EFSA seemed to better reflect measured BD values from LUCAS (2018). By updating the PERSAM software with more accurate OM and BD data (e.g. mixture of EFSA and SoilGrids based on the region), the new underlying spatial soil data would correspond more to the real soil conditions in Europe.

3.17.P-Tu277 Spatially Distributed Numerical Soil Exposure Modelling – First Experiences and Concepts

***Sebastian Multsch*[1], *Mohammad Hatamjafari*[2], *Shanghua Li*[2], *Sebastian Gebler*[2] *and Garcia Lucas*[2], *(1)APD/EFM, BASF SE, Germany, (2)BASF SE, Germany*

The soil exposure assessment has been recently revised by EFSA in a new guidance document (EFSA Soil GD). An entirely new tiered assessment scheme considering new modelling software, spatial environmental datasets and process-based physical modelling are proposed. In a previous impact assessment by Croplife Europe, predicted environmental concentrations in soil (PECsoil) were calculated using the current approach by FOCUS and the new one proposed by EFSA to evaluate 56 active ingredients and metabolites covering a broad range of substance properties and uses. The failure rate of the lower tier risk assessment for soil organism increased from 10% (current FOCUS approach) to 67%, 58% and 36% at Tier1, Tier-2 and Tier-3A (EFSA) respectively. The higher failure rates originate from high PECsoil values triggered, among other conservative factors, by atypical pedoclimatic scenarios, representative of agronomically unrealistic soil conditions (e.g. organic carbon content).
The EFSA Soil GD defines a higher tier refinement using spatially distributed numerical models (Tier-3B) allowing for a more realistic spatial assessment and relevant exposure scenarios selection. However, it further states that agreed software tools and methods are required to apply Tier-3B. Thus, the objective of this work is to present first experiences to establish Tier-3B. Firstly, spatial input datasets are evaluated comparing the well-accepted but partly outdated datasets used by the EFSA Soil GD with up-to-date information on environmental conditions and land use based on remote sensing and observations. Secondly, the scenario selection procedure for the calculation of relevant PECsoil is investigated with respect to the refined modelling approach and the more realistic assessment. Thirdly, the technical applicability of Tier-3B is evaluated from the perspective of (i) the requirements for the underlying technical infrastructure to execute the numerical models FOCUS PEARL and PELMO at EU scale (from multi-core local machines to cloud computing) and (ii) the software requirements to process European scale spatiotemporal data by using specific tools to store (e.g. hierarchical data format - HDF) and process (e.g. Python NumPy and Dask) large scale multidimensional data (often referred as 'datacubes' or 'hypercubes').

3.17.P-Tu278 A Study on the Impact of Surfactants on the Transport of Plant Protection Products (PPP) Under Different Hydrodynamic Conditions

*Reza Zolfaghari[1], Daniel G. Duff[2], Jun Dong[2], **Gerald Reinken**[3] and Mohaddeseh Mousavi Nezhad[4], (1)Exposure Modelling, Bayer AG - Crop Science Division, Germany, (2)Bayer AG - Crop Science Division, Eritrea, (3)Bayer AG - Crop Science Division, Germany, (4)Civil and Environmental Engineering, University of Warwick, United Kingdom*

In this study, we investigated multicomponent reactive solute transport in top agricultural soils. The impact of the concentration of surfactants/adjuvants on the transport of plant protection products (PPP) under different hydrodynamic conditions was studied numerically. These investigations aimed to contribute to better mechanistic understanding for determination of the application rate of PPPs and bioavailability of PPPs in the soil, which ultimately are used for ensuring efficiency in production in support of sustainable agriculture.

Numerical simulations of competitive sorption with linear, Langmuir, and Freundlich models were performed using the PHREEQC package. Adsorption, absorption, and desorption mechanisms were included in the modeling system to capture all interactions between solute-solute and soil-solute simultaneously. Factors that potentially can influence the sorption of PPPs in soil including soil texture, the active ingredient, and adjuvant properties have been examined. Furthermore, the effect of hydrodynamics including boundary conditions on sorption behavior have been studied.

The numerical model was extended, based on the attachment-detachment concept, to simulate colloidal-facilitated chemical transport. The preliminary numerical results indicate that the presence of the colloid particles in the system may influence the transport of adjuvant and active ingredients in soil depending on the boundary conditions and soil properties.

3.17.P-Tu279 Application of Spatially Distributed Leaching Modelling to Quantify FOCUS Tier 3b Reduction Factors for the National Situation in UK, FR, and NL

***Gerald Reinken**[1], Nils Kehrein[1], Denis Weber[2] and Abderrahim Mamouni[2], (1)Bayer AG - Crop Science Division, Germany, (2)Exponent*

The European FOCUS groundwater models and scenarios are intended to assess the potential for movement of pesticide active substances and their metabolites to groundwater considering a Tiered approach. At Tier 1, the default FOCUS GW scenarios are employed together with mean values for the different model input parameter (e.g., geometric mean DT50 and Koc; arithmetic mean 1/n). At Tier 2a parameter refinements can be made so that an observed pesticide-specific behavior can be incorporated in the assessment (e.g., consideration of pH dependent adsorption and degradation). At Tier 3b spatially distributed leaching modelling approaches can be employed to reflect the spatial and temporal variability of the underlying processes. However, a harmonized approach for such assessments at EU MS level does not currently exist.

A FOCUS Tier 3b modelling framework was employed to evaluate the leaching behavior at the national level in the UK, FR and NL considering: 1) annual foliar fungicide application in cereals (BBCH 30-39, 80% crop interception) 2) parent with Tier 1 input; metabolite with Tier 2a input for pH dependent behavior; 3) FOCUS groundwater model PEARL 3.3.3 and PEARL 4.4.4 as employed by the individual spatial model frameworks; 4) exposure evaluation based on the overall 90th risk percentile 5) computation of SDLM reduction factors based on comparison to the worst-case FOCUS scenario (Hamburg).

As no “ready to use” Tier 3b approach or tool currently exists, the individual approaches had to be chosen with the methodology being in detail somewhat country-specific. As a first step, the SDLM approach used the specific data already available at the national level of the three countries. Soil information for England and Wales it taken from the SEISMIC 2.0 database, corresponding data for Scotland is taken from the Scottish Soils Knowledge and Information Base. Soil information for France is taken from the FROGS 2.2.2.2 and FROGS 3.3.3.3 model systems whereas corresponding information for the Netherlands is taken from the Dutch GeoPEARL 333 and GeoPEARL 444 model versions.

Outcome of the Tier3b modelling and resulting Tier3b refinement factors compared to lower Tiers are presented and discussed. The outcome clearly demonstrates a significant safety margin of the lower Tiers.

3.17.P-Tu280 Assessment of the Protectiveness of Predicted Environmental Concentrations in Surface Water Based on a Vulnerable, High-Use-Intensity Catchment in Belgium

***Claudia Hörold-Willkomm**[1], Marco Herrmann[1] and Robin Sur[2], (1)RIFCON GmbH, Hirschberg, Germany, (2)Environmental Safety, Bayer AG - Crop Science Division, Germany*

In the process of pesticide approval in the European Union it has to be shown by the applicant that an unacceptable risk for the aquatic environment by the active substance can be excluded. For this aim, standardised models, scenarios and agreed pesticide input parameters must be used to calculate the exposure as required by the FOrum for the Co-ordination of pesticide fate models and their Use (FOCUS). The use of so-called realistic worst-case scenarios in combination with average compound input parameters ensures that the predicted exposure is at least protective of 90 percent of all spatio-temporal exposure situations. In this study, the question should be answered whether these Predicted Environmental Concentrations in Surface Water (PEC_{sw}) are actually protective in the sense of their definition by comparison to Measured Environmental Concentrations in surface water (MEC_{sw}) from a vulnerable, high-use intensity catchment under “real world” conditions in Europe.

The present monitoring dataset contains surface water concentrations of 12 herbicides and one metabolite on a daily basis along with application rates, application dates and the treated crops over 3.5 years for a catchment in Belgium at two different sampling points. One sampling point represents the whole surface water outlet of the catchment, while the second one only drains the eastern portion of the catchment area.

The behaviour of the compounds in the regulatory standard watershed was simulated by a combination of the models MACRO or PRZM with the aquatic fate model TOXSWA to simulate PEC_{sw} due to drainage, runoff and spray drift entries. The regulatory

PEC_{sw} reflects an “edge-of-field” situation. There, stream scenarios (for Belgium D4 and R1) receive direct drainage or runoff fluxes from a treated 1 ha field adjacent to the watercourse and in addition baseflow from a 100-ha upstream catchment, where 20% of the area is treated at the same time. Since the sampling points in the monitoring study are downstream or even at the outlet of the catchment without any known application in direct vicinity, the simulated concentration only in the upstream catchment without an edge-of-field contribution, i.e. the $PEC_{upstream,}$ was considered as a potentially better metric, in addition to the regulatory edge-of-field PEC_{sw} for a comparison with the MEC_{sw}.

3.17.P-Tu281 Drainage Mitigation by Soil Litter Layer under Conservation Tillage

Anastasiia Bolekhan*, Andrew C. Chapple and Robin Sur, Environmental Safety, Bayer AG - Crop Science Division, Germany*

Continuous conservation tillage is often associated with an increase of pesticide leaching and transport to drains, due to increased water infiltration and preferential flow processes. However, the scientific literature shows different effects of conservation tillage practices on drainage and leaching of pesticides indicating great complexity and interplay of relevant environmental processes. Conservation tillage and direct drilling operations also result in a build-up of previous crop residues on top of the soil as litter or mulch. This litter acts as an extra layer which initially intercepts applied pesticides and where degradation may be faster and adsorption more effective than on bare soil, leaving less substance to be transported deeper into the soil. This may not only counterbalance the effect of increased transport due to preferential flow but may even lead to a substantial decrease of drainage and leaching concentrations and could be thus used as an effective mitigation measure.
The aim of this work was to assess the effect of a soil litter layer on the surface water predicted environmental concentrations using standard regulatory modelling tools. First results show that depending on tested scenario and application period the decrease of predicted environmental concentrations in drainage scenarios may range between 30% and 99% compared to the standard FOCUS calculation. These findings suggest the need to further investigate leaf litter layer processes under conservation tillage and their potential effect on pesticides concentrations in the environment. A realistic field study has been started which may bring more in-depth process understanding and provide further proof in favor of the tested hypothesis.

3.17.P-Tu282 Comparison of Regulatory Waterbody Models

Amy Ritter *and Mark Cheplick, Waterborne Environmental*

This presentation will show a comparison of predicted environmental concentrations (PECs) using regulatory waterbody models used in the United States, EU, and Andean countries. A single application to EU winter cereal and potato crop scenarios were run with winPRZM (Pesticide Root Zone Model) simulating the runoff/erosion from a field transferring into a waterbody. Three different adsorption coefficients (Kocs) were modeled with half-lives of 100 days. The mass loads from winPRZM were input into three regulatory waterbody models: TOXic substances in Surface Waters (TOXSWA), Variable Volume Water Model (VVWM), and EXposure Analysis Modeling System (EXAMS). The comparison shows the range of variation or similarity between PECs for pond and stream environments between the different models. While an attempt was made to create identical parameterization of inputs for the models there are some algorithmic differences for the stream environment that cannot be duplicated in all three models. These differences lead to more variation in the PECs when simulating higher Kocs and the stream environment. The pond environment did not exhibit this trend and results were much more aligned.

3.17.P-Tu283 Comparison of Measured and Predicted Environmental Concentrations of Chemicals Using The Surface Water Model STEPS

Paula Scharlach[1] *and Andreas Focks*[2]*, (1)Osnabrück University, Systems Science Group, Institute of Mathematics, Germany, (2)Institute of Mathematics, University of Osnabrueck, Germany*

Predicted environmental concentrations (PEC) result from mathematical fate models and are used as an indicator for the occurrence of pesticides and other chemicals in the environment. There is a plenty of fate models, differing amongst others in the level of detail of their process descriptions. The FOCUS TOXSWA model as the standard model used in the EU for pesticide registration has a high level of complexity in process descriptions, specifically concerning the sediment compartment. In contrast, models exist with less detailed process descriptions and thus less input data. An example for this is the STEPS 1-2 model developed by Michael Klein from the German Fraunhofer IME, which is kept much simpler than TOXSWA and based on a single equation only. To investigate the impact of the level of detail of process descriptions on the quality of the PEC, we used the STEPS 1-2 model to generate PEC values. STEPS 1-2 implements different levels of complexity according to the FOCUS Tier 1 and Tier 2 risk assessment. First, Step 1 calculates a single loading to the water body, and in that sense “worst case” surface water and sediment concentrations without considering loss processes. Second, in Step 2 a series of individual loadings resulting from drift events is considered including basic loss processes following first-order kinetics. The predicted STEPS-derived Step 1 and Step 2 PEC estimations are then compared to measured environmental concentrations (MEC) as reported in a study about a comparison between PEC and MEC values based on the FOCUS TOXSWA model (Knaebel et al., 2012). Furthermore, PECs from STEPS are compared to FOCUS-TOXSWA-derived PEC values as reported in Knaebel et al. (2012) with the aim to explore the relation between the level of detail of the process description and the accuracy of model predictions of environmentally occurring pesticide concentrations. aim for understanding the basic relation between process details and accuracy of predictions, and to identify the relevant processes and parameters

3.17.P-Tu284 Primary Distribution Model of Pesticide for Japanese Paddy Field

Marika Muramoto[1]*, Longlong Tang*[2] *and Norihiro Itsubo*[1]*, (1)Tokyo City University, Japan, (2)National Agriculture and Food Research Organization, Japan*

Life Cycle Assessment (LCA) studies on the toxicity assessment of pesticides are underway. The database used for the

calculation: Ecoinvent, has a scenario in which all the emissions are deposited in soil within agricultural land. Therefore, a model has been developed that divides the emission rate into compartments for air, freshwater, and soil. The latest model is a new version of the previous model with a different calculation method for each parcel. This study aims to understand the differences and issues in the calculation methods for each partition in the primary distribution between the conventional model and the latest model, and to develop a more appropriate method.
The models studied are the Japanese paddy field model based on the conventional model and the latest PestLCI consensus model. The setup of each primary distribution plot was investigated, and the estimation method for each plot was studied. Then I compared the emission factors calculated by both models using a common drift curve.
The Japanese paddy field model divides the emission plots into three categories: air, surface water, and leaves, while the PestLCI consensus model divides the emission plots into four categories: air, agriculture soil, crop, and off-field soil.
The estimation methods are the same for surface water and agriculture soil, leaves, and crops, but air and off-field soil are different. Specifically, the paddy field model assumes drift in the air and the PestLCI consensus model assumes deposition to off-field soils. It also estimates emission air rates based on the combination of application methods and target crops.
As a result, the off-field deposition fraction of the PestLCI consensus model is basically larger than the atmospheric fraction of the paddy field model. However, Aerial differs in the PestLCI consensus model, about 20% is deposited, while in the paddy field, 4% to 40% is dispersed to the atmosphere.
This is because the variables in each model are different. For the paddy field mode are the application width, the size of the farmland. However, the PestLCI consensus model variable is the ratio of farm to off-farm width, integrated over the drift curve coverage.
Based on the above results, I will improve airborne and off-field deposition and propose a more appropriate model.

3.17.P-Tu285 TOXSWA Simulates Pesticide Exposure in Intermittently Dry Ponds Hosting Amphibians
*Wim Beltman[1] and **Pauline Iris Adriaanse**[2], (1)Environmental Risk Assessment, Wageningen University & Research, Netherlands, (2)Environmental Risk Assessment, Wageningen Environmental Research (WUR), Netherlands*
Amphibians often breed in small water bodies in or adjacent to agricultural fields. Field applications of pesticides may pose harm to the amphibians, because pesticides may enter the water bodies via spray drift deposition, surface runoff or drainage from the treated fields. In the EU aquatic risk assessment, pesticide exposure is characterized by surface water scenarios that do not include the typical, small-sized amphibian breeding ponds. Current EU pond scenarios are not suitable as the simulated ponds are too large to represent realistic worst-case dimensions of amphibian ponds. Moreover they do not reflect the often highly variable or decreasing water depths in such ponds.
In 2020 the EU COST Action "PEsticide RIsk AssessMent for Amphibians and Reptiles" (PERIAMAR) (CA18221) was started to identify and fill knowledge gaps. One of the aims is to design ad-hoc scenarios to predict pesticide exposure concentrations in amphibian breeding ponds across the EU.
TOXSWA has been adapted to be able to simulate variable water depths in small ponds with sloping sides, using precipitation, evaporation, downward seepage and a minimum, 1-cm water depth to mimic "falling dry". A pond scenario has been developed. Dimensions of the pond are based on requirements of artificially constructed amphibian breeding ponds in The Netherlands. FOCUS R1 26-year weather data have been used for daily water temperature, rainfall and evaporation. The water depth of the pond was calibrated to fall dry once in five years. Example simulations for spray drift entries of a weakly sorbing and strongly sorbing pesticide show the significant impact of low water levels on aqueous concentrations in amphibian breeding ponds. A next step is to simulate runoff entries of the PRZM model.

3.17.P-Tu286 Spatial and Temporal Distribution of Herbicides along Railroad Tracks in Germany
***Sabrina Michael**[1], Gina Bode[1], Silvio Klügel[2], Thomas Grischek[3], Majo Karthe[4] and Markus Zingelmann[4], (1)German Centre for Rail Traffic Research at the Federal Railway Authority, Dresden, Germany, (2)GEPRO Ingenieurgesellschaft mbH, Germany, (3)University of Applied Sciences Dresden, Germany, (4)Beak Consultants GmbH, Germany*
Rail traffic places high demands on the functionality and safety of rail constructions, which are directly linked to systematic vegetation management. For decades, chemical vegetation control by means of herbicides, especially applied to the track bench and bed, has been one of the main control measures used in Germany. In earlier years, vegetation-free track systems were mostly achieved by using poorly degradable and environmentally hazardous herbicides. However, the properties of the herbicides used, such as adsorbability and biodegradability, as well as structural characteristics of the track substructure, led to pollutant accumulation in the different layers of the track body and in the environment. The objective of the present study is to identify dispersion patterns and fate of herbicides in and along track systems for a comprehensive environmental risk assessment. In contrast to other emitted pollutants, herbicide input into the track area occurs only once a year, which allows the degradation and dispersion behavior to be systematically investigated. For this purpose, soil samples were taken and analyzed at selected measuring points in a period of 0 to 90 days before and after vegetation control at different depths (0–10 cm and 20–30 cm) as well as different distances (2.5 m and 5.0 m) from the track center line. In addition, precipitation-dependent seepage water samples as well as surface and groundwater samples were collected and characterized. The analyses focused on chemical-analytical sample characterization, degradation behavior, and derivation of hazard potential using standardized test procedures and evaluation standards (ISO 14001). The results show that out of the formerly used herbicides, only a few active agents are still detectable in the soil. Due to their adsorption on the railway ballast and cohesive soils, a sufficient retention capacity is guaranteed and a possible hazard is limited to soils with a low depth to water table. For the currently approved herbicides (e.g., glyphosate), the highest risk potential was determined up to 10 days after herbicide application for runoff rainwater and surface water. Systematic spatial and temporal sampling of various environmental compartments provided an in-depth understanding of

contaminant dispersal occurring in and along railroad tracks. The investigations form the basis for an adapted environmental risk assessment of railway tracks and the optimization of hazard prediction models.

3.17.P-Tu287 Effect of stone content on alternative railway pesticide leaching in a coarse textured soil

Sixtine Cueff*, Roy Kasteel, Thomas Poiger and Ignaz Buerge, Plant Protection Products – Impact and Assessment, Agroscope, Switzerland*

In Switzerland, only glyphosate is authorized to control weed pressure on railway tracks. However, due to its suspected carcinogenicity and upcoming ban in Europe, the Swiss Federal Railways is searching for alternatives with the objective to withdraw from usage by 2025. In the framework of a governmental project, many non-chemical alternatives are under study, as well as chemical ones relying on more eco-compatible substances with a minimum leaching to groundwater. For the latter part, Agroscope conducts a lysimeter experiment, evaluating the leaching behaviour of several alternatives to glyphosate. Lysimeters are filled with railway tracks substrates, collected from three different Swiss locations. These substrates are characterised by a high gravimetric stone content (32–69 %), which may deeply affect the soil hydraulic properties and thus the transport of solutes. However, to date, little is known about the reactive solutes transfer, such as pesticides, in these soils. The complex responses observed under natural climatic conditions in the lysimeters could complicate our understanding of the effect of stones on pesticide transfers. A complementary experimental-modelling study under controlled laboratory conditions (constant irrigation rate 2 cm/d, temperature 20°C and unsaturated conditions –15 cm) was then designed. We aim at evaluating the mobility of a water tracer (bromide ion) and six herbicides and some of their metabolites in repacked soil columns where we gradually increase the stone content (0, 20, 40, 60%). The herbicides were chosen to cover a range of leaching potential properties. All substances travelled rather rapidly (sometimes equally fast) through the soil columns under a ‘no stones’ condition. Considering the risk of an identical behaviour even at the lowest stone content (limiting our ability to understand the effect of stones on pesticide transfers), lower mobility substances were added for the following experiments with stones. Indeed, either due to the decrease of the soil transport volume or the presence of preferential flow pathways at the soil-stones interface, pesticide transfer is expected to be faster under "stones” conditions. Simultaneously, the presence of stones may create immobile areas that modify the physical and/or chemical non-equilibrium of herbicides, which has not been evidenced yet. When fitting the experimental breakthrough curves, a two-region model will then likely be the most suitable.

3.17.P-Tu288 Deposition of pesticides via spray drift in off-crop vegetation: A study of the vertical and horizontal distribution in flower strips

Fabienne Maire[1]*, Thomas Poiger*[2]*, Mikko Lehto*[1] *and Judith F. Blom*[3]*, (1)Agroscope, Switzerland, (2)Plant Protection Products – Impact and Assessment, Agroscope, Switzerland, (3)Plant Protection Products - Impact and Assessment, Agroscope, Switzerland*

The authorization process for plant protection products (PPP) includes an assessment of adverse effects on non-target arthropods (NTA) both in the treated field and off the field (“off-crop” areas). While the exposure assessment for example aquatic species is well established, a solid experimental basis is still lacking for the exposure assessment in off-crop vegetation. Particularly, information about the distribution of PPP deposited in off-crop vegetation via spray drift is limited. One of the objectives of the Swiss Biodiversity Strategy and the Swiss Action Plan for Risk Reduction and Sustainable Use of Plant Protection Products (AP PPP) is therefore to further develop the risk assessment of PPP towards NTA in off-crop vegetation. To characterise the horizontal and vertical distribution of PPP deposited in off-crop vegetation via spray drift, we conducted extensive field experiments using a fluorescent tracer. The tracer was applied with a conventional boom sprayer onto a surrogate crop (artificial meadow). The spray drift in the adjacent vegetation (a 6 m wide flower strip) was collected on filter paper targets (area per target, 500 cm^2) positioned at different heights (at the level of the leaf canopy, half way up and a few centimetres above the ground) and at distances of 1, 2, 3, and 6 m, respectively, from the edge of the treated field. Wind speed and direction were recorded with high temporal resolution during each tracer application. Data analysis was carried out using a linear mixed-effect model using R Studio. First results indicate similar dependence of spray drift on the distance from the edge of the field, both for spray drift deposition on ground level and on off-crop vegetation. In addition, interactions between different variables such as the pressure / nozzle type and wind speed are evaluated.

3.17.P-Tu289 Evaluation of Mechanistic Model Simulation of Field Study Spray Drift from Unmanned Aerial System

Michael F Winchell[1]*, Sebastian Castro-Tanzi*[1]*, Jane Tang*[2]*, Dan Martin*[3]*, Brad Fritz*[3]*, Yaning Yang*[2] *and* ***Hendrik Rathjens***[4]*, (1)Stone Environmental, (2)Bayer AG - Crop Science Division, (3)USDA ARS, (4)Stone Environmental*

Recently, with the increased use and availability of unmanned aerial systems (UAS) for application of agrochemical sprays, a better understanding of spray drift from these platforms has emerged as a particular area of interest from many stakeholders. The approaches to better understanding off-target spray drift from UAS are being addressed from both field study and modeling perspectives. Field studies are allowing direct measurement of spay drift deposition from UAS under a range of environmental and application conditions, and this data is necessary to validate mechanistic models under development for the simulation of these emerging types of applications. Two independent field studies were conducted to evaluate spray drift for varied droplet sizes and application conditions using two different UASs. These field datasets were then used to evaluate the predictions of spray drift deposition from a recently developed mechanistic model to simulate within spray block and off field drift and deposition from UAS agrochemical sprays. The sensitivity of the model simulation results to several input assumptions, including the parameterization of the UAS structural configuration and associated flow field, were assessed. The field study measurements and model simulation results were also compared with regulatory modeling results for traditional ground spray application platforms. The results of these comparisons will be presented along with field study results which demonstrate that best management practices (BMPs), such as swath offset, are important in achieving targeted sprays and reducing off-target spray drift from UAS. Regulatory drift evaluation should also consider such BMPs to reflect field practices.

3.17.P-Tu290 Deriving triggering, persistence and modelling endpoints for GB risk assessment: a tool to simplify
***Lily Elizabeth Summerton**, Chloe Blackham and Emily Cumming, Chemicals Regulation Division, Health and Safety Executive, United Kingdom*
The derivation of DT50 values for use in the pesticide active substance risk assessment is a complex process. The available guidance encompasses several documents (for example, FOCUS (2014) kinetics guidance, DG SANCO Working Document (2012), EFSA (2014) $DegT_{50}$ guidance, FOCUSgw (2000; 2014) guidance) and therefore, the complete information required to select endpoints for trigger endpoints, modelling endpoints and persistent, bioaccumulative and toxic chemicals (PBT) assessments is not presented in its entirety in any one place. The process is further complicated by the wide range of factors that must be considered when selecting the endpoints (for example, biphasic behaviour, normalisation, pH dependence and statistical differences in laboratory and field DT50s). Accurate derivation of these endpoints for active substances and their associated metabolites is critical for conducting the PBT assessment, determining whether field studies are required, and calculating predicted environmental concentrations (PECs) used in the GB risk assessment for human health (PECgw) and non-target organisms (PECsoil and PECsw).

HSE has utilised both current and new guidance to produce a comprehensive flow map that standardises the selection of endpoints to determine if field studies are required, assess PBT criteria, and select input parameters for the respective PEC calculators and models. This visual tool breaks down the HSE approach into simple steps and is intended for the use of both applicants and evaluators.

The purpose of this poster is to provide clarification of the guidance for deriving trigger, PBT and modelling endpoints for GB. More specifically, it includes how to derive DT50 values from biphasic kinetic models, clarifies when values should be normalised, how to determine pH dependence and explains the use of the endpoint selector tool for laboratory vs. field DT50 values. Important considerations in the handling of the endpoints for parent and metabolites are also detailed. The poster presents an overall picture of the endpoint selection approach for GB risk assessment.

3.17.P-Tu291 Normalisation of laboratory and field degradation endpoints – modelled vs. measured data
***Lily Elizabeth Summerton**, Chloe Blackham and Emily Cumming, Chemicals Regulation Division, Health and Safety Executive, United Kingdom*
Temperature and moisture have a significant effect on the soil degradation rates of pesticides. Therefore, in cases where degradation studies are performed under non-standard conditions, it may be necessary to normalise the dissipation half-life (DT50) values to reference temperature and moisture conditions (20 ± 2°C and pF2). For example, DT50 values derived from laboratory studies should be normalised to reference conditions before being used in the environmental risk assessment, PBT assessment or used to determine if field studies are required. DT50 values derived from field studies should also be normalised when their intended use is for calculating PECgw and PECsw values. The Organisation for Economic Co-operation and Development method 307 states that laboratory studies should be carried out at 20 ± 2°C and soils adjusted to a pF of between 2 and 2.5. For normalisation to pF2 conditions, when measured pF2 values are not available, default inputs specified in FOCUS Ground Water (2014) guidance are used. These values, however, are approximations based on the generic properties of various soil types, and the guidance states that there is potential to produce anomalous results.

In addition, field residue data undergo time-step normalisation to derive modelling endpoints, as recommended in the FOCUS (2014) kinetics guidance. This process is required to determine a degradation rate that would be observed if temperature and moisture had been constant over the study duration. However, issues can arise as in-situ field monitoring is often unreliable (particularly soil moisture monitoring). Historically where significant gaps in the monitoring data occur (for example equipment malfunctions), soil temperature and moisture have been simulated using programmes such as PEARL and PERSIST.

This poster presents a HSE investigation into the significance of using default pF2 values and modelled temperature and moisture data when normalising laboratory and field data. Based on the results of this investigation, HSE provides recommendations on modelling soil moisture and temperature as well as minimising the impacts of using modelled data and default pF2 values in the normalisation of both laboratory and field DT50 values.

3.17.P-Tu292 Assessing the relevance of non-European field studies in GB pesticide active substance risk assessment
*Chloe Blackham, **Lily Elizabeth Summerton** and Emily Cumming, Chemicals Regulation Division, Health and Safety Executive, United Kingdom*
Organisation for Economic Co-operation and Development (OECD; ENV/JM/MONO) (2016)6 suggests that provided the conditions in a field dissipation study conducted in one country are representative of conditions in another country, the results of that study could be used in regulatory assessments in that other country. Therefore, field dissipation studies conducted at non-European sites can be accepted for use in European pesticide active substance risk assessments if the conditions during the study are representative of European conditions. To support this concept the OECD ENASGIPS tool was developed to consider North American and European Union (EU) conditions and uses an “ecoregion” approach to compare soil and climatic conditions. The appropriateness of this approach for the GB pesticide regulatory system is considered.

The ENASGIPS ecoregion similarity scoring system can be useful in demonstrating broad similarities between areas. However, the use of mean annual temperature and precipitation data within ENASGIPS, as well as mean soil pH and soil organic carbon, provides a non-specific comparison between broad geographical areas. In practice, the actual conditions at each study site should be comparable to European conditions. ASGIPS does not provide this detailed comparison and therefore is not used as the sole determinant as to whether conditions in a non-European field dissipation study can be considered comparable to GB conditions and thus if the study can be used for GB risk assessments.

HSE's Chemical Regulation Division has been applying the limited recommendations provided in the EFSA DegT50 guidance (2014) on assessing the relevance of non-EU field studies to GB risk assessments. The GB expectation is that information on the comparability of the site-specific soil and weather conditions during the actual course of the study in relation to European conditions is submitted as part of the active substance data package.

This poster aims to outline GB regulatory expectations. This poster describes an approach where at least monthly average air temperature and precipitation at each site is compared and the representativeness of the soil to European conditions is considered.

3.17.P-Tu293 C2D2: An Open-Source, Pan-European, Harmonised Crop Development Database for Use in Pesticide Exposure Modelling and Risk Assessment

***Gregory Hughes**[1,2], Andrew Eatherall[3], Michael Bird[4], Jonathan Blake[5], Philip R Branford[6], Sebastian Gebler[7], Anthony Lozano[8], Paul Massey[9], Gerald Reinken[10] and Liz Whitworth[5], (1)Cambridge Environmental Assessments (CEA), United Kingdom, (2)GeoSpatial Analytics, Wolverhampton, United Kingdom, (3)Corteva Agrisience, United Kingdom, (4)Syngenta, United Kingdom, (5)RSK ADAS, United Kingdom, (6)ADAMA Deutschland, Germany, (7)BASF SE, Germany, (8)Sumitomo Chemical Agro Europe SAS, France, (9)FMC Agricultural Solutions, Afghanistan, (10)Bayer AG - Crop Science Division, Germany*

Determining appropriate pesticide application windows is an important part of pesticide exposure modelling. Increasingly, regulators are constraining application windows using the AppDate software. Given exposure assessments are a function of the application dates this software generates, it is important to understand how representative they are; however, an appropriate pan-European crop phenology dataset was previously unavailable for such an assessment. Efficacy trial datasets sourced from seven members have been harmonised to create the **C**rop Life Europe **C**rop **D**evelopment **D**atabase (C2D2) that meets this need. The C2D2 spans two decades (2000–2020), >250 crops and 30 European countries.

Evaluation of C2D2 against an independent dataset (PEP725) showed good agreement for equivalent time periods, crop growth stages and geographical regions. This supports the underlying premise that efficacy trials are typically conducted in line with expected agronomic practice and are appropriate for this purpose. In addition, the data's alignment suggests that the data cleaning/processing has not affected the utility of the resulting dataset. C2D2 critically covers a fuller description of crop growth stages across a broader geographical region and is specifically aligned with the risk assessment procedures under 1107/2009/EC having standardised crop and FOCUSsw/gw scenario attribution.

Despite the large dataset compiled and the geographical coverage of C2D2, not all FOCUSsw/gw scenarios have sufficient data to facilitate comparison, with smaller scenarios, like FOCUSgw Porto, being under-represented. For those scenarios with sufficient data, significant differences between the CLE and AppDate crop development dates are often indicated over some/many growth stages suggesting that amendment of the existing representation of crop development within the risk assessment process may be required. While the provenance of the data underpinning AppDate crop development is not documented in the software manual and associated reports, much of the difference is ascribed to C2D2 comprising mostly post-2010 data describing crop development of modern crop cultivars bred to match current agronomic and weather constraints more closely.

The C2D2 will be made freely available under a Creative Commons licence to facilitate innovation in exposure science to allow for more accurate and realistic risk assessment leading to enhanced crop and environmental protection.

3.17.P-Tu294 A New European Dataset of Artificially Drained Agricultural Areas

***Gregory Hughes**[1] and Steven Anthony[2], (1)GeoSpatial Analytics, United Kingdom, (2)RSK ADAS, United Kingdom*

The use of artificial pipe drainage in agriculture is an important control for soil waterlogging and shallow groundwater tables. A well-designed drainage system will reduce the risk of detrimental waterlogging to acceptable levels, increasing crop yields and the number of available machine working days. While the drains rapidly remove excess soil water they also facilitate the rapid movement of soil pollutants, like nutrients and pesticides, to surface water.

An inventory of the extent to which soils requiring drainage have actually been drained is an important input for spatially distributed models seeking to investigate the fate and behaviour of agricultural chemicals. In the absence of such data a gross assumption of complete drainage of all soils requiring drainage is made. This poster presents an updated digital map of the extent of pipe drainage in arable agriculture across Europe. The map is compiled from national sources of pipe drainage compiled using diverse approaches ranging from agricultural surveys of farmers/drainage contractors to digitised field maps of historic installations. For most countries the revised map represents a marked improvement over existing spatial datasets of artificial drainage. The poster also provides a summary of the age of drains installed in various countries as an indicator of the likelihood that drains are still operating optimally as is typically represented in chemical fate models.

3.17.P-Tu295 Analysis of Glyphosate, Glufosinate and AMPA in environmental water with direct injection

*Benjamin Wuyts[1], **Janitha De Alwis**[2] and Claudia Rathmann[3], (1)Waters Corporation, Belgium, (2)Food and evironment, Waters*

Corporation, United Kingdom, (3)Waters Corporation, Germany
Monitoring highly polar, small organic pesticides in waters as well as in food presents an analytical challenge. The purpose of this work was to demonstrate a direct injection ultra-performance liquid chromatography-tandem mass spectrometry (UPLC-MS/MS) method for the determination of highly polar anionic pesticides in drinking and environmental waters. The method performance study was completed on an ACQUITY UPLC I-Class PLUS™ System with a Xevo TQ Absolute™ mass spectrometry.
A method validation study was carried out on drinking, reservoir, river, and ground water. The method performance was assessed for glyphosate, AMPA, and glufosinate using 2 spike levels at 20 and 60 ng/L for all analytes, with 11 replicates through inter-day and intra-day testing. The coefficients of determination (r^2>0.999) and residuals (<10%) were all excellent. Average method performance for trueness was between 95 and 103% across all matrices, while the RSDs were below 11%.
This poster demonstrates the performance of a method, combining stable retention on Waters' Anionic Polar Pesticide Column (APPC), ultra-performance chromatography on the ACQUITY™ I-Class and absolute MS power with the Xevo™ TQ Absolute to provide a fast and robust solution to one of the most challenging and time-consuming applications in environmental analysis.

3.17.P-Tu296 DIRECT AQUEOUS ANALYSIS OF PESTICIDES AND PPCPS IN DRINKING AND BOTTLED WATER AT PARTS PER TRILLION LEVELS
***Daniel McMillan*[1]*, Jianru Stahl-Zeng[2], Bertram Nieland[3], Jack Steed[1], Ian Moore[4] and Philip Taylor[1], (1)SCIEX, United Kingdom, (2)SCIEX, Germany, (3)SCIEX, Netherlands, (4)SCIEX, Canada*
Drinking water analysis is subjected to extremely low and rigid prescribed consent values (PCV) for determinands. Water suppliers and utility companies need to ensure that the final water product they send out for bottling or into supply networks is safe and complies with state and country regulations. Water can be a challenging matrix, in particular if it is sourced from a river, lake or reservoir before entering the water treatment process.
A series of experiments was conducted in collaboration with Vitens Water Company, to test several types of water samples spiked with a mixed standard of 431 determinants, including pesticides, pharmaceuticals and personal care products.
Direct aqueous injection was performed of spiked water samples - MilliQ water, tap water, Evian bottled water and Fiji bottled water. The samples were spiked with a custom mix standard, containing 431 analytes. A series of 11 standards were made in the respective matrices at sequential concentrations from 0.1 to 500 ng/L. A collection of unknown blank samples was also included in this study. The analysis was performed using a SCIEX 7500 system, operated in both positive and negative electrospray ionization with fast polarity switching.
The analytical method presented shows ultra-high levels of sensitivity with LOD values of 0.1 ng/L reported. All data was acquired through direct aqueous injection with no SPE needed. Good chromatographic peak-to peak separation was achieved with a total run time of 25 minutes. Even at low level concentrations, excellent levels of precision and accuracy were achieved (e.g. %CV ≤6.76 at 0.1 ng/L). There is scope to expand the number of analytes tested and apply this system to other individual workflows which demand very low limits of quantification. This method provides solutions for drinking water analysis and problematic determinands such as dicamba.

3.17.P-Tu297 Automated Workflow for At-Instrument Extraction and Analysis of Organochlorine Pesticides
***Bryan White** and Callum Morgan, Agilent Technologies, Inc., United Kingdom*
Analysis of Organochlorine Pesticides (OCP's) in water is traditionally performed by solvent: solvent extraction and requires at least 100 ml of sample and a minimum of 25 ml of organic extraction solvent. A fully automated instrument solution for the analysis of OCPs in water has been developed and fully validated. The method requires only 15 ml of sample (with the addition of a small quantity salt) to be added to a 20 ml headspace vial. The rest of the sample preparation is fully automated utilizing a CTC Pal3 RTC autosampler, thus removing any human error from the process and requiring only 2 ml or organic solvent. Analysis is done utilizing concurrent mid column backflush on an Agilent 8890 GC coupled to a 7010 Triple Quad equipped with High Efficiency Source operating in EI mode. Linear calibrations (R^2> 0.998) for all analytes are achieved for calibrations from 0.01 to 0.25 ug/L. Excellent sensitivity is shown with all analytes having S: N >50 at the 0.01ug/L level. The poster details aspects of the automation and the tools used together with techniques to maximize robustness within the analysis.

3.17.P-Tu298 HIGH SENSITIVITY QUANTIFICATION OF CHLOROTHALONIL METABOLITES IN SURFACE, GROUND AND BOTTLED DRINKING WATER
*Michael Scherer[1], Jack Steed[2], **Aidan Harrison**[2] and Jianru Stahl-Zeng[3], (1)SCIEX, Switzerland, (2)SCIEX, United Kingdom, (3)SCIEX, Germany*
Chlorothalonil is a fungicide that was widely used around the world for grain and vegetable cultivation. In Switzerland it was one of the top 10 agrochemicals used during the last few years. Due to increasing concerns about the toxicity of chlorothalonil and the discovery of several metabolites in the environment it was banned in 2020. The two main metabolites R471811 and R417888 were detected at high concentrations in ground and surface water. Therefore, there is a growing need to analyze and monitor these metabolites, to protect drinking water supplies, map the distribution, and to understand pathways and long-term behavior.
Different types of water such as ground water, surface water and drinking water should be analyzed to assess potential exposure.
A total of 10 chlorothalonil metabolites were analyzed: R471811, R417888, SYN507900, R611968, chlorothalonil 4-hydroxy, SYN548580, SYN548581, R611965, R611553, and M7. Isotopically labelled internal standards (IS) were used for R471811 and R417888. A calibration curve from 0.1 to 1000 ng/L was prepared in mineral water. HPLC separation was performed on a Kinetex Polar C18 column (100 × 4.6 mm, 2.6 µm). Thflow rate was 0.9 mL/min. The injection volume was 20 µL and the total LC runtime was 17 minutes.

The analytical method presented shows quantification of 10 chlorothalonil metabolites down to 0.1 ng/L. Samples were quantified using an external standard calibration in bottled drinking water, with specificity confirmed using ion ratios and retention time confirmation. Recoveries were between 90 to 105% for all water matricies analyzed and excellent reproducibility was observed at 10 ng/L with RSD values between 0.4% and 4.3%. R471811 and R417888 were observed frequently, and sometimes at very high concentrations. 5 other metabolites were detected at lower concentrations, and 3 metabolites were not present in any sample investigated here. Accurate results for early eluting polar compounds such as chlorothalonil R471811 can be obtained in several water types with low matrix and salt content such as drinking water and lake water without isotopically labelled internal standards. The method described here allows the monitoring and analysis of these metabolites, to protect drinking water supplies, to map the distribution, and to understand pathways and long-term behavior.

3.17.P-Tu299 LC-MS/MS analysis of triazole derivative metabolites in complex matrices

*Agnieszka Godziek-Botor[1], **Katarzyna Winiarska**[2], Agnieszka Żmijowska[1], Marcin Wójcik[1] and Edyta Rogalska[1], (1)Łukasiewicz Research Network-Institute of Industrial Organic Chemistry Branch Pszczyna, Poland, (2)Institute of Industrial Organic Chemistry, Poland*

Every year, 2.6 mln metric tons of pesticides contaminate the environment. Most of them, (85%), are used in agriculture. There is no doubt that pesticides play an essential role in maintaining a high level of food production, but on the other hand, they can get to the agricultural crops, and their presence in food should be constantly monitored. Triazoles as systemic fungicides are used for control and treatment of a wide range of fungal diseases on a wide variety of crops. All pesticides belonging to the triazoles group contain the 1,2,4-triazole moiety and are metabolized to four main common metabolites known as triazole derivative metabolites (TDMs): 1,2,4-triazole (TRZ), triazole alanine (TA), triazole acetic acid (TAA), and triazole lactic acid (TLA), which commonly occur in plant materials. Hence, it is extremely important to develop analytical methods which allow the determination of triazole derivative metabolites in the plant material. Due to their physical-chemical properties, TDMs analysis in the complex matrices is very difficult. The main aim of this study was to develop a method for the analysis of these analytes that is quick, easy to handle, and enables quantification at a residue level of 0.01 mg/kg.
The analytical methods were developed and fully validated for the determination of triazole derivative metabolites. The developed methods offer the determination of triazole derivative metabolite, combining selectivity, high resolution capacity and fast analysis time with the advantages of simple, rapid and reliable extraction procedures. Validation criteria (linearity, the regression residual (di), selectivity and specificity, precision, matrix effect, accuracy, and limit of quantification and detection) were performed in compliance with the SANTE/2020/12830, Rev. 1 guideline, ensuring the suitability of the method.

3.17.P-Tu300 Development of an environmental monitoring database "Biocides in the environment"

***Maria Vogel**[1], Inga Hilbrandt[1], Stephanie Graumnitz[2], Christiane Meier[1], Annika Stoll[2], Manja Wachsmuth[1] and Dirk Jungmann[3], (1)German Environment Agency (UBA), Germany, (2)University of Applied Sciences Dresden, Germany, (3)University of The Free State, South Africa*

They are part of our daily lives: biocidal products - whether as disinfectants, insecticides, or rodenticides, but also as preservatives for wood or textiles. Their widespread use is closely linked to unavoidable emissions into the environment and leads to potential risks to non-target organisms in various environmental compartments.
The question of how serious the problem of biocide contamination of the environment really is and whether risk assessment and risk management actually lead to the prevention of unacceptable concentrations can be examined by reviewing environmental monitoring data. However, a European collection of biocide monitoring data in various environmental compartments and the evaluation of these data does not yet exist.
Therefore, our objective is to develop the database "Biocides in the environment": It contains environmental monitoring data for biocidal active substances and relevant metabolites acquired between 2015 and 2022 from all over Europe. The data were collected by an intensive literature research in scientific publications and reports, but also measured environmental concentrations from different monitoring databases (e.g. NORMAN) were included. As a stand-alone module in the database "Information System on Chemicals" (ChemInfo) of the German Federal Government and the German Federal States, the data will be open to the general public and decision-makers in politics and society and will raise awareness of possible environmental hazards of biocides. Through the evaluation of the data, priority substances can be identified as well as substances with missing monitoring data which is useful for regulatory authorities and scientific communities. A geographic mapping of the data allows to identify regions with high densities of measured data for biocides and regions with unsatisfying data. Also, information on the degree of coverage of the single compartments is gained. Emission pathways and fate of the active substances used in different product types may be reproduced by means of analysing the monitoring data. Concentration trends over time mirror the changing use of the biocidal products throughout the examined time span. Furthermore, the database can be a useful tool for post-authorisation monitoring to evaluate the environmental exposure and risk assessment and to review or adapt risk reduction measures in the context of the regulation of biocidal active substances.

3.17.P-Tu301 Preliminary Report of the Exposure to Glyphosate and Glufosinate of a Male Population in the Province of Córdoba (Argentina)

*Iohanna Filippi[1], **Rocío Inés Inés Bonansea**[2,3,4], Mariana Butinof[5], Marta Llorca[6], Ricardo Antonio Fernandez[7], Marinella Farre[6], Sonia Muñoz[2] and María Valeria Amé[8], (1)Universidad Nacional de Cuyo, Argentina, (2)Instituto de Investigaciones en Ciencias de la Salud (INICSA - CONICET), Argentina, (3)Facultad de Ciencias Químicas, Argentina, (4)Universidad Nacional de Cordoba, Córdoba, Argentina, (5)Facultad de Ciencias Médicas. Universidad Nacional de Cordoba, Argentina, (6)IDAEA-CSIC, Spain, (7)Facultad de Ciencias de la Salud, Universidad Católica de Córdoba, Argentina, (8)Centro de Investigaciones en*

Bioquímica Clínica e Inmunología (CIBICI, CONICET, UNC), Argentina
Argentina is one of the world leaders in the production and export of agricultural products. The volume of pesticides application increased during the last decades, being the herbicides, mainly glyphosate (GLY), the top sold products in the phytosanitary market. In recent years a notable increase in sells of herbicides no-GLY, as glufosinate (GLU), has been reported due to the weed resistance. In the province of Córdoba, the production of wheat, corn and soybeans requires the use of GLY and GLU. However, physicochemical characteristics of GLY, its main metabolite, aminomethylphosphonic acid (AMPA), and GLU make their detection particularly complex at low concentration levels, and the exposure of the local population remains unknown.
The aim of this work was to develop a sensitive technique to detect and quantify GLY, AMPA, and GLU in plasma and urine of a male population with different scenarios of exposure residing in the province of Córdoba.
Urine and plasma samples were adequately pre-treated, derivatized with FMOC-Cl and further extracted by solid phase extraction. Identification and quantification of the herbicides were carried out using high performance liquid chromatography (HPLC) system coupled to a triple-quadrupole mass spectrometer equipped with a heated electrospray ionization source (TSQ-Quantiva). Then, urine and plasma samples from 31 subjects were analysed; 12 of them were people from the general population, and 19 were occupationally exposed to pesticides.
The developed analytical procedures reached limits of quantification between 0.3 and 5.1 ng/mL with recoveries between 39 and 84 %. The most frequently detected analyte in plasma was GLY, followed by GLU (32 and 10 % in the total population, respectively). In urine, the most frequently detected herbicide was GLU, followed by GLY (13 and 6 % of the total population, respectively). The metabolite, AMPA, was the less frequently detected in both matrices. No differences between groups of subjects were found regarding the median concentration of the analytes.
In conclusion, the analytical methodologies for the quantification of GLY, AMPA, and GLU were adequate to analyze the biological samples. This study is the first report of concentration of GLU in plasma and urine in human population.

3.17.PC Measuring, Modelling, and Monitoring the Environmental Fate and Exposure of Pesticides

3.17.P-Tu259 Spatial and Temporal Patterns of Pesticides Among Other Organic Pollutants in Seasonal Pools

Daniela Abramov[1]*, Tom Topaz*[2] *and Sarig Gafny*[3]*, (1)The School of Marine Sciences, Ruppin Academic Center, Israel, (2)The Faculty of Marine Science, Ruppin Academic Center, Israel, (3)Ruppin Academic Center, Israel*
Seasonal pools are defined as ephemeral wetlands that fill with water during the rainy season and dry out completely or mostly during the dry season. These water bodies support distinctive biodiversity and have great importance in conserving endemic species. Yet, due to anthropogenic stress, their occurrence has dramatically declined around the globe. In addition, surface water and runoff are increasingly contaminated with pollutants including microplastics, pesticides, and pharmaceuticals etc. This may strongly impact the pools, which function as sinks for compounds washed with surface runoff and shallow underground flows. Although seasonal pools are gaining attention in the research literature, there is very limited information on the transport and dynamic of organic pollutants in them. This contrasts with their potential to serve as an efficient representative environmental model system for understanding pollutant mixtures transport mechanisms, dynamics and fate in aquatic environments. This study aims to shed light on the spatial and temporal dynamics of pollutant mixtures, (mainly pesticides), and examine the parameters controlling these dynamics in seasonal pools located in Israel. Therefore, sediment, water and plant tissue samples were collected from 12 pools across Israel throughout one year. Preliminary results indicate that pollutant residues are present in the sediments and the water of all the pools, even those that seem separated from direct human influence. Plant protection products constituted the largest functional group of organic pollutants found in sediment and water during wintertime (47% and 38% respectively). A total of 25 different plant protection products were found in the sediments, ranging from zero in an isolated pool to 8 to 10 in pools adjacent to agricultural areas. On the other hand, 44 plant protection products were found in the winter sampling water, ranging between 6 to 30 different pollutants in each pool. The incompatibility in pools' ranking by plant protection products variety between sediment and water requires further consideration. Additional data from the spring sampling will allow us to examine and discuss the temporal changes and the effect of other pools' characteristics such as vegetation presence. The presentation will discuss the spatial and temporal dynamics of pesticides with the aim to shed light on mechanisms that may provide authorities with science-based tools for managing runoff and seasonal pools.

3.17.P-Tu260 Water and pesticide transfers in undisturbed soil columns sampled from a Stagnic Luvisol and a Vermic Umbrisol both cultivated under conventional and conservation agriculture

Sixtine Cueff[1]*, Lionel Alletto*[2]*, Marjolaine Bourdat-Deschamps*[3]*, Pierre Benoit*[3] *and Valérie Pot*[3]*, (1)Plant Protection Products – Impact and Assessment, Agroscope, Switzerland, (2)University of Toulouse, France, (3)Université Paris-Saclay, INRAE, AgroParisTech, France*
Conservation agriculture consists of a combination of (i) a strong reduction of tillage, (ii) the diversification of crop rotations, and (iii) a permanent soil cover by living plants or residues. Under such practices, mechanical disturbances are minimised and the water and organic pollutant dynamics are deeply modified. In particular, a "vertical dominant" functioning is favoured, thus limiting erosion and runoff (behind surface water contamination). The risk of groundwater contamination is, however, generally favoured and even more problematic when the increase in weed pressure, due to reduced tillage, can lead to a greater use of herbicides.
The objective of our study was to characterise water and pesticide transfers in two soils from the South West of France (Pyrénées-Atlantique and Gers regions) managed under contrasted agricultural practices (regularly tilled vs. conservation agriculture). To do so, we performed a percolation experiment on undisturbed soil columns sampled from the surface horizon. A molluscicide (metaldehyde) and two herbicides (nicosulfuron and mesotrione) frequently detected in the rivers of the studied fields catchment

area were used. They were applied all together with a conservative water tracer. Columns were subjected to a series of two rainfall events (high and low intensities) separated by a two-day flow interruption, while maintained under unsaturated conditions (–80 cm).
Preferential flows were shown at both sites and for both agricultural managements, but breakthrough curves showed a clearly different transport pattern between sites. At the Pyrénées-Atlantique site, behaviours were partly related to the pesticide sorption properties. Nicosulfuron and mesotrione were delayed compared to the tracer and slightly more under conservation agriculture. At the Gers site, we observed an early and simultaneous breakthrough of all substances under both management (independently of their sorption properties), suggesting a strong degree of preferential flow. At this site, experiments were carried out on shorter columns for the regularly tilled plot since a low conductive plow pan (evidenced by X-ray tomography) prevented flow beyond 20 cm. Due to this plow plan, surface and sub-surface runoff (observed in the field) are likely to be induced. Conservation agriculture practices performed for almost two decades seem, however, to have restored transfers to a 30 cm depth (at least), favouring the risk of groundwater contamination.

3.17.P-Tu261 Evidence for aged sorption to be used in combination with field degradation studies in regulatory assessments

***Ian Hardy**, Battelle UK, United Kingdom*

In the EU Aged Sorption Guidance (SANTE/12586/2020) the use of field DegT50 values in combination with aged sorption parameters is only possible to an extremely limited extent. If the leaching assessment for a PPP is based on field DegT50 values only, it is not recommended by the current guidance to derive a $DegT50_{equilibrium}$ (rescaling of DegT50) for input in exposure models in combination with aged sorption parameters (f_{NE}, k_{des}) as described for laboratory DegT50 values. This virtually prevents the mitigating effect of aged sorption on leaching and limits the applicability of the aged sorption guidance in combination with field DegT50 to very few cases.
However, the guidance mentions that "Industry is preparing evidence for aged sorption in field studies and this option should replace the current recommendations as soon as appropriate guidance has been developed and tested".
Therefore, additional field studies were evaluated to show the relevance of aged sorption in the field. The evaluation was mainly based on the comparison of observed concentration depth profiles versus FOCUS-PEARL simulations with and without consideration of aged sorption. Where possible, site-specific aged sorption parameters from laboratory studies with the respective field soils were used. The depth to which 95% of the residues are found was defined as metric for comparison. It was found that in all studies and sites the simulated soil profiles without aged sorption significantly overpredict the leaching of the substances. When considering aged sorption in the simulation the leaching was mostly still overpredicted but to a lesser extent which confirms the relevance of aged sorption in the field. In addition, the increase of apparent K_d-values from field and laboratory aged sorption studies with the same soils were compared with the result that the effects of aged sorption in field soils are similar to what is observed in laboratory studies.

3.17.V Measuring, Modelling, and Monitoring the Environmental Fate and Exposure of Pesticides

3.17.V-01 Microextraction and Chromatographic Determination of Selected Carbamate Pesticides in Soil Samples

*Luleka Luzi-Thafeni[1] and **Vernon S Somerset**[2], (1)Department for Environmental Food & Rural Affairs, South Africa, (2)Cape Peninsula University of Technology, South Africa*

Pesticides are generally applied to agricultural crops for protection but their residues present a potential risk to non-target organisms, affecting aquatic ecosystems and posing risks to human health. Organophosphates and carbamates impair nerve transmission in insects and poses even higher human health risks if left undetected. Recent advances have shown that these pesticides can be extracted and preconcentrated from aqueous samples by liquid-phase micro-extraction (LPME), solid phase extraction (SPE) and headspace solid phase micro extraction (HS-SPME), while supercritical fluid extraction (SFE) and pressurised fluid extraction (PFE) can be employed for sediments. This study has shown that improved extraction allows for sensitive detection of carbamates in soil and fruit samples.
The study involves the testing of a rapid, reliable, and low-solvent extraction procedure for selected carbamate pesticides of carbaryl, carbofuran, and methomyl from soil and fruit samples. It involves an investigation to determine which solvents to use, extraction optimisation, and how much of the applied carbamates are found in the fruit, compared to the soil in the same geographical location.
Preliminary results have shown that the concentrations are accumulated in the soil samples and have seasonal trends.

3.17.V-02 Organic Matter Reduces the Sorption Capacity of the Pesticide Fipronil onto Polyethylene Microplastics in Surface Water

***Camila Leite Madeira,** Mariana A. Dias, Karen N. Morishita, and Cassiana Montagner, Institute of Chemistry, State University of Campinas, Brazil*

Microplastics are ubiquitous contaminants in the environment. In water, they can sorb hydrophobic contaminants, leading to their accumulation and transport in the aquatic environment consequently exposing organisms to their toxic effects. Several pesticides are hydrophobic and persistent; therefore, they have great potential for sorption onto microplastics. Fipronil, a pesticide detected in several water bodies in Brazil, is susceptible to transformations such as reduction, oxidation, hydrolysis, and photolysis. Fipronil-sulfone and fipronil-sulfide are major biodegradation products of fipronil. We aimed to assess the interactions of fipronil, fipronil-sulfone, and fipronil-sulfide with polyethylene (PE) microplastics in ultrapure water and river water to evaluate the sorption capacity of the contaminants onto PE. Kinetics experiments were conducted in 10-mL glass test tubes containing 4 mL of contaminants dissolved in ultrapure or river water (1000, 250, and 800 µg/L of fipronil, fipronil-sulfone, and fipronil-sulfide, respectively) and 20 mg of PE microplastics (average particle size = 107 µm). The tubes were kept in a rotating shaker at 40 rpm for different contact times. Liquid samples were analyzed by LC-MS/MS. In ultrapure water, fipronil and its degradation products were greatly sorbed by PE microplastics. At equilibrium (48 h), we observed sorption of 86, 86, and 76% of the fipronil, fipronil-sulfone, and fipronil-sulfide initially present in the solution, respectively. For the three compounds, the sorption was described as a pseudo-second-order reaction. No sorption was observed in the controls without microplastics. In river water, the sorption capacity of PE microplastics was substantially reduced. Sorption was slightly higher in the treatment containing fipronil and microplastics (46%) than in the treatment without microplastics (36%). For fipronil-sulfone and fipronil-sulfide, no difference between the treatments with and without microplastics was observed. Experiments with added humic acids showed that high concentrations of dissolved organic matter in the water lead to lower sorption capacity. Our results indicate that experiments conducted in ultrapure water might not represent the complexity of sorption reactions in natural environments. Therefore, further studies are needed to understand the impact of microplastics on the retention and transport of contaminants in freshwater bodies and their effects on aquatic organisms.

3.18 One Health Next Generation Wastewater Management and Reuse: The Role of Non-target and Retrospective Analysis, Bioassays, and Wastewater Surveillance

3.18.T-01 Microbiota as Drivers and Markers of Water and Soil Pollution and Recovery

***Benjamin Pina**[1], Claudia Sanz[1], Marta Casado,[2] and Laia Navarro-Martin[2], (1)Environmental Chemistry, Spanish Research Council (CSIC), Institute of Environmental Assessment and Water Research (IDAEA), Spain, (2)Department of Environmental Chemistry, Spanish Research Council (CSIC), Institute of Environmental Assessment and Water Research (IDAEA), Spain*

Microbia are the universal drivers of all geochemical cycles, on which all the Biosphere depends. On a smaller scale, microbial composition has been long used as a marker of anthropogenic impact, mainly by the identification and quantification of human microbial pathogens and commensals. The current ability to describe whole microbiomes by high throughput DNA sequencing opened whole new ways of monitoring alterations, anthropogenic or not, on the ecosystems. In turn, microbial metabolism and growth are central in the process of depuration of water bodies, polluted soils, and other potentially harmful environments. We observed in different field studies how the microbiome was changed by the presence of anthropogenic pollution and how its reversal took place under distinct scenarios. These processes applied to both biological (pathogens, antibiotic resistance, gut bacteria) and chemical hazards (CECs). We propose microbiota analysis as a way to monitor the pollution of impacted sites and, at the same time, a guide to develop treatment schemes favoring the displacement of gut-related, copiotrophic bacteria by oligotrophic or mesotrophic microbiomes. We found this mechanism operating in processes as water depuration through managed aquifers, manure composting, and soil re-naturalization after organic amendment. Our results also suggest that the lack of such a microbiome substitution in current water treatment processes is responsible for their failure in eliminating many relevant hazards, including Antibiotic Resistant Genes (ARGs) and CECs.

3.18.T-02 Environmental proteomics in wastewater-based monitoring. Determination of large biomolecules as biomarkers of population health and activities.

***Montserrat Carrascal**[1], Ester Sanchez-Jimenez[2], Carlos Perez Lopez[1], Antoni Ginebreda[3], Joaquin Abian,[2] and Damià Barceló[4], (1)Spanish Research Council (CSIC), Institute of Environmental Assessment and Water Research (IDAEA), Spain, (2)Institute of Biomedical Research of Barcelona, Spanish National Research Council (IIBB-CSIC/IDIBAPS), Spain, (3)Spanish National Research Council (CSIC), Spain, (4)ICRA, Spain*

The analysis by mass spectrometry of small molecules in wastewater is a widely adopted approach for population monitoring by governmental institutions. Typical applications are for example monitoring the consumption of tobacco, alcohol, or drugs by a community (and, more recently, using PCR, to evaluate COVID prevalence by measuring virus RNA in wastewater. Current development of mass spectrometry allows extending this approach to large molecules such as proteins opening the window to the monitorization of human health biomarkers already known in clinics.

Previously, we reported for the first time on the peptide and protein components absorbed in a support submerged in wastewater at a WWTP. We detected proteins from prokaryotic to higher eukaryotic organisms, covering plant, animal, and human proteomes as well. We were able to identify not only major components like albumins, keratins, etc., but also less abundant ones (ie, S100A8, uromodulin, defensins, etc.) that are known as disease biomarkers.

We study the composition of the soluble fraction of wastewater collected at the entrance of 10 different WWTP in Catalonia at three different times of the year. The objectives are (a) the deep proteomic characterization of the wastewater proteome (b) the comparison of the protein profile of wastewater derived from 10 different places in Catalonia covering a range of different sizes and influent characteristics (relative contribution of domestic and industrial load, and lastly (c) to contribute to the improvement of the WWTPs operation and management.

We identified near 1000 proteins from human and other species. The most abundant proteins include human pancreatic enzymes and albumin from different livestock animals. Our results show how the protein profile in each of these municipalities reflects their agricultural activity and its potential application to pest control or to monitor the levels and source of animal tissues dumped by the industry. Also, the proteome of influent and effluent of some of this WWTP were compared. The results indicated that almost all the proteins are eliminated in the treatment plant.

3.18.T-03 Operational Invertebrate Behaviour Videotracking for Real-Time Wastewater Surveillance and Management

***George Ruck**[1], Alexandre Decamps[2], Jean-Baptiste Aubin[3], Jean-Luc Bertrand-Krajewski[4], Maxime Dauphin[2], Laura Garnero[5],*

Kassandra Montalbano[2], Hervé Quéau[6], Didier Neuzeret[2], Olivier Geffard Pr[7], and Arnaud Chaumot[8], (1)UR RiverLy - Ecotox, National Research Institute for Agriculture, Food and Environment (INRAE), France, (2)ViewPoint, France, (3)INSA de Lyon, France, (4)INSA LYON, France, (5)UR RiverLy - ECOTOX, Laboratoire d'écotoxicologie INRAE, France, (6)INRAE, France, (7)UR RiverLy, Institut national de recherche pour l'agriculture, l'alimentation et l'environnement (INRAE), France, (8)INRAE (Institut National de la Recherche Agronomique), France
As availability of water resources decreases, the apparition of new contaminants of concern (CEC) identified in water networks continues to increase. Current wastewater monitoring in treatment plants relies on interval-based grab sampling measurements for a select few chemicals or for punctual effluent toxicity assessment using a restricted choice of bioassays. As this strategy is known to omit at large portion of micro-pollutants and contaminants of emerging concern (CECs), innovative approaches to wastewater management are essential to both avoid potentially detrimental impact of largely unknown CEC discharge in aquatic ecosystems and improve efficiency of urban water re-use.
In previous work using the biomonitoring apparatus ToxMate, whereby the video-tracking of locomotor behaviour of bio-indicator invertebrates (*Gammarus*, *Radix*, and *Erpobdella*) generates positional data in the on-line wastewater multi-species monitoring device, we showed the bio-test method to be effective in non-targeted effect-based screening of micro pollutant presence (including little known emerging contaminants). In continued research we illustrate results from long term surveillance in WWTPs to optimise operation, where the characterization of the effluents in real-time for the multispecies approach alerts operators and allows strategic sampling and affluents and effluents to better understand treatment efficiency. Finally, continued laboratory testing has led to the accumulation of behavioural reaction analysis for over 80 micropollutants. Definition of multi-species behavioural fingerprints to characterise causes for temporal variability in CEC discharge is presented using functional data analysis (FDA) and artificial intelligence.
Continuous surveillance not-only identifies critical moments but has incorporated timely sampling techniques to validate reactions. Coupled with behavioural fingerprinting, these moments may help adapt wastewater management strategy in real-time. Thus, the potential is not only limited to the improvement of aquatic environmental quality through wastewater management, but could also provide concrete indicators of the suitability of re-use in various domains such as urban, agricultural and leisure use.

3.18.T-04 Nutrient Recycling from Urine and Faeces: Problematic of Micropollutants
***Christa McArdell**[1], Isabell Köpping[2], Birge Oezel Duygan[2], Lena Schinkel[2], Yves Eberhard[2] and Kai M Udert[2], (1)Swiss Federal Institute of Aquatic Science and Technology, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (2)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland*
Most nutrients from human metabolism are excreted with urine. Therefore, urine collection and treatment allows production of a valuable fertilizer and promotes sanitation in areas where no sewer-based sanitation is available. To treat the urine, nitrification followed by distillation is the best tested technology. However, pharmaceuticals are not well removed during storage or biological treatment of urine. Therefore, we aimed to test the removal of pharmaceuticals from nitrified urine by granular activated carbon (GAC) in a flow-through filter to evaluate the capacity until breakthrough at different hydraulic retention times. GAC can be used in convenient filter beds and has, compared to powdered activated carbon, the additional benefit that it can be regenerated and reused. Two GAC columns with 2 m height and 1.3 kg material were run with nitrified urine and had valves at several heights to allow sampling at empty bed contact times (EBCTs) of 25-115 min. Complete removal of 11 investigated pharmaceuticals from nitrified urine was achieved for up to 660 bed volumes at an empty bed contact time (EBCT) of 70 min. The recommended EBCT for urine treatment (70 min) is much longer than what is suggested for the treatment of municipal wastewater treatment plant effluents (≥ 20 min), and the amount of treated bed volumes until breakthrough is shorted. This is probably due to the approximately twenty times higher DOC content in nitrified urine compared to municipal wastewater. These results have led to the production of a urine fertilizer that is authorized for use on vegetables and flowers in Switzerland. Beside urine, human faecal compost from commercial public composting toilets was investigated for its content of pharmaceuticals. Currently, the use of faecal compost from composting toilets for land application is prohibited in Switzerland.

3.18.T-05 Development of a Reusable Super-biochar With Antibiotics Degradation Capacity
***Adekunle Christopher Faleye**, Environmental Chemistry, Umea University, Sweden*
Antibiotics-resistant gene development has been linked directly to the presence of antibiotics in our environment. The various reports on antibiotics resistance indicate that the ubiquitous nature of these antibiotics in the environment will eventually lead to an outbreak of total drug resistance diseases if adequate precaution is not taken. Several methods for the removal of various antibiotic contaminants have been proposed. These approaches include advanced chemical oxidation, membrane filtration, adsorption using activated charcoal, and recently biochar. Among these techniques, biochar-based adsorbent for antibiotics removal provides a low-cost and environmentally friendly approach. There has been development of various biochar-based remediation systems for efficient removal of a number of antibiotics from contaminated water. However, biochar is known to remove the antibiotics by absorption mechanism and could not mineralize the antibiotics. The inability of biochar to degrade or mineralize adsorbed antibiotics may lead to the production of secondary pollutants. Also, the desorption of the antibiotics to regenerate the biochar often results in additional cost, which in effect limits the cost advantage of using biochar-based antibiotics adsorbents.
Since its discovery in 1990, various advanced chemical oxidation processes (ACOP) have shown the potential to oxidize and mineralize various persistent organic pollutants (POPs), such as antibiotics, to an acceptable level without producing toxic by-products. However, ACOP is expensive due to the requirement of an activation process. Developing systems that could allow for efficient and reusable activation catalysts for ACOP would be beneficial. Therefore, the research aims to develop a low-cost and highly efficient treatment system that combines the benefit of biochar-based adsorbents with a persulphate-based chemical

oxidation process for the complete removal and mineralization of antibiotics contaminants. Overall the project aims to reduce the cost of antibiotics remediation without the generation of secondary pollutants, with a view to making this technology available to low-income countries with water scarcity.

3.18.P One Health Next Generation Wastewater Management and Reuse: The Role of Non-target and Retrospective Analysis, Bioassays, and Wastewater Surveillance

3.18.P-Tu302 High Resolution Mass Spectrometry for the Analysis of Contaminants and Metabolites from Treated Wastewater: The Case Study of Saudi Arabia

Yolanda Pico[1]*, Julian Campo*[2]*, Mohamed El-Sheikh*[3]*, Ahmed Alfarhan*[3]*, and Damià Barceló*[4]*, (1)Centro de Investigaciones sobre Desertificación, Universidad de Valencia, Spain, (2)CIDE (CSIC UV GV), Spain, (3)2Department of Botany and Microbiology, King Saud University, Saudi Arabia, (4)ICRA, Spain*

Anthropogenic pollution can assume different forms and impacts on all environmental compartments. Particularly, a high number of contaminants and their metabolites and/or degradation products have been widely reported in the environment. Chemical monitoring based on the determination of target compounds fails to consider most known environmental micropollutants, not to mention the unexpected and unknown chemicals. Currently, high-resolution mass spectrometry (HRMS) data with wide-scope target, suspect, and non-target screening is recommended.

The purpose of this study was to investigate and compare plants growing in two Saudi Arabia areas, one corresponding to the South Riyadh (large industrial city, >10 million inhabitants, intense traffic) and the other to Abha (small city, < 760000 inhabitants, near a natural park), as bioindicators and biomarkers of anthropic pollution. To this end, ThermoScientific™ Orbitrap Exploris™ 120 mass spectrometer and Thermo Scientific™ Vanquish™ UHPLC coupled with Thermo Scientific™ Tracefinder™ and Compound Discoverer™ software, which achieved quantification as well as data interpretation and structure elucidation were used.

Various MS^2 modes were investigated, including the combination of full scan mass range at a resolution of 60000 followed by MS^2 with 4 precursor isolation windows for the full MS range or S^2 (target acquisition) against a mass list. This approach facilitated identification without unnecessary increase in the cycle time. Using this system, several unexpected environmental contaminants were identified showing the possibilities of the application of mass spectrometry.

Explores 120 MS high sensitivity, high dynamic range, and high mass accuracy enabled accurate identification of trace level contaminants in complex environmental matrices, such as water, sediment and food.

3.18.P-Tu303 Polystyrene Nanoplastics Removal from Urban Wastewater by Aerobic Membrane Bioreactor

Anamary Pompa Pernía[1]*, Serena Molina*[2] *and Junkal Landaburu-Aguirre*[2]*, (1)MEMTECH, Foundation IMDEA Water, Alcalá de Henares, Madrid, Spain, (2)IMDEA Water Institute, Spain*

Micro- and nano-plastics as emerging contaminants have become an increasing environmental concern given their persistent and ecotoxicological effects on the aquatic environment. Although the retention capacity of identified microplastics in wastewater treatment plants (WWTPs) ranges between 98 % to 99 %, WWTPs are still considered the main pathway for microplastics to get into the aquatic environment. In this context, membrane-based advanced technologies for wastewater treatment, such as membrane bioreactors (MBRs) have been demonstrated to reach a removal capacity of 99.9 % of microplastics (MPs). However, the removal of nanoplastics (NPs; < 1 µm) has been scarcely investigated. Thus, the present work aimed to evaluate the removal capacity of nano-plastics by an aerobic MBR (aMBR) of submerged-membrane configuration.

To evaluate the removal capacity of NPs (polystyrene (PS) of 120 nm sizes) by aMBR, two systems were employed (working volume of 30 L). One system was used as control (aMBR-Control) (i.e., without PS addition), and the other with PS nanospheres spiked (aMBR-PS). The performance of three different membranes (microfiltration, ultrafiltration, and recycled ultrafiltration membranes) was compared and their surface morphologies were evaluated. The quality analysis of the aMBR permeates and the characterization of the mixed liquor (ML) properties (i.e., physical-chemical parameters, microbial community compositions, and floc micro- and macroscopy characteristics) were conducted. In addition, the PS quantification for ML and permeate samples by pyrolysis gas-chromatography mass was examined. Preliminary results showed an overall efficient performance of the technology for NPs treatment in terms of permeate quality. However, the membrane resistances were highly increased due to the internal pore blocking under NPs. Indeed, the total resistance of the microfiltration membranes evaluated in the aMBR-PS was 4.1 times more than the submerged membrane in aMBR-Control at the end of the 38-day experiment. Regarding the influence of PS nanospheres on the ML, analysis of the floc characteristics, microbial community compositions, and soluble microbial products are under current study. By the completion of the current research, our findings could offer valid insight into the NPs removal capacity of aMBR technology, sludge floc characteristics, and membrane fouling behavior.

3.18.P-Tu304 Minimization of environmental impact of protein containing wastewaters by membrane treatment

Saeed Hamad Al Marri*, QEERI- Water center, Hamad Bin Khalifa University, Qatar*

The dairy industry generates a large amount of protein-containing wastewater, which is characterised by high values of chemical oxygen demand (COD) and biochemical oxygen demand (BOD). Dumping such wastewater into water bodies without proper treatment may cause serious environmental harm.

Currently, membranes are utilised for various water treatment and desalination applications, including the treatment of protein-containing wastewater; however, developing innovative membranes with improved properties is necessary to handle membrane fouling/scaling concerns better and enhance the chemical/mechanical properties of membranes.

We prepared novel polyethersulfone (PES) ultrafiltration membranes incorporated with carrageenan, which is a natural polysaccharide extracted from seaweed. We employed these membranes to treat both model bovine serum albumin (BSA) solutions and real protein-containing wastewaters from the dairy industry. The fabricated membranes were characterised, including water contact angle and zeta potential analysis, SEM, total porosity, and pore size measurements. The properties of the prepared membranes were compared against neat PES and commercial ultrafiltration membranes. It was found that the carrageenan incorporation in the PES polymer matrix enhances the hydrophilicity, surface charge and compaction resistance of PES/carrageenan membranes. The prepared membranes underwent filtration and fouling tests using bovine serum albumin (BSA) solutions. It was found that the PES/carrageenan membranes possessed higher resistance to BSA fouling than the neat PES membranes, with a notable decrease in irreversible fouling while maintaining BSA rejection above 96%. Finally, PES/carrageenan membranes successfully reduced COD and BOD values when employed for the treatment of total protein–containing wastewater from the dairy industry in Qatar.

3.18.P-Tu305 Removal of pharmaceuticals and personal care products from hospital effluents by biochars produced by cookstoves

Brigitte Mukarunyana*, Chemistry, Umea University, Sweden*

The occurrence of pharmaceuticals and personal care products (PPCPs) in water systems can affect aquatic life. Wastewaters including those discharged by hospitals can contribute to the increase of PPCPs in the environment. Conventional methods applied in most wastewater treatment plants have been used to remove PPCPs from wastewaters, however, different studies showed that those methods are not efficient in terms of PPCPs removal. To mitigate that issue, different carbonaceous adsorbents like activated carbon have been used to treat PPCPs but the activated carbon is costly therefore, it is challenging to use, especially in countries with low incomes. Biochars could thus be an alternative because the raw materials used to produce them are locally sourced. Various studies have been performed to investigate the efficiency of biochars in treating wastewater, however, the results are not yet coherent, in addition, biochars have different characteristics depending on the feedstock from which they are made and the conditions applied during their production. Further research on biochars as adsorbents and experimental studies are of high importance in the wastewater treatment domain. This study aimed to investigate the ability of biochars produced by cookstoves to remove PPCPs from hospital wastewater.

Wastewater samples were taken at Rwanda's University Teaching Hospital of Kigali (CHUK). The biochars produced by 3 different cookstoves using 3 feedstocks have been characterized using DRIFTS, Raman spectroscopy, XPS and BET. Wastewater samples have been analyzed using LC-MS/MS method before and after being treated by biochars. The results from XPS analysis showed a high % of carbon for all biochars, this observation was supported by the abundance of C-H peaks for aliphatic and aromatic functional groups indicated by DRIFTS and Raman spectra. 28 PPCPs have been detected and quantified with the abundance of antibiotics. PPCPs have been removed at different degrees depending on the type of biochar. The removal rates (RR) ranged between 0.2 and 97.7% and about 52% of PPCPs were removed at a RR $\geq$70% by the top 2 best biochars. Results showed that the surface area of biochars might not be the main driving force of PPCPs removal. Findings will contribute to further studies on biochars especially on characterizations to investigate the driving forces of PPCPs removals.

3.18.P-Tu306 Antiviral Performance of Metal Foam in Water Disinfection

Jinghan Zhao, ***Rafael M. Santos,*** *and Emily Yi Wai Chiang, School of Engineering, University of Guelph, Canada*

It is well known that waterborne bacteria is a significant health concern in water safety, which can cause immediate illness. However, the presence and health impact of waterborne viruses are less appreciated. The potential health risks caused by viruses shed in the wastewater are undervalued, and effective virus disinfection techniques are urgently needed to eliminate the risks of viruses. A broad spectrum, effective, mobile, and economically feasible point-of-use water treatment system is urgently desired in developing or remote households and emergency relief settings.

This study investigated the antiviral properties of the micro-structured copper foam in the water environment. The bacteriophage MS2 was adopted as a surrogate for the human virus to predict the interaction and behavior in a water environment. The experiment was carried out under both a virus sole-existance in water environment, and host cell/virus co-existance in a water environment to study the life cycle inhibition and reveal which stage of the virus replication cycle could be blocked by copper foam. The effect of retention time, host cell presence, and virus load were considered, and the potential mechanism is discussed. The result demonstrated that the micro-structured metal foam cannot effectively inactivate viruses in a virus-only environment but can effectively inactivate viruses in a virus/host cell co-exist environment. With the presence of host cell *E. coli*, the killing rate of copper foam was significantly improved, reaching 92% after two hours. Comparatively, the killing rate of MS2 with host cells and with no copper foam treatment was only 15.9% at the end of the experiment, which is explained by the replication process of the MS2 with host cell supply. The hypothesis of the mechanisms is that the virus is attached to its host cell using virus attachment protein to facilitate its docking onto the host cell. Furthermore, the initial contamination level and the attachment status between viruses and host cells play an important role in the survivability of viruses in water and the antiviral performance of the copper foam. The copper foam demonstrated higher inactivation rates under low contamination levels and also higher inactivation rates on viruses at the latent period.

The study validates the hypothesis that metal foam can have effective virucidal performance, and is valuable for further research on antiviral applications of microscale metal materials.

3.18.P-Tu307 Toxicity of Carbamazepine after Plasma Oxidative Degradation in Freshwater Green Algae (Raphidocelis subcapitata)

Warich Leekitratanapisan*[1], Jarne April[2], Karel De Schamphelaere[1], Pieter Van Aken[2], and Raf Dewil[2], (1)Ghent University - GhEnToxLab, Belgium, (2)Department of Chemical Engineering, KU Leuven, Process and Environmental Technology Lab,*

Belgium
The anticonvulsant drug carbamazepine (CBZ) is continuously discharged into natural water, as it is not well removed by conventional wastewater treatment plants, which may pose a concern to the aquatic ecosystem. Advanced oxidation processes (AOPs) have been proven to effectively remove CBZ and other pollutants. Plasma oxidative degradation (POD) is being thoroughly researched because of its fast, feasible, and low environmental impact characteristics. A gas phase surface di-electric barrier discharge plasma system is used, where reactive oxidative species are generated in situ and brought into contact with the contaminants via a carrier gas to degrade them. However, unwanted toxic transformation products (TPs) could be generated. In this study, the toxicity of CBZ TPs after POD was examined using freshwater green algae (*Raphidocelis subcapitata*). The POD experiment was conducted using 10 mg/L CBZ with an applied voltage of 14-15 kV,and the samples were collected at different time points, including 0 min (without POD treatment), 12 min, 22 min, and 30 min. After 12 min of degradation, all CBZ was degraded, and mixtures of TPs were present. The results revealed that the samples after treatment with POD induced algae toxicity at all time points. However, no toxicity was observed in the sample before POD treatment. The algae toxicity increased after a longer POD treatment time. For the longest degradation time, the lowest EC10 is observed at 11.9% of the original sample. Based on our observation, the oxidation of CBZ was likely through a reaction with ozone-reactive species generated during plasma discharge. We hypothesize that CBZ ozonation byproducts, including carbamazepine-(10,11)-epoxide and 1-(2-benzaldehyde)-(1H,3H)-quinazoline-2,4-dione (BQD), could be the main effect drivers due to the high toxicity according to ECOSAR for algae toxicity. Further chemical analysis will be performed to confirm and link CBZ TPs with the observed toxicity. Our study highlights the importance of toxicity evaluation before discharging AOP-treated (waste)water streams into the environment due to possible toxic transformation products.

3.18.P-Tu308 Stop Wasting Wastewater! Wastewater Quality Assessment After Advanced Treatment for Potential Reuse.
***Jan Christof Specker**[1], Antonia Praetorius[2], Nora Sutton[3], and Annemarie van Wezel[2], (1)Institute for Biodiversity and Ecosystem Dynamics, University of Amsterdam, Netherlands, (2)University of Amsterdam, Institute for Biodiversity and Ecosystem Dynamics, Netherlands, (3)Environmental Technology, Wageningen University, Netherlands*
Water reuse applications, such as the reuse of treated wastewater (TWW), are attracting global interest. This is being accelerated by increasingly frequent freshwater shortages, as water resources are under increased pressure due to rising populations and climate change. However, conventional wastewater treatment plants (WWTPs) do not focus on the abundance of anthropogenic chemicals potentially present in the water cycle, resulting in the fact that TWW generally contains micropollutants and their transformation products. Consequently, in circular systems, this increases the potential for the accumulation of hazardous and persistent compounds and may lead to negative consequences for human and environmental health. Thus, to utilize the true potential of water reuse and achieve acceptable risks, these pollutants must be removed from the water prior to its reuse.
In Wervershoof, the Netherlands, a pilot plant was installed on the local WWTP to study the potential reuse of TWW for potable to non-potable reuse applications. The WWTP effluent served as the intake for the pilot plant and was treated by a variety of additional treatment techniques. In summary, these consisted of ozonation, later replaced by advanced oxidation, ceramic membrane filtration, and activated carbon. Over the summer of 2022, a total of 90 grab samples were taken in triplicates. Sampling points included the pilot intake and directly after the aforementioned treatment steps. The samples were supplemented by field blanks and all samples were analysed for common micropollutants covering pharmaceuticals, personal care products, pesticides, and industrial chemicals. After solid-phase extraction (Oasis HLB), the extracts were analysed by LC-HRMS and effect-based tools such as *in vitro* CALUX bioassays. This approach not only covers known target substances but also unknown compounds, and the overall mixture toxicity is assessed.
This poster presents the first results of this study and gives indications about the potential water reuse applications of TWW that could be achieved by the respective treatments of the Wervershoof pilot plant. Future work will also include suspect and non-target screening, as well as more intensive bioanalysis. Our results will help water authorities develop an improved understanding of the linkage between appropriate water treatment techniques for potential water reuse applications, suitable monitoring techniques, and of potential environmental and human health risks.

3.18.P-Tu309 Comparison of ozone- and UV-based technologies for trace organic compounds removal from wastewater
***Alberto Cruz-Alcalde**[1], Nuria López Vinent[2], Laura Poch[2], Nicola Montemurro[2], Carme Sans[1], and Sandra Pérez[2], (1)Department of Chemical Engineering and Analytical Chemistry, University of Barcelona, Spain, (2)Department of Environmental Chemistry, IDAEA-CSIC, Spain*
Trace organic pollutants (TOrCs; aka micropollutants [MPs], contaminants of emerging concern [CECs], etc.) such as pharmaceuticals and personal care products, hormones and pesticides, as well as their transformation products reach wastewater treatment plants (WWTPs) on a continuous basis. Conventional wastewater technologies are not designed to deal with this kind of pollution, and therefore many organic compounds leave treatment facilities after being only partially removed/transformed. As treatment wastewater is usually discharged into surface water bodies or the ocean, WWTP effluents can be considered to be one of the main sources for TOrCs into the aquatic environment.
Chemical oxidation processes can be effective technologies for the removal of micropollutants from water and wastewater. Among all available systems, the homogeneous ozone- and UV-based oxidation technologies, both based on the action of hydroxyl radical (•OH), are especially promising due to their potential action against different classes of chemicals and their relative maturity/potential implementability at full-scale. However, a rigorous comparison of processes considering techno-economic and environmental criteria is required to decide which technology is most suitable in terms of pollutant destruction efficiency, running costs and associated impacts.

In this work, a range of ozonation, O_3/H_2O_2, UV/H_2O_2, UV/persulfate and UV/Cl_2 processes were compared in the abatement of 20 organic pollutants with different structure/physicochemical properties, spiked at trace level (1 µg/L) to 5 different wastewater effluents collected in the Barcelona metropolitan area and presenting different physicochemical characteristics (total organic carbon [TOC]: 5.5–18.5 mg C/L; alkalinity: 67–360 mg $CaCO_3$/L; pH: 7.4–8.2; NO_2^-: 0.05–1.6 mg N/L). Oxidation experiments were conducted at lab-scale level simulating actual operational conditions regarding both oxidant doses and exposure to UV light. Samples of treated effluents were collected and subjected to solid-phase extranction (SPE) folllowed by analyses by HPLC-MS/MS. The economical and environmental evaluation of each process was based, respectively, on the capital/operational costs and life cycle impacts associated to the treatment of a given volume of wastewater effluent to reach particular micropollutant abatement levels.

3.18.P-Tu310 Nature-Based Solutions as a Pretreatment of Photo-Fenton at Natural pH to Enhance the Removal of Contaminants of Emerging Concern

Nuria López Vinent[1], Alberto Cruz-Alcalde[2], Ana Piera Santacruz[3], Albert Sales Alba[1], ***Nicola Montemurro**[1]*, *and Sandra Pérez[1], (1)Department of Environmental Chemistry, IDAEA-CSIC, Spain, (2)Department of Chemical Engineering and Analytical Chemistry, University of Barcelona, Spain, (3)Universitat de Barcelona, Spain*

The increasing concern on the presence of contaminants of emerging concern (CECs) in water bodies and their potential risk for human healh and ecosystems has motivated the development of new suitable technologies to eliminate diverse type of CECs. Advanced Oxidation Processes (AOPs) have proven to be efficient in the abatement of a wide amount of recalcitrant compounds. However, elevated costs and energy demand for their implementation and maintance are linked to these processes. In this regard, Nature-based Solutions (NbS) such as constructed wetlands (CW) have emerged as a green alternative since they have also demonstrated their potential in the removal of CECs. Nevertheless, this technology also presents disadvantatges which could limit its implementation at full scale: requirement a larger area footprint and long operation treatment times. In this study hybrid system composed by CW coupled to photo-Fenton process (type of AOP) at natural pH was investigated to solve the individual limitations of using two technologies separately.

Therefore, the purpose of this study was to evaluate the performance of four CW (lab-scale, 1.5 L) planted with *Phragmites australis* or *Cyperus haspan* and two operational modes: with and without recirculation on the removal of 17 micropollutants at 1 µg/L in secondary wastewater effluent. Additionally, the potential of CW as an effluent pretreatment for solar photo-Fenton at natural pH using DTPA-Fe (III) was also investigated.

Regarding the CW unit, obvious differences were shown when two modes of operation were compared. Highest removals of CECs and dissolved organic carbon (DOC) were found in CWs with recirculation. An average of 8 cycles revealed the elimination of 50% of DOC and 65% CECs in two CW with recirculation, while only 35 and 40%, of DOC and CECs, respectively, were achieved in CWs without recirculation.

Concerning the hybrid system, the results disclosed a reduction of more than 4 times of operation time when wastewater was pretreated with CW with recirculation. For instance, total metronidazole removal was achieved at 30 minutes while without any pretreatment only 80% removal was observed after 2 h of treatment. In the pretreatments without recirculation the improvement was lower (total metronidazole removal was found at 2 h). This fact highlights the potential of recirculated constructed wetlands coupled with solar photo-Fenton as efficient and ecofriendly solution for the possible reuse of wastewater.

3.18.P-Tu311 Wastewater based epidemiology used for monitoring the trends of covid-19 epidemic in the Czech Republic

***Kateřina Sovová**, Hana Zvěřinová Mlejnková and Vojtěch Valášek, T.G.Masaryk Water Research Institute, Czech Republic*

Shortly after the outbreak of the coronavirus, it was found that its genomic fragments are secreted not only by the respiratory system but also by the digestive and excretory tracts. In this way, they enter wastewater, sewage systems and wastewater treatment plants. This principle has been used in many countries to test the possibility of objective monitoring of the incidence of the disease in the population.

Our research began in 2020 by evaluating the possibilities to use Wastewater Based Epidemiology (WBE) approach in the Czech Republic by monitoring the occurrence of SARS-CoV-2 RNA in untreated water from wastewater treatment plants (WWTP). Since the beginning of monitoring, 66 WWTPs of various categories (most of 10s–100s of thousands inhabitants served) have been monitored in various sampling regimes.

RNA concentration was performed by direct flocculation. It was followed by RNA isolation using QIAamp Viral RNA Mini Kit. Quantitative detection of SARS-CoV-2 RNA in wastewater samples was performed using RT-qPCR. The amount of genomic equivalents of viral RNA was compared with numbers of positively tested people connected to the relevant WWTP.

The results, in most cases, showed correlation between these data. The chosen method captured the trends of decrease and increase of all epidemic waves. The method seems to be very promising in systematic monitoring as an early warning tool and in helping to ensure that appropriate measures are taken.

3.18.P-Tu312 Application of Nanofiltration Processes for Removal of Active Pharmaceutical Ingredients in Hospital Wastewater Treatment

***Marten Klatt**[1], Joern Einfeldt[2] and Falk Beyer[2], (1)Environmental Engineering, Hamburg University of Applied Sciences (HAW), Germany, (2)Hamburg University of Applied Sciences (HAW), Germany*

In wastewater treatment, conventional processes are not suited for efficient removal of POPs and emerging pollutants, which can pose a threat to aquatic wildlife and human healthcare. To mitigate their release to the environment, various technologies were investigated in recent years, with a focus on adsorption, oxidation and membrane filtration processes. While nanofiltration

processes are more expensive, they can play a part in closing the loop of the water economy, as nanofiltration processes generate high quality effluent due to complete rejection of pathogens and high rejection of extracellular resistance genes.
To investigate the capability of nanofiltration processes for removal of active pharmaceutical ingredients in hospital wastewater, flat-sheet membranes with different rejection and permeability characteristics are screened with a laboratory-scale membrane filtration unit. This work aims at selecting suitable nanofiltration membranes and provides the basis for further process optimization and pilot-scale studies. Emerging from the interdisciplinary PharmCycle project at the Hamburg University of Applied Sciences, this research work is part of a cooperation project coordinated and financed by HAMBURG WASSER. Accompanied by the Hamburg University of Applied Sciences and the University Medical Center Hamburg-Eppendorf, micropollutant removal efficiencies of various stand-alone and hybrid processes are evaluated for future applications in municipal wastewater treatment.

3.18.P-Tu313 Microplastics removals in two drinking water treatment plants with different treatment technology supplying Barcelona city (Spain)

Nora Exposito Lorenzo[1]*, Lara Dronjak*[2]*, Erika Torres*[3]*, Jordi Sierra*[4]*, Fernando Valero*[5]*, Pere Emiliano*[5]*, Marta Schuhmacher*[1] *and Joaquim Rovira*[6]*, (1)Chemical Engineering, Universitat Rovira i Virgili, Spain, (2)SEKAI CORPORATE TRAVEL S.L.U, Spain, (3)Universitat Rovira i Virgili, Spain, (4)Enginyeria Química, Universitat Rovira i Virgili, Spain, (5)ATL, Spain, (6)Departament Enginyeria Química, Universitat Rovira i Virgili, Spain*
Microplastics (MPs) are frequently ingested by humans, demonstrated by their presence in human faeces in several studies. One of the routes for human MPs consumption is drinking water, thus some studies have reported MPs in bottled water and tap water, however there are no enough studies about the effect of technology of drinking water treatment plant (DWTP) in MPs removal efficiency to provide MPs-free water. The aim of this study was the identification of MPs in large volumes of drinking water derived from two different drinking water technologies in a densely populated region of Spain, as well as the determination of the effect of water conditioning treatment. Sampling included raw water inflow and outflow of different treatment units of both, conventional DWTP and desalination plant (DP). Sampling strategy consisted in a filtration of large volumes of water with an in-line hermetic stainless steel filter holder containing a PTFE filter (10 µm pore size) connected to each treatment unit's representative pipes by 8 to 9 h. Sample treatment consists of oxidation with Fenton's reagent or hydrogen peroxide 35% according high colour and organic matther content. To remove inorganic matter, density separation was applied using zinc chloride (density: 1.8 g/mL). Visual identification was performed with a stereoscopic microscope LEICA MZ10 coupled to FLEXACAM C1 camera and Olympus CX41 optical microscope. All particles detected ≥20 µm were picked up and analyzed by µFTIR on calcium fluoride slides and ATR-FTIR spectroscopic techniques. To avoid the loss of MPs by missing particles recruitment from 20 to 50 µm, filters were washed and filtered on siliceous filters pore size 5–6 µm wide. Both, DWTP and DP, presented high MPs removal effiency set at 98.3 and 92.6%, respectively. Units involving addition of chemical reagents, such as coagulation-floculation-air flotation in DP and remineralization units, presented a decrease of removal efficiency. In the reverse osmosis process, high removal of up to 99.9% was observed. The fibres were predominant in outflow of first treatment units, but fragments were in the last units. Assuming a water consumption per capita of around 1.0 L/day and all tap water are coming from DWTP and DP without extra incorporation of MPs in distribution pipelines system, the annual intake of MPs through tap water was set at 27 and 44 MPs/person/year respectively.

3.18.V One Health Next Generation Wastewater Management and Reuse: The Role of Non-target and Retrospective Analysis, Bioassays, and Wastewater Surveillance

3.18.V-01 Adsorption of Congo Red and Methylene Blue on Zinc Oxide Nano-particles and Zinc Oxide Nano-particle modified Cassia fistula Seed pod

Alimoh Helen Alabi*, University of Ibadan, Nigeria*
Pollution of water bodies by highly carcinogenic and hazardous chemical substances such as dyes which is detrimental to human-health and the environment is now a major concern. Adsorption of dyes by low-cost adsorbents have been reported, but with a few shortcomings. This study therefore aims to use zinc oxide nanoparticles (ZNP) and zinc oxide nanoparticle modified *Cassia Fistula* (ZNPMCF) pods as adsorbents for the removal of Congo Red (CR) and Methylene Blue (MB) from aqueous solution. The ZNP and ZNPMCF was prepared using a simple precipitation method. Fourier Transformed-Infra-Red (FT-IR) was used to determine the functional groups on the adsorbent surface. ZNP and ZNPMCF were used as adsorbents for the removal of CR and MB. The effects of various process parameters i.e., adsorbent dosage, pH, contact time, initial concentration and temperature were investigated for each adsorbent for both CR and MB from aqueous solutions. The adsorption data was fitted using Langmuir, Freundlich, Temkin, Sips and Redlich-Peterson adsorption isotherm. Also, the Pseudo-first order, pseudo-second order and the intra-particle diffusion kinetic models were used to fit the kinetic data.
Both adsorbents demonstrated relative dye removal efficiencies with that of ZNPMCF exerting a higher adsorption for CR. CR was found to adsorb well onto ZNP and ZNPMCF at initial concentrations ranging from 20 to 70 ppm, with 98.87% at high concentration. The Redlich-Peterson model was found suitable for describing the equilibrium data for the removal of CR by ZNP and Temkin model for ZNPMCF, while the Freundlich model was best for fitting the adsorption data of MB by both adsorbents. The pseudo-second order kinetic model was also the best fit for describing the kinetics of adsorption of CR and MB on both adsorbents is the pseudo-second order kinetic model. Intra-particle modelling revealed that intra-particle diffusion does not control the dye sorption process and is not the rate limiting step.
It was concluded that the ZNPMCF is a promising adsorbent that is viable for the removal of CR dye from aqueous solutions.

3.18.V-02 Development of a label-free immunosensor for the detection of HAV in recycled waters

***Asia Grattagliano**, Rocco Cancelliere, and Laura Micheli, University of Rome Tor Vergata, Italy*

The World Resource Institute (WRI) in recent years is alarming us about the water stress we are going through, saying that by 2025, as many as 3.5 billion people could experience water scarcity. To face this problem, ISPRA/ARPA/APPA have proposed guidelines on the reuse of purified wastewater. For many years, the potability of water or the quality of fresh seafood has been determined on the basis of the presence of coliform bacteria or different types of phages, excluding the presence of enteric viruses, as the virus of Hepatitis A (HAV). HAV (and enteric viruses in general) shows greater resistance in the environment, making it necessary to continuously monitor it. Actually, to detect HAV in aqueous media, traditional techniques such as ELISA and PCR techniques are used, but they are cost and time consuming. This work aims to develop an electrochemical sensor for the monitoring of HAV in recycled waste waters. In this regard, screen printed electrodes (SPE) drop casted with multiwalled nanotubes functionalized with carboxylic groups as enhancing material and as anchoring system were used. Upon it was built the immunologic chain through the use of the protein A and the anti-HAV which is able to recognize the HAV. The electrochemical measurements were carried out using voltammetric analysis through the use of a Palmesens4™ portable potentiostat system. The immunosensor allowed to build a calibration curve with LOD equal to 10^{-16} IU/mL and a linearity range between 10^{-16} and 10^{-7} IU/mL, showing an RSD% of 7%. By comparing real sample results between the immunosensing platforms and PCR analysis, an important quantitative discrimination was observed. The immunosensor was able to detect HAV concentrations with higher sensitivity. In conclusion, it was possible to develop an immunosensor for HAV monitoring, able to make the detection in a short time using portable and cheap instruments, which results to be more sensitive compared to PCR technique.

3.18.V-03 Critical Review and Meta-Analysis of Hazardous Pollutants in Treated Wastewater for Environmental Policy of Water Reuse in Sweden

***Uzair Akbar Khan**[1], Karin Wiberg[1], Cecilia Stålsby Lundborg[2], Claudia von Brömssen[3], Lutz Ahrens[1], Foon Yin Lai[1] and Lars Sonesten[1], (1)Department of Aquatic Sciences and Assessment, Swedish University of Agricultural Sciences (SLU), Sweden, (2)Department of Global Public Health, Karolinska Institutet, Sweden, (3)Department of Energy and Technology, Swedish University of Agricultural Sciences (SLU), Sweden*

Treated domestic wastewater is increasingly being considered a useful resource to cope with global water scarcity. However, hazardous pollutants such as metals, organic micropollutants such as pharmaceuticals, and microplastics are not completely removed in conventional municipal wastewater treatment plants and are frequently encountered in treated wastewater. Current reclaimed water quality requirements for agricultural irrigation defined by the European Union do not include these pollutants and can be an important impediment to safe reuse of treated municipal wastewater. Proposed revisions to urban wastewater treatment directive of the European Commission also promote reuse of treated wastewater and include obligation to apply quaternary treatment to urban wastewater. Therefore, it is essential to evaluate occurrence and removal of hazardous pollutants in municipal wastewater treatment plants to develop effective regulatory requirements and monitoring guidelines. The key aim of our work is to enhance the knowledge on the sustainability of wastewater reuse as a resource, focusing on the impacts of hazardous pollutants in the treated wastewaters. To this end, we compiled data and information through a systematic literature search of peer-reviewed scientific articles (by far 1785 articles retrieved through Web of Science and Scopus) as well as grey literature of Sweden (by far 49 documents retrieved through google scholar and DiVA portal). Most relevant studies from the retrieved literature will be selected using abstract screening aided by Rayyan. We will then investigate regional differences in the rate of reuse, hazardous pollutants composition in the wastewater, and key factors that contribute to these differences. A priority list of hazardous pollutants will also be compiled based on their frequency of occurrence and measured concentrations. Our study, focusing primarily on Swedish conditions, could be an example to other countries with similar climate and socio-economic conditions. Our work will also support environmental authorities in the development of future guidelines for compulsory level of treatment, keeping in view the goal of reaching a circular economy.

3.19.P Pet Animals' Exposure to Chemicals and Health Effects of Relevance for Humans - One Health

3.19.P-Mo235 Non-Invasive Sampling to Evaluate Complex Environmental Mixtures in Pet Dogs and the Application in a Bladder Cancer Case-Control Study

***Catherine F Wise**[1], Claire A Wiley[2], Nicholas J Herkert[1], Shelly L Vaden[2], Matthew Breen[2] and Heather M Stapleton[1], (1)Nicholas School of the Environment, Duke University, USA, (2)College of Veterinary Medicine, North Carolina State University, USA*

Pet dogs are considered a good comparative model for many human diseases, especially cancer. Due to their shorter lifespan, dogs have a reduced latency period between environmental exposures and cancer development and can serve as a sentinel species for identification of possible environmental risk factors linked to cancer. We established that people and their pet dogs have very similar environmental exposures by using silicone samplers as passive exposure monitors. Silicone samplers were analyzed for a suite of chemicals across many compound classes, including flame retardants, plasticizers and pesticides. Significant and positive correlations were observed between humans and dogs (r_s=0.38–0.96, p<0.05) for 35 of 45 chemicals measured in ≥50% of all samplers. Urinary biomarkers of organophosphate esters and pesticides were correlated with silicone sampler concentrations; stronger correlations were observed in dogs compared to humans. These data demonstrate that pet dogs can act as surrogates for human exposures in the home environment. In a follow-up study, we used silicone samplers to measure exposure to mixtures in a canine bladder cancer case-control study. Cases were defined as dogs with detectable urinary *BRAF* mutation levels (range 0.29–21%; n = 25). Controls were sex, breed and age matched with no detectable *BRAF* mutation (n = 76). The silicone samplers were analyzed using targeted and untargeted GC-MS approaches. Targeted analyses focused on 115 chemicals, of which 39 were detected in ≥50% of all samples. Higher levels (2–3×) of 4 chemicals were measured in silicone samplers worn by cases compared to controls ($p<0.05$). While 2 more chemicals were higher (1.5×) in samplers worn by cases, this was not statistically significant ($p\leq0.09$). Untargeted analyses revealed a higher burden of environmental chemical exposures experienced by cases, both in the number of chemicals detected and the magnitude of exposures. Of the 1,407 features detected in >50% of samples, 668 were detected more in cases and 505 were detected more in controls. This study is the largest to investigate such a wide breadth of exposures associated with canine bladder cancer, the first to objectively measure exposures and the first to assess a population with subclinical disease. These data combined with the whole exome sequencing data from our cases will allow for advances in gene-environment interactions and translational medicine that may improve clinical outcomes for humans and pets.

3.19.P-Mo236 Contamination status and risk assessment for environmental micro-pollutants in house dust and commercial pet food collected from Japan

***Hazuki Mizukawa**, Ehime University, Japan*

A wide variety of man-made chemicals are used in the indoor environment, including plasticizers, insecticides, flame retardants, paints, pharmaceuticals, and personal care products, etc., and it is feared that indoor chemical exposure is one of the causes of allergic diseases and/or chemical hypersensitivity. It is known that humans spend 85 to 90% of their day indoors, and maintaining a healthy indoor environment is important. In Japan, more than 87% of domesticated dogs and cats are also indoors, and it is estimated that they are constantly exposed to indoor chemical substances in the same way as humans. It has been suggested that environmental chemicals may be a cause of diseases in pet animals, for example, associations between hyperthyroidism and polybrominated diphenyl ethers (PBDEs) in pet cats, and between obesity and bisphenol A exposure in pet dogs have been noted. In this study, quantitative analysis and a risk assessment of household chemicals such as insecticides and fungicides, and screening analysis of 942 environmental micro-pollutants using an automated identification and quantification system with database (AIQS) in house dust and commercial cat food collected from Japan which are important exposure media for pets. As a result, a total of 53 compounds were detected in house dust ($n = 39$), including neonicotinoids, phenylpyrazole, pyrethroid insecticides, triazole fungicides, phthalates, and phosphorus flame retardants. Contaminant profiles in the dust samples seem to be affected by several factors such as region of residence, history of household drug use, and family composition. A total of 26 pesticides were detected in commercial cat foods ($n = 31$), with high detection frequency and concentration of nitenpyram, chlorfenapyr, and difenoconazole. In the risk assessment based on the house dust data hazard quotient (HQ) for children, cats, and kittens exceeded 0.1 for phthalates and phosphates and exceeded 1 for fipronil, indicating considerable children and animal health risks. All the micro-pollutants analyzed in pet dog ($n = 7$) and pet cat ($n = 12$) serum samples were below the detection limit except only in one canine sample. Further studies and continuous monitoring based on simultaneous analysis of various micro-pollutants in dust, air, and food would be needed to clarify potential sources and exposure pathways of contaminants and to improve the indoor environment.

3.19.P-Mo237 Toxic Metals in Hair and Blood of Pet Dogs in Finland

***Sarah Rosendahl**, Karperö, Finland*

Toxic metals are widespread in our environment and pose a health threat to both us and our pets. Pet dogs can be exposed to toxic metals through their living environment, diet, and drinking water, but the research in this area is scarce. The burden of toxic metals can be assessed in numerous ways, for example by measuring concentrations in hair and blood. Hair analysis provides a reading of metal deposition in the cells and interstitial spaces of the hair over a 2–3-month period and has therefore been considered to reflect long-term or chronic exposure, whereas blood analysis indicates current exposure. The correlation between hair and blood has been studied a few times in dogs, but the research is still scarce. In our previous study on 50 healthy pet dogs, we showed that mercury and lead concentrations correlated between hair and blood, and that both diet type (dry food, raw food, or mixed diets) as well as specific food items (wild game, rice) were associated with toxic metal burden. However, the sample size of this study was small considering the number of variables studied. Therefore, as we have now collected more samples, the aim of this work is to repeat our previous investigations on a larger sample population. Thus, the first aim is to study the correlation between toxic metal concentrations in hair and blood, and the second aim is to search for associations between toxic metal burden and diet type or specific food items (e.g., wild game, rice). The concentrations of lead (Pb), mercury (Hg), cadmium (Cd), and arsenic (As) were measured in whole blood ($n = 120$) and hair ($n = 187$) from client-owned pet dogs living in Finland using inductively coupled plasma mass spectrometry (ICP-MS). In addition, aluminum (Al) was assessed in hair. The correlation between hair and blood elements was controlled using Pearson's correlation and the association between diet variables and toxic metal burden was studied using generalized linear mixed models, with the selection of tested variables based on our previous studies in the area.

3.20 PMT/vPvM substances: Assessment, Management and Regulation

3.20.T-01 Are PMOCs Less Toxic? Linking Physicochemical Compound Properties With Measured Toxicity

***Renske P. J. Hoondert**[1], Milo Leon de Baat, PhD[1], Tessa E. Pronk[1] and Thomas L. ter Laak[1,2], (1)KWR Water Research Institute, Netherlands, (2)Ibed, University of Amsterdam, Netherlands*

Persistent and mobile organic chemicals (PMOCs) are gaining attention as a threat to the quality of water resources. Their high mobility (i.e., polarity) and persistence lead to the presence and accumulation of PMOCs in surface water and drinking water sources. Yet, given the only recent attention to this vast group of compounds and the analytical challenges that researchers face, little is known about their toxicity. As a result, despite a growing body of environmental concentration data, risk assessment of PMOCs remains in its infancy. Therefore, the present study aimed to gain insight into the toxicity and toxic mechanisms in relation to the physicochemical properties that determine the persistence and mobility of chemicals in the environment. It was hypothesized that the mobility of PMOCs makes them inherently less toxic than non-polar compounds. To test this, a dataset was compiled matching physicochemical data for 3360 water-relevant compounds with their measured effects in 534 unique toxicity tests from the ToxCast program. Random forest analyses identified the physicochemical properties that relate most strongly to the induced effects and linear regression analyses quantified the strength and direction of these relationships. This indeed showed that compound properties related to polarity, particularly K_{OW} and K_{OC}, are inversely related to effect concentrations, confirming that more polar compounds are, generally, less toxic. The subdivision of the dataset into particular substance groups illustrated that these relationships are more or less pronounced depending on the mode of action of chemicals, providing mechanistic insight into their toxicity. The high polarity of PMOCs may mean that they interact less with tissues, cell membranes, and receptors than their lipophilic counterparts, leading to lower compound toxicity. Although PMOCs appear to be inherently less toxic than more hydrophobic compounds, their diversity and pervasiveness in water cycles warrant further investigations into their potential threat to water quality.

3.20.T-02 Aqueous Leaching of Ultra-Short Chain PFAS from Fluoropolymers: Targeted and Non-targeted Analysis
Shira Joudan[1,2]*, Jeremy Gauthier*[3]*, Scott A. Mabury*[4] *and Cora Young*[5]*, (1)Chemistry, York University, Canada, (2)Chemistry, University of Alberta, Canada, (3)University of Toronto, Canada, (4)Chemistry, University of Toronto, Canada, (5)York University, Canada*
Due to the high persistence, bioaccumulation potential, and toxicity of some PFAS, the entire class is flagged as potentially concerning. Within PFAS, there are polymeric and non-polymeric PFAS, the latter of which are more thoroughly studied. Small molecule PFAS, including perfluoroalkyl carboxylic acids (PFCAs), have been measured from polymeric PFAS including side-chain fluorotelomer polymers and some fluoropolymers, but thus far, fluoropolymers have not been investigated as sources of ultra-short chain PFCAs (C_2-C_4). Fluoropolymers are widely used in laboratory settings and during our research on C_2-C_4 PFCAs, we have observed laboratory materials as sources of contamination. The objective of this work is thus twofold: to identify possible sources of C_2-C_4 PFCA laboratory contamination from fluoropolymers, and to identify additional uncharacterized sources of C_2-C_4 PFCAs to the environment. Fluoropolymer tubing (PTFE, PFA, FEP) and non-fluorinated polymer tubing (PVC, PP, PEEK) were tested by extraction three times into water with sonication. C_2-C_4 PFCAs were quantified using ion chromatography-mass spectrometry (IC-MS) with complementary non-targeted analysis of the leachate using quantitative ^{19}F NMR. FEP tubing had the highest concentration of trifluoroacetic acid, exceeding 100 ng/g, followed by PFA. All tubing materials, including non-fluorinated tubing were sources of trifluoroacetic acid above our blank controls. Perfluoropropanoic acid was highest in the PFA extracts (>10 ng/g), while perfluorobutanoic acid was the highest in PTFE extracts. The heterogeneity of the PFBA measurements from PTFE (3.00–520 ng/g) suggests it may be a residual from a processing aid. NMR results aligned with IC-MS results for C_2-C_4 PFCAs, and also identified longer chain PFCAs, fluorotelomer compounds, and compounds containing aromatic singly-substituted fluorine atoms. The direct and unbiased nature of NMR limits additional instrument-related introduction of PFAS to the sample, strengthening the hypothesis that the PFAS are present as a result of leaching from fluoropolymers. Overall, the polymers tested had different fingerprints of C_2-C_4 PFCAs and other PFAS, which may be related to their synthetic processes such as processing aids, residuals, and inhibitors used. The outcome of this work allows us to better perform trace analysis in the lab and reports previously unidentified sources of these contaminants that are not currently in the global budget.

3.20.T-03 Efficacy of activated carbon filtration and ozonation to remove persistent and mobile substances – a case study in two full-scale wastewater treatment plants
Daniel Zahn[1]*, Isabelle Neuwald*[2]*, Alina H. Seelig*[3]*, Matthias Muschket*[3]*, Thomas P. Knepper*[4] *and Thorsten Reemtsma*[5]*, (1)Analytical Chemistry, Helmholtz Center for Environmental Research (UFZ), Germany, (2)Hochschule Fresenius, Germany, (3)Helmholtz Center for Environmental Research (UFZ), Germany, (4)Institute for Analytical Research, Hochschulen Fresenius gem. Trägergesellschaft mbH, Germany, (5)Department of Analytical Chemistry, Helmholtz Center for Environmental Research (UFZ), Germany*
Persistent and mobile (PM) substances are able to spread quickly in the water cycle and where thus identified as potentially problematic for the environment and water quality. If also toxic (PMT) or very persistent and very mobile (vPvM) their regulation under REACH as substances of very high concern is foreseen. Yet, knowledge on the effectiveness of advanced wastewater treatment in removing PM-substances from WWTP effluents is limited to a few, rather well-known, chemicals. The occurrence, concentrations, and behaviour of 112 suspected and known PM-substances in advanced treatment was investigated. Two full scale wastewater treatment plants employing either powdered activated carbon (PAC) or ozonation with subsequent filtration through sand and granular activated carbon (GAC) were sampled. 73 of the 112 PM-substances analysed were detected at least once in the tertiary effluent of either wastewater treatment plant, resulting in total concentrations of 104 µg/L and 40 µg/L, respectively. While PAC was able to remove 35% of PM-substances by at least 70%, the total PM burden in the effluent was only reduced from 104 µg/L to 87 µg/L, indicating that PAC alone may not be able to reduce the PM burden in municipal wastewater significantly. Ozonation and the subsequent GAC filtration was able to reduce the PM burden in wastewater from 40 µg/L to 13 µg/L, showing a higher removal effectivity than PAC alone in this study, but also facilitating the formation of transformation products. Some PM-substances with high effluent concentrations (> 1 µg/L) could not be removed by either treatment. Among these chemicals were the scarcely studied ionic liquid constituents tetrafluoroborate and hexafluorophosphate.

3.20.T-04 Chemical Stripes – Visualizing Chemical Trends of the Past Influencing Today
Dagny Aurich[1]*, Hans Peter Arp*[2]*, Sarah Elizabeth Hale*[2]*, Kerry Sims, PhD CEnv*[3] *and Emma Schymanski*[4]*, (1)Luxembourg*

Centre for Systems Biomedicine, University of Luxembourg, Luxembourg, (2)Norwegian Geotechnical Institute (NGI), Norway, (3)Chief Scientists Group, Environment Agency (England), United Kingdom, (4)University of Luxembourg, Luxembourg
The number of chemicals threatening global health is rising rapidly, with increasing numbers of persistent compounds accumulating in our environment. There are alarming signals that elimination of existing and prevention of further contamination can no longer be delayed. Communicating this need for action to the scientific and non-scientific community in an understandable way poses a challenge for many researchers.
This work shows the possibility to use *chemical stripes* to help communicate this message, modifying the existing graphics of the *climate stripes* - showing the trend of global warming - and applying it to the chemical space. Specific persistent organic pollutants (POPs) including per- and polyfluoroalkyl substances (PFAS), triazines and triazoles were selected based on their presence in regulatory lists, such as the Stockholm Convention. With the use of patent data for those compounds coming from the World Intellectual Property Organization (WIPO) and the comparison to the rise of overall chemical numbers registered in databases like the Chemical Abstract Service (CAS) registry, a definite trend can be seen: Patent and overall chemical numbers are on the rise and regulations do not stop this trend. Often the drafting, discussion, and adoption of legislation takes decades, even when there is need for quick action.
The minimalistic but intuitive visualization of the *chemical stripes* helps communicate this information by indicating the evolving chemical numbers in traffic-light colours. The chemical and historical data presented, using the model of *stripes,* will be accompanied with open-source code (in progress) for others to generate their own stripes for a given set of chemicals.
The colour scheme raises awareness of the "red" state we face today, with environmental pollution impacting our health and the ecosystems we live in. All substance classes investigated so far revealed the same pattern. Overall, the aim of these graphics is to emphasize the urgent need for elimination and prevention of persistent chemicals by illustrating the exponential growth of patent and chemical numbers over time, in the hope that this will help with the identification and prioritization of harmful substance classes and to help stimulate further action, without decades of delay.

3.20.T-05 Occurrence of PMT and vMvP Substances in Spanish and Portuguese Transnational River Basins and Coastal Water

Rosa Montes[1], Sandra Mendez[2], ***Rosario Rodil[2]****, Nieves Carro[3], Julio Cobas[3], Nélson Alves[4], Teresa Neuparth[4], Miguel M. Santos[4] and José Benito Quintana[2], (1)University of Santiago de Compostela, Spain, (2)Universidade de Santiago de Compostela, Spain, (3)INTECMAR-Technological Institute for the Monitoring of the Marine Environment in Galicia, Portugal, (4)University of Porto, Interdisciplinary Centre of Marine and Environmental Research, Portugal*
There is a huge amount of chemicals included in a wide range of everyday use products with industrial or domestic applications such as pharmaceuticals, surfactants, plasticizers, UV filters, industrial additives, etc. that are still unregulated but may be candidates for future regulation according to their presence and incidence in the environment and their possible harmful effects for health. In this sense, there are several initiatives for the elaboration of pollutants' prioritization lists, based on different criteria, such as persistence (P), mobility (M), and toxicity (T) in the environment. The study of the prioritized substances' occurrence in the water cycle, considering the wastewater treatment plants (WWTP) as direct contamination sources and the surface and sea water as receiving compartments is of great importance to verify the experimental P and M of such substances. This work studied the presence of 52 contaminants of emerging concern (CECs) selected using a prioritization strategy based on P, M, and T criteria and on detection frequency (DF) data from screening studies in 93 samples collected in 2021. The 33 sampling sites included river and marine environments and WWTP located in or near national and transnational river basins and in the coast in Spain and Portugal.
The studied PMT and very mobile and very persistent (vMvP) substances presented a high DF in the national and transnational river basins being the coastal waters the less polluted ones (in terms of number of substances detected, DF and concentration levels). Although the removal efficiency (RE) in WWTP is adequate for most of compounds there are some substances, e.g. the pesticide fipronil or the pharmaceutical sulpiride, with low RE and whose levels remained high in the receiving medium, and even in points of the basin that were further away from the emission sources, endorsing the high M and P of them in the water cycle. In some cases, the concentration levels were higher than the predicted no-effect concentration (PNEC), posing a risk to aquatic organisms.

3.20.P PMT/vPvM substances: Assessment, Management and Regulation

3.20.P-Th231 Exploring Data Availability and Variability for the Classification of Persistent and Mobile Substances

Sivani Baskaran[1]*, Raoul Wolf[1] and Hans Peter Arp[1,2], (1)Norwegian Geotechnical Institute (NGI), Norway, (2)Norwegian University of Science & Technology (NTNU), Norway*
Chemical hazard and risk assessments often use physical-chemical properties to categorize and identify chemicals of concerns. For persistence and mobility, we rely on simulated half-lives in different environmental compartments, organic carbon–water partition ratios (K_{OC}), octanol–water partition ratios (K_{OW}), octanol–water distribution ratios (D_{OW}), and acid dissociation coefficients (pK_a). The use of experimental data in these risk assessments is preferred but often not available. In a previous assessment, 41% of substances in the REACH registry and 36% of substances found in drinking water lacked reliable experimental and estimated property data to determine persistency and mobility. The OECD's eChemPortal allows for the extraction of experimental and estimated physical-chemical property data including those reported in the REACH dossiers. In this work we take a closer look at the availability of experimental data found using the OECD's eChemPortal property search function for the classification of persistent and mobile substances. We use a Bayesian analysis approach to include non-point estimate data,

such as maximum and minimum values, and interval ranges in our analysis. This approach will allow us to determine a consensus experimental value (and its uncertainty) based on all available data.
The project ZeroPM seeks to identify substance groups and substructures that are common in persistent and mobile substances. Thus, building a dataset of reliable physical-chemical property data for persistent and mobile categorization is critical. In this work, we take a closer look at the availability and variability of data in REACH dossiers for the classification of persistent and mobile substances. The data curated in this work will be used to identify substructures and functional groups commonly present in persistent and mobile substances.

3.20.P-Th232 "cleanventory": A Data Science Approach to Identify Persistent and Mobile Substances Regulated in Global Trade Markets
Raoul Wolf[1]*, Sivani Baskaran*[1]*, Emma Schymanski*[2]*, Zhanyun Wang*[3]*, Hans Peter Arp*[1] *and Sarah Elizabeth Hale*[1]*, (1)Norwegian Geotechnical Institute (NGI), Norway, (2)University of Luxembourg, Luxembourg, (3)Swiss Federal Laboratories for Materials Science and Technology (EMPA), Switzerland*
To enable data-driven decision making and to advance the ability to assess, manage, and regulate the use of persistent and mobile substances, a sound overview of the chemical diversity regulated within global trade markets is necessary. As part of the H2020 project ZeroPM (https://zeropm.eu), an open-source global chemical inventory – the "cleanventory" – is being developed to help identify, prioritize, and group persistent and mobile substances. A modern database infrastructure will facilitate wide-spread use of the database: it will be publicly available and will also provide programmatic access.
So far, 33 individual files from 18 inventories in twelve global trade markets are considered. These contain over 960,000 inventory entries with over 215,000 unique CAS Registry Numbers and over 360,000 unique chemical names. While this amount of information could be considered "big data", we put considerable efforts towards the quality of the data, therefore, also ensuring "good data".
Four API services are used to convert inventory identifiers to chemical structures: PubChem, CAS Common Chemistry, NCI/CADD Chemical Identifier Resolver, and ChemSpider. The workflow aggregates the structure information returned by the API services. To identify the "most probable" chemical structure for every inventory entry, a weighted consensus ranking approach was developed to assign each structure an identification score between 0 and 1.
The work on the "cleanventory" is ongoing and new data sources will be incorporated. These include important additions such as chemical substances regulated as pharmaceuticals, pesticides, and food-packaging materials. Workflows to identify "moieties of interest" for prioritization and grouping of persistent and mobile substances are being investigated. Future work will also explore the integration of fully defined chemical mixtures as well as polymers and UVCBs and explore the possibility of automatic integration of curated QSAR model predictions.
This high-quality "cleanventory" will enable effective prioritization and substance grouping strategies to help regulators, industry, and the water treatment sector achieve zero pollution of persistent and mobile substances.

3.20.P-Th233 Current status of the implementation of the new hazard classes PMT and vPvM into CLP and REACH regulation
Michael Neumann*, IV 2.3 Chemicals, German Environment Agency (UBA), Germany*
The European Green Deal (EGD) sets an ambitious zero pollution vision for 2030. The overall objective is to reduce the pollution of air, water, and soil to levels that are not harmful to human health and the environment. In this context the European Commission published on October 14th, 2020, its Chemicals Strategy for Sustainability Towards a Toxic-Free Environment (CSS). The CSS is one important pillar of the Zero-Pollution Ambition for a Toxic Free Environment.
The European Union has one of the most comprehensive and ambitious legislations on chemicals globally. The Regulation on the Registration, Evaluation, Authorisation and Restriction of Chemicals (REACH; COM, 2006) and the Regulation on the Classification, Labelling and Packaging of hazardous substances (CLP) are the two horizontal legislations on chemicals in the European Union.
The European Commission aims to revise the REACH Regulation and to strengthen the CLP regulation as cornerstones of EU chemicals legislation. The “One substance, one assessment” process will ensure simplification and greater transparency of chemical hazard assessment. In 2021 the process started to amend the CLP Regulation to introduce new hazard classes on endocrine disruptors, PBTs/vPvBs and PMTs/vPvMs and apply them across all legislation.
On September 24th, 2021, the Commission proposed new hazard classes and criteria in the CLP Regulation to fully address environmental toxicity, persistency, mobility, and bioaccumulation. Initial discussion took place at ECHA´s PBT expert group. The criteria for PBT/vPvB and PMT/vPvM have been discussed and subsequently commented on in writing by the MS CAs, industry, NGOs, and stakeholders. On September 20, 2022, the European Commission began a public consultation on a draft delegated regulation that would amend the CLP Regulation to add new hazard classes and their criteria e.g. for PMT and vPvM. The Final referral with CARACAL is planned for 29.11.2022 including the reflection of comments within the framework of WTO notification. Adoption is planned for 19.12.2022. The delegation act will then be directed to the European Parliament and Council and the final publication in the Official Journal is planned for March 2023.
We present the current status of the implementation of the PMT/vPvM criteria into CLP and REACH regulation since November 2022. We will also apply the new hazard classes PMT and vPvM to REACH registered substances detected in raw water and drinking water.

3.20.P-Th234 QSARs for abiotic degradation and biodegradation of chemicals in the environment
Trevor N Brown, PhD[1]*, Alessandro Sangion*[1]*, James M Armitage*[2] *and Jon A. Arnot*[1]*, (1)Arnot Research and Consulting (ARC),*

Canada, (2)AES Armitage Environmental Sciences, Canada
Persistent, mobile, and toxic (PMT) chemicals are perceived as an emerging threat to aquatic environments and drinking water quality. Due to their chemical properties and persistence these compounds can be transported from sources of release to groundwater or remote ecosystems and may also have relatively low removal efficiencies during water treatment. Therefore, it is essential to screen and prioritize potential PMT chemicals. Many factors govern the occurrence of a chemical in drinking water, including but not limited to persistence in soil and water (biodegradation, hydrolysis, and photolysis). By developing QSARs for environmental degradation this project will address uncertainty and data gaps in assessing water-soluble chemicals for persistence (P). We will develop databases by aggregating and curating measurements of biodegradation and hydrolysis from the literature. Based on the datasets we will develop new QSAR models for predicting biodegradation and hydrolysis predict half-lives. Most existing biodegradation QSARs are limited to qualitative predictions, or they have narrow applicability domains (AD) making quantitative predictions for specific chemical classes. We aim to expand the biodegradation database and developed QSAR models for quantitative or semi-quantitative estimates of biodegradation half-life with a wide AD. Hydrolysis QSARs in the literature have similar limitations, they are developed from rather limited datasets and focus on specific classes of compounds. To address this issue, we plan to collect and critically evaluate data on hydrolysis and build new comprehensive QSAR models for predicting hydrolysis the half-lives for organic chemicals.

3.20.P-Th235 Towards the Development of an Analytical Framework for the Determination of Persistent and Mobile Chemicals in Human Urine for Further Exploration of Human Exposure

*María Lage-Díaz[1], **Rosario Rodil**[1], José Benito Quintana[1] and Rosa Montes[2], (1)Universidade de Santiago de Compostela, Spain, (2)University of Santiago de Compostela, Spain*
There is a growing interest in the last decade on persistent, mobile, and toxic (PMT) / very persistent and very mobile (vPvM) chemicals (from herein abbreviated as PMs). Their high polarity (i.e., mobility in water) combined with persistence makes it difficult to remove them from the water cycle. Thus, they can constitute a potential harm for the aquatic environment and human health because they can break through natural and anthropogenic barriers into drinking water.
This high polar character also renders PMs hard to determine by conventional analytical methods, mostly relying on reversed-phase (RP) solid-phase extraction (SPE) combined to liquid chromatography-mass spectrometry (LC-MS). Several improvements have been introduced in the last years in the analysis of PMs in water by exploring other sample preparation and chromatographic approaches, such as hydrophilic interaction LC (HILIC), mixed-mode LC (MMLC) and supercritical fluid chromatography (SFC).
Despite those recent advances, there is so far no (comprehensive) knowledge on human exposure to PMs. This can be approached by biomonitoring, e.g., by urine analysis, if analytical methods are available. Therefore, in this work we aimed at moving forward toward the development of an analytical framework and build on former knowledge in water analysis, that could be then used for human urine analysis. To that end, we selected 38 different compounds with polar character (logD at pH 7 from –7.0 to 3.4) and different acid/base/permanent charge characteristics, to be used as model compounds. Then, the retention of these compounds was investigated on a total of 9 different columns from 4 different chromatographic modes (RPLC, MMLC, HILIC, and SFC) with pure standards and in matrix. Among the tested approaches, SFC with a Torus Diol column afforded the best retention and peak shape, while being less affected by matrix effects. On the other hand, we made a preliminary assessment of a generic SPE with large Oasis HLB (500 mg) cartridges as a preconcentration step at different pHs. This method allowed the satisfactory extraction (recoveries >80%) of up to 19 chemicals. Hence, further work is being directed towards a better coverage of PMs by improving this sample preparation step.

3.20.P-Th236 Evaluating the occurrence of and exposure to persistent and mobile chemicals using a comprehensive fate and exposure model PROTEX

***Zhizhen Zhang**[1], Alessandro Sangion[2], Shenghong Wang[1], Trevor N Brown, PhD[2], Jon A. Arnot[2] and Li Li[1], (1)School of Public Health, University of Nevada, Reno, (2)Arnot Research and Consulting (ARC), Canada*
Persistent, mobile, and toxic (PMT) chemicals are perceived as an emerging threat to aquatic environments and drinking water quality because they can penetrate through natural barriers and contaminate riverbank filtrate and groundwater. Different from “legacy” environmental pollutants, which are largely non-ionizable hydrophobic, PMT chemicals are polar or ionizable, with high hydrophilicity. Due to the low removal efficiency during wastewater and drinking water treatment, it is essential to identify potential PMT chemicals and quantify their environmental fate, human and ecological exposures, and potential risks. Environmental fate and exposure models are cost-effective and user-friendly tools to achieve this goal, with one of the examples being the PROduction-To-EXposure (PROTEX) model. In this presentation, we report our efforts to upgrade and evaluate PROTEX to allow for (i) hydrological water balance and compartments (shallow and deep groundwater, representing riverbank filtrate and groundwater, respectively) relevant to chemical exposure through drinking water, (ii) partition behavior of ionizable chemicals in aqueous environments, and (iii) sorption of chemicals onto geosorbents other than natural organic matter, such as minerals and black carbon. For illustrative purposes, we apply the updated PROTEX model to predict concentrations of perfluorooctanoic acid (PFOA) in surface water, riverbank filtrate, and deep groundwater. The result shows that PFOA concentration in surface water is responsive to cessation of emissions, whereas it takes time for PFOA to be transported to and accumulated into shallow and deep groundwater. Such a time-lagging effect highlights the irreversibility of historical contamination of PMT chemicals. By using the updated PROTEX model, one can predict the time-dependent chemical concentration in different environmental compartments. In this case, regulatory efforts can leverage this information to understand the temporal accumulation of PMT chemicals and the irreversibility of historical contamination of PMT chemicals. This work

provides a holistic computational method to predict the environmental fate and human and ecological exposure for PMT chemicals.

3.20.P-Th237 Should we assess the P&M chemicals from a perspective of the "hazard" or "exposure"?

Zhizhen Zhang[1]*, Alessandro Sangion*[2]*, Shenghong Wang*[1]*, Trevor N Brown, PhD*[2]*, Jon A. Arnot*[2] *and Li Li*[1]*, (1)School of Public Health, University of Nevada, USA, (2)Arnot Research and Consulting (ARC), Canada*

Persistent and mobile (P&M) chemicals are considered emerging threats to the environment and drinking water because they can be transported over long distances, penetrate natural and artificial barriers, and resist removal by traditional water treatment procedures. Current chemical regulatory practices define P&M chemicals based on the presence of chemicals in drinking water and the potential for human exposure. However, when screening the myriad of commercial chemicals for mobility, most existing efforts utilize bright-line criteria based on chemicals' intrinsic "hazard" properties, such as biodegradation half-lives for P and organic-carbon-water partition coefficients for M. In this work, we compare and contrast the proposed intrinsic "hazard" criteria with chemicals' concentration in drinking water predicted by a fate and transport model, based on the data of 112,000+ discrete organic chemicals registered in different countries' chemical inventories. We evaluate the consistency of chemicals prioritized by "exposure" potential (chemicals with the highest concentrations in drinking water sources) and those by "hazard" assessment (chemicals with high P&M scores). We find that while chemicals with high P&M scores tend to possess a high potential to contaminate drinking water, P&M are not the only properties related to a chemical's potential to contaminate drinking water. An example is the low potential of volatile chemicals to contaminate drinking water, even if they have high scores in P&M. Thus, screening chemicals based on the P&M hazard indicators alone may, unfortunately, lead to "false positives" and "false negatives". It is therefore inappropriate to evaluate P&M chemicals by using hazard indicators as a proxy. This work addresses the academic and regulatory need for a better understanding of the processes and properties related to drinking water contamination and for developing and evaluating scientifically defensible methods and criteria to identify and potentially regulate chemicals of concern for the safe and sustainable use of chemicals in commerce.

3.20.P-Th238 Tracking vPvM in Urban Waters of Barcelona

Francesc Labad Roig *and Sandra Pérez, Department of Environmental Chemistry, IDAEA-CSIC, Spain*

On October 2022, the European Parliament proposed an amendment to Directive 2006/118/EC, which is the legislation governing groundwater (GW) quality and protection. In the Directive, pesticides were already regulated individually and together. The persistent mobile and toxic (PMTs) and very persistent and very mobile (vPvM) substances do not appear in these regulation lists. These kinds of compounds demonstrate a high frequency of detection in urban waters and specifically in groundwater bodies and they have the potential to cause adverse effects on human and environmental health. As polarity increases, common C18 reversed-phase chromatographic columns are less effective on retention. Thus, polar substances are less retained than hydrophobic compounds, in which other column chemistries are required such as normal phase (HILIC) or ion exchangers. However, the number of studies investigating the toxicity of urban water is still limited compared to studies on the presence of contaminants. Here, urban water (GW and runoff water) from Barcelona city has been analysed using an evaporative enrichment methodology to search for polar organic compounds of a wide range of uses from polar pharmaceuticals to industrial or tire wear substances.

The urban water samples were first filtered under vacuum at 0,7 µm employing glass fiber filters and next, 10 mL of water were enriched using vacuum-assisted evaporation (VAC) using a BÜCHI™ Syncore Plus®. The bath temperature was set to 55°C, 250 rpm orbital rotation, and a vacuum gradient to 20 mbar. Reconstitution was done using 100% H_2O for the C18 column analysis and 95:5 (ACN:H_2O) for HILIC or ion exchange column analysis. For chromatographic purposes, three different chromatographic column chemistries were selected to achieve a good separation (77 compounds with log D <0 analysed). Generally, compounds between log D = 0 to –2 were efficiently separated with the T3 column which for more polar compounds, the HILIC column demonstrated better performance. Finally, for some specific compounds, the very polar and ionic substances, the ion exchange column was selected.

PMTs and vPvM substances must be monitored to obtain high-quality drinking water. As they are challenging compounds, a simple evaporative enrichment showed the most trustworthy approach to preconcentrate these substances and up to three different column chemistries were employed.

3.20.P-Th239 Screening of very persistent and very mobile compounds in groundwater by LC-HRMS

Arianna Bautista[1]*, Maria Björnsdotter, PhD*[2]*, Laura Scheiber*[3]*, Estanislao Pujades*[2]*, Marta Llorca*[2] *and* ***Marinella Farre***[2]*, (1)Institute for Environmental Diagnosis and Water Studies (IDAEA-CSIC), Spain, (2)IDAEA-CSIC, Spain, (3)IDAEA-CISC, Spain*

There is an urgent need to identify very persistent and very mobile (vPvM) substances present in the environment and their sources, to provide a basis for future monitoring, toxicity testing, and potential regulation. For this purpose, two analytical workflows were developed to screen vPvM in groundwater from the aquifer of the Besòs river delta in Barcelona (Spain) included in an in-house developed database.

The first one is based on enrichment by weak anion exchange solid phase extraction (WAX-SPE). In this case, 200mL of filtered water samples at pH 3 were extracted using Oasis®WAX. The chromatographic separation was performed using an Acquity™ Ultra High-Performance Liquid Chromatograph (UHPLC) system from Waters using a mixed-mode liquid chromatography (MMLC) Waters Atlantis Premier BEH C18 AX Column (2.1 mm id, 100 mm length, 2.5 µm particle size) from Waters, using as mobile phase 10 mM ammonium formate in water (A) and methanol (B). The chromatographic system was coupled to a HRMS equipped with a heated electrospray ionisation source HESI-II from Thermo Fisher Scientific working in negative mode.

The second approach consisted of a sample enrichment procedure based on the extraction and purification of 200 mL of filtered samples at pH 4 by weak cation exchange solid phase extraction (WCX-SPE) with Oasis®WCX from Waters followed by analysis using hydrophilic interaction liquid chromatography (HILIC) with a SeQuant®ZIC®-HILIC chromatographic column (2.1mm id, 100 mm length, 3.5µm particle size; Merck KGaA) using as mobile phases 10 mM ammonium acetate in water with 0.1% acetic acid, pH 4 (A) and acetonitrile with 0.1% acetic acid (B). The ionization source was a HESI-II operated in positive conditions.
In both cases, mass spectrometry was fulfilled in a Thermo Scientific QExactive from Thermo Fisher Scientific with an Orbitrap analyser. The full scan data acquisition was in the range of 50-800 m/z at 70,000 full width at half maximum (FWHM) of resolution.
Most of the PMT/vPvM identified in the samples were PFAS with concentrations in groundwater ranging from 0.3 to 11500 ng/L. Short-chain compounds were in general predominant and PFPeA has been detected at higher concentrations. Other compounds that were detected in the samples were methyl 4-hydroxybenzoate, diphenil guanidine, sulfanilic acid, and venlafaxine.

3.20.P-Th240 Appearance in and Removal of PFAS From Tunnel Wash Water

***Hanne Vistnes**[1], Nadine A. Sossalla[1], Gabriela Castro Varela[2] and Thomas Meyn[3], (1)Civil and Environmental Engineering, Norwegian University of Science & Technology (NTNU), Norway, (2)Norwegian University of Science & Technology (NTNU), Norway, (3)Department of Civil and Environmental Engineering, Norwegian University of Science & Technology (NTNU), Norway*

Road tunnels are constructions built under fjords or through mountains to allow traffic to move faster and safer from one place to another. For visibility and traffic safety, tunnels are cleaned regularly. After the wash, the tunnel wash water (TWW) remains as a highly polluted matrix, containing substances, such as trace elements (e.g., Cu, Zn, and Ni), polycyclic aromatic hydrocarbons (PAH), per- and polyfluorinated alkylated substances (PFAS), benzothiazoles (BTH), benzotriazoles (BTR), and their derivatives. Therefore, TWW needs to be treated before released into the municipal sewage system or to natural water bodies.
For two years, a treatment pilot has been operated and monitored to reduce the contaminant load in the TWW from a tunnel located close to Oslo, Norway. The Bjørnegård tunnel with two tubes is 2.3 km long and located in an urban area with an annual average daily traffic (AADT) count of approximately 17.000 vehicles per day in each tube. A sedimentation basin serves as a preliminary treatment step for the TWW for 35 days. This treatment step has been proven efficient for contaminants attached to particles, while the dissolved compounds are still present in the TWW. In this project the sedimented water was further treated with three different treatment steps: a system with two consecutive bag filters (5 and 1 µm mask openings), a ceramic membrane system with a pore size of 0.1 µm, and an adsorption column (220 cm high,95 cm in diameter) filled with granulated activated carbon (GAC).
Grab samples of fresh and sedimented TWW, as well as before and after each secondary treatment step, were collected and analysed by LC-MS/MS to detect the presence and investigate the removal efficiencies of 22 PFAS in both, particulate and dissolved phase. Results show that several compounds from this class of pollutants are present in the TWW. In fresh TWW, the total sum of PFAS compounds (Σ_{22}PFAS) in the particulate phase was 0.14 µg/L, and 1.4 µg/L in the dissolved phase. A 96% removal efficiency was observed for particle bound Σ_{22}PFAS by sedimentation. For the dissolved Σ_{22}PFAS 76% removal efficiency was obtained by sedimentation and the secondary treatment step adsorption with GAC. The results of this study provide insight into the complex matrix that TWW represents and will assist road agencies in making decisions regarding the implementation of TWW treatment systems in new and existing road tunnels.

3.20.P-Th241 Occurrence of PMT/vPvM substances in groundwater of the Czech Republic

***Vit Kodes**[1], Ganna Fedorova[2] and Roman Grabic[2], (1)Czech Hydrometeorological Institute, Czech Republic, (2)University of South Bohemia in Ceske Budejovice, Faculty of Fisheries and Protection of Waters, Czech Republic*

PMT/vPVM substances were monitored in groundwater from 2021 to 2022. Artificial sweeteners saccharine and acesulfame, 1H-benzotriazole and 1,2,4-triazole as substances included in regular groundwater monitoring were analyzed in 1408 samples from 704 monitoring sites. The most frequently found substance was acesulfame (in 258 of 1408 samples), followed by 1,2,4-triazole (in 116 samples) and 1H-benzotriazole (in 93 samples), saccharine occurred just in 9 samples. Acesulfame occurred in concentration above 100 ng L^{-1} in 163 samples, maximum concentration reached 2050 ng L^{-1}. 1,2,4-triazole, 1H-benzotriazole and ccharine occurred in concentrations above 100 ng L^{-1} in 7, 21, and 7 samples, reaching maximum concentration of 404, 12900, and 723 ng L^{-1} respectively. Other 20 substances such as HEPES, Dimethyl 5-sulfoisophthalate sodium salt, Methacrylamido propyl trimethyl ammonium chloride, 3-Allyloxy-2-hydroxypropane sulfonate sodium salt, 4'-Aminoazobenzene-4-sulphonic acid, 4,4′-Diaminodiphenylmethane, 1-Ethyl-3-methylimidazolium ethyl sulfate, Dimethylamino propyl methacrylamide, N,N-Dimethylbenzylamine, 6-Methyl-1,3,5-triazine-2,4-diamine (Acetoguanamine), Benzyltrimethylammonium chloride, Naphthalene-1-sulfonate, Sodium ethylenesulphonate, Sodium methyl sulfate, 2-Methyl-2-propene-1-sulfonic acid sodium salt, 1-Adamantylamine, 2,4-Xylenesulfonic acid, 3,5-Di-tert-butylsalicylic acid, 2-Acrylamido-2-methyl-1-propanesulfonic acid sodium salt, and p-Toluenesulfonic acid were analyzed in 125 samples from 125 monitoring sites in 2021. Of those 9 compounds occurred in groundwater samples, p-Toluenesulfonic acid was found in all 125 samples, 3,5-Di-tert-butylsalicylic acid in 114 samples, Sodium methyl sulfate in 94 samples, 2,4-Xylenesulfonic acid in 92 samples, 1-Ethyl-3-methylimidazolium ethyl sulfate in 35 samples, Naphthalene-1-sulfonate in 31 samples, 1-Adamantylamine in 7 samples, 4,4′-Diaminodiphenylmethane in 4 samples, and Benzyltrimethylammonium chloride in 3 samples. Maximum concentrations of individual substances ranged between 44 ng L^{-1} (Benzyltrimethylammonium chloride) and 8700 ng L^{-1} (p-Toluenesulfonic acid). The other 11 substances were not found.

3.20.P-Th242 Nontarget Analysis of Water by Online Solid-Phase Extraction Coupled to Reversed Phase and Hydrophilic Interaction Liquid Chromatography with High-Resolution Mass Spectrometry Detection

May Britt Rian[1], *Bénilde Bonnefille*[2] *and Jonathan Martin*[2]*, (1)Södra Långgatan 21C, Sweden, (2)Department of Environmental Science, Stockholm University, Sweden*

A wide variety of organic micropollutants have been reported in water resources, e.g., industrial and commercial chemicals, pharmaceuticals, per-and polyfluoroalkyl substances, and pesticides. Many other current-use chemicals have yet to be targeted in routine water analysis, representing unknown risks to ecosystems and human health. Liquid chromatography-high-resolution mass spectrometry (LC-HRMS) based nontarget analysis has already evolved as a powerful approach to characterize micropollutants in waters. However, comprehensive chemical-space coverage is limited by the analytical method's performance for a wide range of analyte physical properties (e.g., polar, non-polar, acids, bases), including extraction recoveries, blank response, chromatographic separation, method sensitivity, choice of MS/MS (i.e. MS^2) acquisition, and mass spectrometric resolution. To allow strategic prioritization of features for identification e.g.,. pollution patterns, or toxicological relevance), a high-throughput workflow collecting abundant data of satisfactory quality is essential. Increasing concern for persistent, mobile and/or toxic compounds, with their potential to accumulate in drinking water sources, have recently shifted the focus towards expanding the analytical coverage to include more polar micropollutants.

To tackle these challenges in nontarget analysis of water, we developed an online-solid phase extraction (SPE)-LC-HRMS workflow. The method requires minimal sample preparation, allowing high throughput and reduction of blank response. To expand the analytical coverage, a variety of column chemistries, i.e., reversed phase, HILIC, and mixed-mode, were assessed to improve online-SPE retention and chromatographic separation of 218 native standards, having predicted log P ranging from –4.6 to 11.2. MS^2 acquisition was optimized by comparing data dependent (top 10 precursors) and data-independent acquisition (5 precursor m/z windows) after data pre-processing and spectral deconvolution in MS-DIAL. Success rate of MS^2 library matching (MS-DIAL; GNPS), and in-silico structural predictions (SIRIUS; MS-Finder) for spiked standards in water matrices of varying complexity were evaluated for both MS^2 acquisition methods. The workflow was applied to groundwater, drinking water, surface water, storm water, and wastewater in Sweden to assess the spatial patterns of target analytes and nontarget features.

3.20.V PMT/vPvM substances: Assessment, Management and Regulation

3.20.V-02 National-scale spatially-explicit health risks associated with persistent mobile and toxic (PMT) chemical exposure via drinking water

Michael John Whelan[1], *Emma Pemberton*[2]*, Chesney Swansborough*[3]*, Christopher Hughes*[4]*, Todd Gouin*[5]*, Simon Cook*[2]*, Emma Goslan*[6]*, Sarah Bull*[7] *and Sarah Fane*[8]*, (1)University of Leicester, United Kingdom, (2)Ricardo Energy & Environment, United Kingdom, (3)The Gemini Building, Ricardo-AEA, United Kingdom, (4)Environmental Chemistry and Toxicology, Ricardo, Harwell, United Kingdom, (5)TG Environmental Research, United Kingdom, (6)Cranfield University, United Kingdom, (7)TARA, United Kingdom, (8)Drinking Water Inspectorate, United Kingdom*

Substances that are persistent, mobile, and toxic (PMT) have a greater propensity to breakthrough standard drinking water treatment processes because of their physico-chemical properties. Here, we present findings from a national-scale spatially-explicit risk assessment of drinking water sources in England and Wales for substances that meet proposed criteria for the hazard class PMT or vPvM. We screened a large number of substances and identified 22 chemicals with PMT/vPvM properties with a high likelihood of release to the environment. The principal exposure route for all substances was assumed to be via wastewater emission to surface waters followed by abstraction. A tiered assessment of exposure was performed with different tonnage tiers. In each case, we assumed consumption of wastewater effluent with and without water treatment. 3D-QSPR modelling was used for estimating the effectiveness for micropollutant removal with ozone- and chlorine-based treatment. Removal in WWTPs was calculated using SimpleTreat v4. The final tier assessment included dilution and riverine transport using spatially-referenced gridded model for the whole of Great Britain which was allowed exposure to be assessed at 296 locations where water is abstracted for drinking water supply. At each tier of the exposure assessment a risk characterisation ratio (RCR) was calculated, assuming that (i) exposure via drinking water only and (ii) only 20% of exposure to the chemical arises from the consumption of drinking water (with additional exposure from unknown sources: RCR_T).

Most substances had a RCR <1 even in the very conservative lower tier screening assessments. Four of the 22 substances were identified as posing potential risks if no treatment were in place but only one substance had RCR_T >1 assuming conventional treatment. For 1,4-dioxane, spatially-referenced model predictions suggest that RCR_T was >1 for 37 abstraction locations (12.5%) under Q_{95} (low flow) conditions, but only when a factor 5 safety factor was used accounting for additional exposure from unknown sources. Risks at these locations should be assessed further via site-specific investigations.

3.21.A Polymer Additives and Their Transformation Products as Chemicals of Emerging Concern: Environmental Emissions, Fate Processes, and Impacts

3.21.A.T-01 Assessing the Effects of Acute and Pulsed Exposures of 6PPDq on Brook trout (Salvelinus fontinalis) Fingerlings and Fry

Danielle A. Philibert[1]*, Ryan Stanton*[2]*, Christine Tang*[3]*, Michael Pirrung*[2] *and Benjamin Patrick de Jourdan*[1]*, (1)Huntsman Marine Science Centre, Canada, (2)University of California, (3)University of California, Davis, USA*

Recent studies on the toxicity of stormwater runoff from urban areas have indicated that *N*-(1,3-dimethylbutyl)-*N*'-phenyl-p-phenylenediamine-quinone (6PPD-quinone) may be responsible for the mass mortality of Coho salmon (*Oncorhynchus kisutch*). Though Coho salmon are the most sensitive species found to date, phylogenetic similarity to Coho salmon is not a good predictor of sensitivity to 6PPDq. The majority of toxicity tests performed so far have been 24-h static exposures to juvenile life stages of each species, the focus being on generating hazard data for a diverse array of fish species. However, due to the kinetics of stormwater runoff, the majority of environmental exposures are more likely to occur as brief pulses, and the effects of these exposures is not well understood. In this study we compared the effects of 24-h 6PPDq exposures to two life stages of brook trout, and the compared our 24-h LC50 values to the mortality data generated using pulsed exposures. Three different exposure designs were used for these studies; a standardized 24-h acute toxicity test for fry and fingerlings, a latent effects exposure where fish were exposed to the same time weighted average concentration (2µg/L for 0.5-h, 1 µg/L for 1-h, 0.32 µg/L for 3-h, and 0.16µg/L for 6-h), and repeat pulsed exposures were fish were exposed to 1µg/L 6PPDq for 0.5-h, moved to clean water for 1-, 3-, or 6-h and then re-exposed for 0.5-h to the same concentration of 6PPDq. Brief exposures for very short durations resulted in higher mortality rates than longer exposure durations. For the repeated 0.5-h pulsed exposures, mortality rate was highest with the shortest gap between pulses (1-h), and there was no notable difference in the mortality rate observed with a 3- and 6-h gap. In our study, brief exposures at higher concentrations resulted in higher mortality rates then longer exposures at lower concentrations, which suggests there may be a threshold exposure concentration after which recovery is no longer possible. The results also highlight how quick 6PPDq uptake is occurring because 0.5-h exposures were long enough to cause 100% mortality, and the delayed onset of mortality that does not start to occur until ~2.5-h post exposure. This study highlights the importance of testing the toxicity of 6PPD-quinone on a range of different life stages of fishes and exposure regimes to better understand the impact of brief exposures that would likely occur in a stormwater runoff event.

3.21.A.T-02 Uptake and transformation kinetics of the tire rubber-derived contaminant 6-PPD and 6-PPD quinone in the zebrafish embryo (*Danio rerio*)

Qiuguo Fu[1]*, Nico Grasse*[2]*, Bettina Seiwert*[2]*, Riccardo Massei, Dr*[2]*, Stefan Scholz*[3] *and Thorsten Reemtsma*[1]*, (1)Department of Analytical Chemistry, Helmholtz Center for Environmental Research (UFZ), Germany, (2)Helmholtz Center for Environmental Research (UFZ), Germany, (3)Chemicals in the Environment Research Section, Helmholtz Center for Environmental Research (UFZ), Germany*

As a widely used antioxidant in tire rubber, N-phenyl-N'-(1,3-dimethylbutyl-p-phenylenediamine (6-PPD) and its toxic metabolite 6-PPD quinone (6-PPDQ) persistently enter surrounding aquatic environments via roadway runoff. 6-PPD and 6-PPDQ showed toxicity toward various aquatic organisms and different fish species showed differential susceptibility to them. In contrast to other fish species (e.g., coho salmon), zebrafish are relatively tolerant to 6-PPD and 6-PPDQ. However, it is unclear whether the tolerance is attributed to the biotransformation of 6-PPD and 6-PPDQ. We hypothesized that 6-PPD and 6-PPDQ undergo biotransformation, leading to their detoxification in zebrafish. To validate our hypothesis, we investigated the uptake and biotransformation of 6-PPD and 6-PPDQ in zebrafish embryos. Both 6-PPD and 6-PPDQ were quickly taken up by the zebrafish embryo and internal concentration reached a maximum after a 6 h-exposure and then decreased. Moreover, we observed extensive phase II conjugations of 6-PPD, 6-PPDQ, and their oxidated transformation products. Predominant conjugates include glutathione, acetylcysteine, and glucuronide, which may contribute to zebrafish's tolerance to 6-PPDQ. Further work is needed to compare the biotransformation in other 6-PPD-sensitive species and determine the contribution of biotransformation to species-specific toxicity.

3.21.A.T-03 Toxicity of 6PPD-quinone to Early-life Stage Rainbow Trout

Catherine Roberts*, Alper James Alcaraz, Evan Kohlman, Niteesh Jain, Natacha S Hogan, Markus Hecker and Markus Brinkmann, Toxicology Centre, University of Saskatchewan, Canada*

Recently, N-(1,3-Dimethylbutyl)-N'-phenyl-p-phenylenediamine-quinone (6PPD-quinone), a rubber- tire derivative that leaches from tire wear particles into roadway runoff, has been identified as a driver of urban runoff mortality syndrome in coho salmon. Sensitivity to this toxicant is highly variable across fish species with potential for ecologically significant effects on relevant species is significant. Rainbow trout (*Oncorhynchus mykiss*) represent a model species which are known to be sensitive to 6PPD-quinone. Given that early life stages of fishes are typically more sensitive than adult, this study aimed to evaluate the toxicity of 6PPD-quinone to early-life stage rainbow trout. Eyed embryos were obtained from Lyndon Hatcheries and alevins were exposed from hatch to time-weighted average (TWA) concentrations of 6PPD-quinone of of 2.35, 1.30, 0.44, 0.20, 0.10, and 0.06 µg/L, as well as a water and solvent (0.01% dimethyl sulfoxide) control in quintruplicates. Fish were kept at 14±0.5°C, on a 16:8-h light: dark period under semi-static conditions, with a 70% water change each day. Alevins were exposed for 28 days, after which they were euthanized in buffered 200 mg/L tricaine mesylate (MS-222), weighed and measured, and samples taken for histological and biochemical analysis. Chronic exposure to 6PPD-quinone resulted in significant mortality at concentrations at and greater than 0.44 µg/L. The 28-day LC50 was 0.56 µg/L and defects occurred in the three highest concentrations, including spinal curvature, yolk sac edema, and notably, pooling blood in the caudal fin. An acute 96-h exposure study was also performed, using five-week post-hatch rainbow trout fry. The 96-h LC50 for five-week post-hatch fry was 0.47 µg/L. From this study, we can conclude that early-life stage rainbow trout alevins are more sensitive than sub-adults, with five-week post-hatch fry exhibiting the greatest sensitivity to acute exposure with 6PPD-quinone.

3.21.A.T-04 Acute Cardiometabolic Responses of Juvenile Salmonids Exposed to 6PPD-Quinone

Summer Selinger[1]*, Alper James Alcaraz*[2]*, David James Montgomery*[1]*, Xiaowen Ji*[1]*, Steve Wiseman*[3]*, Markus Hecker*[2]*, Lynn Weber*[1]*, David M. Janz*[4] *and Markus Brinkmann*[2]*, (1)University of Saskatchewan, Canada, (2)Toxicology Centre, University of Saskatchewan, Canada, (3)University of Lethbridge, Canada, (4)Western College of Veterinary Medicine and Toxicology Centre, University of Saskatchewan, Canada*

N-(1,3-Dimethylbutyl)-N′-phenyl-p-phenylenediamine-quinone (6PPD-quinone) is a transformation product of the most widely used rubber tire antioxidant, 6PPD. Commonly found in road-way runoff, this compound has been reported to cause acute lethality at approximately ≤1 ug/L in a variety of salmonid species including coho salmon, rainbow trout, and brook trout. However, additional studies have shown other salmonid species such as arctic char and bull trout to be insensitive, even at significantly greater concentrations (20 ug/L). Sensitive species show distinctive symptoms including gasping, spiraling, increased ventilation, and loss of equilibrium, suggesting a possible impact on cardiorespiratory physiology. We investigated the acute cardiorespiratory effects of 6PPD-quinone to two salmonids of differing sensitivity: a sensitive species, rainbow trout, and a tolerant species, Arctic char. Fish were exposed to 1 ug/L or 10 ug/L 6PPD-quinone in respirometry chambers for 48 h to assess temporal changes in resting oxygen consumption compared to unexposed controls. Following exposure, cardiac ultrasound was used to characterize cardiac function by analyzing changes in ejection velocity, stroke volume, ventricular and atrial contractile rates, and cardiac output. Furthermore, electrocardiography was used to determine changes in the heart's electrical activity, and blood gas analyses was used to analyze changes in 19 parameters of the blood. Preliminary data show that 6PPD-quinone exposure does not significantly impact oxygen consumption rates in either species. In contrast, exposure appears to cause a significant increase in passive ventricular filling in both Arctic char and rainbow trout. In addition, in just rainbow trout, a decrease in end systolic volume and increase in atrial and ventricular contractile rates were observed, providing evidence of sympathetic stimulation. Cardiorespiratory symptoms observed in rainbow trout exposure might partly be driven by a significant increase in methemoglobin, resulting in an impaired ability to oxygenate the tissues. This is the first study to analyze the toxicity of 6PPD-quinone to the cardiorespiratory system of fishes of commercial, cultural, and ecological importance at environmentally relevant concentrations and provides information invaluable to a better understanding of the mechanism of 6PPD-quinone toxicity.

3.21.A.T-05 Prioritization of consumer plastics for further testing based on artificial weathering combined with bioanalytical and chemical screening

Mara Römerscheid[1], *Stefan Lips*[2], *Lars Michael Hildebrandt*[3], *Mechthild Schmitt-Jansen*[4], *Daniel Pröfrock*[3] *and Annika Jahnke*[1], *(1)Department of Ecological Chemistry, Helmholtz Center for Environmental Research (UFZ), Germany, (2)Deparment of Bioanalytical Ecotoxicology, Helmholtz Center for Environmental Research (UFZ), Germany, (3)Helmholtz Center Hereon, Germany, (4)Department of Bioanalytical Ecotoxicology, Helmholtz Center for Environmental Research (UFZ), Germany*

The ever-increasing plastic pollution poses a threat to the aquatic environment. While the formation of microplastic particles has been extensively investigated, leaching of plastic additives only recently became a major research interest. They account for up to 70% of the polymer and are not chemically bound to the polymer backbone. Plastic additives can leach into the environment where they may be transformed and bioaccumulate. Toxic effects have been reported for plastic leachates, which may be driven by additives from different classes, such as metals, antioxidants, flame retardants, or UV-stabilizers. The project P-LEACH (www.ufz.de/p-leach) systematically addresses the investigation of the leaching of additives from selected consumer products combined with chemical analysis and biological effect screening.

Seven polymer materials from different consumer applications were purchased to investigate the potential impacts of related leachates to the environment. Subsequently the materials were weathered in an artificial weathering wheel. After weathering, the toxicity of the leachates was evaluated by exposing synchronized *S. vacuolatus*. The leachates were screened in a non-targeted approach using a reversed phase HPLC–HRMS-system. For comprehensive analysis, leachates and acid digests of the raw, UV-treated and dark control materials were also screened for 55 metals and metalloids by ICP-MS/MS.

Our study indicates the relevance of leachates in plastic consumer products for phytotoxicity. The compact study design enabled us to rank plastic materials in their potential risk toward freshwater algae. The non-target screening workflow used will help identify additives contributing to the observed toxicity and provide insight into their release characteristics regarding heavy metals and organic constituents. In future experiments it will be possible to compare custom-made polymer materials with known patterns and mass fractions of additives to commercially manufactured consumer products.

3.21.B Polymer Additives and Their Transformation Products as Chemicals of Emerging Concern: Environmental Emissions, Fate Processes, and Impacts

3.21.B.T-01 Improved Kinetic and Mechanistic Understanding of Atmospheric Chemical Transformations of Polymer Additives Through Laboratory Studies

John Liggio[1], *Amandeep Saini*[1], *Tom Harner*[1], *Xianming Zhang*[2], *Cassandra Johannessen*[3] *and Chao Peng*[1], *(1)Environment and Climate Change Canada, Canada, (2)Chemistry and Biochemistry, Concordia University, Canada, (3)Chemistry, Trent University, Canada*

Vehicle tires are a complex mixture of chemicals that are generally added to the rubber to increase their durability and stability. Tire wear related chemicals are expected to be emitted to the atmosphere through mechanical processes, particularly in a near road environment as $PM_{2.5}$ and PM_{10}. Such tire wear particles (TWP), contain a wide array of organic contaminants such as microplastics, benzothiols, polycyclic aromatic hydrocarbons, and amines, some of which have been implicated as having toxic environmental impacts. While there is significant literature on the fate and toxicity of these particles (and chemicals therein) in aquatic environments and surface waters, there is limited knowledge about their fate and toxicity as a result of exposure to the atmosphere. An important class of tire wear chemicals are the substituted phenylamines, which are frequently used as anti-oxidants during the manufacturing of tires, and contain multiple phenyl groups and secondary amine functionality. Recent studies have indicated the presence of such a molecules (6-PPD in particular and its oxidation products) in surface waters impacted by highway and road runoff. However, 6-PPD and the subsequent detected quinone product (6-PPDQ) represents a single parent – transformation product pair, out of the dozens of antioxidants used, and potentially hundreds of transformation products formed.

In addition, the transformation chemistry expected to occur in the atmosphere (especially in a near road environment) will be rather different than what is likely to occur within surface water, and yet little is known about the atmospheric chemical reactions and fate of these antioxidants. In our study, a series of laboratory experiments are performed using atmospherically relevant conditions and real-time instrumentation to investigate the kinetics associated with heterogeneous oxidation of 6-PPD and DPPD in air and to derive atmospherically relevant chemical transformation mechanisms leading to a range of previously unidentified oxidation products. The results indicate that both OH radical and ozone reactions are important oxidation pathways, with >40 different products formed, including both aromatic ring retaining and ring opening products of diverse functionality. Of particular importance is the formation of highly toxic nitrosamines and nitramines which form in the presence of NOx. The atmospheric oxidation of tire wear antioxidants found to be rapid and possibly as important as other aquatic oxidation mechanisms, leading to different and potentially toxic species. The atmospheric oxidation products observed warrant further scrutiny with respect to their inherent toxicity and their prevalence in atmospheric and/or aquatic samples from the ambient environment.

3.21.B.T-02 Plant Uptake and Metabolism of Tire-derived Compounds

Anya Sherman[1]*, Stephanie Castan*[2]*, Thorsten Huffer*[1] *and Thilo Hofmann*[1]*, (1)University of Vienna, Austria, (2)EDGE-Environmental Geoscience, University of Vienna, Austria*

Tire wear particles are expected to reach agricultural fields via biosolids application, atmospheric deposition, or irrigation with recycled water. In the field, tire wear particles will release a suite of organic additives in the root zone of plants. These compounds are then available for uptake by edible plants, which could be a route for human exposure to tire-derived compounds, as has been previously shown for pharmaceuticals and personal care products. In this study, we exposed lettuce plants to tire-derived compounds and tire particles and monitored the concentration of five common tire-derived compounds: hexamethoxymethylmelamine (HMMM), benzothiazole (BTZ), 1,3-diphenylguanidine (DPG), N-phenyl-N'-(1,3-dimethylbutyl)-p-phenylenediamine (6PPD), and 6PPD-quinone (6PPD-q) in lettuce roots and leaves. We found that all five compounds were taken up and translocated to lettuce leaves. Translocation was compound dependent and was hindered by differential affinity of compounds to lettuce root tissues. This affinity was driven by varying $\log K_{ow}$ and charge of the compounds. All five tire-derived compounds were metabolized in lettuce plants, and we used untargeted high resolution mass spectrometry to identify the transformation products. We found that the five compounds were transfomred via various metabolic procceses within the plants. We identified novel transformation products of several compounds, including HMMM and 6PPD-q. We also found that for all compounds, except 6PPD, the transformation products formed were highly stable in the lettuce leaves. In our second set of experiments, when we exposed lettuce to tire particles, the long-term leaching of tire-derived compounds from the particles provided a resupply of these compounds and was able to overcompensate for the rate of metabolism in plants, leading to continuously increasing concentrations of the tire-derived compounds in the lettuce leaves over the duration of the experiments. Altogether, our findings indicate that if plants are exposed to tire wear particles during growth, the compounds contained in the tire wear particles may be taken up by plants, and these compounds and their transformation products may be present in the edible parts of the plants up through the time of consumption. This work highlights an important potential route of human exposure to tire-derived compounds.

3.21.B.T-03 Products and Reaction Pathways of the Multiphase OH Radical Oxidation of 2-Ethylhexyl Phthalate in Pure Films and Indoor Dust

William D. Fahy *and Jonathan P. D. Abbatt, Chemistry, University of Toronto, Canada*

Today, many people spend most of their time indoors where they have the potential to be exposed to emissions of chemical contaminants from consumer products. While many of these primary emission sources are relatively well-understood, all indoor contaminants have the potential to react over time, whether in the gas phase or the condensed phase where most hydrophobic organic contaminants are likely to be found. One of the most universal oxidizing agents is the OH radical, which is present at low but relevant concentrations indoors and which has been shown to heterogeneously react with organic compounds over timescales of weeks to months. However, the products of multiphase OH radical oxidation of organic contaminants are not well-understood. We have shown that thin films of di(2-ethylhexyl) phthalate (DEHP), a common contaminant with significant human toxicity, heterogeneously react with OH radicals to produce more than 10 unique condensed-phase products identified using liquid chromatography coupled to a high-resolution mass spectrometer (LC-HRMS). Many of the observed products have multiple structural isomers and some have been shown to be more potent toxicants than the parent compound. These products exist in indoor dust, and we observe additional product formation following further OH oxidation of a standard reference material dust sample containing high concentrations of DEHP. Product semi-quantification is accomplished using a nonlinear regressor between predicted chemical descriptors and normalized MS signal response trained on a standard curve of a mixture of compounds with similar structural features, and tentative structural assignments are made based on a weight-of-evidence approach using exact mass analysis, retention time calibration, and existing knowledge of OH radical reaction mechanisms. This study is the first to characterize the complex mixture of transformation products resulting from multiphase OH oxidation of indoor contaminants, expanding the range of anthropogenically-derived organic compounds humans are likely exposed to indoors. Little is known about the toxicological properties of most of the transformation products observed, indicating that future work examining the effects of exposure to indoor heterogeneous transformation products on human health is critical to understanding the health effects of human xenobiotic exposure in the indoor environment.

3.21.B.T-04 Formation potential and in-vitro toxicity of chlorinated disinfection by-products of the polymer additive 1,3-diphenylguanidine (DPG)

Mauricius Marques dos Santos[1]*, Camille Cheriaux*[2]*, JIA Shenglan*[3]*, Mikael Thomas*[4]*, Hervé Gallard*[4]*, Jean-Philippe Croué*[4]*,*

Pascal Carato[4] and Shane Allen Snyder[5], (1)Nanyang Environment & Water Research Institute (NEWRI), Nanyang Technological University, NEWRI, Singapore, (2)Université de Poitiers, Laboratoire Ecologie & Biologie des Interactions, France, (3)Nanyang Technological University, NEWRI, Singapore, (4)Université de Poitiers, Institut de Chimie des Milieux et des Matériaux de Poitiers, France, (5)Nanyang Environmental & Water Research Institute, Singapore, Singapore
1,3-diphenylguanidine (DPG) is a commonly used rubber and polymer additive, that has been found to be one of the main leachate products of tire wear particles and from HDPE pipes, with recent estimates putting the yearly usage of DPG at up to 10,000 metric tons in Europe alone. Its introduction to aquatic environments and potentially water supplies lead to further questions regarding the effects of disinfection by-products potentially formed. We present a comprehensive study of the potential toxic and genotoxic effects of chlorinated by-products of DPG; as well as their potential formation under conditions like those found during water treatment disinfection processes and within water distribution networks. Using different bioassay approaches and NGS RNA-sequencing, we show that some of the chlorinated by-products of DPG exert significant toxicity. DPG and its chlorinated by-products also can alter cell bioenergetic processes, affecting cellular basal respiration rates and ATP production, moreover, DPG and two of its chlorination products, 1,3-bis-(4-chlorophenyl)guanidine and 1-(4-chlorophenyl)-3-(2,4-dichlorophenyl)guanidine, have an impact on mitochondrial proton leak, which is an indicator of mitochondria damage. Evidence of genotoxic effects in the form of DNA double strand breaks (DSBs) was suggested by RNA-sequencing results and further validated by an increased expression of genes associated with DNA damage response (DDR), specifically the canonical non-homologous end joining (c-NHEJ) pathway. Immunofluorescence analysis of phosphorylated histone H2AX, another DSB biomarker, also confirmed the potential genotoxic effects observed for the chlorinated products. In addition, chlorination of DPG leads to the formation of different chlorinated products, with the 5 analyzed compounds in this work representing up to 42% of formed products. These findings indicate that DPG reaction with free chlorine doses commonly applied during drinking water treatment or in water distribution networks (0.2–0.5 mg/L) can lead to the formation of toxic and genotoxic chlorinated products. While the potentially genotoxic 1,3-bis-(4-chlorophenyl)guanidine product is formed at lower concentrations than less toxic products (1,3-bis-(2-chlorophenyl)guanidine and 1-(2,4-dichlorophenyl)-3-phenylguanidine) it could still pose a threat to human and environmental health.

3.21.B.T-05 Are Wastewater Treatment Plants an Effective Barrier Against Tire Leachables?-Biotransformation and Screening Experiment

***Kathrin Müller**[1], Alicia Hartmann[2], Daniel Zahn[2], Thomas P. Knepper[3] and Stephan Wagner[2], (1)Institute for Analytical Research, Hochschule Fresenius, Germany, (2)Hochschule Fresenius, Germany, (3)Institute for Analytical Research, Hochschulen Fresenius gem. Trägergesellschaft mbH, Germany*
Tire and road wear particle act as source for a variety of organic and inorganic contaminants that can be released into the aquatic environment. Yet, only few so-called tire leachables are known as systematic studies of tire leachables and their environmental fate are scarce. A potential entrance and distribution pathway of tire leachables into the aquatic environment are combined sewer systems with wastewater treatment plants (WWTPs). To investigate the relevance of WWTPs as entrance pathway for tire leachables their biotransformation was investigated with tire leachates of new and used tires and with eleven standards of known tire leachables (N-tert-butyl-2-benzothiazolesulfenamide, N-cyclohexyl-2-benzothiazolesulfenamide, dibenzylamine, 1,3-dicyclohexylurea, 1,3-diphenylguanidine, 1,3-diphenylurea, 2-hydroxybenzothiazole, 4-hydroxydiphenylamine, 2-mercaptobenzothiazole, 6-PPD-quinone, tributylamine). The biotransformation experiment was carried out over 28 days in the dark and under aerobic conditions. Sample aliquots were taken regularly and analysed with RPLC-ESI-QTOF MS. Eventually, WWTP samples were retrospective evaluated to validate the results generated by the laboratory experiments.
The majority of investigated tire leachables was found to be primary transformed and 63 transformation products (TPs) were tentatively identified. For each TP the precursor assignment and structure elucidation were attempted but has proven problematic due to the complexity of the tire leachates. For the TPs of the standards the assignment was more feasible and noteworthy are 13 identified TPs for 2-mercaptobenzothiazole and two identified 6-PPD-quinone TPs. For most assigned TPs, structures could be identified, which corresponded mainly to the methylated, hydroxylated, or oxidised precursors.
The comparison of the laboratory experiment with full scale WWTPs showed a general compliance of the results. However, a transformation of up to 100 % for some of tire leachables as seen in the laboratory experiment could not be observed in the sampled WWTPs but only a partial decrease. This is attributed to the lag phase of several tire leachables of up to 11 days. Hence, WWTPs represent a possible entry pathway and contribute to the distribution of tire leachables and their TPs in the aquatic environment. Based on these results extensive monitoring studies are required to allow a risk assessment of the different tire leachables and their newly identified TPs.

3.21.C Polymer Additives and Their Transformation Products as Chemicals of Emerging Concern: Environmental Emissions, Fate Processes, and Impacts

3.21.C.T-01 Tire-derived Compounds in the Atmospheric Environment

***Cassandra Johannessen**[1], Amandeep Saini[2], Tom Harner[2] and Xianming Zhang[1], (1)Chemistry and Biochemistry, Concordia University, Canada, (2)Environment and Climate Change Canada, Canada*
Investigations of environmental tire contamination have mostly been limited to aquatic systems, and there are few studies pertaining to gaseous and particulate-sorbed contaminants that originate from tire wear in the atmospheric environment. In this study, to acquire an understanding of the current state of atmospheric tire contamination, a variety of air samples from across the globe were monitored for tire pollution. Using ultra-pressure liquid chromatography coupled with high-resolution mass spectrometry, archived passive air sampler extracts, air filter samples, and organic film samples were analyzed using both targeted

and non-targeted methods. First, to better understand the global ubiquity of this form of air pollution, samples from major cities across the globe, under the Global Atmospheric Passive Sampling (GAPS) Network (GAPS-Megacities) initiative, were analyzed and screened for tire-compounds of emerging concern. Secondly, to study the contamination trend of tire-derived chemicals on a regional scale, temporally-resolved samples from various source sectors, including roadside, urban, industrial, and residential areas in the Greater Toronto Area, ON, Canada were also investigated. Air sample filters deployed near high-traffic sites in Toronto were also screened to determine environmental levels of emerging transformation products of concern of common tire chemicals. Finally, to further investigate air exposures of tire-derived chemicals in urban settings, organic film samples were acquired by wiping impervious surfaces in areas exposed to high rubber tire use (Montreal, QC, Canada). For comparison, organic film samples were also acquired from locations that are more isolated from this pollution source (Montreal, QC and Toronto, ON, Canada). This study presents some of the first data for airborne concentrations of chemicals associated with tire-wear that can be used for modeling and exposure assessments. Due to the presence of many tire-derived contaminants in urban air across the globe, and the current lack of toxicity data for these chemicals, this study highlights the need for human health considerations pertaining to tire-derived chemicals.

3.21.C.T-02 Spatial and temporal trends for regulated plasticizers and their emerging substitutes in biota and non-biota samples from German rivers

Regine Nagorka[1]*, Tomasz Goral*[2] *and Jan Koschorreck*[2]*, (1)Water and Soil, German Environment Agency (UBA), Germany, (2)German Environment Agency (UBA), Germany*

The objective of the new European Chemicals Strategy is effective protection of citizens and the environment by sustainable chemicals management. Restrictions of hazardous substances in manufacture, use or placing on the market are already instruments of risk management. However, are existing measures sufficiently sustainable? Plasticizers are high production volume chemicals used as main additives in the manufacture of flexible PVC. Due to their endocrine effects, the former dominant plasticizer Di(2-ethylhexyl) phthalate (DEHP) and some short-chain phthalates were banned in the EU. As a result, their concentrations have declined significantly in suspended particulate matter (SPM) from freshwater environments and DEHP is now mainly replaced by Di(2-propylheptyl) phthalate (DPHP) and by non-phthalates. DPHP has a high structural similarity to DEHP and its further marketing is under regulatory scrutiny as it has been flagged as a potential endocrine disruptor (REACH CoRAP). Until now, data are missing on the presence of DPHP and other substitutes in freshwater biota.
We analyzed zebra mussels *Dreissena polymorpha* and quagga mussels *Dreissena bugensis* for the presence of 16 plasticizers, i.e., 12 phthalates and 4 non-phthalates. The samples were retrieved from the German Environmental Specimen Bank (ESB) between the early 2000s and 2020 and covered sampling sites from major rivers, including Rhine, Elbe, and Danube.
In agreement with the SPM investigations, current mussel samples from all ten river sites in Germany showed DEHP substitutes. Our results indicate a fast appearance of DPHP as the main replacement plasticizer and of non-phthalates in both freshwater biota and SPM. Today, the high molecular weight phthalates Diisononyl phthalate (DINP) and Diisodecyl phthalate (DIDP) were the most abundant plasticizers detected in mussel samples from the rivers Rhine, Saar, and Danube. These results confirmed our spatial and temporal study in SPM. However, contrary to the SPM study and despite the strict EU regulations, DEHP has not dropped in general and was the dominant plasticizer in current mussel samples at the most sites from river Elbe (up to 80% of the total plasticizer load). Comparing both mussel species, *D. bugensis* showed higher concentrations of DEHP and its substitutes than *D. polymorpha*. These findings clearly highlight the need for better linking of environmental monitoring data with chemical legislation.

3.21.C.T-03 New Alternative Plasticizers in Foodstuffs: Occurrence, Migration from Packaging and Exposure Through Diet

Julio Fernández-Arribas*, Teresa Moreno, and Ethel Eljarrat, Spanish Research Council (CSIC), Institute of Environmental Assessment and Water Research (IDAEA), Spain*

Plasticizers and flame retardants represent 47% of total additives in plastic products. Nowadays, phthalates have been replaced by other substances apparently less harmful, such as citric acid esters, and adipates. Acetyl tributyl citrate (ATBC) is a plasticizer commonly employed as phthalate substitute in food-contact materials, cosmetics, toys, or medical devices. Some studies described cytotoxicity and gene activation effects on organisms exposed to this compound. Di(2-ethylhexyl) adipate (DEHA) is frequently used in flexible PVC films. Both compounds are easily migrated from food packaging materials, which is another route of exposure.
The main objective of our study is to assess the exposure to alternative plasticizers through foodstuffs ingestion. Eighty-eight samples from different groups of foodstuffs (baby foods, cereals and legumes, chocolate, condiments, dairy products, eggs, fish, fruit and vegetables, meat, and oils) were selected. Four alternative plasticizers (ATBC, DEHA, diisononyl adipate (DINA) and 1,2-cyclohexanedicarboxylic acid 1,2-diisononyl ester (DINCH)), nine phthalates and twenty organophosphate esters were included in the instrumental LC-MS/MS method. In addition, migration tests were carried out with different packed food (vegetables, purée, potato omelette, and meat), to determine contamination of chemicals from plastic food contact materials (FCMs) used for microwave and conventional oven heating (roasting bags, microwavable plastic trays and microwave oven bags).
Results showed the presence of new alternative plasticizers in human diet, which is an outcome of plastic pollution. ATBC was the compound with the highest concentration in sweeteners (14.2 mg/g wet wt), followed by DEHA in serrano ham (10.6 mg/g wet wt), ATBC in fish baby food (3.38 mg/g wet wt) and meat baby food (3.35 mg/g wet wt), and DEHA in semi-cured cheese (3.30 mg/g wet wt) and fresh salmon (2.95 mg/g wet wt). Infants and toddlers were the most vulnerable population groups to plastic additives exposure. New plasticizers had higher presence than traditional phthalates. Moreover, migration from FCMs of

ATBC phthalate substitute increased with cooking. Hence, it is required to carry out more toxicity assessment studies of these new additives in humans, and the environmental consequences of their use. Overall, detection of chemicals associated to plastic pollution in foodstuffs may contribute to develop a restrictive legislation in the use of plastics for food packaging.

3.21.C.T-04 Chemicals Present in Plastics Pose a Risk to Health, Environment, and the Transition to a Circular Economy

***Helene Wiesinger*[1]**, *Zhanyun Wang*[2], *Christophe Bleuler*[3], *Roxane Pasquettaz*[3], *Philippe Favreau*[3], *Anna Shalin*[1,4], *Lu Meng*[1], *Armin Siegrist*[1], *Nils Plinke*[1] *and Stefanie Hellweg*[1], *(1)ETH Zürich, Switzerland, (2)Swiss Federal Laboratories for Materials Science and Technology (EMPA), Switzerland, (3)Service de l'air, du bruit et des rayonnements non ionisants - SABRA, Switzerland, (4)University of Toronto, Canada*

Plastics are widely used materials employed in various industrial sectors. They can contain various chemical substances, including residual monomers, additives, processing aids, and non-intentionally added substances (NIAS), which can be released and negatively impact human and environmental health and the circular economy. Information on the presence and concentration of individual substances in specific plastics products is scarce and scattered. In this study, we aim to fill this gap by systematically reviewing recent measurement studies and conducting a case-study on polyvinyl chloride (PVC) building materials in Switzerland. More than 3000 substances have been detected in different products in recent literature, however, approximately 75% of these substances were only found in non-targeted workflows, targeted workflows, and quantification efforts focused on few typically well-regulated substances (e.g., metals, brominated flame retardants, phthalates). Our PVC building materials' case-study also focused on these well-regulated substances (i.e., metals, phthalates); surprisingly, many of the new samples still contained toxic heavy metals (mainly lead), restricted phthalates (mainly bis(2-ethylhexyl) phthalate [DEHP]) or alternative phthalates (mainly diisononyl phthalate [DiNP]). The increased presence of lead and DEHP in products made from recycled material points to phased-out hazardous substances being retained in the economy by recycling. Overall, non-targeted studies show that many more substances than regularly measured in targeted analysis may be present in plastic products. At the same time, even when focusing solely on well-known and regulated substances, many new products on the market still contain them and thus can pose a risk to human health, the environment, and the transition to a circular economy, as shown in our case study of building materials. Given the immense workload needed for large-scale measurement campaigns, even the best efforts by the monitoring community will not be sufficient to comprehensively understand the presence and levels of chemicals present in specific plastic products to guide the safe use and recycling of such products. Therefore, concerted action is urgently needed to ensure transparency of chemicals in plastics.

3.21.C.T-05 Toxicological and Chemical Evaluation of Leaching Substances from Conventional and Bioplastics - A Holistic Approach

***Moritz Kielmann*[1]**, *Silja Denise Kroeger*[2] *and Gesine Witt*[3], *(1)Environmental Engineering, Hamburg University of Applied Sciences (HAW), Germany, (2)Hamburg University of Applied Sciences (HAW), Germany, (3)Environmental Technology, Hamburg University of Applied Sciences (HAW), Germany*

Global production of plastics is increasing yearly. This trend is of environmental concern because hazardous chemicals can be released from plastic products. Polymers are not considered to be toxically hazardous because they are inert and their transport through biological membranes is limited. The release of additives, non-polymerized monomers, by-products and the formation of destruction and transformation products is of high environmental concern because these substances can provoke toxic effects. The aim of this study was to investigate toxicity of conventional and biodegradable plastics by acute and chronic testing with *Daphnia magna* in addition to chemical analyzation of toxic substances. Two fishing lures based on soft polyvinyl chloride (PVC) and four biodegradable plastic compounds were ecotoxicologically investigated.

Leachates of fishing lures and bioplastic compounds were prepared with ISO water. The acute and chronic test with *D. magna* was performed according to OECD Guidelines 202 and 211, respectively. The test was conducted using dilutions from the leachate stock solutions to determine EC50 values for comparison purposes. The stock solutions were extracted by liquid-liquid extraction and analyzed by GC-MS. Hydrophobic organic substances such as PAHs, bisphenol A, and phthalates were quantitatively determined. Qualitative screening for non-target substances was also performed.

Leaching of contaminants from plastics has shown strong effects in acute tests of fishing lures and chronic tests of bioplastics. Chemical analysis indicated correlations between the leached chemicals and the toxic effects of the plastics. A holistic approach that includes both ecotoxicology and chemical analysis is needed to understand how and why plastic compounds provoke effects. The identification of toxic substances is necessary mainly because additives do not have to be labeled and bioplastics can be as toxic as conventional plastics.

3.21.P Polymer Additives and Their Transformation Products as Chemicals of Emerging Concern: Environmental Emissions, Fate Processes, and Impacts

3.21.P-Tu314 Acute Toxicity of 6PPD-quinone Across Fishes of Commercial, Cultural, and Ecological Importance

***Markus Hecker*[1]**, *Hannah Mahoney*[2], *David James Montgomery*[2], *Summer Selinger*[2], *Francisco da Silva*[3], *Justin Miller*[4], *Eric Stock*[4], *Alper James Alcaraz*[1], *Jonathan Karl Challis*[5], *Neil Mochnacz*[6], *Andrew Chapelsky*[6], *Lynn Weber*[2], *David M. Janz*[7], *Steve Wiseman*[4] *and Markus Brinkmann*[1], *(1)Toxicology Centre, University of Saskatchewan, Canada, (2)University of Saskatchewan, Canada, (3)Toxicology, University of Saskatchewan, Canada, (4)University of Lethbridge, Canada, (5)Lethbridge Research and Development Centre, Agriculture and Agri-Food Canada, Canada, (6)Department of Fisheries and Oceans Canada, Canada, (7)Western College of Veterinary Medicine and Toxicology Centre, University of Saskatchewan, Canada*

N-(1,3-dimethylbutyl)-N′-phenyl-p-phenylenediamine-quinone (6PPD-quinone), a transformation product of the rubber tire antioxidant 6PPD, has been shown to be acutely toxic to coho salmon with a median lethal concentration (LC50) of 0.095 µg/L. Interestingly, subsequent studies have failed to confirm comparable sensitivity in a few other select fish species including chum salmon, medaka and zebrafish. This study aimed to assess the acute toxicity of 6PPD-quinone to seven fishes of commercial, cultural, and ecological importance in North America, rainbow trout, brook trout, westslope cutthroat trout, brown trout, bull trout, Arctic char, and white sturgeon. Furthermore, in vitro experiments with rainbow trout liver and gill cells were conducted to characterize the potential of 6PPD-quinone to affect mitochondrial respiration, which has been hypothesized as a possible mechanism of toxic action. This study revealed dramatic differences in the acute toxicity of the rubber-tire transformation product 6PPD-quinone across the tested fishes that may have significant implications for ecological risk assessment of urban runoff events. No mortality occurred for Arctic char, brown trout, bull trout, westslope cutthroat trout, and white sturgeon, while brook and rainbow trout were sensitive to 6PPD-quinone exposure with LC50 values of 0.59 and 1.00 mg/L, respectively. Even species from the same genus showed vastly different responses (*O. mykiss* vs *O. keta*; *S. alpinus* vs. *S. fontinalis*). Initial experiments with primary cultures of rainbow trout gill cells suggest that the mechanism of toxicity may be related to uncoupling the mitochondrial electron transport chain. Further research is needed to characterize the mechanism driving the dramatic differences in sensitivity of fishes to 6PPD-quinone.

3.21.P-Tu315 Mutagenicity In Vitro and In Vivo of 6PPD Quinone, a Rubber Tire Oxidant By-Product
Marina Tenório Botelho[1], *Gabriely Groto Militão*[1], *Amanda dos Santos*[1], *Markus Brinkmann*[2] *and Gisela Umbuzeiro*[1], *(1)School of Technology – State University of Campinas, Brazil, (2)Toxicology Centre, University of Saskatchewan, Canada*
N-(1,3-Dimethylbutyl)-N′-phenyl-p-phenylenediamine-quinone (6PPD quinone) is a transformation product of the tire rubber antioxidant 6PPD. 6PPD quinone reaches the aquatic environment by stormwater and urban runoff and was recently associated with high mortality of salmon. There is still limited information about the toxicity of 6PPD quinone in different aquatic species; but it is clear that among the species analyzed they range from extreme sensitive to no effect. The objective of this study was to determine the acute toxicity of 6PPD quinone in the marine amphipod *Parhyale hawaiensis* and verify its mutagenicity in vitro (Salmonella/microsome assay - Microplate agar) and in vivo (micronuclei in *P. hawaiensis*). 6PPD quinone was dissolved in DMSO at the limit of solubility (5000mg/L). Acute toxicity of *P. hawaiensis* neonates (<7 days old) was evaluated in 5 concentrations ranging from 31.25 to 500µg/L. For the in vitro mutagenicity assessment, 6PPD quinone was tested in concentration-response experiments from 0.125 to 100mg/L. Five strains of Salmonella/microsome assay (YG1041, TA100, TA98, TA102, and TA1535) were used with and without metabolic activation (rat liver S9, 5%). For the in vivo assessment, *P. hawaiensis* adults (<8 months old) were exposed to two concentrations of 6PPD quinone (250 and 500µg/L) and the hemolymph was collected to evaluate the micronuclei frequency in the hemocytes. No acute toxicity was observed in *P. hawaiensis*. 6PPD quinone showed mutagenic effect only in TA100 in the presence of S9, indicating that it requires metabolic activation. With 5% S9, a weak increase in the number of revertants/well was observed starting from 6.25mg/L in the two independent experiments, and with 10% S9 the increase started at 12.5mg/L. An increase in the micronuclei frequency in the hemocytes of *P. hawaiensis* was observed after exposure to both concentrations of 6PPD quinone compared to the negative control. We conclude that 6PPD quinone was weakly mutagenic in the in vitro test and induced micronuclei in *P. hawaiensis*. This mutagenic activity could be a concern for the less sensitive species. Because DNA damage in the reproductive cells can be easier correlated to populational level adverse effects, our next step will be to verify if this compound is able to damage DNA (comet assay) in the sperm cells of *P. hawaiensis*.

3.21.P-Tu316 Potential Toxicokinetic Mechanism for 6PPD-Quinone Toxicity: Cross-Species Biotransformation and Metabolite Identification
David James Montgomery[1], *Xiaowen Ji*[1], *Alper James Alcaraz*[2], *Danielle A. Philibert*[3], *Garrett Foster*[4], *Matthew Schultz*[2], *Summer Selinger*[1], *Jenifer McIntyre*[5], *Benjamin Patrick de Jourdan*[3], *Steve Wiseman*[6], *Markus Hecker*[2] *and* ***Markus Brinkmann***[2], *(1)University of Saskatchewan, Canada, (2)Toxicology Centre, University of Saskatchewan, Canada, (3)Huntsman Marine Science Centre, Canada, (4)Washington State University Puyallup Research & Extension Center, USA (5)Washington State University, USA (6)University of Lethbridge, Canada*
N-(1,3-Dimethylbutyl)-N'-Phenyl-P-Phenylenediamine-Quinone (6PPD-Q) is an abiotic transformation product of N-(1,3-Dimethylbutyl)-N'-Phenyl-P-Phenylenediamine (6PPD) found in rubber tires. Tire wear particles accumulate on roads and are washed into waterbodies via runoff resulting in maximum 6PPD-Q concentrations of 1.4 µg/L along the South Saskatchewan River. This is concerning because acute toxicity (< 96 h) to select salmonids occurs at 0.095 µg/L. There are considerable differences to interspecific responses without explanation. However, the proposed toxicity mechanism appears well-conserved across species. This study utilized ex situ isolated liver perfusion assays, in conjunction with in vivo bile samples to quantify the extent of 6PPD-Q biotransformation and qualitatively determine respective metabolites among fish species.
In vivo exposure of coho salmon, brook trout, rainbow trout, Atlantic salmon, westslope cutthroat trout, white sturgeon, and Artic char yielded bile samples for initial screening level non-target analysis, followed by targeted analysis of suspected biliary metabolites, using liquid chromatography and high-resolution mass spectrometry. Ex situ rainbow trout liver perfusions were used to quantitatively determine the extent and rate of hepatic biotransformation in the presence and absence of an active transport inhibitor, cyclosporine A (CSA).
Results from the sensitive trout ex situ assays include negligible differences to average hepatic clearance values between control and CSA groups and a high average extraction fraction (> 0.70). These findings indicate a negligible contribution of active transport to hepatic clearance and the presence of rapid biotransformation of 6PPD-Q.
Analytical chemistry of bile samples collected from acutely exposed fishes provided strong evidence for the presence of both hydroxy-6PPD-Q and 6PPD-Q-*O*-glucuronide metabolites. In vivo bile samples generated cross-species semi-quantitative data

depicting relative quantities of each metabolite suggesting 6PPD-Q is detoxified sufficiently by tolerant fishes but insufficiently by sensitive fishes.
Ex situ results from one sensitive species in conjunction with biliary compounds across species strongly suggests detoxification of 6PPD-Q via phase I hydroxylation as the primary toxicokinetic mechanism for interspecific differences to sensitivities. This insight will help provide future direction to the risk assessment of 6PPD-Q.

3.21.P-Tu317 Searching for Transformation Products of 6PPD that are Toxic to the Aquatic Larvae of the Mayfly, *Neocloeon triangulifer*
Viviane Yargeau[1]*, Marco Pineda*[2]*, Daniel Furlong*[3]*, David J. Soucek*[4]*, Rebecca Dorman*[4]*, Jeff A. Steevens*[4]*, Erin Bennett*[5] *and Chris D. Metcalfe*[5]*, (1)McGill University, Canada, (2)Chemical Engineering, McGill University, Canada, (3)Department of Chemical Engineering, McGill University, Canada, (4)US Geological Survey, USA (5)School of the Environment, Trent University, Canada*
The substituted phenylamine compound, N-(1,3-dimethylbutyl)-N′-phenyl-p-phenylenediamine (6-PPD) is added to tire rubber as an antioxidant. Recent studies have shown that an oxidation product of 6-PPD, namely 6-PPD-quinone (6-PPDQ) is extremely toxic to Coho Salmon, Brook Trout, and Rainbow Trout, but this compound is less toxic to several other fish species and does not cause mortalities in toxicity tests with the invertebrates, *Daphnia magna* and *Hyalella azteca*. Our toxicity studies with aquatic larvae of the mayfly, *Neocloeon triangulifer* confirmed that 6-PPDQ is not acutely toxic to this insect larvae at concentrations up to its limit of solubility. However, 6-PPD is very unstable in solution and several transformation products in addition to 6-PPDQ are formed by the degradation of this compound. In our 96-h acute toxicity tests conducted with *N. triangulifer* at µg/L nominal concentrations of 6-PPD, the test solution caused mortalities. Targeted analysis of several transformation products of 6-PPD indicated that another transformation product, 4-HDPA was present in the test solution at high concentrations. In tests with 4-HDPA at nominal concentrations between 100 to 800 µg/L, there were mortalities of mayfly larvae of between 30 to 50% but the responses did not closely match predictions based on the 6PPD test. More work is required, but it is possible that a transformation product of 4-HDPA may be causing toxicity. Our subsequent analyses of the test solutions using non-targeted analysis by liquid chromatography with high-resolution mass spectrometry (LC-HRMS) indicate that there are candidate transformation products that could contribute to toxicity to the mayfly larvae.

3.21.P-Tu318 Evaluating the Transcriptomic Points of Departure in Early-life stage Rainbow Trout Exposed to 6PPD-quinone
Catherine Roberts*, Alper James Alcaraz, Evan Kohlman, Niteesh Jain, Natacha S Hogan, Markus Hecker and Markus Brinkmann, Toxicology Centre, University of Saskatchewan, Canada*
The rubber tire derivative N-(1,3-Dimethylbutyl)-N'-phenyl-p-phenylenediamine-quinone (6PPD-quinone) found in roadway runoff has recently been implicated as a driver of urban runoff mortality syndrome in coho salmon. Further studies have indicated a highly variable species sensitivity distribution. While classical exposures are integral to determining initial species sensitivity, transcriptomic analysis can provide a broader picture of potential gene expression and biological pathway disruption, as well as providing transcriptomic points of departure (tPODs). An early-life stage toxicity test was conducted on rainbow trout (*Oncorhynchus mykiss*) alevins, beginning at hatch. Treatment groups consisted of a water control, solvent control (0.01% dimethyl sulfoxide), and time-weighted average 6PPD-quinone concentrations of 2.35, 1.30, 0.44, 0.20, 0.10, and 0.06 µg/L. Whole-body alevins were sampled after 96 h of exposure and flash-frozen for transcriptomic analysis. Three individuals were pooled from each replicate, across five replicates per treatment group. RNA was extracted using QIAGEN RNeasy Universal Mini Kits, with a minimum 100ng/µL in 25µL per sample, analyzed by Genome Québec. Analysis using FastBMD will focus on pathway BMDs, and cross-species comparisons.

3.21.P-Tu319 Chemicals Leaching from Rubber Microplastics are the Key Drivers of Toxicity Towards Early Life Stages of Atlantic Cod (*Gadus morhua*)
Lisbet Sorensen[1]*, Stefania Piarulli*[1]*, Andy Booth*[2]*, Laura Amat Martinez*[3]*,* ***Julia Farkas***[1]*, Augustine Arukwe*[4]*, Amaia Igartua*[1]*, Clementine Zammite*[5]*, Maren Christensen*[4]*, Martin Haraldsvik*[4]*, Mari Creese*[1]*, Alessio Gomiero*[6]*, Tania Gomes*[7] *and Bjørn Henrik Hansen*[1]*, (1)SINTEF, Norway, (2)Climate and Environment, SINTEF, Norway, (3)University of Barcelona, Spain, (4)Norwegian University of Science & Technology (NTNU), Norway, (5)University of Limoges, France, (6)NORCE AS, Norway, (7)Norwegian Institute for Water Research (NIVA), Norway*
Methods to accurately assess the toxicity of chemicals in plastics are needed. Importantly, there is a lack of studies successfully deconvoluting particle and leached chemical effects on organisms. A recent investigation by our group indicated elastomer chemicals are more potent than common thermoplastic chemicals in acute toxicity tests. The toxicity of car tire rubber (CTR) leachates and chemicals to marine species have recently been demonstrated in a range of studies, but other rubbers have been less studied. We present a comprehensive study of chemicals leaching from rubber MPs, (rMPs) and their toxicity to cod (*Gadus morhua*) embryos. This study aimed to unravel the role of CTR (rMP model material) as a pollutant particle and as a carrier of chemicals, and thus distinguish between the effects derived from rMPs from those resulting from associated chemicals.
To study the influence of experimental parameters on leachate composition, leachates of dishwashing (DG) and lab gloves (LG), balloons (BAL), and CTR were prepared and the effect of particle loading, size, water temperature, salinity and turbulence, as well as leaching time, on the chemical composition of the resulting leachate, were investigated. Early life stages of Atlantic cod (*Gadus morhua*) were used to study the effects of leachates, particles and a combination of the two. First, CTR, DG, BAL leachates were compared in terms of toxicity. Second, we compared 1) CTR particles pre-leached for 30 days to allow desorption of associated chemicals, 2) chemicals leached from the CTR over 7 days, and 3) pristine CTR particles (pCTR) not subjected to

pre-treatment, thus including all associated chemicals. Both experiments were conducted with 4-day exposures, followed by a recovery period of ~11 days. Endpoints included mortality, hatching, developmental alterations, and gene expression.
DG and CTR exposure led to lower hatching success and increased mortality compared to BAL leachates, which did not cause any significant effect. Embryonic development was impacted by exposure to CTR, resulting in smaller larvae at hatch. Leachate and pCTR exposures led to significantly lower hatching success and increased mortality compared to pre-leached particles. Larvae exposed to pCTR showed a smaller eye diameter and an increased yolk/body fraction. Only leachates affected eye-to-front distance in a dose-dependent way. Larvae exposed to leachates and pCTR also showed significant reduction in myotome length.

3.21.P-Tu320 Identification and Quantification of Tire Wear Particles and Associated Compounds in UK Marine and Freshwater Habitats.
***Henry Ebele Obanya**[1], Nick Molden[2], Fay Couceiro[1] and Alex Ford[1], (1)University of Portsmouth, United Kingdom, (2)Emissions Analytics, United Kingdom*
The report that shows the toxicity of 6PPD-quinone (6PPD-q), a by-product of a tire manufacturing additive, to coho salmon (*Oncorhynchus kisutch*) has made the discussion of the impact of tire wear particles in aquatic ecosystems a growing environmental concern. Little is known about the specific environmental presence of the particles and associated compounds, but progress has been made with regards to detection. This study seeks to analyse for Tire Wear Particles and some target compounds, 6PPD-quinone (6PPD-q), 1,3-diphenylguanidine (DPG) and 2-mercaptobenzothiazole (MBT) in surface water and sediment samples which were originally collected from River Hamble and Langstone harbour (S. England, UK). Samples were collected in close proximity to major multi-lane highway storm water discharge zones to determine if these compounds were present in stormwater-influenced flows. These particles and target compounds will be analyzed using GC X GC–TOF–MS method. The concentrations of 6PPD-quinone will be compared with the acute LC50 for coho salmon (0.8−1.2 μg L^{-1}). Levels of 6PPD-q, DPG and 2-MBT will be determined as well as their limits of quantification in all extracts. Particles will be compared with a reference data base of tire, brake, and road material. This study will contribute to the growing literature indicating that potentially toxic tire-wear particles and compounds are present at elevated levels and are transported via road runoff into urban surface waters during rain events.

3.21.P-Tu321 Antioxidants in the European Environment: A Hidden Hazard for Biota?
***Romana Hornek-Gausterer**, Anna-Lena Grabher, Helene Walch and Dennis Worgull, Environment Agency Austria, Austria*
It is assumed that the number of cars worldwide will almost double in the next 30 years: 1.3 billion in 2020 to 2.5 billion in 2050. Tire and road wear particles (TRWP) are formed by mechanical abrasion during road contact. Thus, roads and traffic serve as a major source of land-based microplastic particle pollution.
Tires contain antioxidants that prevent the ageing of rubber by oxygen and ozone. Para-substituted phenylenediamines (PPDs e.g., 6PPD, 7PPD, IPPD, 77PD) are commonly employed for this purpose at concentrations up to 1 to 2%. PPDs are registered in Europe between 1 and 100,000 t / year; the highest registered tonnage in Europe is 6PPD with 10.000 to 100.000 t / year. A CLH dossier for harmonized classification on 6PPD is currently under development.
A recent study identified a transformation product from tires, 6PPD-quinone, which is highly toxic to juvenile silver salmon (24-h-LC50 = 0.095 µg/L). It is responsible for the mass mortality syndrome observed in rivers after heavy rainfall in the USA and Canada. Not only silver salmon are affected, but also species that occur in Europe, such as rainbow trout and brown trout. Some of the substances have a potential to accumulate in organisms, which is proven for 8PPD, for others more research is needed. In general, too little is known about the fate and behavior of TRWP and PPDs including their transformation products.
Our laboratories have developed a method for the determination of various PPDs and the transformation product 6PPD-quinone. Consequently, Austrian surface waters, road run-offs, influents from wastewater treatment plants and freshwater fish were investigated. In none of the 12 investigated surface waters were PPDs were detected. In surface run-off following substances were found: IPPD, 6PPD and 6PPD-quinone. In some influents, 6PPD-quinone was found in concentrations higher than the LC50-value for salmon. In one of ten pooled fish samples, 6PPD was above the limit of detection.
In Austria, the amount of TRWP according to calculations is approximately 20,000 tons per year. More research on the occurrence and distribution of TRWP and PPDs including their transformation products in the environment is necessary to set measures for hot spots and to mitigate potential risks for aquatic organisms.

3.21.P-Tu322 Leaching of Metals and Organic Compounds from Tires Over Time – Exploring the Effects of Road Pollution Sedimentation Treatment for Tire Leachates
***Elisabeth Støhle Rødland**, Tania Gomes and Muhammad Umar, Norwegian Institute for Water Research (NIVA), Norway*
Road pollution have been studied for decades due to the release of particles and pollutants from road maintenance, vehicles, tires, brakes, and the road surface. Some of the most important road-related pollutants are metals such as zinc, copper, nickel, inorganic minerals, road salts, and organic compounds such polycyclic aromatic hydrocarbons, benzothiazoles, and phthalates. Recent studies have also identified new organic compounds linked to toxic effects in organisms, such as 6-PPD-quinone (N-(1,3-dimethylbutyl)-N′-phenyl-pphenylenediamine, 6-PPD), HMMM (hexa(methoxymethyl)melamine), and DPG (N,N′-Diphenylguanidine). Several have investigated the toxicity of these compounds in different organisms, as well as identified and quantified their levels in different environmental compartments. This study is comprised of three parts where we investigate the leachate level at different times over 21 days (Day 0, 3, 7, 14, and 21). In part 1 we investigated the level of zinc, copper, and nickel and a range of organic compounds (including benzothiazoles, 6-PPDs, HMMM, DPG) in leachates from three car tires (winter studded, winter non-studded, summer) and one truck tire (winter non-studded) at relevant concentrations for tunnel wash water (35 mg/L) in a lab experiment at room temperature. In part 2 we collected samples in a sedimentation treatment basin for

tunnel wash water, where water is treated for 21 days before being released into the environment. These samples will be analyzed similarly to the leachates in part 1. In part 3, the toxicity of the leachates from the different car tires will be assessed using the marine microalgae *Skeletonema pseudocostatum*, focusing on growth inhibition and photosynthetic capacity. Because we only have results for the metals in part 1 so far, the results described are preliminary and will be updated before the conference. For the metals in part 1, the highest levels were found for zinc (4.8–202 µg/L). The levels between different tire types were also significant, and the highest levels coming from truck tires (111 ± 73 µg/L). The levels for zinc showed a statistically significant increased with time, with highest levels found at Day 21. For nickel (0.10–1.48 µg/L) and copper (0.20–2.62 µg/L), the levels decreased over time, with the highest levels found at Day 0. More statistical analysis will be performed on these data when all analyses are finished.

3.21.P-Tu323 Biofilms Can Accumulate and Transform Tire-derived Compounds in Urban Rivers

***Anya Sherman**, Thorsten Huffer and Thilo Hofmann, University of Vienna, Austria*

Organic compounds leach from tire wear particles and enter urban rivers around the world at concentrations in the µg L^{-1} range. N-(1,3-Dimethylbutyl)-N'-phenyl-p-phenylenediamine-quinone (6PPD-q) is acutely toxic to several salmonid species at environmental concentrations, and 1’3’-diphenylguanidine (DPG) and benzothiazole (BTZ) also demonstrate toxicity to aquatic organisms. Understanding the environmental fate of tire-derived compounds in urban rivers is crucial. Biofilms are important for the environmental dynamics and fate of organic compounds. Their complex structure, negative charge, and hydrophobic nature allow for sorption of many organic compounds, and their unique microbial communities can biotransform these compounds. We hypothesized that biofilms might accumulate and transform tire-derived compounds in urban rivers. To test this hypothesis, we selected two points where a small urban stream in Vienna receives untreated road runoff and grew biofilms directly upstream and downstream of each point. We brought the mature biofilms to the lab, where we exposed them to N-(1,3-Dimethylbutyl)-N'-phenyl-p-phenylenediamine (6PPD), 6PPD-q, hexamethoxymethylmelamine (HMMM), DPG, 2-hydroxybenzothiazole (OH-BTZ), and 5-Methyl-1H-benzotriazole (BTR) for 48 h. We monitored all compounds using high-resolution mass spectrometry. Compounds were depleted from the aqueous phase, and taken up into biofilms. Neutral compounds accumulated in biofilms in accordance with their $\log K_{ow}$ (6PPD-q >> OH-BTZ>HMMM>BTR). The accumulation of these compounds varied between biofilms, likely due to varying biofilm organic carbon content. Positively charged compounds (DPG and 6PPD) showed generally higher accumulation than the neutral compounds, and accumulation was less biofilm dependent. All compounds accumulated more in biofilms grown downstream of road runoff points, suggesting active uptake in biofilms with previous exposure to tire-derived compounds. Upstream biofilms accumulated tire-derived compounds continuously throughout our experiments, while in downstream biofilms, concentrations increased then decreased, suggesting that downstream biofilms transformed tire-derived compounds, while upstream biofilms did not. The transformation rates varied between the different compounds and biofilms but correlated well with the maximum accumulated concentration. Our data suggests that biofilms accumulate tire-derived compounds and can evolve capacities to transform them.

3.21.P-Tu324 Aquatic Ecotoxicity of Safe and Sustainable by Design Organophosphate Flame Retardants

***Bianca Stadelmann**[1,2], Hannah Flerlage[1], Chris Slootweg[1] and Michiel Kraak[3], (1)Van 't Hoff Institute for Molecular Sciences, University of Amsterdam, Netherlands, (2)University of Amsterdam, Netherlands, (3)University of Amsterdam, Institute for Biodiversity and Ecosystem Dynamics, Netherlands*

Organophosphate flame retardants (OPFRs), common polymer additives, were introduced as replacements for polybrominated diphenyl ethers following concerns about environmental and human health effects. However, today OPFRs have established themselves as notorious environmental contaminants. Two widely used OPFRs, tris(2-chloroethyl) phosphate (TCEP) and tris(3-chloropropyl) phosphate (TCPP) are frequently detected in a range of environmental matrices, especially fresh water. Both compounds are classified as very persistent and exert toxicity to aquatic organisms.

To mitigate these adverse effects from the very start of the chemical’s life cycle, TCEP and TCPP have been structurally redesigned as a case study of putting the Safe and Sustainable by Design concept into practice. The alternative design is based on a computer-aided framework developed in-house. The aim of the redesign was to retain the flame-retardant properties of the compounds but minimize adverse environmental effects, taking persistent, bioaccumulative, mobile, and toxic properties into consideration. A multicriterial analysis of millions of structures similar to the original chemicals generated in silico, yielded a set of structures predicted to be the most benign, informing our design of structural alternatives for TCEP and TCPP.

To assess the environmental safety of the newly designed compounds, as well as the viability of the computer-aided design approach, the two alternative chemicals were synthesized and together with the original compounds, subjected to a series of aquatic ecotoxicity tests. To gain possible clues about the relationship between ecotoxicological effects and structural trends of OPFRs, we also tested the structural intermediates tris(ethyl) phosphate and tris(propyl) phosphate, which are themselves used as polymer additives. This poster will present the acute and chronic effects of this set of structurally related OPFRs on three aquatic model organisms: algae, daphnids, and chironomids, which are determined following OECD test guidelines. Based on predictions employed during the alternative compound design (USEPA EpiSuite Ecosar), it is expected that in both acute and chronic tests, the proposed alternative compounds are less toxic to all test organisms. The findings of this study will support the Safe and Sustainable by Design concept and precautionary approach including extensive testing of additive chemicals to prevent adverse effects on aquatic ecosystems.

3.21.P-Tu325 Property Estimations of Organophosphate Ester Transformation Products: Interpreting Environmental Fate with Chemical Space Plots

*Cassandra Johannessen[1], **J. Mark Parnis**[2] and Eric Wootton[3], (1)Chemistry, Trent University, Canada, (2)Trent University,*

Canada, (3)Department of Biology, McGill University, Canada
TCPP (Tris (2-chloroisopropyl) phosphate) and EHDP (2-ethylhexyl diphenyl phosphate) are two highly dominate organophosphate ester flame retardants (OPFRs) in air. Numerous transformation products (TPs), produced by heterogenous atmospheric oxidation, have been identified for both TCPP and EHDP. However, there is limited understanding of the partitioning tendencies of these compounds. The primary objectives of this study were to predict physico-chemical partitioning properties of these two model OPFRs and gain a preliminary understanding of how the environmental fate of both chlorinated and non-chlorinated airborne OPFRs are altered on heterogenous transformation. However, commercial standards of the TPs are not available, so it became necessary to estimate their physico-chemical properties using computational software. As a result, a secondary objective arose, which was to compare two common property prediction methods, BIOVIA COSMOtherm and the OPEn structure-activity/property Relationship App (OPERA), in terms of their impact on environmental fate assessments for the two suites of OPFR transformation products. OPERA is a popular estimation tool based on quantitative structure–activity/property relationships (QSAR/QSPR), whereas COSMOtherm utilizes quantum mechanisms to calculate the chemical potential of chemicals in solvated environments to calculate macroscopic properties. Using interpretative Chemical Space Plots (CSPs) created with a newly developed RShiny App, it became apparent that heterogeneous oxidation has a significant impact on the partitioning behaviour of the various oxidation products. There is a general decrease in log K_{AW} with increasing extent of oxidation, leading to a lowering in vapour pressure and increased distribution to aqueous (TCCP) and lipid-rich (EHDP) media. In addition, the agreement between the two computational prediction methods is shown to be best for chemicals that are within the applicability domain of OPERA and are reported by OPERA with high confidence, giving credence to COSMOtherm as a property estimation tool for OPFRs.

3.21.P-Tu326 Toxicity of DEHP related to cellular damages and sex-steroid hormone depletion in vitro
Tomas Jambor[1]*, Lucia Zuscikova*[2]*, Hana Greifova*[2]*, Nikola Knizatova*[2]*, Anton Kovacik*[2] *and Norbert Lukac*[2]*, (1)Institute of Applied Biology, Slovak University of Agriculture in Nitra, Slovakia, (2)Institute of Applied Biology, Slovak University of Agriculture in Nitra, Faculty of Biotechnology and Food Sciences, Slovakia*
Numerous reproductive issues such as poor semen quality, lower epididymal weight, or increasing incidence of testicular cancer have been related to daily exposure to phthalates. di-(2-ethylhexyl) phthalate (DEHP) is widely used in many industrial applications and is easily released from these products into foods or beverages, which may directly affect human health. Therefore, it is important to identify the exact molecular mechanisms of action and determined the cellular aberrations that could be responsible for decreased reproductive capacity of males. The present in vitro study was undertaken to examine the direct effect of DEHP´s treatment on mice Leydig cell line. TM3 cells were cultured and treated with different concentrations (0.05–1 M) of DEHP for 48-h. To determine cell viability and cell membrane integrity, the tetrazolium assay (MTT) and, 5-carboxyfluorescein diacetate, acetoxymethyl ester assay (CFDA-AM) were used. In addition, sex-steroid hormone level fluctuation was quantified by enzyme-linked immunosorbent assay (ELISA). The obtained data clearly demonstrated a dose-dependent effect after the respective treatment. Lower experimental doses of up to 0.25 M of DEHP did not significantly affect cell viability and membrane integrity. Overall, rising experimental doses significantly ($p<0.0001$) inhibited presented parameters after 48-h exposure. Furthermore, analyses of sex-steroid hormone secretion revealed, that increased experimental doses (starting from 0.15 M) significantly ($p<0.001$, $p<0.01$, and $p<0.05$) reduced the testosterone production in TM3 mice Leydig cells. Taken together, the results of our in vitro study reported that higher experimental doses of DEHP could affect cell viability and cell membrane integrity. In addition, experimental concentrations higher than 0.15 M could inhibit steroidogenesis, resulting in a decreased level of testosterone in vitro. A more detailed and systematic research in DEHP toxicology is required for a better understanding of reproductive health risks.

3.21.P-Tu327 Leaching and Degradation Kinetics of Legacy and Emerging Plasticisers in Contrasting Soils
Alex Billings[1]*, Kevin C Jones*[2]*, M. Gloria Pereira*[1] *and David J Spurgeon*[1]*, (1)UK Centre for Ecology & Hydrology (UKCEH), United Kingdom, (2)Lancaster University, United Kingdom*
Plasticisers are a widely used class of organic additives designed to increase the flexibility of plastic products. Historically, phthalates have been the most commonly used class of plasticiser, although concerns surrounding the endocrine disrupting properties of some commonly used phthalates have led to increasingly stringent legislation surrounding their production and use in the USA and Europe. This has coincided with an increase in market share of so-called "emerging plasticisers" such as terephthalates, citrates, and adipates.
Although the persistence of phthalates in soils has been fairly well-studied in the laboratory (e.g., common phthalates appear to have half-lives on the scale of weeks to months), the persistence of emerging plasticisers in soils is essentially unstudied (or at least unreported) in scientific literature. This has potential implications for the accumulation of emerging plasticisers in soils and terrestrial biota. In addition, the factors affecting the rate at which plasticisers can leach from microplastics directly into soils represents a further knowledge gap which should be addressed if the impacts of plastic waste on the terrestrial environment are to be fully understood.
We carried out medium-term (3-month) experiments to investigate the leaching and degradation kinetics of legacy and emerging plasticisers in three natural test soils with contrasting properties. The leaching experiment involved spiking soils with PVC microplastic pellets and monitoring the release and degradation of the emerging plasticiser di-ethyl-hexyl terephthalate (DEHTP). The degradation experiment involved spiking the test soils with 8 phthalates and 4 emerging plasticisers. The test soils were the same for both experiments and allow for the comparison of how soil properties affect the leaching and degradation rates of plasticisers, in addition to the comparison of legacy and emerging plasticiser persistence in soils.

Initial results from the leaching experiment suggest that leaching of DEHTP from the PVC microplastics directly into soils was rapid, and that the rate of subsequent degradation of DEHTP was at least partly dependent on soil pH, with lower DEHTP degradation rates in the soils towards the extremes of the pH range found in natural soils. The results from the degradation experiment will represent, as far as the authors are aware, the first scientific study to investigate the degradation rates of emerging plasticisers in soils.

3.21.P-Tu328 Role of Soil Organic Matter on the Fate of Common Plastic Additives, Di(2-ethylhexyl) Phthalate, Bisphenol A and Benzophenone, in Soil

Dinusha Sammani Ramanayaka[1]*, Hao Zhang*[2] *and Kirk T Semple*[2]*, (1)Lancaster Environment Centre, Lancaster University, United Kingdom, (2)Lancaster University, United Kingdom*

Plastic additives, for example fillers, plasticizers, UV scavengers, and stabilizers, are being added during the production process to obtain the expected properties such as flexibility and light weight of mulch films. These additives are not chemically bonded with the polymeric chain; therefore, there is a risk of leaching during the degradation and fragmentation of plastics in the environment. Hence, the objective of this study are to understand the factors affecting the retention of selected plastic additives, namely Di-(2-ethylhexyl)-phthalate (DEHP), Bisphenol A (BPA), and Benzophenone (BP). Red yellow podzolic soil was air-dried (24 h) and sieved (2 mm) prior to the experiment. A portion of the soil sample (20 g) was subjected to ignition at 600 °C for 2 h in a muffle furnace to remove the total OM of the soil. The pH edge experiment was conducted at 20 g/L soil suspension spiked with 10 mg/L of each additive (DEHP, BPA, and BP), whereas isotherm experiments were carried out at concentrations of 1 to 20 mg/L of additives spiked into two different soil suspensions (with and without OM). Filtered samples were diluted and analyzed using HPLC. DEHP demonstrated the highest retention, 331 and 194 mg/kg in the presence of OM and absence of OM, respectively, at pH 6.6. However, BPA and BP had their highest retentions at pH 4.2 and 4.4 with soil OM of 90 and 19.5 mg/kg, respectively. The modelling of isotherm data together with FTIR measurements enabled further understanding of the adsorption mechanisms. The results indicate that DEHP was involved in corporative adsorption to soil OM. Yet, physisorption was depicted in soil without OM. BPA was physically bound to soil OM while the mineral component showed strong chemisorption. Nevertheless, BP demonstrated chemisorption on both soil OM and mineral components. The implication of these results suggest that DEHP and BPA could be easily released into soil water; however, BP would most possibly be immobilized in soils.

3.21.P-Tu329 Investigating the Effects of Substances Leaching out of FFP2 Masks on the Aquatic Organism *Danio rerio*

Katharina Wiessner[1]*, Arian Bassiri Gharb*[2]*, Alena Bogomolova*[2]*, Dario Mayer*[2]*, Filip Necov*[2]*, Jonas Sametinger*[2] *and Elisabeth Simboeck*[2]*, (1)FH Technikum Wien, Austria, (2)University of Applied Sciences Technikum Wien, Austria*

Even if it looks like the COVID-19 pandemic is coming to an end in many countries, its long reign has brought some new challenges with it: an enormous amount of plastic waste generated by the massive, albeit necessary, use of FFP2 and other face masks. Although the use of face masks varied across countries between <15% and 70%, depending on sociodemographic factors and strictness of wearing policies, the number of masks entering the environment has increased during the last years (~17.000 tons are estimated to enter waterbodies per month), due to false disposal. FFP2 masks have been shown to contain substances that exhibit endocrine disrupting properties, such as phthalates. These substances have the potential of leaking out of the masks into the environment.

To test the effects of substances leaking out of FFP2 masks on aquatic organisms, embryos and larvae of *Danio rerio* were exposed to FFP2 leachates. Leachates were obtained by performing a column percolation according to DIN 19528, where 50 g of FFP2 masks (~12 masks) were leached for 7 h using zebrafish system water as mobile phase. Zebrafish eggs (1.5 hpf) were then exposed to leachates in different concentrations (100%–25%) for 96 hpf according to OECD guideline No. 236 to investigate acute toxicity and potentially occurring abnormalities in their development. An LC50 value of 51% and abnormalities occurring at 40% could be observed. Furthermore, locomotor behavior of 96 hpf larvae were determined using a DanioVision observation chamber (Noldus) and tracking software EthoVision XT (Noldus), resulting in altered velocity and distance moved between 25% and 40% exposure. Also, the performance of RT-qPCR with 96 hpf larvae, investigating effects on gene expression of the *vtg1* gene (normalized against *elfa*) compared to 1 µM 17β-estradiol to investigate endocrine effects and a GC-MS detection of the phthalate concentration in the tested leachates are planned.

The results of the experiments indicate that substances could be leached out of the FFP2 masks under conditions similar to the environment (freshwater) and that they show effects on the tested organism, thus posing a potential threat for the aquatic environment. However, detailed ecotoxicological risk assessments that analyze or reliably estimate the actual concentration of substances being leached into the environment (for freshwater as well as for marine waters) must be performed before any conclusion can be drawn.

3.21.P-Tu330 Environmental Fate of Plastic Pellets in the Harbour of Antwerp

Hanne Diels[1]*, Ronny Blust*[2] *and Raewyn M. Town*[2]*, (1)University of Antwerp, Belgium, (2)ECOSPHERE, University of Antwerpen, Belgium*

The harbour of Antwerp is the leading polymer hub in Europe for production, handling, and distribution of preproduction plastic pellets. In the marine environment, microplastics, including plastic pellets, are a big source of plastic pollution. Transportation, transformation, and environmental risk are the main factors that determine the fate of released plastic pellets. Exposure of plastic pellets to mechanical stress and environmental conditions can lead to breakdown of the pellet into smaller pieces, leach of additives, changes in physical and chemical properties, absorption of pollutants.

The Port of Antwerp and the companies of the production chain (industry, transport, logistics) are taking measures to reduce pellet losses to the surrounding environment. However, little is known about the efficacy of the measures. So, the question is:

How many pellets are still being released into the environment and where is this occurring? A total of 57 critical points on the public road and 5 accumulation points on the slopes of the docks were intensively monitored using manual sampling site with a quadrant of 50 by 50 cm. The results show a considerable ongoing plastic pellet loss and a high pollution degree on the accumulation points on the slopes of the docks. On the road there was a decrease of the released pellets during 2022. Intensive communication about the research took place with the companies of the plastic value chain, the port authority, and government authorities. Highlighting the problem and sharing the results could be one of the factors that decreased the number of released plastic pellets.
Despite the increasing awareness, there is still not much known about the effect of plastic pellet pollution on biota in the surrounding area, i.e., the dock water and the Scheldt estuary. Because of trade secrets, there is not much known about the exact recipe and additives of the plastic pellets. After gaining the confidence of the companies by open communication about the research, in 2023 we will set up an in situ experiment in the port, under relevant environmental conditions, with relevant plastic pellets as they are produced in the same area. New plastic pellets will be exposed to environmental conditions (terrestrial, aquatic), samples will be taken and analysed to identify physical-chemical modifications occurring. The aim of the study is to build knowledge and perspective to better understand the environmental risk of a released plastic pellet and its additives.

3.21.P-Tu332 Leachate Effects in Biodegradable Geotextiles

Antonia Weltmeyer *and Martina Roß-Nickoll, RWTH Aachen University, Germany*

In recent years, a development from petroleum derived synthetic non-biodegradable polymers to biobased and biodegradable polymers can be observed in various sectors, amongst them the agricultural, consumer product, and building sectors. The latter stands out due to its direct contact and implementation into the environment, but also its large-scale application. A widely used application in this field is geotextiles, which can be found integrated into different soil layers, on top of them or even above with only a small contact surface. It is therefore highly commendable to develop a sustainable alternative to conventional products that guarantee stability and function as well as environmental compatibility. One crucial factor in developing an environmentally friendly polymer is their composition, which ideally should not pose a risk to the environment due to, for example, additives. Critical additives, which for example pose threads of mutagenicity, endocrine activity, reproductive toxicity, or accumulation, may be released during use of these applications. This risk needs to be prospectively screened to assess the overall impact of geotextiles. In our project, we want to examine 4 different biodegradable geotextiles and optionally petroleum derived equivalents in terms of potential leaching of substances in accordance with DIN EN 16637-2. After eluating the materials in water for 6h, 1 and 36 days, the eluates will be investigated in different biotests. Hereby mutagenicity via micronucleus assay, dixoin-like acitivity via micro EROD, and acute aquatic toxicity via Daphnia toxicity test are screened with potential addition of other test systems after positive findings. First results from these experiments will be presented.

3.21.P-Tu333 Leaching of Endocrine Disrupting Chemicals from Plastic Food Packaging – In Vitro Toxicity and Chemical Composition

Sarah Stevens[1]*, Zdenka Bartosova*[1]*, Johannes Völker*[2] *and Martin Wagner*[1]*, (1)Norwegian University of Science & Technology (NTNU), Norway, (2)IES, Switzerland*

Plastics are chemically highly complex materials. More than 10,000 substances are used in plastic production (e.g., plasticizers, antioxidants) and even more non-intentionally added substances (e.g., reaction byproducts, impurities) are associated with them. While there is abundant scientific evidence that some compounds used in plastics, such as bisphenols and phthalates, are endocrine disrupting chemicals, little is known about the composition and toxicity of the complex mixtures of chemicals leaching from everyday plastic products. Therefore, this study aims at characterizing the in vitro toxicity and the chemical composition of leachates from plastic food contact articles (FCAs) as relevant sources of human exposure. Fourteen plastic FCAs covering the 7 polymer types with the highest global market share were leached into water and a water-ethanol mixture for 10 days at 40°C according to European Regulation 10/2011/EU. The leachates were analyzed with reporter gene assays for a set of nuclear receptors relevant to human health, including pregnane X receptor (PXR), peroxisome proliferator-activated receptor gamma (PPARγ), estrogen receptors alpha (ERα), and androgen receptor (AR). Further, these plastic mixtures were analyzed using non-target high-resolution mass spectrometry to quantify the number of chemical features and tentatively identify the chemicals leaching from the FCAs. Thirteen of the fourteen FCA leachates interfered with at least one of the nuclear receptors. PXR and PPARg were the predominant targets of the plastic chemicals, but both steroid receptors were also activated or inhibited by several samples. The water leachates were less toxic than the water-ethanol leachates and none of the latter was estrogenic. Also, lower numbers of chemicals were leaching into water as compared to water-ethanol mixture. To identify the active compounds in these complex mixtures, an effect-directed analysis will be performed. This research shows that plastic FCAs leach endocrine disrupting chemicals into food simulants and highlights the importance of analyzing whole mixtures of finished plastic products to cover the toxicity of unknown compounds and mixtures.

3.21.P-Tu334 Establishing a Database of Plastic Additives Used in Commerce and Their Regulatory Status Across the Globe

John Norman*, American Chemistry Council*

The International Council of Chemical Associations (ICCA) is engaging with the global community to contribute to the ongoing discussion regarding plastics in the environment and circularity. Attention to plastic waste has grown and global efforts are underway to reduce and prevent its entrance into the environment. With this increase attention on plastics, there is also an increased focus on the additives used in plastic materials.

Additives are substances intentionally added to plastics that impart functional, fit for purpose characteristics to the plastics. Additives improve, modify, or retain plastic properties such as providing flexibility or stability during the plastic life cycle. Without additives, plastic materials would have limited applications, be brittle, and potentially degrade prematurely making them unsuited for critical uses (e.g., safety equipment, medical devices, etc.). Certain additives are designed to enable plastics of different qualities to be blended, increasing the ability to use recycled plastic for products and packaging. Additives are typically classified and categories by the function or purpose of their use (e.g., antioxidants, impact modifiers, heat stabilizers, etc.). One potential barrier to innovating new technologies and reduce and eliminate plastic waste is the lack of a comprehensive database containing the composition of additives by polymer type, by application, and the relevant safety information.

ICCA is developing a searchable database to allow users to determine whether a substance is currently being used as a plastic additive, what type of application it is being used for, and whether that substance – application combination is currently assessed and/or regulated by relevant governmental agencies across the globe. A vast amount of information has been generated for the polymer type being used and for many of the chemicals used as additives. Regulatory programs like TSCA in the USA; CEPA in Canada; REACH in the EU; K-REACH in Korea; CSCL in Japan; and AICIS in Australia are only a few of many that have evaluated materials for safe use. Assembling all this information in one place will allow environmental modelers and bench scientists to design targeted research to close information gaps. This presentation will give an update on the progress of the project and give attendees an opportunity to engage with researchers to ensure the database meets the needs of the scientific community.

3.21.P-Tu336 Evaluating Migration of Polymer Additives Under Environmentally Relevant Conditions – Validation of Modeling Approaches and Application for Product Classification & Labeling under EU CLP & UN GHS

Craig Warren Davis[1]*, Cynthia Mitchell*[2] *and David Simpson*[3]*, (1)Toxicology & Environmental Science, ExxonMobil Biomedical Sciences, (2)Technology Division, ExxonMobil Product Solutions , USA, (3)ExxonMobil Chemical Company*

With inclusion of polymers within the scope of REACH (EU & Korea), efforts to characterize the potential migration of additives, oligomers, monomers, and non-intentionally added substances (NIAS) as well as their relevance for grouping and data generation for registration have increased considerably. Technical limitations as well as the considerable cost associated with method development for additive chemistries and their potential transformation products necessitate an approach which combines systematic experimental data generation with physical-chemical property estimation and migration modeling. While specific guidance for data generation as well as migration modeling is established for specific use cases (e.g., food contact applications), to date, limited data and practical guidance is available for environmentally relevant systems (e.g., aquatic toxicity test systems). Novel data is presented quantifying migration potential of 9 common polymer additives (and identified transformation products) across a broad range of polymer matrices (PE, PP, PVA-copolymers). Migration was then compared to modeling results obtained assuming equilibrium partitioning (EqP) in the test system as well as results from USEPA's AMEM model (which incorporates diffusion, partitioning and surface mass transfer limitations). Results were also compared, where available, to migration studies performed under food contact relevant conditions. In addition, migration of low molecular weight oligomer materials from several grades of adhesives was quantified using biomimetic extraction techniques (BE-SPME) and compared to experimental ecotoxicity thresholds established for the BE-SPME technique. Finally, migration data were used to estimate potential exposure of aquatic organisms to additives under environmentally-relevant conditions (30-d chronic exposure in fresh and seawater). Predicted environmental concentrations (PECs) were computed and compared to experimental and modeled toxicity thresholds for the materials (e.g., PNECs) and risk characterization ratios (RCRs) were computed. The combination of data generation and modeling can be used to support efficient grouping and data generation for polymer categories under EU REACH as well as to support existing and future classification and labeling of finished polymers under EU CLP and UN GHS.

3.21.P-Tu337 Toward a Framework for Rapid, Tiered Risk Assessment, & Prioritization of Additives, Impurities, and non-Intentionally Added Substances (NIAS) in Polymers & Plastic Articles

Craig Warren Davis[1]*, Allison L Isola*[1]*, Laura Maurer*[1] *and David Simpson*[2]*, (1)Toxicology & Environmental Science, ExxonMobil Biomedical Sciences, (2)ExxonMobil Chemical Company*

With the inclusion of polymers within the scope of REACH as well as UN efforts surrounding additives in polymers and plastic articles, efforts to identify and prioritize substances of potential concern has increased substantially. While attempts have been made to prioritize additives, impurities, and non-intentionally added substances (NIAS), these approaches often focus on high-level hazard properties (e.g., GHS classification) and minimize or ignore physical-chemical properties which govern fate and transport of these materials between polymer matrices and their surrounding environments (i.e., exposure). Further, limitations of chemical identifiers (e.g., CASRN) to adequately capture availability of categorical and structural-analogue data presents a challenge to reliably prioritizing truly data-poor substances against those which may be adequately evaluated via read-across or weight of evidence (WoE) approaches. The combination of "hazard-only" frameworks and incomplete data collection may result in a significant over-estimation of chemistries for which adequate data to quantitatively evaluate risk is not available.
The purpose of this work is three-fold: (1) A systematic workflow for the collection and synthesis of in-silico, in-vitro, and in-vivo hazard data for chemicals is proposed which leverages existing QSAR models, experimental databases, and existing regulatory evaluations (e.g., GHS, TDI/ADI values). (2) A systematic workflow for the collection and synthesis of environmental fate, migration, uptake, and exposure for aquatic organisms as well as man exposed via the environment (MvE) is proposed which provides a basis for establishing predicted environmental concentrations (PECs) and human oral dose estimates to be used in quantitative risk assessment and prioritization. (3) A tiered framework is proposed which incorporates both exposure and hazard

information to develop quantitative and categorical assessments of risk, which can be used to effectively prioritize and screen additives and associated chemicals in a consistent and transparent way.
The utility of the framework is demonstrated using a database of polymer and plastic-associated chemistries (n = 4756) developed by the Food Contact Forum (FCF). Risk characterization ratios (RCRs) as well as data completeness metrics are used to prioritize and evaluate the database of chemistries. Finally, this prioritization approach is compared to those developed by FCF, ECHA, and others.

3.21.V Polymer Additives and Their Transformation Products as Chemicals of Emerging Concern: Environmental Emissions, Fate Processes, and Impacts

3.21.V-01 Additive chemicals in plastic marine debris and fishing gears
Mi Jang[1]*, Youna Cho*[2]*, Gi Myung Han*[3]*, Sung Yong Ha*[4] *and Sang Hee Hong*[2]*, (1)Risk Assessment Research Center, Korea Institute of Ocean Science and Technology (KIOST), Korea, (2)Korea Institute of Ocean Science and Technology (KIOST), Korea, (3)Risk Assessment Research Center, Korea Institute of Ocean Science and Technology (KIOST), Korea, (4)1Risk Assessment Research Center, Korea Institute of Ocean Science and Technology (KIOST), Korea* Plastic marine debris can remain in the ocean for long periods of time. Plastic products contain numerous additive chemicals, which are present in large amount (~70% by weight) and can be transferred to the marine environment. In this study, additive chemicals and persistent organic pollutants (POPs) were quantified in marine plastic debris and fishing gear, along with their corresponding new plastic products in markets, categorized by fisheries (n = 35), package (n = 12) and cigarettes (n = 7). Additive chemicals significantly higher than POPs in plastic samples (t-test, $p<0.05$), indicative of high use of additives in plastics. New products contained a significantly higher amount of additives than debris samples (t-test, $p<0.05$), implying their potential leaching or degradation during use or after disposal in the marine environment. In the fisheries category, buoys generally contained high concentrations of antioxidants (0.28–91 µg/g) such as 2,4-di-tert-butylphenol (2,4-DTBP) and butylated hydroxytoluene (BHT), Irgafos168, Irganox1010, and Irganox1076. Among the buoy, polyurethane covered buoy had a high amount of phthalate such as Di-(2-ethylhexyl) phthalate (DEHP; 47 µg/g). Black colored polypropylene (PP) type of buoy contained high concentration of ultraviolet stabilizers (UVs; 4.3 µg/g) and brominated flame retardants (BFRs) such as BDE 209 (3.5 µg/g) and DBDPE (200 µg/g). Polyvinyl chloride (PVC) type of rope used for aquaculture farm had a highest concentration of phthalate (DEHP, 520 µg/g) and biphenyl A (BPA; 101 µg/g), and the second highest concentration of UVs (1.4 µg/g). Polyethylene (PE), polypropylene (PP), polyester (PES), and polyamide (PA) types of ropes, eel trap (PP) and net (PE) for fisheries generally had a low concentration of additive chemicals compared with buoys. Rubber bars from tires for aquaculture farms contained the highest concentration of tire antioxidant (6PPD-quinone; 11.4 µg/g), which is the toxic chemical responsible for killing salmon. Among the package category, plastic bag had a high number of antioxidants (2,4-DTBP, 11.5 µg/g) and BFRs (BDE209, 5.2 µg/g). Targeted additive chemicals were detected in the lowest concentration in all cigarette samples. The present study provides quantitative information about additive chemicals contained in plastic marine debris and their products. Further study of release, transfer, and accumulation of these additive chemicals from plastic debris to marine environment is needed.

3.21.V-02 Environmental Monitoring of 6PPD-quinone Present in Stormwater Across Canadian Cities
Niteesh Jain[1]*, Steve Wiseman*[2]*, Emily Mertens*[2] *and Markus Brinkmann*[1]*, (1)Toxicology Centre, University of Saskatchewan, Canada, (2)University of Lethbridge, Canada*
N-(1,3-Dimethylbutyl)-*N′*-phenyl-*p*-phenylenediamine-quinone (6PPD-quinone), a transformation product of the rubber tire antioxidant 6PPD found in road runoff, has been found to be acutely toxic to some species of fish. While previous studies have shown the great importance of stormwater as a source of 6PPD-quinone, less is known about environmental and land-use drivers, and spatio-temporal dynamics across a larger study area. Therefore, this study aims to assess the levels of 6PPD-quinone in stormwater from three Canadian cities: Calgary, Edmonton, and Lethbridge. Stormwater samples were collected from these cities throughout May to October 2022 and stored frozen. Samples were extracted using solid phase extraction (SPE) and 6PPD-quinone quantified using Liquid Chromatography-High-Resolution Mass Spectrometry (LC-HRMS). Preliminary analyses show a range from 4.03 ng/L to 1.23 µg/L of 6PPD-quinone in stormwater samples from the City of Calgary. Because the median lethal concentrations (LC50s) of 6PPD-quinone in brook trout and rainbow trout, two species found in the receiving water bodies, are 0.59 and 1.00 µg/L, respectively, the presence of 6PPD-quinone in stormwater might affect aquatic ecosystem health adversely. This research will provide information that will help improve the ecological and environmental risk assessment of this important contaminant of emerging concern.

3.22.A POPs and Emerging Pollutants: Environmental Fate, Research, and Monitoring at the Interfaces of Science and Policy and Application of Green Removal Technologies

3.22.A.T-01 What Do We Know about the Production and Release of Persistent Organic Pollutants in the Global Environment?
Li Li[1]*, Chengkang Chen*[2]*, Dingsheng Li*[1]*, Knut Breivik*[3]*, Golnoush Abbasi*[3] *and Yi-Fan Li*[4]*, (1)School of Public Health, University of Nevada, USA, (2)Peking University, China, (3)Norwegian Institute for Air Research (NILU), Norway, (4)Harbin Institute of Technology, China*
Humans have manufactured and commercialized huge quantities of persistent organic pollutants (POPs) for various agricultural, industrial, and consumer applications. However, these substances have been revealed to be persistent, bioaccumulative, toxic, and ubiquitous in the global environment. Information on the global production and environmental releases of POPs is of critical

importance for regulating and eliminating these chemical substances of worldwide environmental and health concerns. In this presentation, we report our efforts of a comprehensive literature review of quantitative information on the historical global production and multimedia environmental releases of 25 intentionally produced POPs. Our assembled data indicates that as of 2020, a cumulative total of 31 306 kilotonnes (kt) of the 25 POPs had been synthesized and commercialized worldwide, resulting in cumulative releases of 20 348 kt into the global environment. As of 2020, short-chain chlorinated paraffins were the most produced POP, with a historical global cumulative tonnage amounting to 8795 kt, whereas α-hexachlorocyclohexane (HCH) had the largest historical global cumulative environmental releases of 6567 kt among these 25 POPs. The 1970s saw the peak in the annual global production of the 25 investigated POPs. The United States and Europe used to be the hotspots of environmental releases of the 25 investigated POPs, notably in the 1960s and 1970s. By contrast, global environmental releases occurred primarily in China in the 2000s–2010s. Overall, our work for the first time reveals the magnitude of global historical production and environmental releases of POPs. We encourage global joint efforts of high-quality data on chemical production, trade, use, waste management, and environmental releases. Such efforts necessitate (i) more comprehensive collection and curation of first-hand national and regional statistical data under the Stockholm Convention and other multilateral environmental agreements, and (ii) global high-level synthesis, comparison, and evaluation of the national and regional statistical data to ensure their transparency, completeness, consistency, and accuracy.

3.22.A.T-02 Persistent Problem: The Global Challenges to Managing PCBs

Lisa Melymuk[1]*, Jonathan Blumenthal*[2]*, Ondrej Sanka*[1]*, Veena Singla*[3]*, Adriana Shu-Yin*[4]*, Katerina Sebkova*[1]*, Kristi Pullen Fedinick*[5] *and Miriam L. Diamond*[4]*, (1)Recetox, RECETOX, Masaryk University, Czech Republic, (2)University of Toronto, Canada, (3)National Resources Defense Council, United States, (4)Department of Earth Sciences, University of Toronto, Canada, (5)Natural Resources Defense Council, Washington D.C., USA*

Polychlorinated biphenyls (PCBs), "famous" as persistent organic pollutants (POPs), have been managed since the 1970s, and the Stockholm Convention on POPs requires environmentally sound management (ESM) of PCBs by 2028. Yet globally, we are not expected to meet this deadline: at best, 30% of countries are on track to achieve ESM by 2028. Over 10 million tonnes of PCB-containing materials remain, mostly in countries lacking the ability to manage PCB waste. The Stockholm Convention guidance and deadlines have proven effective in many high-income regions: Canada (Ontario) and Czechia, both parties to the Stockholm Convention, are close to achieving the 2028 goal, having reduced their stocks of pure PCBs by 99% in the past 10 years. In contrast, the USA, the world's largest producer and consumer of PCBs, is not a party to the Stockholm Convention, and continues to have a substantial but poorly-inventoried stock of PCBs, with only minimal reductions since 2006. The failure to manage global PCB stocks >30 years after the end of production highlights the urgent need to prioritize reducing production and use of newer, more widely-distributed POPs, such as chlorinated paraffins and per- and-polyfluorinated alkyl substances, because these management challenges are unlikely to be resolved in the coming decades.

3.22.A.T-03 Contamination of Mine Water Effluents by Polychlorinated Biphenyls (PCBs)

Katrin Wiltschka[1]*, Christian Wolkersdorfer*[2]*, Rolf-Alexander During*[1] *and Leonard Böhm*[1]*, (1)Institute of Soil Science and Soil Conservation, Research Centre for BioSystems, Land Use and Nutrition (iFZ), Justus Liebig University Giessen, Germany, (2)SARChI Chair for Mine Water Management, Tshwane University of Technology (TUT), South Africa*

Polychlorinated biphenyls (PCBs) are among the persistent organic pollutants (POPs) that have been globally banned since 2001 due to their persistence, bioaccumulation, and chronic toxicity. Manufactured as industrial chemicals, PCBs were used in pure form or as an admixture, mainly as insulating oils in transformers and capacitors. In underground mining, they were even required by fire safety regulations. Due to its high salt concentrations and associated high loads of metals and metalloids, mine water represents one of the world's largest pollutants streams in terms of volume. To date, mainly inorganic pollutants are considered and treated. However, as a legacy of mining, (abandoned and closed) mines may contain relevant quantities of PCBs. Mine water must be pumped out in most circumstances and is discharged into receiving water courses. Where monitoring of PCB contamination takes place, it is mainly targeted at receiving waters. Of the PCBs with theoretically 209 congeners, the six indicator PCBs and one dioxin-like PCB are normally considered in analysis. Therefore, the aim of the present study was (i) to develop a simple, rapid, miniaturized, and solvent-free method with low detection and quantification limits for PCB congeners analysis in mine water and mine water-affected rivers, and (ii) to elucidate both congener-specific patterns and their time-dependent changes within specific mines by determining PCB concentrations and annual loads. For PCB analysis, a solid-phase microextraction (SPME) method combined with gas chromatography-mass spectrometry (GC-MS) was optimized for the extraction and detection of several PCB congeners directly from untreated mine water. As a result, more than 50 PCB congeners could be quantified in the samples from five different mines in Germany, some over a period of 3 years. The presented method allows a comprehensive and labor-saving analysis of PCBs even in the smallest amounts of 10 mL of untreated, matrix-rich mine water, with very low detection limits (LOD 0.005–0.58 ng L^{-1}). The PCB concentrations and annual loads (80–660 g a^{-1} per mine) indicate that mine water is an additional source of PCBs in the environment. Because PCB discharge occurs at point sources, targeted water treatment is recommended to achieve a load reduction.

3.22.A.T-04 Multimedia Assessment of Legacy and Current Use Halogenated Flame Retardants in Air, Precipitation, Herring Gull Eggs and Lake Trout in Lake Ontario

Wenlong Li[1]*,* ***Hayley Hung***[2]*, Tana V. McDaniel*[3]*, Shane R. deSolla*[4]*, Lisa E. Bradley*[3]*, Alice Dove*[3]*, Daryl McGoldrick*[3] *and Paul Helm*[5]*, (1)Environment and Climate Change Canada, Canada, (2)Environment and Climate Change Canada, Canada, (3)Water Quality Monitoring and Surveillance Directorate, Environment and Climate Change Canada, Canada, (4)Wildlife and Landscape Science Directorate, Environment and Climate Change Canada, Canada, (5)Ontario Ministry of the Environment, Conservation*

and Parks, Canada
In support of the Canada/US Great Lakes Water Quality Agreement and the Stockholm Convention on Persistent Organic Pollutants (POPs), polybrominated diphenyl ethers (PBDEs) and alternative halogenated flame retardants (HFRs) were measured in air (2005–2017), precipitation (2006–2018), lake trout (1997–2019) and herring gull eggs (2008–2018) in the Great Lakes region. All targeted HFRs were detected in one or more air [detection frequency (DF): 0.80–98%], precipitation (DF: 6.4–97%), lake trout (DF: 34–100%), and herring egg (DF: 8.3–100%) samples throughout the sampling periods. Temporal analysis showed declining trends for PBDEs in air, precipitation and lake trout since mid-2000, while herring gull eggs showed little or no change in trends. Non-PBDE HFRs do not show clear temporal trends. Hexabromocyclododecane (HBCDD) was the only non-PBDE HFR that was detectable in all 4 media. Concentrations of HBCDD decreased from 2006 to 2011 but started to increase after 2011 both in air and precipitation. On the other hand, HBCDD showed no trends in lake trout and herring gull eggs. While atmospheric concentrations of HFRs are directly impacted by emissions from sources, concentrations in biota are influenced by many other factors including changes in diet, chemical bioavailability, metabolism, and excretion rates; thus, may result in differing trends and a time lag in our ability to detect any change in trends. These multimedia long-term datasets were combined with a multimedia environmental model, the modified Quantitative Water Air Sediment Interaction (QWASI) model, based on site-specific environmental parameters from Lake Ontario to better understand the observed trends and environmental fate of HFRs in the region. Model results suggest that the loadings from tributaries and wastewater effluent were the primary sources for PBDE and HFR input to the lake. Total degradation in the water and sediment were the dominant removal pathway for BDE 47, 209 and HBCDD, followed by sediment burial.

3.22.P-Mo238 Halogenated Flame Retardants in Irish Waste Polymers: Concentrations, Legislative Compliance, and Preliminary Assessment of Temporal Trends

***William A. Stubbings**[1], Daniel Drage[1], Martin Sharkey[2], Layla S. Al-Omran[3], Harald Berresheim[2], Marie Coggins[2], André Henrique Rosa[4] and Stuart Harrad[1], (1)University of Birmingham, United Kingdom, (2)School of Physics, National University of Ireland Galway, Ireland, (3)Department of Chemistry, University of Basrah, Iraq, (4)São Paulo State University (UNESP), Institute of Science and Technology, Brazil*

Halogenated flame retardants (HFRs) were measured in 470 waste plastic articles from Ireland between 2019 and 2020. We identified articles containing concentrations of polybrominated diphenyl ethers (PBDEs), hexabromocyclododecane (HBCDD), and tetrabromobisphenol-A (TBBP-A) exceeding European Union limits. Other HFRs targeted were detected infrequently and predominantly at very low concentrations. However, 2,4,6-tris(2,4,6-tribromophenoxy)-1,3,5- triazine (TTBP-TAZ) was detected in 3 display/IT product samples at 14,000 to 32,000 mg/kg, indicating elevated concentrations of FRs used as alternatives to PBDEs and HBCDD, will likely increase in future. Comparison with data for Ireland in 2015–2016, revealed concentrations and exceedances of limits for PBDEs, HBCDD, and TBBP-A were similar or have declined. For end-of-life vehicle fabrics and foams, HBCDD and ΣPBDE concentrations declined significantly ($p < 0.05$) since 2015–2016. Moreover, ΣPBDE concentrations in waste small domestic appliances are significantly lower in 2019–2020, with a similarly significant decline for TBBP-A in waste IT and telecommunications articles. In contrast, HBCDD concentrations in waste extruded polystyrene increased significantly between 2015–2016 and 2019–2020. For other waste categories studied, no statistically significant temporal trends are evident ($p > 0.05$). Fewer samples exceeded PBDE and HBCDD limits in 2019–2020 (7.8%) than 2015–2016 (8.7%), while exceedances for TBBP-A fell from 2.4% in 2015–2016 to 0.57% in 2019–2020. Enforcement of existing limits of 1000 mg/kg will render an estimated 3.1% (2800 t) of articles in the waste categories studied unrecyclable, increasing to: 4.0, 4.9, and 5.6% if limits were reduced to 500, 200, and 100 mg/ kg respectively. Meanwhile, enforcing limits of 1,000, 500, 200, and 100 mg/kg will respectively remove 78, 82, 84, and 85% of PBDEs, HBCDD, and TBBP-A present in such waste. While comparison between the 2015–2016 and 2019–2020 datasets provide a preliminary indication of changes, further monitoring is required if the impact of legislation designed to eliminate HFRs from the waste stream is to be fully evaluated.

3.22.P-Mo239 Assessment of the Risk Caused by PCBs, PAHs, PCDD/Fs, and PFAS in Bio-based Fertilizers (BBFs) from Various Waste Origins and Obtained Through Different Valorisation Methods

***Nicolas Estoppey**[1], Gøril Aasen Slinde[1], Gabriela Castro Varela[2], Alexandros G. Asimakopoulos[2], Hans Peter Arp[1,2] and Gerard Cornelissen[1], (1)Norwegian Geotechnical Institute (NGI), Norway, (2)Norwegian University of Science & Technology (NTNU), Norway*

Agriculture strongly relies on imported mineral phosphate and nitrogen fertilizers whose production is energy intensive and depletes natural resources. Increasing the usage of bio-based fertilizers (BBFs) can allow the reduction and dependence on mineral fertilizers and close nutrient loops. However, persistent organic pollutants (POPs) including PFAS potentially present in organic waste risk ending up in the BBFs, and thus in the environment. Few studies have investigated the presence of PFAS and other POPs in BBFs and assess the risk they constitute for soils, plants and humans. To fill this gap, several classes of POPs – i.e., PCBs, PAHs, PCDD/Fs, and PFAS – were quantified in BBFs from various waste origins (e.g., plants, animal, sludge) and produced through different valorisation methods (e.g., calcination, pyrolysis, hygienisation); then the risk caused by the BBF application to soils, plants, and consumers was assessed.
Nineteen BBFs representative of different risk levels were chosen based on the waste origins and the valorisation methods. Total concentrations of POPs were measured by gas or liquid chromatography coupled with tandem or high-resolution mass spectrometry (GC/MSMS, GC/HRMS or LC/MSMS) after solvent extraction. The POP concentrations expected in amended soils and plants were calculated using recommended/regulated application rates of fertilizers and bioaccumulation factors (BAFs).
For most of the BBFs, the concentrations of organic contaminants were (much) below the (few) existing (national) limit values (200 ug/kg for ∑7 iPCBs, 6 mg/kg for ∑16 PAHs, 100 ngTEQ/kg for PCDD/Fs, 100 ug/kg for ∑PFOS and PFOA). However,

certain valorisation methods (e.g., hydrothermal conversion) or types of waste (e.g., animal waste) were shown to be more sensitive, leading to high concentration of PAHs (up to 6.9 mg/kg) and PFAS (up to 73.3 ug/kg) in some BBFs. Calculated concentrations in soils fell in the background contamination levels, which is good news to the large-scale implementation of BBFs and the closure of nutrient cycles in the EU. To substantiate this conclusion, the next project activity will be to compare the calculated concentrations in soils and plants to those measured in samples from field trials.

3.22.P-Mo252 The Impact of Sediment Turbidity on PAH Resuspension and Potential Baseline Toxicity
Betty Chaumet[1]*, Elena Gorokhova*[2]*, Sofi Jonsson*[1]*, Stefano Bonaglia*[3]*, Johanna Hedberg*[1] *and Anna Sobek*[1]*, (1)Environmental Science, Stockholm University, Sweden, (2)Department of Environmental Science, Stockholm University, Sweden, (3)Gothenburg University, Sweden*
Sediments store a wide range of contaminants, particularly hydrophobic ones, such as PAHs. Under high turbulence, sediment particles are resuspended in the water column, where chemicals are released. In the water phase, the freely dissolved concentration (Cfree) represents the bioavailable fraction of the chemical. This study aims to understand how sediment resuspension affects PAH leakage from sediment to the water and how this leakage is modulated by PAH hydrophobicity.
An experiment was carried out with cores of spiked sediment with 4 PAHs (acenaphthene, fluorene, phenanthrene, and fluoranthene; 3 mg kg^{-1}) with a gradient in log Kow from 3.9 to 5.2. A polyethylene passive sampler (PE) was added to each core, and different flow velocities were applied to create different resuspension levels. The turbidity was measured and used as a proxy for sediment resuspension. PEs were collected after 2, 3, and 4 weeks of exposure and PAHs were extracted from the PE and quantified by GC-MS. The chemical activity (the effective concentration of a chemical in a compartment, e.g., water) was calculated for each PAH and summed to estimate the baseline toxicity of the mixture.
The turbidity increased with the flow velocity but decreased after two weeks of exposure, probably due to particle aggregation. The uptake of PAHs by the PE was affected by turbidity and the molecule's hydrophobicity, with a significant interaction between the two variables. At low turbidities (<3 NTU), PAHs were accumulated according to their gradient of hydrophobicity with higher accumulation for lower Kow. However, as turbidity increased, the uptake of congeners with different Kow converged to become similar at >7 NTU. These dynamics are most likely driven by PAH diffusion and desorption from the resuspended particles at low and high turbidities, respectively. Finally, a model ensemble was established to (1) predict Cfree using turbidity and logKOW values from the experiment and (2) estimate the potential baseline toxicity of the mixture from the Cfree values. Our findings show that using passive samplers in field surveys should be combined with turbidity measurements to obtain PAH concentrations (and other hydrophobic contaminants) under environmentally relevant conditions. Thus, this study contributes to improved hazard assessment of pollutants in the sediments and demonstrates the need to account for the natural variability of resuspension in the environment.

3.22.B POPs and Emerging Pollutants: Environmental Fate, Research, and Monitoring at the Interfaces of Science and Policy & Application of Green Removal Technologies

3.22.B.T-01 A Combined Time-Trend and Trophic Magnification Study on POPs and Emerging Contaminants in a Baltic Sea Food Web
***Andriy Rebryk** and Peter Haglund, Umea University, Sweden*
Many chemicals that were discovered, synthesized on an industrial scale, and used in everyday life according to the needs of humankind during the 19th and 20th centuries, like the pesticide DDT, were later shown to be responsible for declining numbers in the various Baltic species populations. These were classified as anthropogenic hazardous substances (AHSs) and investigated further. Many AHSs are toxic and, due to their fat-soluble nature, can be stored in fatty tissues. Moreover, they magnify in species at high trophic level (predator) of the food web, as a result of persistence and transfer from the lower-level species (prey). This transfer is called trophic magnification and is characterized by trophic magnification factor (TMF). AHSs can be divided into known contaminants (e.g., persistent organic pollutants (POPs), such as DDT and PCBs) and contaminants of emerging concern (CECs), including various polymer additives, flame retardants, and others. Some AHSs have been regulated since the 1970s. To evaluate whether the regulations are successful, a retrospective analysis of the samples from different years, a time-trend study, characterized by annual change value (AC, in %), is used. In this work, a non-target screening (NTS) approach was utilized to find and identify a wide variety of chemicals (POPs and CECs) and assess their time trends and/or trophic magnification. An efficient gas chromatography–high-resolution mass spectrometry (GC-HRMS)-based NTS workflow (including sample extraction, clean-up, and instrumental analysis) was established. It was accompanied by a new highly-automated data processing NTS workflow. Both workflows were then applied to a set of Baltic biota samples, revealing time-trend and biomagnification data for a plethora of organic contaminants in a given Baltic Sea food web: >600 identified and unknown compounds showed significant temporal trends and >500 showed significant trophic magnification. A number of CECs were reported for the first time in environmental biota samples. Nowadays, the legacy POPs show decreasing time trends meaning the restrictions work. The workflows developed and data acquired can contribute to the NTS analytical tool development and to the assessment of the influence of AHSs on the ecosystem, respectively. Furthermore, the outcome of these studies can be used in various mitigation actions on AHSs.

3.22.B.T-02 Passive Air and Water Sampling in High-Mountain Lakes: Distribution of Legacy and Emerging Organic Pollutants
***Raimon M. Prats**, Barend Leendert van Drooge Sr, Pilar Fernández and Joan O. Grimalt, Environmental Chemistry, Spanish Research Council (CSIC), Institute of Environmental Assessment and Water Research (IDAEA), Spain*

Remote high mountains allow the study of the environmental fate of legacy and emerging anthropogenic semi-volatile organic compounds like polychlorinated biphenyls (PCBs), polycyclic aromatic hydrocarbons (PAHs), organophosphate esters (OPEs), and other organochlorine compounds like hexachlorobenzene (HCB) that have become ubiquitous through long-range atmospheric transport. Passive samplers provide significant benefits for studying remote sites: low cost, ease of use, no energy supply required, and time-integrated assessment of average concentrations. Here, polyurethane foam and low-density polyethylene were used in air and water from six alpine lacustrine areas (1619–2453 m) in the Pyrenees, Spain.
In air, the mean concentrations of ΣPCBs, HCB, and PeCB, 13±4 pg/m^3, 44±18 pg/m^3, and 23±20 pg/m^3, respectively, were similar to those measured 20 years ago in the same area, showing the persistence of these compounds. ΣPAHs was 631±238 pg/m^3, half of those measured 20 years ago, which agrees with reductions in European atmospheric emissions. ΣOPE concentrations, 16–53 pg/m^3 on average, were measured for the first time in this area. Statistically significant temperature dependences of the gas phase concentrations of many compounds revealed the prominence of secondary emission sources (e.g., soils, snow) for OPEs and the heavier PCBs and PAHs, as their lower volatilities cause them to partition more prominently towards other environmental compartments. HCB and the lighter PAHs and PCBs did not present significant changes with temperature, as expected from their higher volatility.
In water, HCB concentrations (1.0–14 pg/L) remained essentially the same as those measured over two decades ago. ΣPAHs (35–920 pg/L) were around half of those observed in the past. ΣPCB concentrations (1.2–2.2 pg/L) were substantially lower, although unexpectedly large differences could be due to comparing yearly averages to seasonally variable episodic pumping measurements from previous studies. ΣOPEs were 139–2849 pg/L. Diffusive exchange fluxes between air and water showed deposition of actively emitted PAHs, near-equilibrium for most PCBs and OPEs, and slight volatilization of HCB. In its current state, this high-mountain region may be acting as a sink for several pollutants that accumulate in its surfaces and waters, including some of emerging concern, but some compounds may reach equilibrium between air and other compartments and experience seasonal secondary emissions.

3.22.B.T-03 The Atmospheric Fate of TBECH: Spatial Patterns, Seasonal Variability, and Deposition to Canadian Coastal Regions
Jenny Oh[1]*, Faqiang Zhan*[2]*, Yuening Li*[2]*, Chubashini Shunthirasingham*[3]*, Ying Duan Lei*[2]*, Abigaëlle Dalpé-Castilloux*[4]*, Zhe Lu*[4]*, Kelsey Lee*[5]*, Frank Gobas*[6]*, Sabine Eckhardt*[7]*, Nick Alexandrou*[3]*, Hayley Hung*[8] *and Frank Wania*[1,2]*, (1)Department of Chemistry, University of Toronto, Canada, (2)Department of Physical and Environmental Sciences, University of Toronto, Canada, (3)Environment and Climate Change Canada, Canada, (4)University of Québec À Rimouski, Canada, (5)Simon Fraser University, Canada, (6)Resource & Environmental Management, Simon Fraser University, Canada, (7)Norwegian Institute for Air Research (NILU), Norway, (8)Environment and Climate Change Canada, Toronto, Canada*
As traditional BFRs are gradually phased out of production and usage internationally, emerging brominated flame retardants (EBFRs) have been increasingly produced and used in recent years, with little to no environmental assessment or regulation. Despite its repeated global detection, concerted efforts in monitoring the air concentrations and atmospheric deposition of the EBFR, 1,2-dibromo-4-(1,2-dibromoethyl)cyclohexane (TBECH), in Canada have been limited. Moreover, its potential environmental behaviour is still poorly understood, particularly any differences in its two main isomers, α- and β-TBECH. With the objective to gain insight in the atmospheric fate of α- and β-TBECH in general and in Southern Canada specifically, we characterized the spatial and seasonal variability in their air and water concentrations using PAS and PWS networks installed across the coastal regions of Quebec (QC) and British Columbia (BC), Canada, which indicated higher levels in populated, urban areas, particularly during warmer deployment periods, and explored their potential for atmospheric deposition using deposition sampling. As one of the banned traditional BFRs, 2,2',4,4'-tetrabromodiphenyl ether (BDE-47) served as a comparison to TBECH, which had comparable distribution and levels to that of TBECH. Seasonal trends in atmospheric TBECH and BDE-47 were also explored in urban (Toronto, Ontario) and remote regions (Saturna Island, BC and Tadoussac, QC) using active air sampling (AAS). TBECH and BDE-47 levels correlated with temperature in Toronto and Tadoussac; however, the relationship was less pronounced on Saturna Island. Air mass origin calculations with FLEXPART estimating the impact of anthropogenic emissions on the measured levels of BFRs in this remote region neither fully explain their seasonal variability, suggesting that the atmospheric fate of BFRs on Saturna Island may be subjected to complex, competing influences of air mass origin and temperature. Despite there being no evidence that TBECH has been produced, or imported for use, in Canada, it is now similarly abundant in the Canadian atmosphere as BDE-47. The recorded spatial and temporal variability of TBECH air concentrations suggest that its emissions are not occurring at specific locations but are generally tied to the presence of humans. The most likely explanation for its environmental occurrence in Canada is therefore the release from imported consumer products containing TBECH.

3.22.B.T-04 Assessing Chemical Mixtures in Urban Air Using PUF-disk Passive Air Samplers: What Can be Achieved via High-resolution Mass Spectrometry Based Nontargeted Analysis
Xianming Zhang[1]*, Cassandra Johannessen*[1]*, Amandeep Saini*[2]*, John Liggio*[2] *and Tom Harner*[2]*, (1)Chemistry and Biochemistry, Concordia University, Canada, (2)Environment and Climate Change Canada, Canada*
Urban air contains complex chemical mixtures from various chemical sources. Chemicals emitted to urban air undergo complex transformations, which act as secondary sources of many chemicals in air. To improve understanding and managing the ever-expanding list of persistent organic pollutants, atmospheric monitoring using passive air samplers provides a cost-effective mean with capability of characterizing environmental exposures of chemicals in air and tracing source attributions. A wide range of chemicals are present in air and sampled by passive air samplers. Evidence has suggested there is a need to capture lesser-known chemicals in air to assess the risk of chemical mixture in air. Gas- and liquid chronography coupled with high-resolution full

spectra mass spectrometer provide a good opportunity to analyze the complex chemicals mixtures in air. The approach referred to as nontargeted analysis (NTA). In this study, we conducted NTA for passive air samplers that were deployed to capture various urban source sectors and based on the variation in concentrations in different groups of samples, we filtered chemicals contributed by specific source sectors (e.g., road) and spent efforts on identifying abundant lesser-known chemical present in urban air. NTA was conducted for 30 extracts of passive air samplers deployed in Toronto to capture influence of various source sectors including traffic, urban, residential, and industrial contributions. Partial least square discriminant analysis (PLS-DA) was used to filter compounds associated with a sample group. A total of 16000 chemical features were extracted from the data. Of the chemical features, 3200 are aromatic compounds with RDBE>8. Chemical features contributing to distinguish the traffic influenced with other sites include some well-known compounds known as from vehicle engine emissions. For example, polycyclic aromatic hydrocarbons such as fluorene, anthracene, etc., and other polycyclic aromatic compounds containing nitrogen and alkyl groups were also found in this cluster of chemicals. For example, 4,5-dimethyl-carbazole, and di-t-octyl-diphenylamine. Di-t-octyl-diphenylamine is known as used in lubricant oil so it can be originated from non-exhaust vehicle emissions. Besides the steric hindered phenylamines, we also observed a number of compounds containing N and O (e.g. $C_{19}H_{23}NO$ and $C_{21}H_{27}NO$). These compounds can be originated from atmospheric oxidation of the precursor compounds.

3.22.P-Mo240 Integrated Treatment of Per- and Polyfluoroalkyl Substances in Existing Water Treatment Plants – Scoping the Potential of Foam Partitioning

***Sanne Smith**, Karin Wiberg and Lutz Ahrens, Department of Aquatic Sciences and Assessment, Swedish University of Agricultural Sciences (SLU), Sweden*

Per- and polyfluoroalkyl substances (PFAS) are environmental pollutants known for their persistent, bioaccumulative and toxic properties. They are ubiquitous in the aqueous environment, but existing water treatment technologies are energetically and financially costly. Recently, foam fractionation has been established as a relatively inexpensive and green water treatment method capable of achieving competitive PFAS removal. It works by introducing air bubbles at the bottom of a water column, to which the PFAS molecules adsorb. If surfactant concentrations in the water are high enough, a PFAS-enriched foam can subsequently be separated from the liquid phase, resulting in a relatively PFAS-free effluent.

Many existing water treatment plants use aeration as part of their treatment train. Often, the presence of surfactants or filamentous bacteria may result in formation of foam on top of such treatment processes. We investigated whether foam formation could be exploited for the integrated removal of PFAS within existing treatment processes. Influent, effluent, and foam samples from seven water treatment plants, where foam formation in an aerated process step was observed, were analysed for the concentrations of 29 PFAS. Treatment processes included in the study were activated sludge, moving bed biofilm reactor (MBBR) and electrocoagulation. In addition, correlation analysis of PFAS concentrations with general chemistry parameters were performed. For each treatment plant, the ΣPFAS concentrations in the foam were indeed higher than in the influent, with ΣPFAS enrichment factors ranging between 1.2 and 150,000. Enrichment in the foam was generally higher for long-chain PFAS than for short-chain PFAS. The enrichment was highest in foam from the MBBR processes. Despite the high PFAS concentrations in the foam, no decrease in effluent PFAS concentrations occurred for most plants, indicating that enrichment in the foam does not necessarily lead to PFAS removal. Nevertheless, the high foam concentrations could possibly be used to contrive an integrated PFAS removal by optimizing existing systems. The findings of this novel green treatment technology will be of interest to water treatment plant operators who are trying to decrease aqueous PFAS contamination, but also to scientists or regulators who must consider foam partitioning in their sampling strategies for PFAS.

3.22.P-Mo241 Evaluation of Anaerobic Digestion and Diverse Thermal Treatments for the Removal of Organophosphate Flame Retardants (OPFRs) from Norwegian Sewage Sludge

***Gabriela Castro Varela**[1], Erlend Sørmo[2], Guahua Yu[1], Shannen Thora Lea Sait[3], Susana V. Gonzalez[3], Alexandros G. Asimakopoulos[1] and Hans Peter Arp[1,2], (1)Norwegian University of Science & Technology (NTNU), Norway, (2)Norwegian Geotechnical Institute (NGI), Norway, (3)Department of Chemistry, Norwegian University of Science & Technology (NTNU), Norway*

Organophosphate flame retardants (OPFRs) are chemical additives widely used in combustible materials to prevent fire or delay combustion processes. Due to their properties, these substances are commonly used as plastic and flame-retardant additives in furniture, upholstery, electronics, and paints, among others. As these substances are not chemically bound to materials, they are easily released into the environment through volatilization, abrasion, or dissolution. Their main routes of entry into the environment are through product life cycles, the discharges from wastewater treatment plants (WWTPs) and atmospheric emissions. Particularly in the case of WWTPs, some OPFRs display limited biodegradation during the treatment and high accumulation in sewage sludge, demonstrating that primary and secondary treatments applied in the WWTPs are not sufficient to remove them from the water or sludge. An alternative waste handling technique for sludge is combustion or pyrolysis, which consists of heating up the sludge in the presence or absence of oxygen, respectively. The combustion process produces mainly low carbon ashes, while the pyrolysis process can result in the production of a porous carbon-rich product called biochar that can be used further as soil amendment. Recently, pyrolysis of sewage-sludge has been widely studied as a promising new treatment alternative that promotes circular economy in waste management.

The behaviour of OPFRs during treatment in WWTPs was assessed, as well as the removal efficiencies of these substances during anaerobic digestion and thermal treatments such as combustion and dry pyrolysis. To that aim, raw-, digested-, combusted and pyrolyzed sludge samples collected from different WWTPs located in Norway were analysed. Obtained results demonstrated the presence of sixteen out of 21 OPFRs in digested sludge samples in concentrations up to 2186 ng g^{-1} (dry wt; total concentration). Combustion of digested sludge was carried out at 100 and 300°C. The ΣOPFR decreased only 4% at 100°C but reached up to

98% when the temperature was increased to 300°C. As for pyrolysis, the digested dry sludge was subjected to pyrolysis at different temperatures, from 500 to 800°C, and at a residence time of 20 to 40 min. According to the results, pyrolysis was considered sufficient to reduce the concentrations of ΣOPFRs to <10% at the lowest temperature (500°C).

3.22.P-Mo242 How Do Trees Capture PAHs? Tree Height Matters and So Does Leaf Shading

Pablo Giráldez[1]*, Zulema Varela*[2]*, Antonio Di Guardo*[3]*, Elisa Terzaghi*[3]*, J. Ángel Fernández*[2] *and Jesús R. Aboal*[2]*, (1)Functional Biology, University of Santiago de Compostela, Spain, (2)University of Santiago de Compostela, Cross-Research in Environmental Technologies (CRETUS), Spain, (3)Department of Science and High Technology (DiSAT), University of Insubria, Italy*

Trees can improve local air quality by capturing **polycyclic aromatic hydrocarbons** (PAHs), which is especially important in cities with heavy motor traffic, but there are many unknowns about the uptake mechanisms. This lack of knowledge limits the application of models and complicates decision-making when deciding the type of trees to plant in urban environments. We investigated intracanopy ability of sequestering PAHs along a city road, and some of the factors responsible for the uptake, as well as we proposed hints for selecting best species to enhance capture ability. For this purpose, we selected 15 ornamental apple trees (*Malus* × *moerlandsii* "Profusion") from a main street in Coruña (Galicia, NW Spain), with a high traffic intensity (average of 12,262 vehicles/day). In each of these trees we sampled leaves from 12 positions corresponding to three variables (3 heights, 2 distances to the trunk, and 2 orientations) and determined the concentration of 16 PAHs and the SLA in each sample. After statistical analysis, we found significant differences between positions, able to explain approximately 30% of the observed variability. The main differences were between heights and, in some cases, between distances to the trunk, with lower and inner leaves having a significantly higher PAH uptake capacity than upper and outer leaves. To determine the importance of SLA in the observed differences, the analyses were repeated with the data corrected for SLA, i.e., expressing concentrations in terms of surface area instead of mass. As a result, we found that the differences between distances to the trunk disappeared and that the R^2 decreased when significant differences were maintained. That is, the concentration differences between inner and outer leaves and part of the differences between leaves of different heights can be explained by differences in SLA. All these results suggest that intra-individual variability is not negligible and should be taken into account in sampling and models designs. Two of the main sources of variability are height (lower leaves uptake more PAHs than higher leaves) and SLA (the higher the SLA, the higher the concentration of PAHs per leaf gram). This may be due to distances to the emitting source, the barrier effect of leaves and leaf illumination (both for its influence on SLA and PAH volatilisation-deposition). Therefore, the ideal vegetation for removing PAHs from the air would be leafy trees or shrubs, not too tall and shaded.

3.22.P POPs and Emerging Pollutants: Environmental Fate, Research, and Monitoring at the Interfaces of Science and Policy & Application of Green Removal Technologies

3.22.P-Mo243 Fractionation and Toxicity Study on Produced Water Discharge

Matteo Ottaviani[1]*, Neri Bonciani*[1]*, Lars Skjolding*[1] *and Karen Feilberg*[2]*, (1)Technical University of Denmark (DTU), Denmark, (2)DTU Offshore, Technical University of Denmark (DTU), Denmark*

Produced water (PW) is the water co-produced with oil and gas from oil wells and it represents the largest volume waste stream in oil and gas production operations on most offshore platforms. In 2021 there was an estimated 30 million tons of produced water discharged from the Danish continental shelf alone. Current regulations cover only the dispersed hydrocarbon content by the legal limit of 30 mg/L; this limit does not address the polar species, such as naphthenic acids and alkyl phenols dissolved in the water, which are potentially more environmentally concerning constituents in produced water. Produced water is high in content of BTEX (benzene, ethylbenzene, toluene, xylene) together with naphthalene and alkylated naphthalene compounds, naphthenic acids (NAs) and Alkyl phenols (APs). NAs and BTEX come from natural contact of crude oil with water, NAs and APs come from added production chemicals but also naturally occurring in crude oil. Nonylphenols (NPs) and Octylphenols (OPs), are covered by EU regulations and included in the list of priority hazardous substances for surface waters. For detailed analysis, samples of produced water discharge from the Danish South North Sea oil production wells are purged in charcoal trap for volatiles analysis, and then fractionated by Solid Phase Extraction (SPE) leading to the isolation of APs, NAs and other organics. The individual extracts are measured for target analysis with GC-MS and LC-ESI-MS. The ecotoxicity of the extracted fractions is tested using standard toxicology tests on bacteria *Aliivibrio Fischeri* and algae *Skeletonema sp*. The results of this study can help to better understand major drivers of toxicity of produced water discharge together helping to develop better technologies for the offshore wastewaters treatments.

3.22.P-Mo244 Factors Influencing Concentrations of Organophosphate Esters in UK Freshwater Sediment

Simeon Ojochogwu Onoja[1]*, Mohamed Abou-Elwafa Abdallah*[2] *and Stuart Harrad*[2]*, (1)Geography Earth and Environmental Sciences, University of Birmingham, United Kingdom, (2)University of Birmingham, United Kingdom*

Because of their extensive application as flame retardants, plasticisers, and anti-forming agents, the environmental presence and toxicity of organophosphate esters (OPEs) has become a subject of serious concern. As wastewater treatment plants (WWTPs) have been suggested as major sources of OPEs to the aquatic environment, this study evaluates the impacts of WWTPs on OPE contamination, as well as spatial and seasonal variations in OPE concentrations in UK riverine and canal sediment, for the first time. Detection frequencies of the target analytes (tris (chloroethyl) phosphate (TCEP), tris (2-chloroisopropyl) phosphate (TClPP), tris (1,3-dichloro-2 propyl) phosphate (TDClPP), tri-n-butyl phosphate (TNBP), tris (2-butoxyethyl) phosphate (TBOEP), 2-ethylhexyl diphenyl phosphate (EHDPP), tris (phenyl) phosphate (TPHP), and tri-m-tolyl phosphate (TmTP)) ranged from 58% to 100%. The relative abundance of Cl-OPEs was TCIPP>TCEP>TDCIPP and the concentration of Σ_8OPEs ranged from 107 ng g^{-1} (dry wt; in the Worcester-Birmingham canal) to 52 ng g^{-1} (dry wt; in both rivers Severn and Sowe). Significantly higher concentrations were observed downstream than upstream of the WWTP for some target OPEs and the highest $\sum_8$OPE concentration for all study locations was recorded within Autumn months (September, October, and November). Concentrations of $\sum_8$OPEs in sediment samples from the River Severn, River Tame, and River Sowe all varied inversely with the river level and flow rate. The potential risk posed by the target OPEs in all study locations was found to be low, except for a moderate risk identified for EHDPP in the Worcester - Birmingham canal, while the average concentrations of each target OPE in each study location were lower than those reported in some previous studies but fall broadly in the middle of the range reported from other countries.

3.22.P-Mo246 Occurrence of Emerging Contaminants and Microplastics in Distinct River Basins (Urbanized and Rural) in the State of São Paulo, Brazil
***Vinicius Sarracini Santos**[1], Altair Benedito Moreira[2], Marcia Cristina Bisinoti[2] and Cassiana Montagner[3], (1)Institute of Chemistry, UNICAMP - University of Campinas, Brazil, (2)São Paulo State University (UNESP), Brazil, (3)UNICAMP - University of Campinas, Brazil*
Different land uses and occupations impact directly water quality due to the release of chemicals by anthropic activities. Agricultural areas are associated with pesticides, while urban and industrial areas are associated with personal care products (PCPs), industrial-origin substances, hormones, plastics, and microplastics (MPs). All these different substances are defined as emerging contaminants (ECs). To date, few studies have established a relationship between land use and occupation and the occurrence of these contaminants in surface water. We aimed to assess the impact of different land uses and occupations on the distribution of ECs in surface water in the state of São Paulo, Brazil. Two distinct watersheds were chosen: the Atibaia river basin, located in an urbanized and industrial area, and the Turvo/Grande river basin, located in an agricultural area with a predominance of sugarcane crops. Seasonal samples were collected at three points from each river to analyze the occurrence of ECs and microplastics. The occurrence of 28 ECs of industrial, urban, and agricultural origin was assessed. The contaminants in water samples were extracted by SPE and quantified by LC-MS/MS. Analysis of similarities (ANOSIM) and similarity percentages (SIMPER) were applied to compare the two different watersheds. MPs were collected in each river with a plankton net. The samples were digested and separated by density before characterization by ATR-μFTIR. ANOSIM analysis of emerging contaminants showed statistical differences between the watersheds ($p<0.05$). In SIMPER analysis, 5 out of 28 ECs (caffeine, carbendazim, tebuthiuron, atrazine and ametryn) contributed to 84% of the difference between the watersheds. Caffeine concentrations were higher in the Atibaia river, while the concentrations of the pesticides carbendazim, tebuthiuron, atrazine, and ametryn were higher in the Turvo/Grande river. The most common types of MPs found in this study were white fragments, ranging from 100 to 250 μm in size, made of polypropylene or polyethylene. Fibers and different color plastics were found near urban areas, indicating the presence of anthropogenic sources. However, more seasonal sampling is needed to confirm this relationship. Our results showed that the occurrence and concentrations of ECs depend on the use and occupation of the basin since higher concentrations of pesticides were found near agricultural areas, while caffeine concentrations were higher near urban areas.

3.22.P-Mo247 Sources of Organophosphate Esters to Coastal Regions in Southern Canada
***Yuening Li**[1], Faqiang Zhan[1], Chubashini Shunthirasingham[2], Jenny Oh[3], Ying Duan Lei[1], Zhe Lu[4], Abigaëlle Dalpé-Castilloux[4], Nick Alexandrou[2], Chunwen Weng[1], Kelsey Lee[5], Frank Gobas[6], Hayley Hung[7] and Frank Wania[1], (1)Department of Physical and Environmental Sciences, University of Toronto, Canada, (2)Environment and Climate Change Canada, Canada, (3)Department of Chemistry, University of Toronto, Canada, (4)University of Québec À Rimouski, Canada, (5)Simon Fraser University, Canada, (6)Resource & Environmental Management, Simon Fraser University, Canada, (7)Environment and Climate Change Canada, Toronto, Canada*
To identify and quantify the sources of organophosphate esters (OPEs) to the atmosphere and waters of the St. Lawrence estuary in Quebec (QC) and the Southern Salish Sea region of British Columbia (BC) in Canada, this study relied on two extended passive sampling networks. Overall, more than 150 XAD resin-based passive air samplers and more than 50 polyethylene sheet-based passive water samplers were deployed between November 2019 and April 2022. In both coastal areas, active air and precipitation samples were also collected for a full year at remote sites in Tadoussac, QC, and on Saturna Island, BC. Six OPEs (tributyl phosphate [TBP], tris(2chloroethyl) phosphate [TCEP], tris (1-chloro-2-propyl) phosphate [TCPP], tris (phenyl)phosphate [TPhP]), and 2ethylhexyldiphenyl phosphate (EHDPP) were reliably detected. The average atmospheric concentration levels of these OPEs are similar in the two sampling regions and comparable with values reported earlier. The concentrations of OPEs in air are correlated with the population density around a sampling site, and, in particular, are elevated in densely populated areas such as Vancouver, Montreal, and Quebec City. Changes in the relative abundance of OPEs with distances from such population centres can shed light on the relative atmospheric dispersion potential of different OPEs. Factors influencing the variability in the concentrations in air and precipitation between different seasons are investigated with the help of relationships with ambient temperature and air mass history. Concentrations of the OPEs in water are also related to human activities. For example, in BC, higher TCPP levels in Esquimalt Harbour may indicate the presence of local sources.

3.22.P-Mo248 Calibrating a Passive Air Sampler for Polychlorinated Biphenyls: The Dependence of the Sampling Rate on Temperature and the Number and Position of Chlorines
***Yuening Li**[1], Faqiang Zhan[1], Ying Duan Lei[1], Chubashini Shunthirasingham[2], Hayley Hung[3] and Frank Wania[1], (1)Department of Physical and Environmental Sciences, University of Toronto, Canada, (2)Environment and Climate Change Canada, Canada, (3)Environment and Climate Change Canada, Toronto, Canada*

Confident use of a passive air sampler (PAS) requires knowledge of its uptake kinetics in their dependence on meteorological conditions and chemical properties. Such knowledge is gained through calibration studies. Whereas the XAD-PAS has previously been calibrated for the polychlorinated biphenys (PCBs), only a limited number of congeners had been quantified. With the increasing interest in investigating the full suite of PCBs congeners, there is a need to understand how the XAD-PAS's sampling rate (*SR*) may vary with a congener's chlorine substitution. We therefore determined the *SR*s of a wide range of PCB congeners in the XAD-PAS during a calibration study in Toronto, Canada, involving continuous high-resolution active air sampling and twelve deployment periods ranging from 4 weeks to 48 weeks. Because of the wide seasonal range of temperatures in Toronto, the study further allowed us to investigate the influence of temperature on the *SR*s of PCBs. Due to the relatively high uptake capacity of XAD resin, the amount of all PCBs taken up in the XAD-PAS increased with deployment length throughout the entire year-long study. This was true even for the most volatile congeners, such as PCB-1. This linear uptake confirms the suitability of the XAD-PAS for quantitative sampling of the full range of PCBs, even for deployment lengths as long as one year. We successfully determined *SR*s for 66 PCB congeners, including the first-ever reported *SR*s for 56 of them. The *SR*s tend to increase with increasing congener volatility. Specifically, the *SR*s decrease with an increasing number of chlorine substitutions. Within a homologue, the *SR* is positively related to the number of ortho-chlorines, which is again explained by the effect of ortho-substitution on volatility. The logarithm of the hexadecane–air partition coefficient at 25°C, *L*, explains 75% of the variability in the measured *SR*s of the PCB congeners. The *SR*s of PCB congeners not detected in this study can therefore be estimated from *L*. We also observed slightly higher *SR*s during warmer seasons. Because volatility increases with temperature, this influence of temperature is consistent with the finding of higher *SR*s for more volatile congeners. The observed dependence of the *SR*s of the PCBs on volatility and temperature is consistent with the behaviour expected for chemicals that sorb strongly to XAD-resin from the gas phase and experience a relatively slow sorption kinetics.

3.22.P-Mo249 Foam Fractionation for Removal of PFAS from Contaminated Water – Towards Closing the Mass Balance
Sanne Smith[1]*, Jeffrey Lewis*[2]*, Karin Wiberg*[1] *and Lutz Ahrens*[1]*, (1)Department of Aquatic Sciences and Assessment, Swedish University of Agricultural Sciences (SLU), Sweden, (2)Emerging Compounds Treatment Technologies (ECT2), Sweden*
Per- and polyfluoroalkyl substances (PFAS) are known for their persistent, bioaccumulative and toxic properties and are notoriously difficult to remove from water. Foam fractionation has recently attracted attention as a low-cost and environmentally green treatment technology for PFAS-contaminated water. The technology works by adsorbing PFAS on rising air bubbles and subsequently sequestering a concentrated foam from the top of the water column, resulting in a PFAS-depleted effluent. However, since foam concentrations are often not determined, data on the mass balance over the foam fractionation process are scarce. Moreover, when foam concentration data are available, gaps in the mass balances are often found. This study verified the high PFAS removal efficiency of a pilot-scale foam fractionation process for treatment of industrial water contaminated with aqueous film-forming foam. ΣPFAS removal reached up to 84 % and the removal of perfluorooctane sulfonic acid (PFOS) up to 97%. Fluctuations in treatment efficiency due to variations in the total organic carbon concentration, pH and turbidity of the influent water were minor, confirming the robustness of the technology. Significant positive correlations between PFAS removal and conductivity as well as influent dissolved salt concentration were observed. Over all experiments, the mass balance closure did not differ significantly from 100%, which was partly due to high measurement uncertainties. Nonetheless, there was measurable PFAS sorption to the walls of the reactor, and high PFAS emissions exited the reactor with the outgoing air. Mass balance closure correlated positively with PFAS emissions in aerosols, which could possibly be caused by underlying correlations with turbidity. The elevated PFAS concentrations in the air around the pilot-scale process have human and environmental health implications for worker exposure and prevention of PFAS releases to the atmosphere, and demonstrate that it is crucial to vent foam fractionation systems to the outside and install appropriate filters on their air outlets.

3.22.P-Mo250 Effect of Clarithromycin Addition on Soil Microorganisms of Agricultural Acid Soils
Vanesa Santás-Miguel[1]*, Laura Rodríguez-González*[1]*, Cristina Pérez-Novo*[1]*, Elena García-Campos*[2]*, Angela Martín*[2]*,* ***Montserrat Diaz-Ravina***[2]*, Manuel Arias-Estévez*[1] *and David Fernández-Calviño*[1]*, (1)Soil Science and Agricultural Chemistry, University of Vigo, Spain, (2)Soil Biochemistry, Misión Biológica de Galicia (MBG-CSIC) Sede Santiago, Spain*
The presence of emergent contaminants such as antibiotics of human use can provoke important damage on non-target-microorganisms of agricultural soils. The microbial community's response to the clarithromycin addition at seven different concentrations was studied in four acid soils located in Galicia (NW Spain) with different organic C content and similar pH after 8 and 42 incubation days. The phospholipid fatty acid analysis was used to estimate the total microbial biomass and specific fungal, bacterial, actinobacterial, Gram-negative bacterial, and Gram-positive bacterial biomass as well as the microbial community structure (PLFA). The microbial biomass (total and specific groups) was different in four studied soils, the highest values being exhibited by soils with the highest organic C. The antibiotic addition showed a positive effect on microbial biomass (total and specific groups), especially at the highest dose; the effect being more accentuated with time passed after the addition (42 days > 8 days). Principal component analysis (PCA) of the PLFA data performed with the whole data set showed that the main determining factors of the microbial structure followed the order: soil > time incubation > antibiotic dose. When the PCA was performed separately for each incubation time, the results showed that microbial communities of four soils were different. Likewise, for each soil, different microbial communities were observed depending on antibiotic concentration.

3.22.P-Mo251 Clarithromycin Sorption by Different Forest and Crop Soils
Ana Barreiro[1]*, Raquel Cela Cela-Dablanca*[1]*, Lucía Rodríguez-López*[2]*, Manuel Arias-Estevez*[2]*, Avelino Núñez-Delgado*[1]*, María J. Fernández-Sanjurjo*[1] *and Esperanza Alvarez-Rodriguez*[1]*, (1)Soil Science and Agricultural Chemistry, University of Santiago de Compostela, Spain, (2)Soil Science and Agricultural Chemistry, University of Vigo, Spain*

Persistent organic pollutants (POPs) bioaccumulate in the environment being both an environmental and a health issue. Among these compounds, pharmaceutical products, such as antibiotics, represent an important percentage of them, since their use is generalized and increases yearly. Clarithromycin is a macrolide antibiotic used to treat several bacterial infections. It has been detected in the sewage systems of different cities around the globe, which involves the risk of ending up in soils when sewage sludges are used as fertilizers. It is important to determine the sorption capacity of soils to estimate the risk of leaching to groundwater and water courses on one side, or the persistence on the soil and consequently availability for transfer to crops on the other side. The aim of this work was to quantify the sorption capacity for the antibiotic clarithromycin by 21 different forest and crop soils covering a wide range of pH and organic matter content. Batch experiments were performed with 3 forest soils (under pine, oak, and eucalyptus), 6 soils under corn and 12 vineyard soils. Clarithromycin was added at different concentrations (2.5, 5, 10, 20, 30, 40, 50 µmol L^{-1}) to the soil samples and the adsorbed and desorbed antibiotic concentration was measured using HPLC equipment. The results showed that the forest soils adsorbed less than the crop soils, both under corn and vineyard, especially at the highest antibiotic concentrations added. The maximum value of adsorbed clarithromycin on the forest soils was 77% for the lower antibiotic concentration on the pine soils, meanwhile several of the crop soils adsorbed 100% of the antibiotic added even at the highest concentrations. Regarding desorption, on the forest soils there were not desorbed clarithromycin, which means that the adsorption process is practically irreversible. On the other hand, some of the crop soils presented desorption, one of the corn soils with maximum desorption of 7%, and three of the vineyard soils with high percentage of desorption (50–80%) for the lower antibiotic concentration added, even though for most of the crop soils the desorption was very low or below the detection level. In general, clarithromycin was adsorbed in high quantities by the crop soils, decreasing the risk of leaching and incorporation into the food chain.

3.22.P-Mo252 The Impact of Sediment Turbidity on PAH Resuspension and Potential Baseline Toxicity

Betty Chaumet[1]*, Elena Gorokhova*[2]*, Sofi Jonsson*[1]*, Stefano Bonaglia*[3]*, Johanna Hedberg*[1] *and Anna Sobek*[1]*, (1)Environmental Science, Stockholm University, Sweden, (2)Department of Environmental Science, Stockholm University, Sweden, (3)Gothenburg University, Sweden*

Sediments store a wide range of contaminants, particularly hydrophobic ones, such as PAHs. Under high turbulence, sediment particles are resuspended in the water column, where chemicals are released. In the water phase, the freely dissolved concentration (Cfree) represents the bioavailable fraction of the chemical. This study aims to understand better how sediment resuspension affects PAH leakage from sediment to the water and how this leakage is modulated by PAH hydrophobicity.
An experiment was carried out with cores of spiked sediment with 4 PAHs (acenaphthene, fluorene, phenanthrene and fluoranthene; 3 mg kg^{-1}) with a gradient in log Kow from 3.9 to 5.2. A polyethylene passive sampler (PE) was added to each core, and different flow velocities were applied to create different resuspension levels. The turbidity was measured and used as a proxy for sediment resuspension. PEs were collected after 2, 3, and 4 weeks of exposure and PAHs were extracted from the PE and quantified by GC-MS. The chemical activity (the effective concentration of a chemical in a compartment, e.g., water) was calculated for each PAH and summed to estimate the baseline toxicity of the mixture.
The turbidity increased with the flow velocity but decreased after two weeks of exposure, most probably due to particle aggregation. The uptake of PAHs by the PE was affected by turbidity and the molecule's hydrophobicity, with a significant interaction between the two variables. At low turbidities (<3 NTU), PAHs were accumulated according to their gradient of hydrophobicity with higher accumulation for lower Kow. However, as turbidity increased, the uptake of congeners with different Kow converged to become similar at >7 NTU. These dynamics are most likely driven by PAH diffusion and desorption from the resuspended particles at low and high turbidities, respectively. Finally, a model ensemble was established to (1) predict Cfree using turbidity and logKOW values from the experiment and (2) estimate the potential baseline toxicity of the mixture from the Cfree values.
Our findings show that using passive samplers in field surveys should be combined with turbidity measurements to obtain PAH concentrations (and, perhaps, other hydrophobic contaminants) under environmentally relevant conditions. Thus, this study contributes to improved hazard assessment of pollutants in the sediments and demonstrates the need to account for the natural variability of resuspension in the environment.

3.22.P-Mo253 Efficient Removal of Flame Retardants by Metal Ferrites Nanoparticle Incorporated in Guar Gum Moiety: Green Synthesis and Photoactivity

Keshu .[1]*, Manviri Rani*[2] *and Uma Shanker*[3]*, (1)Chemistry, National Institute of Science, India, (2)Chemistry, Malaviya National Institute of Technology India, (3)Chemistry, DR. BR Ambedkar National Institute of Technology, India*

In the COVID-19 pandemic, several reports concluded that improper disposal of plastic has caused adverse impact on environment in form of debris and leaching of chemicals present in it. Brominated Flame Retardants (BFRs) mainly Terabromobisphenol-A (TBBPA) used in many plastic industries proved to be endocrine disruptor, persistent and create genotoxicity. Seeing environment safety, the present study investigated the removal of TBBPA from water by using green synthesized ferrites nanomaterials. Seed extract of *Sapindus mukorossi* was used as capping and reducing agent. For structural and morphological analysis, PXRD and different microscopic techniques were used, respectively. The water samples were collected from different fields where plastic wastes were collected and centrifuged to remove solid impurities. The traces of TBBPA were confirmed by LC-MS and UV-Visible spectrometer. Various parameters were also optimized to get maximum removal of TBBPA under sunlight. Green nanomaterial followed both adsorption as well as photocatalytic degradation to convert complex structure of TBBPA into safer metabolites. LC-MS technique was used to find out formation of metabolites formed during photocatalytic degradation. Thus, such metal ferrite photocatalyst could be used as a promising material for application in industrial wastewater treatment processes.

3.22.P-Mo254 Organoclay for Sorption of PFAS Mixtures from Natural Waters

Paul Scapan[1], *Björn Bonnet*[2], *Martin Bertau*[3] *and Lutz Ahrens*[2], *(1)Institute of Chemical Technology, Technical University Bergakademie Freiberg, Germany, (2)Department of Aquatic Sciences and Assessment, Swedish University of Agricultural Sciences (SLU), Sweden, (3)Technical University Bergakademie Freiberg, Germany*

As a class of well-known pollutants, per- and polyfluoroalkyl substances (PFAS) are extremely persistent and potentially bioaccumulative as well as toxic, and have been detected ubiquitously in the environment. In the context of increasing concentrations in the environment over the years, as well as current and new legislations with strict guideline values, the need for cost-effective and environmentally friendly treatment techniques is given. In particular, this involves the removal of PFAS from various water matrices using sorption filter materials.

Organically modified clay materials (Organoclays) have been developed that meet the requirements for an efficient removal option for PFAS. The material is based on low-cost as well as globally available clay and is modified with a sustainable surfactant. In this study, three different organoclays were tested in batch mode for removal of a wide range of different PFAS in aqueous solutions. In addition to the synthesis and characterization of organoclays in terms of active surface area by BET surface area analysis, infrared spectroscopy and thermogravimetric analysis, adsorption experiments have been performed.

At the beginning, the optimal solid/liquid ratio was determined. Experiments were performed as a function of time to determine kinetic parameters. Furthermore, results of PFAS removal from sampled water samples were evaluated. For this purpose, four natural water samples were spiked with a PFAS mixture and the removal was subsequently determined. Comparatively, activated carbon was tested for the same experimental parameters. The results showed higher removal rates with even over 80% removal of short chain compounds such as perfluorobutanoic acid and perfluoropentanoic acid for one organoclay compared to activated carbon. This value is reached after two hours of adsorption. Furthermore, the results from real water samples demonstrated that PFAS removal is lower compared to ultrapure water.

This research highlights that low-cost and sustainable adsorbents for PFAS removal are feasible. Moreover, they can reach similar or even better efficiencies in removing PFAS compared to activated carbon.

3.22.P-Mo255 Synthesis of Magnetic α-NiMoO4/ZnFe2O4/biochar and Study of Ketoprofen Decomposition Through Photocatalytic Reaction

Schindra Kumar Ray and ***Sungjun Bae****, Konkuk University, Korea*

Pharmaceutical organic pollutants have been found in various environments such as surface water, wastewater, and groundwater over the past decades, and these pharmaceutical pollutant residues have a problem that negatively affects aquatic ecosystems and human health. In this study, a heterojuntion structure/biochar composite (α-$NiMoO_4$/$ZnFe_2O_4$/ coffee biochar) containing nickel molybdenum oxide and zinc iron oxide capable of magnetic separation was synthesized through hydrothermal synthesis to decompose ketoprofen, one of the pharmaceutical substances. Through a batch reaction, it was confirmed that more than 98% of ketoprofen could be removed within 180 min under irradiation of visible light, and through a reusability test, it was confirmed that there was high decomposition efficiency and chemical stability even after reuse 5 times. In addition, α-NiMoO4/ZnFe2O4/coffee biochar showed excellent photocatalytic efficiency in the presence of various anions and a wide pH range, proving that it is a promising material for treating water environments. ESR analysis and scavenger test results showed that the hydroxyl radical formed through the photocatalytic reaction plays a key role in the decomposition of ketoprofen. The results of liquid chromatography-tandem mass spectrometry analysis revealed 24 degraded intermediates byproducts indicating three degradation pathways of ketoprofen in this study.

3.22.P-Mo256 Screening Chemicals for POP-Like Long Range Transport Behaviour

Knut Breivik[1], *Michael McLachlan*[2] *and Frank Wania*[3], *(1)Norwegian Institute for Air Research (NILU), Norway, (2)Department of Environmental Science, Stockholm University, Sweden, (3)Department of Physical and Environmental Sciences, University of Toronto, Canada*

Persistent organic pollutants (POPs) are likely as a result of their long-range environmental transport (LRT) to lead to significant adverse human health and/or environmental effects in remote regions. It is therefore of considerable interest to identify organic chemicals with a potential to result in environmental and human exposure in remote regions. However, most simple models motivated by regulatory needs, such as The OECD Pov and LRT screening Tool (Wegmann et al. 2009), do not explicitly calculate the potential for accumulation, and therefore for resulting in exposure, in a remote region. Currently, The Tool calculates (i) the distance it takes to reduce the chemical concentration by 63% in a plug-flow system (CTD), (ii) a transfer efficiency (TE) expressed as the mass flux from the atmosphere to remote surface compartments divided by the emission mass flux in a source region, and (iii) an overall persistence (Pov). Recently, we have developed three new LRT potential metrics, collectively referred to as the emissions fractions approach. Each of these metrics is expressed as a fraction of the emissions in a source region and quantifies the extent to which a chemical has the potential to (i) reach a remote region in both air and water (dispersion, $\varphi 1$), (ii) be transferred to surface media in the remote region (transfer, $\varphi 2$), and (iii) accumulate in these surface media (accumulation, $\varphi 3$). The new metrics were implemented into The Tool's code along with the CTD and the TE. This amended model was used to categorize 12,615 high-production volume chemicals (HPVs) for potential POP-like behaviour using threshold values for $\varphi 1$, $\varphi 2$, and $\varphi 3$ that were derived using a selection of chemicals categorized as POPs. For comparison we similarly categorized the HPVs based on the existing metrics. An assessment based on CTD and TE, unlike one based on $\varphi 1$ and $\varphi 2$, fails to recognize the potential for LRT in water for numerous chemicals. Even when combined with Pov, the existing LRT metrics therefore cannot fully account for a chemical's potential for accumulation in the remote region as a result of LRT in the same way that $\varphi 3$ does. An assessment based on $\varphi 3$ flags about twice as many HPVs as having POP-like LRT than an assessment based on the Pov and CTD. The main causes for the discrepancies in HPV categorization, along with the implications for ranking chemicals according to LRT potential, will be highlighted.

3.22.P-Mo257 Progressing Modeling of PFAS Bioavailability to Support Water Permitting and Effluent Monitoring Regulations

*Markus Hjort[1], **Craig Warren Davis**[2,3], Jennifer Lawrence[4], Jennifer Field[5], Mark J Benotti[4], Carla A. Ng[6], David W. Moore[7], Michael Mayo[8], Timothy C Schutt[8] and Harley R McAlexander[7], (1)Concawe, Brussels, Belgium, (2)Toxicology & Environmental Science, ExxonMobil Biomedical Sciences, (3)ExxonMobil Biomedical Sciences, (4)NewFields, (5)Oregon State University, USA (6)University of Pittsburgh, USA (7)U.S. Army Corps of Engineers, (8)U.S. Army Engineer Research and Development Center (ERDC)*

The unique chemical properties of per- and poly-fluoroalkyl substances (PFASs) present a challenge for developing regulatory guidelines to protect organisms in the environment. While long-chain perfluorinated alkyl acids (PFAAs) are bioaccumulative and frequently detected in biota and humans, their bioavailability and biological uptake are more complicated than other hydrophobic contaminants, such as PAHs or PCBs. Where PAHs and PCBs bind predominantly to storage lipids, PFAAs have the potential to interact strongly with proteins such as serum albumin, fatty acid binding proteins, and phospholipid membranes, and storage lipids. This challenge is further compounded by the fact that only a fraction of the PFAS structures identified or inferred in environmental samples can be reliably quantified with standard analytical methods. As such our understanding of PFAS bioavailability and environmental risk is incomplete and based on experiments and modelling from a limited domain of PFAS chemistry.

This poster outlines the framework for developing a reliable methodology for estimating biological uptake of PFAS based on protein-water (K_{PW}), membrane-water (K_{MW}), and octanol-water (K_{OW}) partition coefficients. These enhanced methods can better estimate PFAS bioavailability and provide practical guidance for regulatory monitoring and permitting of PFAS while minimizing vertebrate and in vivo testing.

Traditional bioaccumulation models, which solely rely on partitioning to storage lipids and are based on K_{OW}, do not accurately predict observed PFAA bioaccumulation. Such models do not consider other biologically relevant partitioning of PFAS. Therefore, there is a need to develop novel bioaccumulation models, or incorporate better predictors of biological partitioning, to develop PFAS regulations protective of the environment. These models may include K_{OW}, as well as K_{PW} and K_{MW} partition coefficients.

There is ongoing research to empirically measure K_{PW} and K_{MW} values for target PFAS. One particular tool, biomimetic chromatography, has the ability to predict K_{PW} or K_{MW} from the retention time on specialized HPLC columns. When coupled with high-resolution mass spectrometry (HRMS), biomimetic HPLC offers the ability to predict K_{PW} and K_{MW} values for suspect or non-target PFAS. Coupled with QSAR, measurements of biologically relevant partition coefficients can provide a more comprehensive understanding of the bioavailability of a larger domain of PFAS chemistries.

3.22.P-Mo258 Implementation of PFAS Transport Modelling to the Pesticide Fate Models PEARL and TOXSWA

***Héloïse Thouément**, Steven Droge, Wim Beltman, Louise Wipfler, Bas Buddendorf, Pauline Iris Adriaanse and Maarten Braakhekke, Environmental Risk Assessment, Wageningen Environmental Research (WUR), Netherlands*

Per- and polyfluoroalkyl substances (PFAS) are emerging threats to water and food safety. Contaminated drinking water can represent an important share of the multiple sources of exposure to PFAS, while water treatment technologies are costly to implement. The protection of water resources from PFAS contamination is therefore of utmost importance. In this context, the understanding of PFAS transport in soil, groundwater, surface water, and plants would help decision-makers to evaluate the most efficient policy measures to tackle this threat, for instance in the context of management of PFAS-polluted soils and waters (biosolids, municipal, and industrial wastewaters).

PFAS is a group representing thousands of molecules with a wide variety of physicochemical properties, which means that as a group they may show unusual environmental behavior compared to conventional environmental organic pollutants. Consequently, the modeling of PFAS requires adjustment of existing fate models. The models TOXSWA and PEARL are commonly used by the agrochemical sectors and regulators, and allow for state-of-the-art modelling of pesticides transport. Those two models therefore seem obvious candidates to be extended for PFAS modelling in the context of transfer to groundwater, surface water, and plant intake, in relation to agricultural practices such as sewage sludge use or atmospheric deposition.

In this preliminary study, we will collect environmental behavior for PFAS clusters, including the best conceptual representation of their behavior and the corresponding required parameters to allow the simulation of PFAS within the models PEARL and TOXSWA. We anticipate the following process descriptions to be improved or incorporated in our models: (i) sorption/repulsion of electrostatic compounds to various matrices such as soil, suspended solids, sediment or macrophytes, and the influence of inorganic ions thereon, (ii) macropore flow in soils induced by surfactants and (iii) air-water partitioning. The latter might lead to significant losses by volatilisation of neutral PFAS structures from surface water because of the high persistence of PFAS.

We will present the challenges arising from this work as well as the recommended next steps.

3.22.P-Mo259 Time Trends of Legacy and Emerging SVOCs in a Kindergarten Undergoing "Green" Retrofitting: Phase 1 – Pre-renovation Conditions

***Lisa Melymuk**, Simona Rozarka Jilkova, Eliska Matulova and Ondrej Mikes, Recetox, RECETOX, Masaryk University, Czech Republic*

Older buildings are often associated with a higher load of semi-volatile organic compounds (SVOCs) such as polychlorinated biphenyls (PCBs), organochlorine pesticides (OCPs), and polybrominated diphenyl ethers (PBDEs), while in newer buildings plasticizers, organophosphate flame retardants (OPFRs), and other plastic additives typically receive more attention. Green building retrofitting, aimed at reducing energy and water consumption, involves the renewal of insulation and ventilation systems, which can greatly impact chemical levels indoors. We investigate the status of chemical pollution in an older urban kindergarten (built in 1952) before renovation. Indoor air and dust in three kindergarten rooms were collected monthly over one year, as well as outdoor air adjacent to the kindergarten, to establish baseline conditions before renovation. Samples were quantified for a broad set of POPs and emerging chemicals, including PCBs, PBDEs, OPFRs, PFAS, PAHs, and current-use pesticides. Indoor dust concentrations were relatively stable over the year, with greater variations between the rooms, attributed to proximity to building materials and classroom equipment. Indoor air had consistent levels of synthetic chemicals over time, with only PAHs having substantial seasonally-driven variations over the year. Indoor air concentrations were consistently higher than in outdoor air for all legacy and emerging chemicals. This is the first phase of a multi-year study that will track building-associated chemical burdens before, during and after green retrofitting. These data provide insight into the major sources of variability driving children's exposure to POPs and emerging SVOCs in a kindergarten and will allow us to evaluate green retrofitting alters the chemical loads in the indoor environment.

3.22.P-Mo260 Evaluation of Best Available Techniques for Toxicity Monitoring of Refinery Effluents

Megan Griffiths[1]*, Christopher Hughes*[1]*, Markus Hjort*[2] *and Eleni Vaiopoulou*[2]*, (1)Ricardo Energy & Environment, United Kingdom, (2)Concawe, Brussels, Belgium*

The Industrial Emissions Directive prescribes that industry emissions should be treated using the Best Available Technology (BAT). The parameters that refineries are obliged to monitor are laid down in a Commission Implementing Decision BAT Conclusions (BATC) document for the mineral oil refining sector (REF). The REF BATC specifies monitoring requirements for wastewater, but without any BAT for toxicity monitoring. Past research has typically focused on identifying, quantifying, and measuring toxicity of individual chemicals. However, Effect-Based Methods (EBMs) have recently emerged as useful bioanalytical monitoring tools that can complement chemical analysis measurements of water/whole effluent quality. EBMs use the responses elicited in bioassays to identify and quantify the toxic effects of chemical families in the sample. This work aimed to identify and evaluate in vivo and in vitro toxicity test methods in order to shed light upon which tests could be appropriate for toxicity monitoring of refinery effluents, such as may be required in future EU legislation.

A total of 13 in vivo and 18 in vitro tests were evaluated against specific criteria based on a literature review and survey of commercial laboratories. The criteria included validation maturity, performance, use, conduct of test, result interpretation and possible application limitations. Our potential test battery includes the *umuC,* AhR activation, AREc32 activation, *Allivibrio fischeri* toxicity, algal growth inhibition, *Daphnia* immobilisation, and Fish Embryo Toxicity (FET)/qFET or bivalve embryo development assays. The latter two are considered interchangeable depending on the type of water sample tested and relevance for the receiving water body. The battery covers *in vitro* modes of action (genotoxicity, metabolism and oxidative stress) as well as apical *in vivo* endpoints (cytotoxicity, developmental toxicity, immobilisation and growth inhibition). All tests are commercially available, commonly used for the assessment of environmental water samples, sufficiently validated, standardised to an ISO guideline (or one is currently in preparation) and are expected to be responsive to refinery effluents. Ultimately, the applied battery can consist of one or more of the tests depending on the assessment objective, the protection goal of the monitoring campaign, the type of receiving water, and the activity undertaken (e.g., routine monitoring, full site risk assessment etc.).

3.22.V POPs and Emerging Pollutants: Environmental Fate, Research and Monitoring at the Interfaces of Science and Policy & Application of Green Removal Technologies

3.22.V-01 Smallholder Farms Irrigating with Water Potentially Containing Contaminants of Emerging Concern: Possible Effects of Contaminated Water on Soil Quality

Fanelesibonge P Vilakazi*, ARC-SCW, South Africa*

Increasing food demand has increased the pressure on farmers to use different chemical inputs such as pesticides to ensure optimum crop yield. Although such chemicals help against food insecurity, they pose a threat to the environment over time as contaminants of emerging concern (CECs). This study evaluates the impacts CECs present in irrigation water and soils have on beneficial soil microorganisms that promote plant growth. Soil and water samples were collected from the North West province, South Africa from 3 vegetable farms. The farms utilize water from the Hartbeespoort dam for irrigation. Soil samples were collected in replicates from the farms at rhizosphere depths of 0–15 cm. Water samples were collected in 5-liter bottles in replicates. Physicochemical parameters such as pH, electric conductivity (EC), and Total dissolved solids (TDS) were measured using a multiparameter meter. Nutrients were analyzed at the Agricultural Research Council - Soil, Climate and Water (ARC-SCW) analytical laboratories following standard procedures. Furthermore, Soil samples were classified by grain size using the sieve method. Obtained preliminary results were compared against the South African Irrigation Water Standards. The water results varied across the farms with Farm 2 and Farm 3 having a higher pH than the recommended range of 6.5–8.4. Farm 1 had more than double the TDS levels compared to Farm 3 with all EC ranging above the recommended 40 mS/m. All water samples had higher levels of bicarbonate (HCO_3^-) and sulfate (SO_4^{-2}) commonly associated with industrial waste. Only Farm 1 had a pH within the recommended range of 6-7. The soils had a neutral to moderately alkaline pH of 6.6 to 7.8. Farms 1 and 2 were classified as clay soils and Farm 3 was sand-dominated thus sandy loam. As such Farm 1 and 2 had higher nutrient concentrations and calcium (Ca) was the most abundant hence the high soil pH. Higher nutrient concentrations in the soil are beneficial for soil productivity. However, when pH is too high or too low it can affect the soil functions and the availability of nutrients to the crop. Preliminary results suggest that irrigation water quality potentially has a negative impact on soil nutrients and cause changes in soil microorganisms that affect crop productivity. Results from this study will give insight on how much CECs affect the environment, shed light on the regulation, monitoring and mitigation methods for a sustainable use of pesticides.

3.22.V-02 Chlorinated Organophosphate Flame Retardants in Childcare Articles
Misbah Hassan Alghamdi[1]*, Stuart Harrad*[1]*, Mohamed Abou-Elwafa Abdallah*[1]*, Martin Sharkey*[2]*, Marie Coggins*[2]*, Harald Berresheim*[2]*, Daniel Drage*[1]*, William A. Stubbings*[1] *and André Henrique Rosa*[3]*, (1)University of Birmingham, United Kingdom, (2)School of Physics, National University of Ireland Galway, Ireland, (3)São Paulo State University (UNESP), Institute of Science and Technology, Brazil*
Cl-OPFRs are chlorinated organophosphate flame retardants that are added to materials to help meet fire safety regulations. As flame retardants, they are used in many commercial products like childcare and nursery items. The most widely used Cl-OPFRs are tris(1-chloro-2-propyl) phosphate (TCIPP), tris(1,3-dichloro-2-propyl) phosphate (TDCIPP), and tris(2-chloroethyl) phosphate (TCEP). Concentrations of Cl-OPFRs were measured in waste childcare articles from the Republic of Ireland (n = 274) between 2019 and 2020 and from Birmingham, UK (n = 89) in 2022. Irish samples (n = 274) include fabric and foams from child car seats (n = 150), cot mattress (n = 21), pushchairs (n = 46), pram (n = 24), changing mat (n = 23), and a miscellaneous of other samples (n = 10) from play mats and baby seats. UK samples (n = 89) include fabric and foams from childcare articles including baby beds, pushchairs, baby feeding seats, baby walkers, play mats, sleeping bags, child car seats, and child booster seats. Considering the carcinogenic nature of Cl-OPFRs and their adverse effects on children, the European Union has made a proposal to limit their use to 1000 mg/kg by weight in childcare articles. Our results show that out of the 274 Irish samples examined, concentrations of Cl-OPFRs exceeded 1,000 mg/kg in 14 samples (5%) for TCEP, 58 samples (21%) for TDCIPP and 75 samples (27%) for TCIPP. A maximum TCIPP concentration of 170,000 mg/kg was found in cot mattress foam, while TDCIPP and TCEP maximum concentrations in car seats were respectively 390,000 and 66,000 mg/kg. On the other hand, out of 89 UK samples, 3 (3%) and 10 (11%) samples exceeded 1,000 mg/kg for TDCIPP and TCIPP, respectively. The maximum concentration of TCIPP (10,000 mg/kg) was found in changing mat fabric, while TDCIPP maximum value (49,000 mg/kg) was identified in booster seat foam. In addition to the waste management implications of our findings, our data raises concerns regarding occupational exposure in waste facilities to Cl-OPFRs and the exposure of children to Cl-OPFRs during the period of items use.

3.23.A Sources, Fate, and Effects of Metals in the Environment

3.23.A.T-01 Metal Analysis in Low-Volume Tissues Using LA-ICP-MS: Benefits for Non-lethal and Non-invasive Biomonitoring
Jennie Christensen[1]*, Kate Mill*[2]*, Geriene LaBine*[1] *and Liz Ashby*[2]*, (1)TrichAnalytics Laboratory, (2)WSP Golder, Canada*
Conventional analytical techniques for metals often require tissue sample volumes that present challenges and inefficiencies to environmental monitoring programs for industry. Non-lethal sampling of fish is encouraged (e.g., tissue plugs), yet may not meet sample volume requirements for conventional bulk tissue analysis for metals. Enough samples mass is required to meet analytical detection limits, and achieve high accuracy and precision. We highlight a novel method using laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS) to quantify metals in low-volume samples of fish tissue. We conducted an interlaboratory study that demonstrated the method’s accuracy, precision, and comparability to conventional bulk analysis using acid-digestion ICP-MS. The objective was to stress-test the ability of various commercial laboratories to meet data quality objectives in the face of sample volume constraints for ovary and dorsal fish muscle tissue. Four laboratories, employing either LA-ICP-MS or acid-digestion ICP-MS, analyzed blind a suite of identical samples and data were compared against *a priori* data quality objectives for accuracy, precision, and sensitivity. Data quality tended to decrease with decreasing sample volume, particularly when samples were less than the minimum volumes requested by the participating laboratories. Effects of sample volume on data quality were not consistent between laboratories or tissue types. For small sample sizes the LA-ICP-MS method was comparable to or slightly better than laboratories employing acid-digestion. These results highlight the potential for LA-ICP-MS to generate high quality data with low sample volume (i.e., 3 mg), and could support non-lethal biomonitoring initiatives.

3.23.A.T-02 Influence of Earthworms on the Bioavailability of Metals and Radionuclides in Soil
Nathalie Vanhoudt[1]*, Jean Wannijn*[2] *and Robin Nauts*[1]*, (1)Belgian Nuclear Research Centre (SCK CEN), Belgium, (2)SCK CEN*
While soil characteristics such as pH, cation exchange capacity, texture and organic matter are known to influence the mobility of pollutants in soil and the transfer to vegetation, far less attention has been paid to the possible non-trophic influence of organisms on pollutant transfer to other species. When pollutants are present in a bound unavailable form in the mineral or organic fraction, they can be made available for uptake by plants through bio-weathering and decomposition of organic material, which is the role of decomposers such as bacteria and earthworms. Within this study, we aim to evaluate the influence of earthworms on the bioavailability of metals and radionuclides in soil.
Belgian soils, historically contaminated with radionuclides and metals, were used. Especially As, Cd, Cu, Ni, Pb, and Zn are present in concentrations above the remediation reference values for natural and agricultural lands in Flanders, Belgium. From a radiological point of view, ^{226}Ra levels are of most concern. After an 8-weeks incubation period of the soil with or without earthworms, microcosm systems were used to mimic the natural interactions between soil, earthworms, and vegetation. The microcosm system consisted of PVC tubes (diameter 10 cm, height 30 cm) filled with 2.2 kg of wetted soil to which earthworms were added. Reference systems had no earthworms. On each column, 0.6 g ryegrass seeds were sown. After 3-week growth, grass and soil samples were collected and radionuclide and metal concentrations were determined in soil, pore water and grass. In addition, soil pH, dissolved organic matter and the ionic composition of pore water were analyzed.

Results show that earthworm presence increased the concentration of ^{137}Cs, Cd, Cu, Ni, Pb and Zn in pore water. However, this was not translated into higher uptake levels by grass. Only for Pb, higher concentrations in grass were found. On the other hand, while no difference was observed for As in pore water, higher As levels were present in grass grown on earthworm worked soil. To evaluate possible direct effects of earthworms on pollutant bioavailability, soil pH, the ionic composition of pore water and dissolved organic carbon were determined. Results indicate that earthworms lowered soil pH and increased ion concentrations in pore water.
These results indicate that biologically induced release or remobilization of pollutants in soil should be considered in risk assessment and site management strategies.

3.23.A.T-03 Mechanism of Arsenite Immobilisation by Different Zerovalent Iron-based Sorbents in Contaminated Soils
***Geert Cornelis**[1], Thiago Formentini[2], Stephanie Nyström[3], Jon Petter Gustafsson[2] and Dan Berggren Kleja[2], (1)Swedish University of Agricultural Sciences (SLU), Sweden, (2)Soil and Environment, Swedish University of Agricultural Sciences (SLU), Sweden, (3)Soil and environment, Swedish University of Agricultural Sciences (SLU), Sweden*
Zerovalent iron-based sorbents are used frequently to remediate contaminated soils *in-situ*, but their effect on arsenic-contaminated soils is less well known, especially in aquifers where reducing conditions prevail and the dissolved As speciation is dominated by arsenite (As(III)). We compared the kinetics of immobilisation of As by four different zerovalent iron-based sorbents in a contaminated soil where reducing conditions prevail using both batch and column tests in a glove box. XANES analysis showed that solid-phase As in control soils (no sorbents added) was dominated by arsenate (As(V)) even though dissolved As in both the field as well as lab tests was predominantly As(III). As(V) was reduced to As(III) in controls soils after a certain period of time in both bat hand column tests suggesting a slow reduction of As(V) controlled dissolved As speciation and concentrations in these soils. The immobilization of As by uncoated zerovalent iron in both micro or nano form was highly efficient and sustainable on the long term reducing As concentration to close to detection limits. XANES analysis showed that both Fe(II) and Fe(III) oxides were formed and it is hypothesized that As was both co-precipitated and adsorbed by these oxides. Sulfidated zerovalent iron products were less efficient, despite previous lab studies showing their efficiency in pure systems. Non-sulfidated zerovalent iron thus appears highly efficient in these lab studies to immobilise As in reducing conditions and these sorbents are now being tested in the field on a pilot scale.

3.23.A.T-04 Behaviour of Advanced Materials in Environmental Aquatic Media - Dissolution Kinetic and Dispersion Stability of Metal-containing Perovskites for the Automotive Catalysis Sector
***Veronica Di Battista**[1], Lars Skjolding[2], Anders Baun[3] and Wendel Wohlleben[1], (1)BASF SE, Germany, (2)Technical University of Denmark (DTU), Denmark, (3)Department of Environmental and Resource Engineering, Technical University of Denmark (DTU), Denmark*
Industry develops increasingly complex and advanced materials (AdMa) while at the same time incorporating the Safe and Sustainable by Design (SSbD) concept into R&D goals. Perovskite-based three-way catalytic converters are an example of AdMa that may potentially replace some of the currently used benchmarks in the field of automotive catalysis. To function properly, all automotive catalytic converters contain noble and/or heavy metals. The metals of potential concern in these materials are cobalt (Co) and nickel (Ni) which are present along with lanthanum (La) in the catalyst structure. Hence, understanding their fate and behaviour is crucial to assess possible detrimental effects on the environment.
We aim to give insights into perovskite's behaviour and fate in simulant waters, with different ionic strength and salt content, compared to well-known nanomaterials (i.e., ZnO and $BaSO_4$), further considering NOM contribution to both dissolution and agglomeration processes. The validity of current OECD guidelines (GD 318 and TG 318) has been tested for AdMa and methodological insights toward their assessment is given. Moreover, evidence on transferability and applicability to other case studies is provided. Our findings rank perovskite's dissolution kinetic in between the two reference materials ZnO and $BaSO_4$. The ionic strength of the media does not seem to impact their overall leachable mass % but plays a role in the kinetic of metals release, which was found incongruent and metal dependent. NOM are shown to increase the dissolution of both benchmarks, however no strong effect is observed for the perovskite materials. Dispersion stability of perovskites in solution is instead substantially increased by presence of NOM and decreased by higher Ca content in the buffer.
The presented discussion can raise awareness on the current and future challenges when testing AdMa, highlighting trade-offs in their chemical and physical behaviour, in different simulant waters.

3.23.A.T-05 Fish Mercury Relevant to Geographic Variations in Socioeconomic Development
*Yuping Xiang[1], Guangliang Liu[2], Yongguang Yin[1], Yanbin Li[3], Dingyong Wang[4], **Yong Cai**[5] and Guibin Jiang[1], (1)Chinese Academy of Sciences, China, (2)Chemistry and Biochemistry, Florida International University, USA, (3)Ocean University of China, Key Laboratory of Marine Chemistry Theory and Technology, Ministry of Education and College of Chemistry and Chemical Engineering, China, (4)College of Resources and Environment, Southwest University, Chongqing, China, (5)Department of Chemistry and Biochemistry, Florida International University, USA*
Fish consumption is a principal route of human exposure to mercury (Hg) and the associated health concern propels global efforts in Hg pollution management. Socioeconomic activities, affecting such factors as emission and aquatic cycling of Hg, fish ecology, and environmental conditions, play a profound role on fish Hg accumulation. In examining the geographic patterns of fish Hg and the possible controlling factors through a comparative study between China and the United States (US), we show that significantly lower fish total Hg (THg), methylmercury (MeHg), and MeHg% are present in China than in the US. Lower Hg levels in baseline organisms, shortened food chain lengths, shorter individual lifespans, and higher individual growth rates contribute to the lower fish Hg in China, despite higher emission, deposition, and environmental concentrations of Hg in China.

We propose a top-down approach to relate geological variability in fish Hg to human activities, where the socioeconomic development status is deemed to determine Hg emission and hydrosphere landscape which in turn affects Hg bioaccumulation through regulating Hg biogeochemistry and food web ecology. This study provides implications on considering regional variability and climate change when managing Hg pollution as a global issue.

3.23.B Sources, Fate, and Effects of Metals in the Environment

3.23.B.T-01 Can Plastic Pollution Affect the Environmental Fate of (Trace) Elements? A Preliminary Investigation in Water

Gilberto Binda[1]*, Luka Supraha*[1]*, Margarida Costa*[1]*, Davide Spanu*[2]*, Christian Vogelsang*[1]*, Eva Leu*[1] *and Luca Nizzetto*[1]*,*
(1)Norwegian Institute for Water Research (NIVA), Norway, (2)University of Insubria, Italy

Plastic pollution is a well-known environmental issue, yet several side-effects on the ecosystems are still mostly unknown. A worrying side-effect is the interaction of plastic with (trace) elements, causing potential alterations of their environmental fate. Plastic ageing processes (i.e., plastic alteration in response to physical, chemical and biological agents) seem to play a pivotal role in regulating plastic-(trace) element interaction, but it is still unclear which agents mainly regulate this phenomenon. Therefore, we assessed which ageing factors can affect adsorption properties of plastic toward (trace) elements. Plastic fragments composed by different polymers (polyethylene, polypropylene and polylactic acid) were tested. Three different ageing processes were analyzed: UV ageing (known to induce surface oxidation and change surface charge), biofouling (using different microalgal species) and the sequential application of both processes. Then, adsorption rates and kinetics were tested using aluminium (Al) and copper (Cu) as target elements (at 1mg/l in 0.01 M $NaNO_3$ buffer solutions). These elements were selected for their role as (micro)nutrients, but potentially toxic if concentrated. Plastic was also characterized considering micromorphology, surface functional groups and water contact angle to observe how surface properties are affected by ageing process. Results highlighted that polymer type limitedly affects adsorption processes of the target elements in water solutions, while UV ageing shows few changes on adsorption rates of plastic, presenting high variance among polymer type and adsorbed element. Biofouling of plastic is instead a key process in regulating this phenomenon: up to 45% of the dissolved Cu and 25% of the dissolved Al are adsorbed by biofilm covered plastic fragments from water solutions. The surface analysis of plastic samples reveals an increase in wettability induced by biofouling, as well as the increase in functional groups typical of peptides (primary and secondary amides) and carbohydrates which are the likely chemical groups enhancing the adsorption capacity of plastic toward metals. The results confirm that environmental ageing of plastic affects the adsorption of (trace) elements and highlight biofouling as the main factor regulating this process. Biofouling, therefore, should be addressed in greater detail to understand the effect of plastic on the fate of (trace) elements in the natural environment.

3.23.B.T-02 Acute and Chronic Effects of Olivine Exposure in the Marine Amphipod Gammarus Locusta

Gunter Flipkens*, Katharina Horoba, Raewyn M. Town and Ronny Blust, ECOSPHERE, University of Antwerpen, Belgium*

Active removal of carbon dioxide (CO_2) from the atmosphere is needed at a gigaton scale in the next decade to keep global warming below 1.5°C. Coastal enhanced silicate weathering aims to increase the natural process of ocean carbon sequestration via chemical weathering finely ground olivine ($Mg_{2x}Fe_{2(1-x)}SiO_4$) rich rock dispersed in dynamic coastal environments. However, the environmental safety of the technique remains in question since olivine contains relatively high amounts of nickel (Ni) and chromium (Cr) which are released to the environment on weathering. This study investigated the acute and chronic effects of olivine exposure in the benthic marine amphipod *Gammarus locusta*. During a first experiment, Ni and Cr accumulation were determined in adult amphipods exposed to different olivine grains sizes for 24 hours. Acute olivine exposure resulted in significant Ni and Cr accumulation, with higher accumulation observed for smaller olivine grain sizes. Microscopic examination of the guts revealed high amounts of olivine particles, indicating the importance of olivine ingestion as a metal exposure pathway. During a second experiment, juvenile amphipods were exposed to natural sediment mixed with different olivine loadings for 35 days. Amphipod survival, growth, reproduction, metal accumulation and malondialdehyde (MDA) concentrations, as a biomarker for oxidative stress, were assessed at the end of the experiment. The Ni and Cr body burden and MDA concentrations increased with higher olivine exposure concentrations and resulted in a significant reduction of amphipod survival, growth, and reproductive success. A highest no observed effect concentration (NOEC) of 1 w/w% olivine (23 and 62 mg/kg Ni and Cr, respectively) was observed for total juvenile production. This NOEC is low compared to possible coastal olivine application concentrations (0.1 – 8 w/w%) and marine sediment Ni and Cr environmental quality standards (43 and 52 mg/kg, respectively). Overall, our results show that fine grained olivine (< 100 µm grain diameter) can easily be ingested by *Gammarus locusta* and lead to toxic effects during chronic exposure at potential coastal application concentrations.

3.23.B.T-03 Monitoring of Trace Metals in Global Air: Results from the GAPS and GAPS Megacities Networks

Jacob Mastin*, Amandeep Saini, Jasmin Schuster and Tom Harner, Environment and Climate Change Canada, Canada*

Trace metals are ubiquitous components of various raw materials and industrial products, and enter the atmosphere through anthropogenic activities and the suspension of natural dust. Many trace metals pose risks to both human health and the wellbeing of natural environments. It is essential to monitor trace metal emissions and generate baseline ambient concentrations to guide risk assessment and public policy. Polyurethane foam disk (PUF) passive air samplers (PAS) are a cost-effective, versatile means to monitor trace metals in ambient air. They are capable of capturing both gas- and particle-phase contaminants, and samples therefore represent the entire air mixture. In 2019, 51 Global Atmospheric Passive Sampling (GAPS) and GAPS Megacities Network locations deployed PUF-PAS to assess air concentrations of 25 metal species. PUFs were exposed for periods of 3-12 months, with metal concentrations determined in both acid- and water-soluble fractions. Time-averaged air concentrations were derived for each metal. Crustal enrichment factors were also determined to evaluate relative anthropogenic impacts and possible source sectors. High crustal enrichment factors were observed for Sn, Sb, Se, Zn, and Mo, which indicates notable anthropogenic inputs of these metals into the atmosphere. Concentrations of Cr, Co, Ni, Cu, As, Ag, Cd, and Pb appear to be the result of mixed crustal and anthropogenic sources. Up to 40% of analyzed metal species were found to be enriched beyond expected crustal concentrations. Total trace metals were highest in Mendoza (Argentina) and New Delhi (India), while lowest total metals were observed across background and polar sites. High proportions of total metal concentrations are attributable to Al and Fe, resulting from soil and dust suspension. Se displayed relatively consistent concentrations globally, suggesting widespread Se contamination. Coal, fossil fuels, and vehicular sources appear to have been influencing factors for a number of trace metals. Al, Cr, Co and Zn were primarily found in the water-soluble fractions, suggesting higher bioaccessibility of these species. Cities with high PM concentrations broadly exhibited higher concentrations of trace metals. Future work will continue to provide cost-effective and time-integrated global baseline and monitoring data for trace metals using PUF-PAS in the GAPS and GAPS Megacities Networks.

3.23.B.T-04 Field Application of a Model of Proton and Metal Mixture Bioavailability and Effects

*Edward Tipping[1], **Stephen Lofts**[2] and Bill Keller[3], (1)Lancaster Environment Centre, UK Centre for Ecology & Hydrology (UKCEH), United Kingdom, (2)UK Centre for Ecology & Hydrology (UKCEH), United Kingdom, (3)Cooperative Freshwater Ecology Unit, Laurentian University, Canada*

Quantitatively predicting of the responses of freshwater ecosystems to the effects of potentially toxic metals and acidification is an ongoing challenge in ecotoxicology. The WHAM-F_{TOX} model is based on the assumptions that toxic effects of protons and metal cations are additively related to their occupancies of binding sites on organisms, and that those binding sites can be represented by the binding sites of humic acid (HA). We applied the model to simulate the species richness (n_{sp}) of crustacean zooplankton in acid- and metal-contaminated lakes near Sudbury, Ontario between 1973 and 2006. Historic emissions from metal smelters at Sudbury have caused contamination of surrounding lakes by acid deposition, while lakes closest to the smelters were also contaminated with metals, mainly Ni and Cu, and to lesser extents Zn, Cd, and Pb. Changes in water chemistry over the study period show partial recovery as a result of emission reductions.

In application, binding of protons and metals to organisms is simulated by applying the WHAM7 model for each water sample. A combined dose term, $F_{\mathrm{TOX},i}$, is computed for each species within a conceptual assemblage, assuming a distribution of species sensitivities to metals. The probability of finding the species in a sample is then computed from a fixed relationship with $F_{\mathrm{TOX},i}$, and n_{sp} is computed by summing these probabilities across all species. The distribution of species sensitivities is found by assuming them to be lognormally distributed and fitting their mean and standard deviation.

The model was able to describe the variability in n_{sp} well, with an R-squared value of 0.84 ($p < 0.0001$). Generally, the model reproduces the temporal patterns of n_{sp} in individual lakes well, although it tends to underestimate the rate at which species richness increases as water chemistry recovers. The most important toxic cations were H, Al, Ni, and Cu, with a small contribution from Zn. The predicted contributions of protons and individual metals to toxicity generally showed declines over time in the contributions of protons and Al as recovery from contamination took place. However, in some cases the contribution of Ni increased over time, despite reductions on the dissolved concentration. This illustrates the potentially complex interplay among water chemistry variables determining metal exposure.

3.23.B.T-05 Using a Dynamic Energy Budget Model to Investigate Nickel (Ni) Toxicity to *Lymnaea stagnalis*

***Kristi Weighman**[1], Karel Viaene[2], Patrick Van Sprang[3] and Karel De Schamphelaere[4], (1)Ghent University - GhEnToxLab, Belgium, (2)ARCHE, (3)ARCHE Consulting, Belgium, (4)Ghent University - GhEnToxLab, Belgium*

Lymnaea stagnalis has been shown to be among the most sensitive species for a variety of metals, including nickel (Ni). However, the observed sensitivity of *L. stagnalis* to nickel is highly variable between studies, without a clear explanation for this variability. The exact mechanism of nickel toxicity to *L. stagnalis* also remains unclear. Under dynamic energy budget (DEB) theory, different physiological modes of action (PMoAs) result in the emergence of distinct changes to the life histories of exposed organisms. DEB models provide a mathematical framework connecting chemical stress at the physiological level to individual-level effects. Consequently, DEB-IBMs can be useful both in determining the PMoA of nickel at an individual level and predicting population level sensitivity.

We calibrated the *Lymnaea stagnalis* DEB-IBM to apical toxicity test data and use the calibrated model to predict nickel toxicity effects on *L. stagnalis* populations. Since no single PMoA emerged as most plausible, several PMoAs were extrapolated to the population level. These population simulations indicated that the relationship between individual sensitivity and population sensitivity is PMoA dependent, further underscoring the need to identify the primary PMoA of nickel to *L. stagnalis*. As a partial validation for our calibrated model, we attempted to predict population level outcomes for *L. stagnalis* as observed in a mesocosm study. In this validation work, simulations assuming increased growth costs as the PMoA consistently provided the best predictions of snail population densities in the mesocosms. However, it should be noted that this validation has important limitations, and the results should be interpreted cautiously. To further examine the PMoA of nickel to *L. stagnalis*, ongoing experimental efforts are investigating the impact of nickel on multiple endpoints, including growth, ingestion, respiration, and reproduction. The experiments have demonstrated a notable difference in the sensitivity of juvenile and adult snails.

3.23.P Sources, Fate, and Effects of Metals in the Environment

3.23.P-We194 Metals Availability in Polluted Fibrous Sediments, Relevant Information for Data-Based Environmental Decision-Making

Gabriela Lucia Paladino[1], *Anka Klecina*[2], *Ruben Basten*[3], *Gabriel Dupaul*[4] *and Erik Hedenström*[4], *(1)NDH, Mid Sweden University, Sweden, (2)Mid Sweden University, Sweden, (3)HAN University of Applied Sciences, Netherlands, (4)Che, Mid Sweden University, Sweden*

Before being prohibited in 1969, unregulated wastewater discharges from the Swedish pulp and paper industry created large deposits of polluted fibrous sediments on the Baltic Sea floor and at the bottom of lakes and rivers, throughout Sweden. These anthropogenic, organic-rich sediments are typically heavily polluted by toxic elements (metals and metalloids) and organic pollutants such as PCBs, chlorinated pesticides, or polycyclic aromatic hydrocarbons, known for their toxicity and persistance in the environment**.** In addition, the degradation of their high content of organic matter under hypoxic conditions leads to the formation of highly toxic methylmercury and the biogenic production of CH_4 and CO_2, two potent greenhouse gases. It is estimated that approximately 10.8 million tons of fiber material were discharged into the Swedish aquatic environment. Fibrous sediments entail a serious threat to human and ecological welfare, and are of high concern for governmental authorities, researchers, and society in Sweden and other pulping countries such as Finland, Canada, and the USA.
Genuine remediation actions should be taken, considering the best suitable ways to uptake and treat the material with minimal impact on the ecosystem. Additionally, resources could be recovered from the sediments, such as valuable metals or reuse for energy production. In any case, pollutants mobility and/or availability in fibrous sediments, which organic nature differentiate them widely from other polluted sediments, requires further and comprehensive understanding in order to produce a well-founded framework for decision making. The aim of this work, is to study metals speciation, using metals sequenciation procedures, in different types of fiber banks and fiber-rich sediments, in a first attempt to understand these processes and provide useful information for their management alternatives. The type and amount of organic matter, the reductive anoxic conditions due to biological degradation under water, the pH and water salinity conditions, among many other factors, will affect to a large extent the distribution of metals in these materials. Thus, this study can aid in predicting metals fate for environmental risk assessments and funded decision making. Further analyses will include the content of organic matter, ligning, and particle size distribution of the material to find possible correlations between these factors and the metals secuenciation in the studied fiber banks.

3.23.P-We195 Trace Metals Dynamics in a Loamy Sand Soil after Application of Non-source-separated Biogas Digestate: A Soil Column Study

Veronica Baldasso[1,2], *Neus Bonet-Garcia*[2,3], *Stéphanie Sayen*[4], *Emmanuel Guillon*[4], *Luigi Frunzo*[5], *Carlos A. R. Gomes*[2,3], *Ana Paula Mucha*[2,6] *and C. Marisa R. Almeida*[2,3], *(1)Chemistry and Biochemistry Department, University of Porto, Portugal, (2)University of Porto, Interdisciplinary Centre of Marine and Environmental Research (CIIMAR), Portugal, (3)Chemistry and Biochemistry Department, University of Porto, Portugal, (4)Molecular Chemistry Institute of Reims, UMR CNRS 7312, University of Reims Champagne-Ardenne, France, (5)Department of Mathematics and Applications Renato Caccioppoli, University of Naples Federico II, Italy, (6)Biology Department, University of Porto, Portugal*

The push for an economic transition towards a circular bioeconomy is constantly growing as global demand for renewable energies and sustainable development increases. Anaerobic digestion (AD) has become a significant element of the circular economy in Europe. One of the AD process's end-products is digestate, which is frequently discarded in landfills because it does not comply with quality criteria imposed by legislations. New strategies for digestate use are needed to improve circular bioeconomy around AD, like its use as amendment for marginal land restoration and bioenergy crop production. However, digestate may contain different types of compounds, as trace metals, resulting in environmental contamination. Therefore, it is important to assess metals dynamics and behaviour in soil systems after digestate application. With this aim, a 90-day mesocosm soil column experiment was conducted to evaluate the fate of trace metals, namely Zn, Cu, Pb, Cr, in a fine loamy sand soil after the application of a layer of digestate-amended soil (14:1, soil to digestate dry wt), with the digestate originating from the organic fraction of municipal solid waste. Two experimental conditions were defined. The first used natural digestate, while the second used digestate spiked with metformin (antidiabetic drug). Soil samples were taken along the columns' lateral sampling ports on days 1, 7, 21, 35, and 90, and were analysed for trace metals' total concentrations and fractionation via atomic absorption spectroscopy. Overall, results showed that metals migrated over time from the top amended soil layer to the underlying one, whereas no migration to the deeper layers was observed. This agreed with trace metals being present in more bioavailable forms in the amended soil layer, and predominantly in immobile less bioavailable forms in the other soil layers. The results also showed that metformin did not significantly influence trace metal behaviour; however, interactions with other potentially present contaminants should be considered. This study shows that digestate can be a valuable resource for marginal land restoration coupled with appropriate bio/phytoremediation technologies that allow for excess pollutant removal from the soil system in situations where more developed technologies/processes are not available or economically feasible.

3.23.P-We196 Using a Risk-based Approach to Monitoring of Targeted Sites on Water Bodies in Proximity to Historical and Operational Mine Sites in Ireland

Joanne Creedon[1], *Jason Smyth*[2], *Simon O'Toole*[2], *Jean Smith*[2] *and Abigail Downing*[2], *(1)EPA, Kilkenny, Ireland, (2)Environmental Protection Agency, Ireland*

Anthropogenic activities such as mining are a source of pollution to the aquatic environment. Mining has been identified as a significant pressure on Ireland's aquatic environment and historical and operational mining activities are point sources of metal contamination in water bodies. Individual water bodies may come under pressure and are at risk of not achieving their Water Framework Directive (WFD) water quality objectives. Previous studies have already reported elevated concentrations of metals – in surface water; stream sediments; mine water discharges and solid mine waste – at historically mined areas throughout Ireland. Using a risk-based approach to monitoring water bodies in proximity to historical mine sites and operational mines in Ireland will better inform WFD surface water monitoring programmes and enable us to perform statistically robust chemical and ecological status assessments. The Environmental Protection Agency (EPA) investigated 90 river monitoring stations on waterbodies across 22 mine sites in Ireland over a two-year monitoring period (2020–2021). River monitoring stations upstream and downstream of mine sites were selected. Arsenic, cadmium, copper, lead, mercury, nickel, and zinc concentrations in surface water samples were measured using inductively coupled plasma source mass spectrometry (ICP-MS). Supporting analysis of pH, dissolved organic carbon, calculated hardness and calcium content were also carried out as they can influence metal toxicity and are used for bioavailability corrections of lead and nickel concentrations. Metal concentrations were compared with annual average (AA) and maximum allowable concentration (MAC) environmental quality standards (EQS) as set out in Directive 2013/39/EU of the European Parliament and of the Council of 12 August 2013 amending Directives 2000/60/EC and 2008/105/EC as regards priority substances in the field of water policy. The results of this study have been used to inform future WFD Monitoring Programmes and to carry out chemical and ecological status assessments of water bodies in proximity to historical and operational mine sites in Ireland. This study highlights the importance of targeted monitoring and data-driven decision making when designing monitoring programmes for water quality assessments.

3.23.P-We197 PhysChemEuro: Introducing a New, Comprehensive Aquatic Chemistry Database of European Waters
Adam C Ryan[1], Elizabeth Traudt Middleton[2], Amy Baldwin[3], Kelly E Croteau[3], David K. DeForest[3], Graham Merrington[4], Adam Peters[4], Iain A Wilson[4] and ***William A. Stubblefield**[5]*, *(1)International Zinc Association, (2)NiPERA, (3)Windward Environmental, (4)wca environment, United Kingdom, (5)Oregon State University, USA*
Bioavailability is a critical concept to understand and evaluate the ecotoxicology of metals. Recently, models have been developed with the ability to incorporate metal bioavailability into the calculation of environmental threshold concentrations (i.e., PNEC, EQS). These models (e.g., Biotic Ligand Model (BLM)) and associated user-friendly platforms (e.g. Biomet), can predict environmental threshold values for several metals including Cu, Co, Ni, Pb, and Zn throughout most European and North American freshwaters. Although substantial progress has been made in the development and validation of these models, their application still depends greatly on the availability of site-specific water quality data for physico-chemical parameters (e.g., hardness, pH, organic carbon). Although some databases already exist (e.g., FOREGS, Waterbase), most resources currently do not contain the range of parameters necessary to perform these analyses, or they fail to report specific details surrounding the geolocation of sampling sites. To address these concerns, the metals research organizations and their partners sought data from European member states and the ECHA Waterbase database to develop a queryable comprehensive database of water quality parameters measured in European waterways. Data were obtained containing records from 1978 to 2022, and the developers intend to perform regular updates to maintain and expand the tool's applicability. Due to the size and scope of this database, a web-based "Shiny application" was developed to enhance user-experience and to assist in the management and query of the database. The resulting web-based tool is publicly available and provides a mechanism to search extant data for water quality parameters filterable by region, country, or location and to obtain simple statistics for each (i.e., mean, percentiles, etc.). It is anticipated that this tool will be valuable in supporting bioavailability calculations and other pertinent analyses related to derivation of environmental thresholds.

3.23.P-We198 A Survey of Copper in Sediments and an Assessment of Potential Stressors to Resident Benthic Communities
David Brown[1], Lenwood Hall Jr[2], Ronald D Anderson[2], ***Adrian Simon Terry**[1]*, Robert Morris[3] and Ann Orth[3], (1)Cambridge Environmental Assessments (CEA), United Kingdom, (2)Wye Research and Education Center, University of Maryland Agricultural Experiment Station, USA, (3)Albaugh*
Copper (Cu) is an essential trace element but can be toxic to biota when present above a certain threshold concentration. Cu enters the aquatic environment mostly linked to particulate debris which settles and is absorbed into the sediment. As a result, surface sediments constitute the major store and sink for copper and other pollutants in aquatic ecosystems. The bioavailability of copper in sediment is controlled by multiple factors including Acid-volatile sulphides (AVS). Sediment is likely non-toxic if the concentration of AVS exceeds concentrations of simultaneously extracted metal (SEM). Therefore, accurate and representative measurements of AVS and SEM in sediment are critical for any ecological risk assessment for divalent metals such as copper. This study presents a global survey of AVS and a focused review of copper concentrations in sediments of a well-studied Californian agricultural catchment. Also, a comparison of different metals as potential stressors to benthic communities is presented.

AVS measurements were reported from 21 different countries and ranged from 0.01 to 503 µmoles/g for 140 different waterbody types. There was high variability within each waterbody type as well as large variability of AVS within specific locations which were often multiple orders of magnitude different with respect to concentration range.

Total copper sediment concentrations from Cache Slough, ranging from 19 to 63 µg/g dry weight, were similar to concentrations reported in European agricultural streams. Concentrations were not reported to increase over time in this agricultural waterbody where copper was used as a fungicide, although some spatial differences in SEM copper sediment concentrations were reported. A comparative analysis of total copper and SEM copper showed that the range of mean seasonal concentrations of SEM copper was much lower, and more sites showed declining trends for SEM copper than for total copper.

Finally, the importance of individual metals within a metal mixture were assessed as potential stressors to resident benthic communities. Arsenic, lead, and cadmium showed the highest number of statistically significant and ecologically meaningful relationships with benthic metrics. Copper was not reported to show any statistically significant relationships with any of the benthic metrics.

These results provide essential data for assessment of ecological risk of copper to the environment.

3.23.P-We199 Development and Evaluation of a Multimedia Model Assessing the Fate, Transport, and Speciation of Heavy Metals in Korea

Ja Eun Jung[1]*, Hee Seok Kim*[2] *and Dong Soo Lee*[3]*, (1)Graduate School of Environmental Studies, Seoul National University of Science and Technology, Korea, (2)Department of Nano, Chemical and Biological Engineering, Seo Kyeong University, Korea, (3)Seoul National University of Science and Technology, Korea*

Heavy metals (HMs) can exist in multiple species in the environment, and their toxicity varies with species. For more accurate and reasonable risk assessments of HMs in Korea, this study develops a multimedia model that simulates the fate, transport, and speciation of 13 different HMs including Al, Co, Ni, Cu, Zn, Pb, Cr, Mn, Fe, Cu, As, Se, and Hg. In the model, HMs speciation is modeled based on equilibrium and kinetic approaches. Dissolved and particulate phases of HMs are calculated using partition coefficients, which are determined by soil organic matter, pH, and total concentration of HMs. The dissolved phase includes free ion, dissolved organic matter (DOM)-metal complex, and inorganic-metal complex, and V.MINTEQ is used to estimate their distributions. Oxidation-reduction states (for Cr, Cu, Fe, Mn, As, Hg, and Se) and organic-inorganic states (for As, Hg, and Se) are simulated by considering the relationships between redox rates and between methylation/demethylation rates, respectively. The ratios of the predicted to measured (average) total concentration in water (i.e., $C_{ratio} = C_{predicted}/C_{mesured}$) are 0.24 (Al), 0.11 (Cd), 0.28 (Co), 0.29 (Ni), 2.67 (Pb), 0.32 (Zn), 4.20 (Cr), 1.02 (Cu), 0.10 (Fe), 1.05 (Mn), 1.17 (As), 8.5(Hg), and 0.06 (Se). The model-estimated concentrations in water fall within the range of measured concentrations for Al (99.9%), Ni (99.9%), Pb (97.6%), Zn (100%), Cr (99.7%), Cu (100%), Mn (96.2%), As (100%), and Hg (100%). Due to data availability, evaluations of the redox states are performed for Cr^{VI} , As^{III} and As^{V}, and those of the organic-inorganic states are conducted for monomethyl arsenic (MMAs) and methylmercury (MMHg). The C_{ratio} of the dissolved Cr^{VI} is 0.23 and 0.16 in water and soil, respectively. The estimated concentration fractions of the dissolved As^{III}, As^{V}, and MMAs in water are 0.25, 0.67, and 0.07 respectively, as compared to the measured values of 0.45, 0.54, and 0.01, respectively. The estimated concentration fraction of the dissolved MMHg in water is 0.06, which is comparable to the measured value of 0.1. The difference in mean concentration between model and measurements are within the 1 order magnitude, which demonstrate the feasibility of the model developed in this study. Our future study will conduct further evaluations and uncertainty analysis of the model.

3.23.P-We200 Effects of Elevated CO2 and Temperature on Physiological Status of Well-watered and Drought-stressed *Brassica napus* Grown in Cd Contaminated Soil in Relation to Their Phytoextraction Efficiency

Austra Dikšaitytė[1]*, Inesa Kniuipyte*[2] *and Jurate Zaltauskaite*[2]*, (1)Vytautas Magnus University, Lithuania, (2)Lithuanian Energy Institute, Lithuania*

Climate conditions, such as elevated CO_2, warming, and drought, may have a significant positive or negative impact on plants growing in heavy metal polluted soil. However, the mechanisms involved in Cd accumulation under changing climate conditions have received little attention, and the presence of Cd in growth media at the same time combined with all these climate change-related variables has not yet been investigated. Therefore, this study aimed to assess Cd phytoextraction efficiency in well-watered and drought-stressed *B. napus* plants grown under the ambient CO_2 and temperature conditions (ATC, 21/14°C, 400 ppm CO_2) and elevated CO_2 and temperature conditions (ETC, 25/18°C, 800 ppm CO_2). The underlying physiological mechanisms underpinning the obtained results were investigated by studying the Cd (0, 1, 10, 50, and 100 mg kg^{-1}) effect on *B. napus* photosynthetic performance and nutritional status. The visible leaf lesions, growth retardation, reduction in gas exchange, ChlF-related parameters, and disturbed balance of mineral nutrients were largely seen only in Cd-50 and Cd-100 treatments but were much more pronounced under ATC conditions at both soil moisture levels. The most important pathways by which Cd affected *B. napus* photosynthetic efficiency were severe Cu deficiency in shoots, resulting in decreased photosynthetic electron transfer between the cytochrome b6f complex (Cytb6f) and photosystem I (PSI) due to a lack of plastocyanin, and the inactivation of some photosystem II (PSII) reaction centers and ferredoxin-NADP+-reductase (FNR). There was no significant difference in phytoextraction efficiency between ATC and ETC conditions in drought-stressed plants. Meanwhile, in well-watered plants, ETC conditions resulted in significantly more Cd accumulation in Cd-50 and Cd-100 treatments. However, only the Cd-50 treatment significantly increased soil Cd removal rate (to 65%), which showed the opposite trend as BCF and had a strong positive relationship with shoot DW.

3.23.P-We201 Elemental Analysis of Co-Produced Water from the Danish Chalk Reservoirs: Trace Compounds in a Complex Matrix

Neri Bonciani[1]*, Matteo Ottaviani*[2] *and Karen Feilberg*[3]*, (1)Danish Offshore Technology Centre, Denmark, (2)Technical University of Denmark (DTU), Denmark, (3)DTU Offshore, Technical University of Denmark (DTU), Denmark*

When crude oil is produced, large amounts of water are co-produced along with the raw material. This produced water (PW) is highly saline and contaminated by crude oil from the geological formation and production additives. Thus, it is heterogeneous and chemically complex. Since this water is being discharged into the sea at most current offshore production sites, reaching “zero harmful discharge” requires stringent produced water management and improved monitoring and toxicology evaluation. Trace elements are often challenging to measure in formation water brine and thus are hard to quantify reliably in many cases. This work aims to characterize the elements present in low ppm and trace amounts for an improved environmental impact assessment and overcome the analytical challenges of a hypersaline and carbon-rich water sample.

This study presents a workflow for trace element analyses of complex aqueous samples. Some elements have primarily been targeted in suspended particulate matter (SPM) and characterized using EDX-SEM. Then ICP analyses have been focusing on Ba, Sr, Fe, Mn, and more environmentally concerning elements like Cu, Cd, Pb, As, Sb, and Se. Additionally, Hg content determination with CV-AAS has been investigated. The overall concentrations variation within different oil platforms and sampling dates has also been evaluated. To improve plasma stability and mitigate the matrix effect within ICP methods, a matrix-matching solution for blanks, calibration standards and quality checks has been implemented. A hydride generator introduction system has also been adopted to analyze As and Sb, which cannot be reliably analyzed with standard ICP-OES/MS techniques. The presentation will include the initial results of these analyses of produced water from the post-separator discharge point of several wells from Danish North Sea offshore platforms.

3.23.P-We202 Evaluation of Cu-toxicity from Diverse Sources in Agricultural Topsoils of Central Chile

Rosanna Ginocchio[1]*, Luz María de la Fuente*[2]*, J. Tomás Schoffer*[3]*, Hyo Ju Méndez*[2] *and Alexander Neaman*[4]*, (1)Facultad de Agronomía e Ingeniería Forestal, Pontificia Universidad Catolica de Chile, Chile, (2)Center of Applied Ecology and Sustainability, P. Universidad Catolica de Chile, Chile, (3)Center of Applied Ecology and Sustainability, Universidad Católica de Chile, Chile, (4)Facultad de Ciencias Agronómicas, Universidad de Tarapacá, Chile*

Topsoils of agricultural areas in central Chile may become polluted by copper (Cu) from several sources as Cu smelter emissions, mine tailings dispersal, and excessive applications of Cu-based pesticides. The long-term exposure of these soils to Cu may decrease their agricultural value. However, few studies have evaluated the increase in Cu levels in topsoils of the area and evaluated their Cu-toxicity effect. Therefore, the aim of this study was to evaluate the effect of field-collected agricultural soils polluted by different Cu sources using a standard laboratory phytotoxicity test. Thirteen agricultural soils were collected from central Chile from sites with suspected Cu pollution. *Lolium perenne* seeds were sowed in each soil (five replicates) and after 4 weeks of cultivation, plants were harvested. Physicochemical characterization of topsoils and chemistry of pore waters were also performed. The shoot length was measured as plant response indicator. Simple and multiple linear regression were carried out to evaluate the effect of soil physical-chemical properties on plant growth. A significative linear regression model ($p < 0.05$; $R^2 = 0.32$) indicated that total soil Cu had a negative effect on shoot length. The best significative multiple regression model obtained ($p < 0.05$; $R^2 = 0.50$), showed the negative effect of total soil Cu on shoot length, but a positive effect of soluble zinc (Zn), organic matter (OM), and nitrogen (N). These results suggest that Zn may alleviate copper toxicity due to competition between Zn^{2+} with Cu^{2+} at root absorption sites. The positive effect of OM may be explained by its capability for Cu adsorption, thus being less bioavailable for plants. We conclude that regardless of the Cu source, the increase of Cu from anthropogenic sources has a negative effect on plant growth and that Zn and OM may alleviate this effect. Nevertheless, more studies are needed to confirm the alleviating effect on the negative effect of Cu in plant growth.

3.23.P-We203 Exposure to Mercury and Fish and Shellfish, Seafood: The 2016 Korea National Institute Environmental Research Survey

Eunhee Lee[1]*, Ji-Eun Oh*[2] *and Younglim Kho*[3]*, (1)Graduate School of Health Science, Far East University, Korea, (2)Department of Biomedical Laboratory Science, Far East University, Korea, (3)Health, Environment & Safety, Eulji University, Korea*

Mercury is an environmental pollutant widely present in the environment, and humans are generally exposed to mercury in three forms (Hg0, Hg2+, and Hg2+), and it is known that the body absorbs a lot of mercury through fish intake. We assessed the association between exposure to mercury and fish and shellfish, seafood. Data were derived from the National Institute Environmental Research Survey (2009). This cross-sectional study was investigated survey data from 2009 to the 3rd anniversary. It calculated national statistical data on the level of exposure to environmental harmful substances in the body, and provides basic data for establishing environmental health policies by continuously analyzing the environmental health status of national and regional units, the temporal and spatial distribution, changes, and influencing factors. We compared the level of mercury and food intake, investigated *p* for trend mercury according to the intake. The higher the frequency of fish intake, the higher the mercury concentration. Correlation of blood mercury and frequency of fish intake was statistically significant. Compared with the lower group, the higher group by median of blood hg had significantly higher risk by frequency of fish(odds ratio, 1.40; 95% CI, 1.332 to 1.472) an shellfish(odds ratio, 1.188; 95% CI, 1.128 to 1.251) intake. The geometric mean values of mercury in eating shark meat group were 5.264 μg/L, which were higher than those in a group that does not eat shark meat (2.793 μg/L). The blood hg had significantly association with frequency of fish and shellfish intake.

3.23.P-We204 Fate of Heavy Metals in Shooting Range Soil: Distribution and Phytotoxicity

Gintare Sujetoviene*, Auksė Daukšytė and Jūratė Česynaitė, Vytautas Magnus University, Lithuania*

Soil contamination with heavy metals still is an environmental concern around the world. Shooting activities play an important role in increasing soil contamination with heavy metals. The outdoor shooting ranges are typically contaminated with various heavy metals, such as Pb, Cu, Zn, Cd, Ni. The scale and amount of contamination depends on shooting activity and soil characteristics. The main contaminant is Pb, as it usually is the main component of a bullet. The aim of the study was to examine the soil contamination with Pb, Cu, Cd, Mn in different types of Lithuanian shooting ranges (practical, small-bore, clay target) and vertical distribution of heavy metals in soil. Study shows that soils were heavily contaminated with Pb; total Pb concentrations exceeded limit concentration in Lithuanian soils (100 mg kg^{-1}). Pb was typically concentrated in the back stop berms of practical and clay target shooting ranges and at the end of the shooting area (target zone) of small-bore shooting ranges. Heavy metals and metalloids accumulate in the soil and can migrate along the food chain, adversely affecting the quality of the soil environment and agricultural products, and ultimately harming animal and human health. Understanding the distribution of pollutants in soil and identifying areas at high risk of pollution is therefore the basis for preventing and controlling soil pollution. The aim of phytotoxicity study was to determine the effect of military firing range soil on the growth of sunflower (*Helianthus annuus*) and oat (*Avena sativa*). Lead and copper accumulated most in the roots and shoots of the plants. The highest nickel translocation factor (TF) and bioconcentration factor were found in oats grown on shooting range soil, while zinc - in sunflower. Lead and copper had the lowest TF in plants compared to other metals.

3.23.P-We206 Geochemical Modelling of Heavy Metal Removal in Wastewater Using Vermiculite

***Rafael M. Santos**, Emily Yi Wai Chiang and Leonardo Gadelha Tumajan Costa de Melo, School of Engineering, University of Guelph, Canada*

The presence and corrosion of zinc from alloys, galvanized steel structures' surfaces, and within soils may induce its leaching into the water collection system and surface waters, which in turn brings the concentration above permitted limits. Collection pond water with zinc concentrations above regulatory limits cannot be discharged into water bodies and into the wastewater collection systems. There is a need for cost-effective options to meet such compliance requirements for greenhouse growers who find elevated zinc concentrations in their waters. Among the options for treating heavy metals contaminated water, selective adsorption using different materials has shown promising evolution and excellent results. While treatment options are available, the effectiveness of treatment is usually investigated by short-term batch experiments. Geochemical modeling is one of the promising tools for verifying and predicting long-term effects of selective adsorption using sorption materials. It may contribute greatly to select best suitable solutions for remediating contaminated sites. In this study, a geochemical model, using vermiculite as a sorbent for zinc removal in aqueous solution, was built. The model was tested against experimental data obtained from previous studies to replicate the environmental conditions and to validate the methodology. Zinc adsorption into vermiculite under more alkaline condition is shown to be efficient and cost-effective, and our modeling results are in line with experimental studies. For the range of pHs expected for greenhouse wastewater, the behaviour of zinc adsorption on vermiculite was very similar, which means it may not be necessary to chemically alter the pH to obtain a good adsorption ratio.

3.23.P-We207 Health Risks Associated with Heavy Metals in the Well-water of Palakkad, Kerala, India

***Abinaya Sekar**[1], George Kuttiparichel Varghese[2], Keerthana A S, Anju Jose, Hiba Sagir, Arunima K Sathian and Mahendran Dileep Rajila, (1)India, (2)National Institute of Technology Calicut, India*

Water is indispensable for the survival of human beings. The presence of heavy metals in water is a matter of serious concern. Ingestion of heavy metals can lead to severe health consequences. The study aims to estimate the heavy metal concentrations in groundwater wells and the associated health risks. The well water samples were collected from various locations across Palakkad district in Kerala, India. Concentrations of Cd, Pb, Cu, Fe and Cr were estimated using Flame Atomic Absorption Spectrometer and compared with the permissible limits as per Indian and WHO Standards. Using Monte Carlo method, the probabilistic non-carcinogenic risk assessment was carried out following the USEPA health risk assessment guidelines. The parameters determined for health risk assessment are the hazard quotient (HQ) and Hazard Index (HI). Except for Copper, all the other analyzed heavy metals were present in concentrations higher than the limit prescribed by IS code for drinking water. The concentrations were found in the order of Cd>Pb>Cr>Fe>Cu. Fe does not contribute to any possible health risk to the local population. The risk caused by cadmium is very high, with an HQ of the order of 10^02. Sensitivity analysis suggested that exposure duration and concentration are the two influential parameters in calculating the risk. Pb and Cd are probable human carcinogens, but the effect of carcinogenic risk is established only for the inhalation route. Hence the carcinogenic risk was not determined in this study. The present study will help create awareness among the public and the local government on the exposure to heavy metals through drinking water in the study area, where groundwater is the major source of water for meeting domestic demands.

3.23.P-We208 Identification of Refinery-originated Metals in River Sediments from Widespread Abandoned Mining Area using Stable Zn and Pb Isotopes

***Dongjin Joe**[1], Mansik Choi[1], Jong-Hyeon Lee[2] and Minseok Choi[3], (1)Chungnam National University, Daejeon, Korea, (2)EH Research & Consulting Korea, (3)Korea Marine Environment Management, Korea*

In order to identify the sources and transport pathway of metals (Zn, Cd and Pb) in river sediments around the Zn refinery, total 58 river sediments samples and potential metal contaminants (ores, Zn concentrates used in refinery, smelting waste and abandoned mine tailings), were analyzed for metal concentrations and stable Pb and Zn isotopes.

Since sediments were already contaminated from abandoned mine tailings through the river, sediments around the Zn refinery would be a admixture by smelter-related substances (imported ores, smelting dust and smelting waste) to tailing contaminated sediments. As the smelter-related materials could be differentiated from the tailing contaminated sediment, the contribution of smelter-related materials could be quantified by Pb isotopes. From the distribution of δZn in river sediments, two types of smelter-derived pollutants (groundwater and dust contaminated soil), and tailings contaminated sediments could be differentiated and quantified for the contribution of three sources for highly contaminated sediments around the Zn refinery.

3.23.P-We209 Investigating the Metal Leaching Potential of Copper-rich Metal Ore Processing Waste Treated with a Deep Eutectic Solvent

***James Symons**, Michael John Whelan and Gawen Jenkin, Centre for Sustainable Resource Extraction, University of Leicester, United Kingdom*

Metal ore processing wastes (tailings) are a mining by-product consisting of residual processed rock after the separation of valuable commodities. It is estimated that upwards of 8 billion tonnes of tailings are produced annually. Inadequate storage of tailings can lead to environmental problems such as acidic mine drainage, metal pollution or tailings dam collapses. Tailings are also a potential source of easily accessible metals. A new class of novel solvents known as Deep Eutectic Solvents (DES) have recently been employed to re-mine tailing deposits. DES are related to ionic liquids and contain both a hydrogen bond acceptor and a hydrogen bond donor, mixed together to form a liquid at room temperature. DES are an attractive alternative for mineral extraction due to their high tunability, cheap components, low (eco)toxicity and lower operating temperatures compared to traditional extraction methods. The environmental fate of DES when applied to tailings has not yet been investigated in any context. To investigate the effect of DES on the liberation of metals to the environment from *in-situ* treated tailings, we conducted an experiment to compare metal leaching from tailings before and after treatment with DES. Samples were collected from a copper mine tailings storage facility in the Philippines and a sub-sample of tailings were leached using a choline chloride:ethylene glycol DES at a 1:2 molar ratio. The leached tailings were sequentially washed with de-ionised water at varying solid:liquid ratios. A control sample consisting of un-leached tailings underwent an identical washing process. Water samples were analysed for metals and chloride (as a marker for residual DES). Experimental data show an increase in metal leaching from the DES treated tailings. Elevated concentrations of metals were also proportional to DES concentrations. This suggests that *in situ* treatment of tailings with DES (e.g., in re-mining) may increase metal leaching risks in the remaining substrate, at least in the short term.

3.23.P-We210 Metallic Profiles of the Most Consumed Rice Varieties in Spain

*J. R. Aguilera-Velazquez[1], A. Calleja[1], J. Bautista[1], E. Alonso[1] and **Isabel Maria MORENO Navarro**[2], (1)University of Sevilla, Spain, (2)Universidad de Sevilla, Spain*

Rice is one of the most consumed staple foods around the world and its trade is highly globalized. Increased environmental pollution generates a large amount of waste that, in many cases, is discarded close to culture fields. Some species are able to bioaccumulate toxic substances, such as metals, that could be transferred to the food chain. The main goal of this study was to evaluate the content of metallic (Al, Cd, Pb, and Cr) and metalloid elements (As) in 14 of the most consumed varieties of rice in Spain. Samples were collected from the most popular Spanish supermarkets in triplicate, taking the same brand for the triplicate. The samples were cooked, and human digestion was simulated by using a standard in vitro digestion method. Metallic and metalloid element levels were analysed by Inductively Coupled Plasma Mass Spectrometry (ICP-MS), previous called microwave digestion.

The statistical analysis did not show significant differences ($p > 0.05$) in the concentrations of Al, Cr, Mn, and Se between all cooked rice in our study. However, significant differences in levels of Cu, Zn, As, Cd, and Pb within the varieties employed were detected. These differences could be due to the ability of each rice variety to bioaccumulate these metals in combination with their concentration in the croplands. In digested rice, there are significant differences in all metals except Pb due to the different digestibility degree in each rice variety. Different correlations were observed in rice produced in Spain with those imported, indicating that the presence of metals and metalloids in rice is mainly impacted by soil composition.

The mean values of the bioavailability of the metallic elements of all varieties studied decrease in the following order: As>Al>Ni>Mn>Cu>Cd>Zn>Cr>Se>Pb. Inorganic arsenic was the element with the highest bioavailability (79.09%) in contrast to the bioavailability of Pb (11.9%).

Lastly, the results obtained in the present work approach a more realistic metal and metalloid exposure through rice intake, as the cooking and digestion procedures were taken into account, which makes a more realistic risk assessment, performed in most of the cases with measurements obtained in raw material. Thus, performing studies of digestion and bioavailability of these foods in raw, to perform a better risk assessment of these pollutants.

3.23.P-We211 Multiple Biomarkers Response of Astyanax lacustris (Teleostei: Characidae) Exposed to Manganese and Temperature Increase

*Karla Giavarini Gnocchi[1], **Larissa Souza Passos**[2], Johara Boldrini-França[1], Aline Silva Gomes[1], Tatiana Miura Pereira[1], Gabriel Carvalho Coppo[1] and Adriana Regina Chippari-Gomes[1], (1)Vila Velha University, Brazil, (2)University of São Paulo, Brazil*

Manganese (Mn^{2+}) is an essential metal for living beings, acting in the metabolism of amino acids, lipids, proteins, and carbohydrates. This metal is essential for fish growth, vertebral development, and metabolism. However, anthropogenic activities, such as the release of industrial effluents, have contributed to the increase in the concentration of Mn in the aquatic ecosystem. This increase can affect the health of organisms since high Mn concentrations can cause neurological dysfunctions and genotoxic, biochemical, and behavioral changes. In addition to the increased concentration of metals in water bodies, there are other environmental stressors, such as sustained temperature increase. The simultaneous presence of thermal and chemical stressors can interact and alter the body's ability to produce adequate defense responses to stress. Thus, the present study aimed to evaluate the toxicity of Mn (6.65 mg/L) at different exposure times (96 h, 7, 14, and 21 days) and evaluate its possible toxic effects on the fish *Astyanax lacustris* (Characidae) through multi-biomarkers and the maximum critical temperature (CT Max). The results show increased Mn accumulation (liver and gills) with increasing exposure time. The glutathione S-transferase (GST) activity showed differences in the group exposed to Mn for 96 h compared to those exposed for 21 days. The acetylcholinesterase (AChE) activity increased in the fish exposed for 7 days compared to the control group. On the other hand, no genotoxic changes were observed. The CT Max showed that the loss of equilibrium of 50% of the fish occurs at a temperature of 39ºC, with and without the Mn presence. Furthermore, the catalase gene expression (oxidative stress) did not show alterations. Therefore, the present study results suggest that under natural environmental conditions, *A. lacustris* can accumulate Mn in liver tissue in exposures more significantly than 14 days and gill tissue in short-term exposures (96 h). Although there was an accumulation of Mn in the gills and liver, these accumulated concentrations were not enough to cause intense damage to the specimens of *A. lacustris* since no alterations were observed in the catalase gene expression nor the presence of genotoxic and expressive alterations in the studied enzymes.

3.23.P-We212 On the Understanding of Trace Metal Sorption by Phytoplankton in Coastal Environments: Preliminary Results from the AMALGAME Project

***Melina Abdou**[1], Yolanda Del amo[2], Yannick Anguy[2], Cécile Gaborieau[2], Laurence Costes[2] and Alexandra Coynel[2], (1)Center of Marine and Environmental Research CIIMAR, Portugal, (2)University of Bordeaux, France*

Anthropogenic activities, associated with climate change, influence the physical and chemical properties of aquatic systems, particularly in coastal areas which are the receptacle of continental emissions. Among these emissions, trace metals are persistent and ubiquitous contaminants that are highly reactive, playing critical roles in the functioning of ecosystems. A large part of trace metals is bioavailable and at the base of the marine trophic chain, numerous algal species are able to sequestrate considerable amounts of these elements from the dissolved phase. Therefore, phytoplankton can exert a control on trace metal concentrations and affect biogeochemical cycling in marine systems. As decaying and settling particles, phytoplankton cells also represent an important vehicle for the vertical transport of trace metals in the water column through cell sinking into deeper waters and/or ingestion by consumers in surface waters. Although phytoplankton communities may play a key role in the geochemical cycling of trace metals in coastal ecosystems, the precise quantification of trace metal concentrations in microalgae remains difficult in environmental studies. Indeed, the collection of Suspended Particulate Matter (SPM) as “bulk material” make difficult the distinction between biogenic and abiogenic origin of trace metals. This technical issue limits the existing knowledge for regulatory elements such as cadmium, copper, or lead, which are now accompanied by emerging trace metals such as Platinum Group Elements (PGEs). One of the main objectives of the AMALGAME Project aims at developing and optimizing methodologies to quantify trace metal levels associated with microalgae, including advanced microscopy techniques such as Scanning Electron Microscopy (SEM) combined with Energy Dispersive X-ray Spectroscopy (EDS). Preliminary results of this study will be presented and discussed.

3.23.P-We213 Perspective on Grey Wolves as Sentinel Species of Ammunition-Derived Lead Pollution in Terrestrial Ecosystems

Catharina Ludolphy[1]*, Claudia A. Szentiks*[2]*, Diana M. Estrada Guerrero*[2]*, Gabriele Treu*[3] *and Oliver Krone*[2]*, (1)Department of Biology and Chemistry, University of Hildesheim, Germany, (2)Department of Wildlife Diseases, Leibniz Institute for Zoo and Wildlife Research (IZW), Germany, (3)German Environment Agency (UBA), Germany*

The exposure route of lead (Pb) ammunition has been extensively studied in avian predators and scavengers, yet only few studies exist on this pathway for mammals. But ingestion of retained ammunition in strafed prey and discarded kills or viscera also poses a periodically high exposure risk to scavenging and predatory mammals. These periodic events can be easily overlooked when monitoring blood or soft tissue due to the relatively short biological half-life of Pb (several weeks in blood to few months in liver tissue). Since Pb follows the same metabolic mechanisms as calcium (Ca), it is mainly stored in mineralized tissues, where it is retained for up to 30 years. Young and growing vertebrates have higher absorption rates of Pb as adults due to their high Ca demand and are more affected by its detrimental effects. Lead trapped in bone, reflecting the sum of life-long exposure events, is considered inert but can be remobilized during periods of physiological stress (e.g., pregnancy, lactation, Ca deficiency).

With the return of grey wolves (*Canis lupus*) to Germany since 2000 and the detailed monitoring on causes of death and diseases established by the IZW, there is an excellent opportunity to systematically study the contaminant burden. Grey wolves are highly opportunistic apex predators and thus prone to bioaccumulation of contaminants, but large carnivores are seldom analysed for Pb accumulation in Europe.

As part of a pilot study, Pb levels in small cortical bone samples (femurs) from 32 grey wolves found dead between 2017 and 2021 were analysed using atomic absorption spectrometry. Lead levels ranged from 0.29 ppm d.w. to 9.51 ppm d.w. ($\bar{x}$: 1.38 ppm; $\tilde{x}$: 0.99 ppm). The highest concentration was found in an adult male that died in a traffic accident. Necropsy reports showed no metal particles, so dietary exposure can be assumed.

The results indicate that grey wolves in Germany may be exposed to elevated Pb levels, however, further investigation is needed to establish baseline levels and to elucidate the sources of Pb. We propose that elevated Pb levels are more likely to occur in regions with higher hunting activity, thus providing indirect evidence of the use of lead-based ammunition. Depending on the property situation and restrictions of lead-based ammunition we would expect lower lead levels in state-owned hunting areas. It is of high importance to examine long-term exposure trends to evaluate if regulations on lead-based ammunition are effective.

3.23.P-We214 Polyethylene Microplastics Interactions on Microbial-mediated Hg Removal – Implication for Naturally Occurring Hg Detoxification

Neusa Figueiredo[1]*, Joana Antunes*[2]*, Vasco Branco*[3]*, Cristina Carvalho*[3] *and* ***Marta Martins***[4]*, (1)MARE - Marine and Environmental Sciences Centre, Portugal, (2)MARE - Marine and Environmental Sciences Centre, Portugal, (3)Research Institute for Medicines (iMed.Ulisboa), Faculty of Pharmacy, Universidade de Lisboa, Portugal, (4)MARE - Marine and Environmental Sciences Centre, NOVA School of Science and Technology, Portugal*

The pollution of coastal areas has become an increasingly recurrent problem, where contaminants such as mercury (Hg) and microplastics (MPs) threaten aquatic organisms and even human health. The presence of Hg in the marine environment is a worrisome problem due to methylmercury formation with its subsequent bioaccumulation and biomagnification. Microplastics may act as a vector for other pollutants such as Hg, which tends to get adsorbed to its surface, increasing the overall toxicity, and also as an attachment surface for microorganisms. Microorganisms are the key player in Hg-biotransformations.

The main goal of this study was to investigate the interference of polyethylene microplastics (PE-MPs) on Hg detoxification processes mediated by microbial communities of a Hg-contaminated marine ecosystem. Microbial communities and *Pseudomonas* strains, isolated from a highly Hg-contaminated area of Tagus Estuary, were exposed for 6 days to PE-MP, Hg (1-2 ppm), and a mixture of both pollutants. A control containing Hg, PE-MPs, and a mixture of both was run. After 1, 3, and 6 days, supernatant and MPs were collected to: (1) quantify the extracellular polymeric substances (EPS); (2) to determine the total Hg concentration (HgT) through atomic absorption spectrometry; (3) to analyze structural changes in the properties of the polymer by FTIR analysis, and (4) to assess the acute toxicity of the supernatant (Microtox acute test). All the collected samples showed the presence of EPS associated with the PE-MPs, which indicates that there was biofilm formation. The HgT was lower in treatments with the microorganisms and Hg, indicating Hg-removal mediated by these microorganisms. The treatments containing PE-MPs and Hg exhibited higher HgT, showing interference of PE-MPs on Hg-removal by these microorganisms. The same was obtained for the acute toxicity results, showing higher toxicity associated to the presence of PE-MPs in the incubation medium. These interfere with the Hg-removal and supernatant toxicity may be related to the formation of biofilm on the surface of PE-MPs and as well the adsorption of Hg to the surface of these microplastics, which decreases its availability to be removed. The PE-MPs did not suffer any degradation. Through this study, it is possible to conclude that PE-MPs interfere with the removal process of Hg mediated by Hg-resistant microbial communities, affecting the overall toxicity associated to the media.

3.23.P-We215 Predicted Environmental Concentrations of Metals and their Environmental Risks, Anticipated by Concurrent In-Water Hull Cleanings of Ship's Biofouling in an International Harbor

***Moonkoo Kim**[1,2], Taekhyun Kim[2,3], Zhi Yang Soon[2,3], Jee hyun Jung[1,3] and Dongju Shin[1,4], (1)Risk Assessment Research Center, Korea Institute of Ocean Science and Technology, Korea, (2)Korea Institute of Ocean Science and Technology (KIOST), Korea, (3)University of Science and Technology, Korea, (4)Department of Marine Environmental Science, Korea University of Science and Technology*

When organisms grow on ship's hull, the drag they produce slows the ship's movement, increasing the consumption of fuel and leading to higher emissions of greenhouse gases. Furthermore, the growth of these organisms can lead to a transfer of invasive species from one place to another, which could lead to the destruction of local ecosystems. By periodic in-water cleaning (IWC) of ship's hull, the biosecurity risk can be mitigated, and the ship's fuel efficiency can be improved. However, during the cleaning of the hull, the active substances (e.g., heavy metals) in the antifouling paints can be released and introduced directly into the marine ecosystem. The active substances can be a source of hazards to marine organisms in the environment. To understand the risk posed by IWC, environmental concentrations of metals released during IWC were predicted using a steady-state 2D integrated hydrodynamic and chemical fate model in one of the world's largest international harbors and compared to no-effect concentrations to characterize risk of target chemicals. Release rate of metals from hull surface was calculated based on the information collected during actual IWC cases, which include metal concentrations in the effluents, effluent volumes, and hull areas. A release rate under realistic worst-case scenario was used for model prediction as a conservative approach. The predicted environmental concentrations were proportional to the number of cleanings and the size of ships under cleaning. A single hull cleaning of any size seems not to clearly damage the marine environment. However, when considering concurrent IWC of ships berthing in the harbor, the predicted environmental concentration exceeded local standards set for the protection of marine environment. Predicting environmental concentration only for single cleaning cannot appropriately assess the environmental risk in a given site, where multiple operations are expected. The daily demand for in-water cleaning at the site should be estimated and this demand needs to be accounted for risk assessment. In-water cleaning should only be allowed if the predicted environmental concentrations is within the threshold of the environmental capacity. The risk assessment framework proposed in this study can be used for environmental management purposes in port areas expecting frequent and multiple in-water cleaning activities.

3.23.P-We216 Regional Exposure Assessment of Metals in the Aquatic Freshwater Environment

***Dagobert Heijerick**[1], Arnoud Dupon[1], Karel Viaene[1], Nora Ferencz[1], Marnix Vangheluwe[1], Violaine Verougstraete[2] and Hugo Waeterschoot[3], (1)ARCHE Consulting, Belgium, (2)Eurometaux, Belgium, (3)Chemicals Management, Eurometaux, Belgium*

Environmental release rates of metals are expected to vary over time due to new uses and changes in used/manufacturer volumes, but also due to improvement of emission-reducing technologies and external conditions like climate change. As a consequence, previously collected regional ambient concentration levels that were used in a regulatory context (e.g., for exposure scenario development under REACH) may not be relevant anymore for current or future situations. An update of these regional metal concentration levels in the aquatic environment is part of Eurometaux's currently ongoing comprehensive "Metals environmental exposure gathering program" (MEED-program), covering today's and expected needs for tomorrow to comply with the Zero Pollution Ambition and biodiversity objectives.

Recent monitoring data (period: 2017–2021) of dissolved metal concentrations in EU surface freshwater systems were extracted from EEA's database on the status and quality of Europe's rivers, lakes, and groundwater bodies (Waterbase). Data sets for 18 metals, covering up to 20 countries, were compiled and represented the basis for the derivation of country-specific reasonable worst-case (RWC) ambient PECs. The followed calculation methodology is stooled on the data treatment procedures that have been laid out in Guidance Documents for environmental risk assessment in the EU and includes an outlier analysis to minimize the impact of local point sources when predicting a representative ambient regional concentration.

Only quality-screened measured samples were considered. Data were categorized into sub-datasets (river basin, a specific waterbody, or an individual sampling location) that were sufficiently large to derive a meaningful 90th percentile; the median of all 90P-values represents the ambient RWC-PEC.

Overall, the determined RWC-ambient PECs were within the same order of magnitude as those that were derived in the past (2000-2010)-period. Observed differences in country-specific RWC-ambient PECs for individual metals are likely caused by factors such as specific geological conditions, (over-)representation of sampling locations that represent major rivers affected by industrial activities (e.g., Rhine, Danube). For most metals, the calculated RWC-ambient PEC is typically situated between the 50th and 90th percentile of known baseline levels (FOREGS-dataset), making the latter a potential reference for estimating the RWC-ambient PEC for metals lacking monitoring data.

3.23.P-We217 Removal of Carcinogenic Metals in Tobacco Obtained From Waste on Roadside

***Jyoti Yadav**[1], Meenu .[2], Manviri Rani[2] and Uma Shanker[3], (1)Chemistry, Malaviya National Institute of Technology Jaipur, India, (2)Malaviya National Institute of Technology Jaipur, India, (3)Chemistry, DR. BR Ambedkar National Institute of Technology,*

India
Smoking habits is a major risk factor for a number of diseases including cancer, chronic obstructive pulmonary and cardiovascular disease. IARC states that human carcinogens include lead, cadmium, arsenic, nickel, and chromium. Cigarettes include these elements, however the amount varies depending on the region where tobacco is grown, how fertilizer is applied, the type of plant, etc. This study attempts to evaluate the levels of these metals in cigarettes sold in India. The tobacco filling was taken out of from different source then independently weighed and homogenized. Samples were desiccated and then put through aqua regia. Atomic absorption spectrometry analysis was used to confirm the presence of heavy metals. Metal oxide doped Prussian blue analogues were synthesized using *A.indica* leaves extract was used for the removal of these heavy metals. The physicochemical properties of all nanoparticles were investigated by different spectroscopic and microscopic analysis. Development of alternative photocatalyst is on –demand to avoid bioaccumulation of particular metallic structures. Co-ordinated complexes like hexacyanoferrates and cobaltates of Zn are completely safe substances for humans, comparatively stable and non-toxic. This leads to creation of defects, an increase in the trapping rate, and enhanced the photocatalytic activity of photocatalyst. Thus, such a photocatalyst could be used as a promising material for application in industrial wastewater treatment processes.

3.23.P-We218 Selenium Accumulation in Sediment in Las Tablas de Daimiel National Park: Identification of Areas of Greatest Risk for Biota

María Mercedes Andres[1]*, Rafael Mateo Soria*[2] *and Manuel Ortiz Santaliestra*[3]*, (1)Toxicology, Institute for Game and Wildlife Research, IREC (CSIC-UCLM), Spain, (2)Wildlife Toxicology, Instituto de Investigación en Recursos Cinegéticos (IREC) CSIC-UCLM-JCCM, Spain, (3)Instituto de Investigación en Recursos Cinegéticos (IREC) CSIC-UCLM-JCCM, Spain*

Tablas de Daimiel National Park (TDNP) is a Mediterranean wetland in the central Spanish plateau. Despite its declaration as a Biosphere Reserve and Ramsar site, its persistence is threatened by desiccation due to groundwater overexploitation and by pollution from untreated wastewater treatment plant effluents. Previous studies of our group have shown high selenium levels in waterbirds and fish from TDNP that can be of concern. In addition, several studies have shown that the soil or sediment of TDNP and parts of the Cigüela basin upstream are seleniferous. This scenario may be similar to that observed in a Kesterson Swamp wetland located in the San Joaquin Valley in California, where run-off of irrigation water used in seleniferous soils caused Se intoxication of waterbirds nesting in that wetland. The objective of this study is to map the Se levels in soils and sediments from TDNP to determine the influence of geological and hydrological variables on Se pollution in the Park. We collected 188 soil or sediment samples in a systematic manner to cover the entire wetland surface. Se levels were analysed with inductively coupled plasma with mass spectrometry (ICP-MS) in samples previously digested with nitric acid and peroxide hydrogen. Periods of drought and flooding can have a significant effect on Se cycles given their influence on the oxidation-reduction reactions that are involved in the formation of different Se species. With this mapping, we will define the areas of greatest risk for birds and other organisms and the potential sources of Se. Further research will be conducted to study the speciation of Se in sediment and water of TDNP and its relationship with the hydrologic cycles of the wetland.

3.23.P-We219 Spatial and Temporal Analysis of the Risks Posed by Metal Contamination in Coastal and Marine Sediments of Bahrain

Ernst Nicolaus[1] *and David Maxwell*[2]*, (1)Science, Centre for Environment Fisheries and Aquaculture Science (Cefas), United Kingdom, (2)Centre for Environment Fisheries and Aquaculture Sciences (Cefas), United Kingdom*

Nine metals including Al, Cd, Cr, Cu, Fe, Mn, Ni, Pb, and Zn were analysed from sediment samples collected from 29 stations since 2007 from Bahraini waters. Within this study, it was investigated whether concentrations of these determinants are at concentrations above internationally established Assessment Criteria (AC). The majority of sites were considered not to pose a toxicological risk in terms of metal contamination. Where breaches occurred, they were mainly from historic samples related to Cr, Cu, and Ni contamination. A trend assessment revealed that out of 59 significant trends, 36 were downwards and 23 upwards, indicating that some determinants like Al, Zn, and Ni are improving strongly across some sites, whilst areas associated with industrial activity still see some increasing trends for Al, Cd, Pb, and Zn.

3.23.P-We220 State-of-Science Review of the Assessment of Chemical Contamination of Abandoned Mines in Nigeria

Ushemegbe Rita Rita Ekhareafo[1]*, Olwenn Martin*[2] *and Rakesh Kanda*[1]*, (1)College of Health, Medicine and Life Sciences, Brunel University, United Kingdom, (2)Arts and Science, University College London, United Kingdom*

Abandoned mines pose serious risks to the environment, through the release of pollutants to land, rivers, and air. Thus, harming plants, aquatic organisms, other animals and may impact human health in areas of high pollution. In Nigeria, over 1200 abandoned mine lands (AMLs) have been identified. To date, only a few have been reclaimed due to the high costs. Many non-reclaimed AMLs have pond waters that are being used for irrigation, fishing, domestic and industrial purposes exposing humans to risk of significant harm.

A systematic evidence map was carried out to review chemical assessment methods of legacy mines environment. Preliminary results revealed that focus has been on heavy metal analysis using routine methods, with little insights into the behaviour and fate of these contaminants in this environment. This is largely due to lack of access to the current state of the art technology in identifying contaminants that are comparable to what is obtainable in other developed nations of the world.

To address these knowledge gaps, an integrated impact assessment methodology for chemical contamination emanating from abandoned mines in Nigeria study will be developed to identify and quantify the chemical contaminants and the interactions between the different media around the mines to ascertain the extent, fate, mobility and impacts of the contaminants on receptors accounting for the risk of exposure to multiple pollutants via multiple sources.

3.23.P-We221 Trace Metals Accumulation with Age in Bats from a Moderately Polluted Area in North-Eastern Ukraine

Olha Timofieieva[1], *Ryszard Laskowski*[2] *and Anna Maria Łabęcka*[2], *(1)Biology, Jagiellonian University, Poland, (2)Jagiellonian University, Poland*

Being particularly long-lived small mammals, bats are especially endangered with metal poisoning due to the tendency of some metals to accumulate in internal tissues throughout the lifetime. The impact of trace metals on bat physiology is generally not well-studied, and effects on bat populations are virtually unknown. In our current research we studied how trace metal concentrations change with an age in different tissues of bats.

Bat carcasses have been obtained from the bat carcasses storing collection at the Bat Rehabilitation Center (BRC) of Feldman Ecopark in Kharkiv, Ukraine. The extracted internal samples were entire organs (liver, kidney). Our focal species is *Pipistrellus kuhlii,* which lives for years in one place and is strongly associated with urban environments and can benefit from urbanization. All samples were analyzed for concentrations of Pb, Cd, Cu, Zn using atomic absorption spectrophotometer AAnalyst 200 and PinAAcle 900Z (Perkin Elmer). Osteochronology was applied to identify the exact age of individuals, using cross sections of the upper canine tooth of each individual (Leica CM1950 cryostat). For age identification number of dentine rings in the sections were counted.

The age of all 40 individuals of *P. kuhlii* was identified. Majority of individuals were this-year-born and one-year-old. The oldest bats were six years old. To test whether metal concentrations in the kidneys and livers of bats depend on age, regression analysis was used. For each metal the regression lines were compared between the two tissues. Statistically significant (≤0.05) increase in metal concentration with age was found for Cd (R^2 = 16.05%), Pb (R^2 = 14.38%), and Zn (R^2 = 10.45%); for Cu the relationship was marginally significant (R^2 = 7.40%, p=0.06). Cadmium accumulated with age only in the liver (p = 0.007), but not in the kidney (p = 0.8).

Assuming that the age structure in our sample represents the age structure in other colonies of *P. kuhlii*, in which indeed the majority of individuals are young and only several are old, the results would have broader applicability and may indicate that in more polluted environments the accumulation of metals in internal organs can lead to chronic effects in older bats. On the other hand, metal concentrations found in this study, even in the oldest individuals, did not reach concentrations at which toxic effects are expected.

3.23.P-We222 Two Thousand Years of Heavy Metal Pollution in Southwest Europe: A Study Through The Cattle Ranch of Cartagena (Southeastern Spain)

Juan Enrique Padilla[1], *Isabel Navas*[2], *Pedro María-Mojica*[3], *Sebastián F. Ramallo*[4], ***Antonio Juan Garcia-Fernandez***[5] *and Milagros Ros-Sala*[4], *(1)Prehistoria, Arqueología, H. Antigua, H. Medieval y CCTT Historiográficas, University of Murcia, Spain, (2)Health Sciences-Faculty of Veterinary-IMIB, University of Murcia, Spain, (3)Health Sciences, Faculty of Veterinary, University of Murcia, Spain, (4)Prehistoria, Arqueología, H. Antigua, H. Medieval y CC y TT Historiográficas, University of Murcia, Spain, (5)Toxicology and Risk Assessment Research Group, Faculty of Veterinary, University of Murcia, Spain*

Environmental contamination by heavy metals in mining areas affects human health. The intake of products from livestock that graze in mining areas is one of the pathways for contaminants into human diet. There are several studies on the greater exposure to metals and metalloids in small ruminant herds and wildlife, especially in areas of extensive mining exploitation. However, studies carried out in a diachronic perspective do not predominate, on broad chronological arcs in which anthropic contamination by heavy metals has varied depending on the greater or lesser exploitation of the territorial metallic wealth according to diverse cultural parameters. Evidence of diverse rates of contamination by these metals have recently been corroborated in above mentioned chronological arc on the soils immediately adjacent to ancient Carthago Nova (present-day Cartagena, southeast Spain).

This study show bone concentrations of Pb, Cu, Zn, Cd, As, Sr, Fe, Cr, Ni of 44 goats (*Capra hircus*) recovered in the excavations of the Roman Theater of Cartagena and in the nearby Iberian settlement "Los Nietos", located on Mar Menor's coasts (Southeastern Spain). Both records cover a wide temporality, from 5th century B.C. to 18th century A.C., to which is added its location in a region rich in silver minerals, concentrated in the Cartagena-La Unión mountain range and the Mazarrón mining area. Both areas show archaeological mining-metallurgical evidence of silver exploitation, at least from the 7th century B.C. in relation to the presence of Phoenicians and Punics in coastal settlements, with an important boom in Roman and Byzantine times, maintaining activity until the 20th century. Analyses were done using an Inductively Coupled Plasma Mass Spectrometry (IPC-MS).

The results of Pb show traces of contamination in Iberian period (214.6 mg/kg) and, to a lesser extent, in 3rd century, Roman period (18.03 mg/kg), with a decline until Byzantine period (6th-7th centuries, 4.66 mg/kg), and a notable increase in Islamic period (12th-13th centuries, 117.87 mg/kg), reaching again very low levels in modern times (18th century, 10.52 mg/kg). Comparison of these results with others from human remains from same periods and sedimentary cores of Cartagena's subsoil allow us to present an almost linear image of the impact that metallurgical activity has had on the inhabitants of Cartagena for more than 2000 years, completing and correcting information from literary and archaeological sources.

3.23.P-We223 Zinc Sources to Water: An Apportionment Exercise for the EU27

Sean Comber[1], *Christopher Cooper*[2], *Adam C Ryan*[3], *Eric J. Van Genderen*[4], *Frank Van Assche*[2] *and Howard Winbow*[2], *(1)Stantec, United Kingdom, (2)International Zinc Association, Belgium, (3)International Zinc Association, (4)International Zinc Association*

Reporting of point and diffuse source emissions of chemicals has been identified as an issue across the globe. Although large emitters report for chemicals through the European Pollution Release and Transfer Register (ePRTR) little is known on a Member State scale regarding diffuse total emissions to water including diffuse as well as point sources. This project focused on estimating

loads to water for zinc for all significant primarily anthropogenic sources, including industry, sewage treatment plants, surface runoff (from traffic, architecture, and atmospheric deposition), septic tanks, agriculture (biocides, biosolids, fertilisers, manures, and atmospheric deposition), mariculture, sacrificial anodes, marine transport (antifoulant leaching) as well as natural processes and sources (atmospheric deposition and soil loss). To achieve this, a combination of European datasets (Eurostat databases), literature and industry data were utilised to generate export coefficients which could be multiplied by activity rates to generate loads.
A total of around 22,500 tons of zinc per annum (tpa) was estimated to enter freshwaters of the EU27 from diffuse sources, mostly associated with natural background concentrations in the soil eroding into the river (~7,000 tpa). Approximately 3,000 tpa of zinc entered freshwaters from rural area run off, and about the same amount entered transitional and coastal waters combined from sacrificial anodes (~3,000 tpa). Sewage treatment plant effluent, urban runoff directly to water, and other wastewater (intermittent discharges from combined sewer overflows and septic tanks) were in the 1000 to 1700 tons per year range with industrial discharges, agricultural runoff from fertilisers and intensive aquaculture all contributing less than a 1000 tpa. Abandoned mine zinc emissions were estimated to be in the 1000's of tpa, but a lack of data prevented quantification to any degree of confidence. There were differences in predominant sources between countries depending on a number of factors including patterns of use within architecture, size of shipping fleets, and land use.
Where possible estimates of uncertainty were performed, highlighting a lack of confidence in data from abandoned mines and many variables and assumptions relating to urban runoff load estimates. This exercise has provided for the first time a methodology and load apportionment, identifying data gaps and uncertainties which may be refined over time.

3.23.P-We224 Copper Toxicity Threshold for *Eisenia fetida* in Copper Pesticide Affected Soil

J. Tomás Schoffer[1], Fiama Solari[2], Lucas Petit dit Grézériat[3], ***Celine Pelosi[4]****, Rosanna Ginocchio[5] and Alexander Neaman[6], (1)Center of Applied Ecology and Sustainability, Universidad Católica de Chile, Chile, (2)Universidad Católica de Chile, Chile, (3)INRAE, Avignon Université, UMR EMMAH, France, (4)INRAE (Institut National de la Recherche Agronomique), France, (5)Facultad de Agronomía e Ingeniería Forestal, Pontificia Universidad Catolica de Chile, Chile, (6)Facultad de Ciencias Agronómicas, Universidad de Tarapacá, Chile*

Copper-based pesticides (CBPs) have been long used as a fungicide and bactericide worldwide, thus resulting in Cu accumulation in soils. Increase in total Cu concentration in agricultural topsoils may harm soil biodiversity and reduce soil quality. Earthworms have been frequently used in ecotoxicological studies to test the effect of Cu-spiked soils with salts (e.g., $CuSO_4$) and also used to test toxicity of Cu mine affected soils collected in the field. However, there are no studies at present using earthworms-based bioassays to evaluate Cu toxicity of agricultural soils contaminated with CBPs. The objective of the study was to determine levels of Cu-toxicity in CBP-polluted agricultural topsoil for earthworms. Fifty orchards' topsoils (0-5 cm) were collected from central Chile (total Cu: 23-566 mg kg^{-1}). None of these soils were under the influence of any other source of Cu (e.g. mining) except CBPs. The *Eisenia fetida* avoidance test was used with proposed modifications of Delgadillo et al. (2017). Each field-collected soil was tested with an artificial control soil, which was amended with peat and a 10 g L^{-1} solution of NaCl to match the organic matter content and electrical conductivity of each field-collected soil. Estimated effective concentrations EC10, EC25, and EC50 were 57, 117, and 243 mg Cu kg^{-1} dry soil, respectively. Results were in accordance with the Cu thresholds for earthworms proposed by Santa-Cruz et al. (2021) of 123 and 282 mg kg^{-1} for EC10 and EC50, respectively. We conclude that *Eisenia fetida* is a good indicator of Cu ecotoxicity in copper pesticide affected agricultural topsoil.

3.23.P-We225 Characterization of Abrasion-Induced Metal Emissions from Rail Transport into the Environment

Gina Bode[1]*, Andreas Schäffer[2], Daniel Fruhwirt[3], Johannes Rodler[3] and Sabrina Michael[1], (1)German Centre for Rail Traffic Research at the Federal Railway Authority, Germany, (2)Institute for Environmental Research, RWTH Aachen University, Germany, (3)Institute of Thermodynamics and Sustainable Propulsion Systems, Graz University of Technology, Austria*

In terms of environmental protection, rail transport is advantageous compared to other modes of transport. Nevertheless, particulate emissions, mainly caused by abrasion, are released into the environment during railway operation. However, only a few studies have been published on the particle size distribution, particle mass and chemical composition of these abrasions. Metal particles, such as copper and iron, are expected to be emitted into the environment as those metals are commonly used in rail transport components (e.g., wheel, rail, brakes, and contact wire). In Switzerland, iron was identified as the main component of abrasion related emissions in rail transport. Similar results were obtained in previous studies, where an increased iron and copper concentration was found in soil samples along the railway tracks. The concentration of these components decreased with increasing distance to the tracks.
The scope of the present work is to obtain detailed information on the particle mass, particle size distribution and chemical composition of the source-specific abrasion emissions. Therefore, extensive test bench investigations of particulate emissions (from wheel-rail, contact wire-pantograph, brakes) as well as field measurements are carried out within the BMDV Network of Experts.
Thes studies consider particles in the range of a few nanometers up to the size fraction PM10. Based on first results, the determined PM10 emission factors for the wheel-rail contact of an entire train ranges from 0.33 to 5.57 g/km. 83 to 90 % of the PM10 emissions were particles of the PM2.5 fraction and 60 to 73 % were classified as part of the PM1 fraction. Significant higher particulate emissions were found in tight curves than on straight tracks and iron was identified as the main component. The obtained data will be used for dispersion calculations and an evaluation of consequences for the environment.
Additionally, the morphology and the fate of abrasion-related emissions in the environment will be investigated more detailed using SEM-EDX.

Overall results will be used for an initial risk assessment including (eco)toxicological aspects to close current knowledge gaps and to enable a comparison of transport systems.

3.23.P-We226 Advances in Methylmercury Effect on Fish: Subcellular Partitioning Associated to Lipid Peroxidation on Northern Pike (Esox Lucius) of the St. Maurice River Near Run-Of-River Dams

Kimberley Desjardins[1]*, Dominic E. Ponton*[1]*, Francois Bilodeau*[2]*, Maikel Rosabal*[3] *and Marc Amyot*[1]*, (1)Groupe interuniversitaire en limnologie et en environnement aquatique (GRIL), University of Montréal, Canada, (2)Hydro-Québec, Canada, (3)Groupe interuniversitaire en limnologie et en environnement aquatique (GRIL), University of Québec à Montréal, Canada*

Methylmercury (MeHg) readily bioaccumulates and biomagnifies in aquatic food webs leading to elevated concentrations in fish, which also represents the main pathway of human exposure to mercury (Hg). The construction of hydroelectric power plants with large reservoirs are known to flood terrestrial soil leading to an anoxic environment favoring microbial Hg methylation and food chain transfer for decades after impoundment. Run-of-river (RoR) dams are smaller facilities with a lower water residence time and a smaller surface of flooded areas (called poundage) that may represent a sustainable alternative. Whereas human Hg health issues are well-known, the literature about Hg toxicity to wild fish is less documented. We performed a field study on northern pike with high liver MeHg concentrations (1–51 nmol g^{-1} dry wt) from the St. Maurice River (Québec, Canada) affected by two RoR dams, artificial wetlands, forest fires and logging activity. A subcellular partitioning protocol was used to separate the liver into metal-sensitive (mitochondria, microsome/lysosome and HDP – heat-denaturated proteins) and metal-detoxified fractions (metal-rich granules and HSP – heat stable proteins). Results showed that 78% of MeHg was associated to the metal-sensitive fractions suggesting potential deleterious effects. Among the metal-sensitive fractions, MeHg was predominantly found in the HDP fraction which contains important antioxidant enzymes. To link MeHg subcellular partitioning to physiological effect, we measured malondialdehyde (MDA) in livers as an indicator of lipid peroxidation. We observed a relationship between MDA concentration and MeHg concentration in the metal-sensitive fractions with the strongest being associated to the mitochondria (R^2 = 0.71, p<0.001). A Se:Hg molar ratio above 1 may protect against Hg toxicity due to their high affinity for each other. In each metal-sensitive fraction, Se:Hg molar ratio were negatively correlated to MDA concentration suggesting that fish with higher Se:Hg subcellular molar ratio yield lower lipid peroxidation levels. This study highlights the importance of combining the subcellular partitioning approach to biomarkers to adequately assess the potential toxicity of MeHg. Lipid peroxidation is not the only effect to occur following metal exposition and other biomarker measurements and omics approaches should be considered.

3.23.P-We227 Assessment of the Metal Contents of Dairy Processing Sludge and Municipal Sludge, Including Their Derived Biochar, as Circular and Sustainable Soil fertilizer Components

Italo Pisano'[1]*, Marzena Kwapinska*[2] *and James J. Leahy*[2]*, (1)Chemical Sciences, University of Limerick, Ireland, (2)Chemical Science, University of Limerick, Ireland*

Industrial dairy/milk processing requires effluent management in wastewater treatment systems, from which a considerable amount of waste activated sludge is produced. Similarly, municipal (or sewage) sludge is produced during the treatment of municipal wastewater. The transformation of sludge into biochar is achieved by thermochemical treatment (e.g., pyrolysis) of the dairy/municipal sludge at high temperatures and in an environment deprived of oxygen.

Dairy and municipal processing sludges both contain important organic nutrients such as nitrogen, phosphorus, calcium, and potassium and can therefore be used as a soil fertiliser (biosolids), since it is the most cost-effective way of their disposal. Additionally, biochar produced from dairy and municipal sludge processing, when used as a soil amendment, can increase the total organic carbon, therefore improving the fertility of the soil. Furthermore, the use of high temperatures to produce biochar allows for the removal of harmful bioplastics, organic contaminants and pathogens present in sludge. Nevertheless, both sludge and biochar may contain also significant concentrations of heavy metals, which might be toxic for the soil and surrounding environment.

In this research, a comparison of the compositional analyses of dairy processing sludge and its biochar versus municipal sludge and its biochar was undertaken for the assessment of heavy metal content. The results clearly showed that dairy sludge and its biochar contained very low levels of heavy metals (arsenic, cadmium, cobalt, chromium, manganese, mercury, nickel, lead, zinc), making these waste products good candidates for use as fertiliser components under the Fertilizing Product Regulation (EC2019/1009). On the other hand, municipal sludge and its biochar showed high levels of heavy metals, proving to be potentially harmful for the soil. In addition, calculations on energy requirements for pyrolysis were carried out, showing that the content of solid matter in dairy/municipal sludge waste is critical for making the process of biochar production self-sustaining. A solids content of minimum of 30% in dairy/municipal sludge is required.

In conclusion, the use of dairy processing sludge and its biochar is suggested as a potential constituent of fertilisers over the use of municipal waste sludge and its biochar, which might cause heavy metal contaminations into the soil.

3.23.V Sources, Fate, and Effects of Metals in the Environment

3.23.V-01 Determination of the Influence of Wastewater Effluents on the Heavy Metal Distribution in Sediments in the Kuils River system, Cape Town, South Africa

Vernon S Somerset[1] *and Nangamso Mabuya*[2]*, (1)Cape Peninsula University of Technology, South Africa, (2)Chemistry, Cape Peninsula University of Technology, South Africa*

Chemical stress in aquatic ecosystems is increasing and receiving the necessary attention. Urban areas are struggling with wastewater management due to rapid industrialisation and urbanisation, especially in developing countries. As wastewater

treatment facilities fail to meet treatment guidelines, effluent discharged from these facilities pose a threat to aquatic ecosystems and human health. Wastewater from sewage treatment plants contain heavy metals, non-metals and organic compounds originating from industrial and domestic sources. The metals contained in effluents are mainly in the form of suspended particulates and they ultimately accumulate in sediments at the bottom of the rivers and water bodies. At high pH, it will be observed that most metals precipitate in the form of oxides and hydroxides.
The goals of this study are (i) to determine the effect of treated effluent discharged to the Kuils River, (ii) the concentration of Zn, Cu, Pb, Cr, Cd, and Hg in sediments and invertebrates. The list of metals is the most common in domestic and industrial effluent and can have serious impacts on the food chain, ecosystem quality and human health.

3.23.V-02 Heavy Metals Associated with Atmospheric Fine Particulate Matter in Cape Town, South Africa
Vernon S Somerset[1] *and Mikhail September*[2]*, (1)Cape Peninsula University of Technology, South Africa, (2)Chemistry, Cape Peninsula University of Technology, South Africa*
Cape Town, South Africa is located at the southern tip of Africa and is surrounded by the Atlantic and Indian Oceans. Cape Town has a Mediterranean climate that is characterised by warm summers and wet winters. In the winter months (June to August) the mean minimum temperature can be as low as 7.1°C (July), while in the summer months (December to February) the mean maximum can rise to 27°C (February). Most of the rainfall occurs during the winter months of June through August. Average precipitation for the region is 515 mm per annum. Cape Town started experiencing its worst drought in 100 years from 2015, with the day zero scenario campaign launched to prevent water shortages, which has seen rainfall dwindle in recent times, due to the impact of global change. The city is also known for its carbon emissions and the threat is poses to human health.
Particulate matter (PM) is known to contain heavy metals in its fine particles, such as $PM_{2.5}$ that specifically poses a threat to human health. The aim of this study is to analyse the metal content at a specific air monitoring station to determine the distribution of selected metal concentrations. The soluble metal fraction bound to $PM_{2.5}$ and collected on filter membranes are analysed by ICP-MS spectroscopy to find the most abundant soluble metals in the particulate matter. The contribution of soot particles from localised sources, vehicle fuel emissions, are some of the local sources currently investigated.

3.23.V-03 The Leaching Behaviour of Rare Earth Elements in Soil Samples Derived from Electronic Waste
*Martin Makombe and **Vernon S Somerset**, Cape Peninsula University of Technology, South Africa*
The dumping of waste electrical and electronic equipment (WEEE) and its recycling commonly known as “urban mining” has caused undesirable impacts on the environment. Many of these products are rich with rare earth and hazardous elements that end up in rubbish dumps and recycling centres. Harmful metals are exposed and leached into the environment. The fate of rare earth elements (REEs) through the disposal of electronic waste and urban mining into the environment has caused pollution and pose a threat to human health and the aquatic ecosystem. In this work, we report the results of several microcosm studies using conditioned soil to investigate the leaching of REEs in lab-scale experiments. The effective leaching of specific rare earth elements (La, Nd and Dy) were conducted under different experimental conditions. The effects of major variables on REE leaching were evaluated, which included lixiviant type and concentration, time, stirring speed, pH and solid to liquid ratio. The temperature was kept constant during all experiments at 23 ± 2°C. The leaching efficiency of La, Nd, and Dy was found to be significantly dependent on acid concentration and leaching time. The best leaching efficiency was obtained with 1 M HCl with a leaching time of 30 minutes, 300 rpm stirring, 50 g/L solid to liquid ratio. It was found that the leaching efficiency of 69%, 75%, and 77% was achieved for La, Dy, and Nd, respectively. In speciation studies, the results showed that 90% of REEs were obtained from acid-soluble fraction and residual fraction. The study is currently investigating the availability of the fractions, chemical behaviour in soil under environmental conditions, and the uptake of the REEs by biota.

3.23.V-04 Heavy Metals and PAHs in Soil from Tyre Pyrolysis Plant located in Egbeda Local Government Area, Nigeria
Felicia Adesina[1]*, Omotayo Sindiku*[2]*, Omolola Adenike Oluboyede*[1]*, Christopher Ogbue*[2] *and Emeka Umezurike*[2]*, (1)Biological Sciences, Lead City University, Nigeria, (2)Biological Science, Lead City University, Nigeria*
As designed by nature, our environment takes in all we give into it and gives them back to us in another form which could be beneficial or harmful. This study is aimed to assess heavy metals and PAHs in soil from tyre pyrolysis plant at Egbeda, Ibadan, Nigeria. Soil samples were collected from seven strategic locations around the plant. Five selected heavy metals name Arsenic (As), Cadmium (Cd), Chromium (Cr), Lead (Pb), and Zinc (Zn) were determined using Atomic Absorption Spectrophotometer (AAS). PAHs were extracted from soil samples through an accelerated solvent extraction system (ASE 200, Dionex, Sunny-vale, CA, USA) with a 1:1 (v/v) acetone/dichloromethane solvent mixture. The results of heavy metals showed that the average concentration of the five metals are As-0.2827 mg/kg, Cd- 0.2177 mg/kg, Cr-0.1726 mg/kg, Pb-0.6753 mg/kg and Zn-1.0232 mg/kg and in decreasing order of abundance ranked Zn > Pb > As > Cd > Cr. One way ANOVA reveals that all the results were significantly different from one another ($p<0.05$), similarly there was no correlation between all the five metals examined. The degree of contamination and the pollution index of the study site are 13.8 and 2.2 respectively and they implied that the site is moderately contaminated. The PAHs result showed that a total of 18 PAHs were determined with average concentration ranking of Naphthalene –381.25 mg/Kg, 1-Methyl Naphthalene –335.50 mg/Kg, 2-Methyl Naphthalene –236.25 mg/Kg, Anthracene –199.75 mg/Kg, Fluoranthene –173.65 mg/Kg, Phenanthrene –140.00 mg/Kg, Pyrene –78.78 mg/Kg, Chrysene –72.20 mg/Kg, Benzo(a)anthracene –48.78 mg/Kg, Benzo(a)pyrene –45.72 mg/Kg, Acenaphthene –36.68 mg/Kg, Indeno(1,2,3-cd)pyrene –31.26 mg/Kg, Benzo(b)fluoranthene –30.35 mg/Kg, Benzo(k)fluoranthene –27.54 mg/Kg, Fluorene – 21.93 mg/Kg, Benzo(g,h,i)perylene –18.51 mg/Kg, Dibenz(a,h)anthracene –15.22 mg/Kg, and Acenaphthylene –12.98 mg/Kg. Seven major carcinogenic and tetratogenic PAHs were detected in slightly elevated levels. One way ANOVA reveals that the concentration of

all the PAHs identified were significantly different from one another, although correlation study indicated that there is strong positive correlation between all the PAHs.

3.23.V-05 Insight into Relationships Between Alkali and Alkaline Earth Metals in a Clay Pit Core Sample, with and without Al-Normalization

Josip Jurković*, Applied Chemistry, University of Sarajevo, Bosnia and Herzegovina*

Clays are fine particle size (less than 2 µm in size) materials comprised mainly of clay minerals, which are basically hydrated aluminum silicates with associated alkali and alkaline earth elements. The small particle size and complex porous structure result in high specific surface area, which allows strong physical and chemical interactions with dissolved species. Metals can also be incorporated inside of clays structure, which can be made from octahedral and/or tetrahedral sheets. Depending on the composition of the tetrahedral and octahedral sheets, the layer will have no charge or will have a net negative charge. If the layers are charged this charge is balanced by inter-layer cations. The recent researches of metals in clays mainly corresponds to heavy metals, but investigations of light metals, is rather rare. For the investigation of behavior of alkali and alkaline earth metals in a clay samples, 110 sub-samples of cored sample were taken. Total content of potassium, magnesium, calcium, sodium, strontium and barium was determined by means of ICP-OES instrument. Descriptive statistics was conducted by means of maximum, minimum, average and median value. For determining of different behavior of metals correlation and PCA analysis with and without Al-normalization were calculated. The concentrations of metals lie in the next sequence: K>Mg>Ca>Na>Sr>Ba. The highest correlation between metals was found between Mg and K (r=0.842) and K and Na (r=0.645). Multivariate statistical analysis distinguished two subgroups: 1) K, Mg, Na, Ba. 2) Ca. After application of Al normalization Ca and Sr showed highest difference in correlation to magnesium. Suggesting a possible different source and behavior. Magnesium is probably part of a clay material, and calcium and strontium are mainly adsorbed onto clay particle.

3.23.V-06 Bioaccumulation of Mercury in Barn Owls and their Foodchain

***Sabnam Mahat**[1], Ingrid Sofia Kjelsen[1], Dan Samuel Marmet[1], Bettina Almasi[2] and Adrien Mestrot[1], (1)University of Bern, Switzerland, (2)Swiss Ornithological Institute, Switzerland*

The fate of mercury as a global pollutant in all the terrestrial compartments is understudied, although majority of the atmospheric mercury is estimated to be deposited in terrestrial environments. As a result, the transfer and bioaccumulation of total mercury (THg) and methylmercury (MeHg), and the associated risks to terrestrial predatory birds and wildlife needs further investigation. This study focuses on bioaccumulation of THg and MeHg in barn owls and their food chain using down feathers of the barn owls, the fur from regurgitated pellets and soil from around the nests. We hypothesize that the source of variation in the barn owl feather concentration are related to the prey species and the diet of the prey species. Furthermore, this study aims to investigate the possible local pollution sources of mercury in Switzerland using the feather, fur, and soil mercury levels.

A direct mercury analyser (DMA-80) was used to quantify THg. A high performance liquid chromatography coupled with inductively coupled plasma-mass spectrometry (HPLC-ICP-MS) was used to quantify MeHg.

THg in the down feathers (n = 245) ranged between 20 and 1474.8 µg kg^{-1} (average ± standard deviation: 170.5 ± 156 µg kg^{-1}). MeHg in down feather (n = 42) ranged between 34.4 and 503.6 µg kg^{-1}(154.5 ± 99.7 µg kg^{-1}). The MeHg fraction of the THg (% MeHg of THg) was 83.7 ± 4% (n=42). THg in the fur samples (n=127) ranged between 11.2 – 1230.8 µg kg^{-1} (165.9 ± 214.5 µg kg^{-1}). %MeHg of THg was 56.4 ± 11.3% (n=12) and 7.3 ± 4.9% for inorganic Hg fraction. THg in the composite soil samples ranged between 34.9 – 118 µg kg^{-1} (63.7 ± 17.1 µg $kg^{-1;}$ n = 64).

The down feathers of barn owl juveniles are good bioindicator of local pollution as they have not fledged out of the nest and the only source of mercury exposure can be related to the diet. The diet is an important source of variation, as the composition (number and species of prey) differ and hence effects the mercury accumulation from the various diet of the prey-species within the food chain. In addition, the mean values for THg in the barn owl feathers and fur of the prey studied are unlikely to cause adverse reproductive or behavioral effects. The possible local pollution sources are understudy. All soil mercury levels were found below the guidance value set by the Swiss Soil Pollution Ordinance for multi-functional land use.

3.24 State-Of-The-Art Analytical Tools for an Enhanced Non-target Screening of Environmental Samples

3.24.P-We234 Class Identification of Nitrated Organic Compounds in Ambient Particulate Matters by Using Electron Capture Negative Ionization

***Xiaodi Shi**[1] and Xinghua Qiu[2], (1)Stockholm University, Sweden, (2)Peking University, China*

Ambient fine particulate matters ($PM_{2.5}$) can pose risks of public health, especially in populated urban regions with intense anthropogenic emissions. Nitrated organic components are potential toxic compounds of $PM_{2.5}$, such as organic nitrates (ONs, with a covalently bound ONO_2 group) and nitrated aromatic compounds (NACs, with NO_2 group connected to an aromatic ring). However, chemical compositions of nitrated organic compounds remain unknown in urban areas. Leveraging the high electron affinity of NO_2 group, this study coupled electron capture negative ionization (ECNI) to gas chromatography and time-of-flight mass spectrometry. 78 unknown ONs were screened through their fragmentation patterns from >1300 organic compounds of $PM_{2.5}$ in Beijing. 12 compounds were confirmed by self-synthesized reference standards. Precursors of 65 compounds are anthropogenic alkenes. Substituent positions (α or β carbon) of ONO_2 group in α-alkene-generated hydroxynitrates indicate the OH-initiated radical addition reaction in daytime is the dominant formation mechanism. Due to low abundance in $PM_{2.5}$, NACs cannot be comprehensively detected by high-resolution mass spectrometry. The molecular characteristic of high electron affinity and resonance-stable structure makes NACs the only nitrated organic components in $PM_{2.5}$ that can yield molecular ions through electron capture ionization, and NO_2^- is the only negative product ion after the collision induced dissociation. Therefore, NACs can be comprehensively detected without the help of reference standards, through the combination of ECNI and gas chromatograph and tandem mass spectrometry. Eventually, 1047 non-polar NACs were detected from $PM_{2.5}$ of Beijing. Element compositions of 128 compounds were acquired from the high-resolution mass spectrometry. 25 compounds were confirmed by reference standards. Except for NPAHs and their alkylated congeners, oxygenated NPAHs were identified, indicating nitration products of oxygenated PAHs. The cluster analysis shows there exist diverse secondary formation pathways such as heterogenous nitration and nitration after oxidation, except for primary emission and gas-phase direct nitration.

3.24.P-We246 Discovery of Carboxylic Acid PAH Metabolites in Fish by Ion Mobility Quadrupole Time-of-Flight Mass Spectrometry

Charlotte Langeland Nakken[1]*, Carey E Donald*[2]*, Denis da Silva*[3] *and Sonnich Meier*[2]*, (1)Department of Chemistry, University of Bergen, Norway, (2)Havforskningsinstituttet/Institute of Marine Research, Norway, (3)National Oceanic and Atmospheric Administration, USA*

Alkylated polycyclic aromatic hydrocarbons (alkyl-PAHs) can be toxic to marine organisms. Carboxylic acid metabolites from various alkyl-PAHs have been detected in humans, rodents, and marine worms. These metabolites have however not been identified in marine fish. The analysis of PAH metabolites in fish bile is an established biomarker for ongoing and recent PAH exposure. But investigations of the full metabolome of PAHs is challenging due to low availability of reference standards. New and sensitive ultra-high-performance liquid chromatography-mass spectrometry (UHPLC-MS) methodology enables tentative identifications with accurate mass and MS^E spectral data. An additional dimension in structure information can be provided by a compound specific collision cross section value obtained from ion mobility spectrometry.

This study hypothesized that marine fish produce PAAs as metabolites after exposure to alkyl-PAHs. Atlantic haddock (*Melanogrammus aeglefinus*) were exposed to phenanthrene, 1-methylphenanthrene or 1,4-dimethylphenanthrene via intraperitoneal injection. A Vion Ion Mobility Quadrupole Time-Of-Flight Mass Spectrometer was used to screen for PAAs in extracted bile samples. An in silico library, in addition to filters for common neutral losses and suspected common fragments were included in the data processing workflow. The results show the first report of PAA metabolites in fish, and how they participate in several different metabolic products. Using modern instrumentation and a comprehensive workflow, we present tentative identifications that expand the scientific knowledge about alkyl-PAH metabolism.

3.24.P-We248 Quality Prediction of Tandem Mass Spectra of Environmentally Relevant Compounds using Machine Learning

Svetlana Codrean[1]*, Benjamin Kruit*[1]*, Nienke Meekel*[2]*, Dennis Vughs*[2] *and* ***Frederic Magnus Béen***[3]*, (1)Vrije University Amsterdam, Netherlands, (2)KWR Water Research Institute, Netherlands, (3)A-Life, Vrije University Amsterdam, Netherlands*

The acquisition of tandem mass spectra (MS2) combined with the ever growing comprehensiveness of spectral libraries have greatly contributed to the improvement of suspect and nontarget screening analyses. Nevertheless, discrepancies still exist between the number of potentially relevant contaminants present in environmental samples and those for which spectral information is available. Moreover, issues concerning the quality of the information in databases still exist, including insufficiently curated tandem mass spectra. Based on promising results obtained in proteomics and the added value of automatically assessing MS2 quality, this work focused on developing a machine learning pipeline that allows determining the quality of MS2 spectra of environmentally relevant compounds. A dataset of 204 reference standards of environmental contaminants acquired with different collision energies, corresponding to more than 1300 MS2 spectra, was used. Initially, the focus was set on finding relevant and non-redundant features which could be used for machine learning purposes and that provided a sufficiently accurate representation of the raw input data. Specifically, three different feature sets were computed, and their performances were evaluated using a Random Forrest Classifier with cross-validation and filtered to select those which explained most of the available data. Subsequently, the optimised feature sets were evaluated against the test set and a final classification model was optimised to discriminate between MS2 spectra of good and bad quality. Favouring precision, to minimise the risk that BAD spectra would be labelled as good, the final classifier was able to reach a precision of 85%, whilst still having an accuracy and recall of 79% and 65%, respectively. To the best of our knowledge, this is the first time that a machine learning algorithm was developed to automatically assess the quality of tandem mass spectra of environmentally relevant compounds.

3.24.T-01 Identification of Emerging Persistent and Mobile Substances by HILIC-Driven Effect-Directed Analysis

Timur Baygildiev*, Jeroen Meijer, Majorie van Duursen, Marja Lamoree and Timo Hamers, Amsterdam Institute for Life and Environment (A-LIFE), Section Environment & Health, Vrije University Amsterdam, Netherlands*

Substances with a certain combination of intrinsic properties pose a risk to drinking water sources. The combination of the two persistent (P) and mobile (M) properties of substances increases the chances of substances passing natural barriers, such as river banks, and artificial barriers in water treatment plants. Consequently, the presence of persistent and mobile (PM) substances in drinking water sources is currently unavoidable and may pose a risk to human health. Non-target screening based on reversed-phase (RP) liquid chromatography high resolution mass spectrometry (HRMS) is being used more frequently to identify emerging compounds. However, unconventional chromatographic approaches should also be considered to analyse PM substances due to their high polarity. Furthermore, identification priority should be given to PM substances that pose a risk to human health, which can be facilitated by the use of bioassays.

This study shows the application of an effect-directed analysis (EDA) method for the analysis of surface and well water samples from the Rhine River. The sample preparation approach used enables a significant preconcentration of a wide range of PM compounds (multi-layered solid phase extraction) and preserves the original composition of the samples (evaporation). The extracts of the samples were separated using two orthogonal separation techniques - RP and hydrophilic interaction liquid chromatography (HILIC) and analyzed by HRMS. The same extracts were fractionated using high-resolution fractionation collector (FractioMate) to guide chemical identification to the biologically relevant fractions, which is greatly reduces the complexity of the identification approach. The prioritization of features for the identification was based on a partly automated transthyretin-binding assay that measures the competitive binding of chemicals to thyroid hormone distributor protein transthyretin (TTR). TTR-binding assay for the RP and HILIC fractionated samples showed active fractions in both separation modes, which facilitated the prioritization of features with human health relevance.

3.24.T-02 Suspect and Non-Target Screening of Per- and Polyfluoroalkyl Substances in Electrochemical Oxidation Treated Water using HRMS and in silico Techniques

Svante Bertil Rehnstam[1]*, Sanne Smith*[2] *and Lutz Ahrens*[2]*, (1)Lennart Hjelms, Swedish University of Agricultural Sciences, Sweden, (2)Department of Aquatic Sciences and Assessment, Swedish University of Agricultural Sciences, Sweden*

Per- and polyfluoroalkyl substances (PFAS) is an anthropogenic class of substances with unique physical and chemical properties. They have a large variety of uses but are mostly utilized due to their non-stick and lubricating qualities. Although PFAS has proven to be useful in industry and consumer products they have less desirable qualities. These qualities include being persistent, mobile, toxic and bioaccumulative. With new destructive treatment methods for PFAS a need for advanced and in-depth analysis is necessary. Electrochemical oxidation (EO) in a complex matrix may cause the rise of transformation products containing CF_2 containing moieties, all of which should be identified and characterized.[1] In this study High-Resolution Mass Spectrometry (HRMS) will be utilized to perform suspect and non-target screening of PFAS on EO treated samples with the goal of identifying previously unknown compounds.

A previous suspect screening study was performed on samples from the same location, which will serve as a foundation for the non-target screening study on the transformation products. Water samples were collected at a wastewater treatment plant which treats leachate originating from a landfill. Each water samples was treated with foam fractionation, then the foam itself was collapsed and treated with EO. Samples were collected at various time points, of which in this study the time points included were 1 h, 3 h, 5 h, 7 h and 9 h, as well as a sample that was not treated with EO. The initial results of the non-target screening resulted in five compounds that contained at least one fragment which belongs to a perfluorinated tail and did not give a hit as a PFAS in any databases. Half of the compounds have an intensity that is higher after being treated with EO as opposed to no treatment. Some compounds have similar fragmentation patterns to that of other known substances that have been recorded in MS^2 libraries, but contain a different chain length on the perfluorinated tail. Currently, only a very basic in silico techniques, based on molecular formulas and transformations from other treatment studies, have been used to predict transformation products.

Several compounds have been tentatively identified as PFAS transformation products. The in silico predictions of transformation products have proven to be useful already in the initial stages of data evaluation for identifying features that the normal peak picking algorithm missed.

3.24.T-03 LC-TIMS-HRMS Combined with Advanced Data Processing Tools - A Powerful 4-D Workflow for the Identification of Biotransformation Products of Zebrafish Exposed to Xenobiotics

Dimitrios E. Damalas[1]*, Eleni Panagopoulou*[1]*, Adamantia Agalou*[2]*, Dimitris Beis*[2]*, Carsten Baessmann*[3] *and Nikolaos Thomaidis*[1]*, (1)National and Kapodistrian University of Athens, Greece, (2)Biomedical Research Foundation Academy of Athens, Greece, (3)Bruker Daltonics, Germany*

The impact of xenobiotics in the aquatic ecosystem is evaluated in more depth when the whole xeno-metabolome (xenobiotics and their biotransformation products (bio-TPs)) of aquatic organisms is studied. Therefore, it becomes compulsory to thoroughly study the biotransformation processes of aquatic organisms.

Despite the technological advancements in LC-HRMS, the identification of bio-TPs remains challenging. A major challenge is the vast number of different biotransformation reactions, while some of them are still under investigation. Thus, there is an urgent need for powerful data treatment workflows to identify yet unknown bio-TPs. On the other hand, even well characterized reactions (e.g., hydroxylation) may lead to different isomeric bio-TPs. To address that, it is imperative to establish efficient analytical methodologies, that provide extensive analytical information. Another important challenge in the context of unknowns' identification, is the lack of experimental DDA MS2 spectra for a great portion of the detected precursors. Therefore, efficient MS2 data acquisition modes are required.

Recent studies, demonstrate i) the combination of complementary chromatographic modes with HRMS and ii) ion mobility spectrometry coupled to HRMS as promising alternatives for the determination of small molecules in complex matrices. To overcome the aforementioned challenges, we propose the combination of different orthogonal analytical techniques (RPLC/HILIC, TIMS and HRMS) with sophisticated acquisition methods (PASEF), aiming to create the highest amount of analytical evidence. At the same time to develop an efficient suspect and non-target screening workflow that utilize the extensive analytical evidence to its maximum to facilitate the identification of bio-TPs.

The improved utility of LC-TIMS-HRMS in the identification of bio-TPs will be demonstrated via illustrative examples from exposure experiments of zebrafish exposed to different xenobiotics. The added value of the developed analytical workflow will be discussed, in the context of isomers separation, enhanced sensitivity, improved DDA MS2 spectra coverage (PASEF) and acquisition of cleaner MS and MS2 spectra though mobility filtering. The use of *in-silico* prediction tools was an integral part of the identification workflow. Examples from the application of suspect and NTS will be demonstrated, highlighting the identification of complex bio-TP structures formed by subsequent biotransformation reactions.

3.24.T-04 Nontarget Liquid Chromatography High Resolution Mass Spectrometry and in silico Structural Characterization of Dissolved Organic Matter from Different Water Sources

Jessica Patrone[1], *Maria vila-Costa*[2], *Jordi Dachs*[2], *Stefano Papazian*[3], *Pablo Gago Ferrero*[1] *and Rubén Gil Solsona*[4], *(1)Spanish Research Council (CSIC), Institute of Environmental Assessment and Water Research (IDAEA), Spain, (2)Environmental Chemistry, Spanish Research Council (CSIC), Institute of Environmental Assessment and Water Research (IDAEA), Spain, (3)Stockholm University, Sweden, (4)IDAEA, CID-CSIC, Spain*

Dissolved organic matter (DOM) of aquatic systems, a heterogeneous mixture of compounds resulting from metabolic activity and decay of organisms, represents one of the largest exchangeable carbon reservoirs on the planet and it is involved in numerous biogeochemical cycles. A holistic comprehension of DOM composition is crucial to assess the health status of the ecosystem, but the complexity of its formulation makes DOM analysis arduous.

Characterization of DOM is commonly performed by direct infusion (DI) high resolution mass spectrometry (HRMS), employing electrospray ionization (ESI) operating in negative mode. However, liquid chromatography (LC) separation represents a complementary alternative to DI which can provide new insights. In this study, LC-HRMS was applied in association with novel HRMS nontarget computational tools to achieve a data analysis workflow that allows, for the first time, the structural identification of DOM composition in water matrixes.

Three water samples (sea, river and drinking water), with different expected content of organic compounds, were considered. Samples were solid phase extracted by PPL cartridges adopting an existing protocol. Analysis was performed in triplicate using both DI and LC coupled to an Orbitrap equipped with ESI. Xcalibur software and MFAssignR package in R were used respectively for peak picking and formula annotation of DI data. While MS-DIAL and SIRIUS were used for LC data. Spectra from LC-HRMS were processed in GNPS (Global Natural Products Social Molecular Networking). Here, features were clustered in molecular networks depending on their MSMS spectral similarity and molecular structures were predicted using the *in silico* Network Annotation Propagation (NAP).

Despite the wide range of molecules detected by DI, this method showed significant limitations since it cannot analyse isomers nor obtain structural information. Whereas, LC and MSMS spectra (from data independent acquisition) ensure the separation of compounds and provide more precise molecular formula annotation and molecular structure prediction. The combination of DI and LC resulted in an improvement in DOM pool characterization. Different fractions of organic compounds were observed by the two acquisition methods. Moreover, LC data treatment workflow allowed the prediction of almost 40% of features detected at a molecular structure level. Implementation of this tool will contribute towards a holistic characterization of DOM composition.

3.24.P State-Of-The-Art Analytical Tools for an Enhanced Non-target Screening of Environmental Samples

3.24.P-We233 A High-Content Screening Method for Target, Suspect, and Non-Target Analysis of Chemicals in Sediments Using Gas Chromatography-Atmospheric Pressure Chemical Ionization-Ion Mobility Spectrometry

Xiaodi Shi[1], *Anna Sobek*[2] *and Jonathan Benskin*[1], *(1)Stockholm University, Sweden, (2)Environmental Science, Stockholm University, Sweden*

Chemical databases have documented over one million chemicals with potential hazards to public health. To keep up with the ever-increasing number of new chemicals in society, environmental analytical chemists are moving beyond characterization of single chemical classes towards complex mixtures. These so-called “high-content” screening methods strive to quantify as many substances as possible, while simultaneously collecting non-target data suitable for identification of unknowns. When applied to dated sediment cores, particularly in remote regions, these methods provide valuable insight into long range transport of environmental pollutants. Moreover, temporal information can be used as a prioritization strategy for identification of emerging chemicals, while at the same time assessing impacts of international regulatory and phase-out initiatives. However, most high-content screening work to date focuses on polar substances using liquid chromatography systems. In this study, a new method was developed and validated for simultaneous target, suspect, and non-target analysis of non-polar substances in sediments. The method utilizes accelerated solvent extraction followed by size-exclusion chromatography, with analysis by gas chromatography-atmospheric pressure chemical ionization-cyclic ion mobility-high resolution mass spectrometry (GC-APCI-cIMS). In comparison to widely-applied electron impact ionization, APCI preserves (quasi-) molecular ions, thereby facilitating identification of unknown compounds. In parallel, cIMS facilitates deconvolution of MS2 spectra while offering additional structural information via the collision cross section (CCS). The newly developed analytical method will be supported by a library of four-dimensional metrics, i.e., retention index, CCS, information of MS1 and MS2, using >100 target compounds with Log K_{OA} and Log K_{OW} ranging 2.69-15.0 and 1.44-17.5, respectively, which is currently under development. Open science databases and *in silico* predication of fragmentation and CCS will facilitate suspect analysis. Liquid chromatography-based prioritization strategies, such as SIRIUS, will be transplanted to interpret unknown compounds. Once completed, the method will be applied to remote Arctic sediments in an effort to assess variations in chemical storage under a changing climate.

3.24.P-We235 Combined Use of GC & LC - QTOFMS for Wide-Scope Screening of Organic Micropollutants in Surface Water and Wastewater from Pasto, Colombia

Felix hernandez Hernandez[1], *Luis A Galeano*[2], *Maria Ibañez*[1], *Tania Portoles*[3], *Ana M Garcia-Mora*[2], *Manuela A. Paredes-Hincapié*[2], *Andres F Hidalgo-Silva*[2] *and Arsenio Hidalgo-Troya*[4], *(1)Research Institute for Pesticides and Water, University Jaume I, Spain, (2)Functional Materials and Catalysis, University of Nariño, Colombia, (3)Research Institute for Pesticides and Water (IUPA), University Jaume I, Spain, (4)Research Group Public Health, University of Nariño, Colombia*

The complexity of the aquatic environment scenario, including urban wastewater samples, together with the huge number of hazardous compounds potentially present in the samples, makes the comprehensive characterization of samples an analytical

challenge, particularly in relation to the presence of organic micropollutants (OMPs). The potential of HRMS for wide-scope screening in environmental samples is out of question, making use of target, suspect and non-target approaches. Considering the different physico-chemical characteristics of OMPs, the coupling to both liquid and gas chromatography to HRMS is indispensable. In this work, the combined use of LC and GC both coupled to Quadrupole-Time-of-Flight Mass Spectrometry (QTOF MS) has been applied for screening of surface water and wastewater samples from Pasto (Nariño, Colombia). The aim was to have a preliminary comprehensive overview of the occurrence of OMPs in the Pasto River, focusing the study on pesticides and pharmaceuticals, to assess the impact of agricultural practices and raw urban wastewater on the quality of the river water.
After SPE with Oasis HLB and C18 cartridges, sample extracts were injected by LC- and GC-QTOFMS, respectively. The searching was made by target and suspect approach, using home-made databases containing more than 1500 compounds (LC-QTOF) and around 500 pesticides (GC-QTOF). The (tentative) identification was possible at different confidence levels, as a function of standards availability and accurate-mass information obtained on the molecular ion/protonated molecule and fragments, and after evaluation of whether the potential fragments were consistent with the chemical structure of the compound. Up to 15 pesticides were identified in surface water in sampling points up-river to the town illustrating the impact of agriculture practices, and 14 pharmaceuticals were found down to the town, illustrating the impact of the urban population. Insecticides and fungicides were mostly identified in the sampling point up to the town, while no pharmaceuticals were found at this site. However, several antibiotics and analgesics, among others, were present in wastewater and the river samples collected in the middle and down to the town. Some metabolites, such as carbofuran-3OH and 4-acetylamino antipyrine, were also identified. Future monitoring will be performed by application of target quantitative LC-MS/MS methods for the most relevant compounds identified in the screening.

3.24.P-We236 Considerations in Developing a GCMS Accurate Mass Screening Workflow for Environmental Pollutants
***Bryan White**, Agilent Technologies, United Kingdom*
When performing non targeted workflows, relying entirely on spectral matching versus a large library such as NIST rarely gives the correct answers, especially what the contaminants are at low level compared to the matrix. Accurate Mass on its own helps but is not the entire answer especially when most GCMS libraries are still nominal mass and molecular ion accurate mass data on its own is rarely enough. We have developed an accurate mass library of >1200 of the most likely environmental contaminants containing accurate mass spectra and retention time on a set method that includes mid column backflush for robustness. Th workflow looks at the ppm mass accuracy of a given peak, the retention time, number of qualifiers and the deconvoluted spectral hit. Should all four parameters be within the limits set then these compounds are listed as green, and the operator can be more confident that these are present in the sample. Should aat least one but not all parameters be met then that component is listed as amber, and some investigation would be required. Isotope ratio information is significant in reviewing compounds as this is shown.
The presentation will also cover the benefits of accurate mass deconvolution for evaluation of components that are not present within the database and show how to append the database to include those found.
The main benefit of this approach to environmental screening is the removal of false positives without any extensive manual evaluation.

3.24.P-We237 Expanding Non-target Screening Capabilities for Per- and Polyfluoroalkyl Substances (PFAS) with Ion Mobility Spectrometry
***Kaylie Kirkwood**[1], James Dodds[1,2] and Erin Baker[2], (1)North Carolina State University, USA (2)University of North Carolina at Chapel Hill, USA*
Per- and polyfluoroalkyl substances (PFAS) are a class of manmade compounds used in various household and industrial applications. Production of PFAS began in the 1940s, however a majority of legacy PFAS have been phased out of use due to their toxicity and environmental persistence. Manufacturers have therefore shifted to a variety of structurally modified alternatives, leading to the production of over 9000 known PFAS. Moreover, researchers are now tasked with both the quantitative monitoring and discovery of novel PFAS. Non-target screening approaches are often applied to face these problems, however they can be subject to quantitation, separation, and data annotation challenges. We demonstrate the ability of a multidimensional method coupling liquid chromatography, ion mobility spectrometry, and high-resolution mass spectrometry (LC-IMS-HRMS) to overcome many of these non-target screening limitations. By adding IMS to traditional LC-HRMS platforms, it provides additional characterization capabilities such as measuring an analyte's collision cross section (CCS), or gas phase surface area, for feature and unknown identification using database or in-silico matching as well as *m/z* versus CCS trend analyses. IMS was also leveraged to enhance fragmentation capabilities via an all-ions data independent acquisition (DIA) fragmentation scheme using ramped collision energies to fragment each PFAS by its size and charge state. Since the IMS drift times of intact precursors and their corresponding fragments align, straightforward annotations of the complex DIA data were possible even in the presence of co-eluting precursors. This capability further aids in discovering new PFAS compared to traditional non-target fragmentation schemes which only use a single collision energy or focus on a set of the most abundant or specific target ions. IMS also facilitated the separation of PFAS from hydrocarbon-based matrix biomolecules such as lipids which co-extract and co-elute with PFAS due to the different molecular sizes. Additionally, IMS filtering of the matrix signals reduced noise and enhanced PFAS quantitative accuracy in complex samples such as plant material and liver tissue. Finally, the ability to separate constitutional isomers not distinguished by LC using the IMS dimension was demonstrated, allowing for enhanced point source fingerprinting due to the isomers not being grouped together as a single compound.

3.24.P-We238 Ion Mobility and Cross Collision Section in Non-target Identification of Environmental Samples – A Need For Prediction Tools

Christine Gallampois[1], *Pedro Ojeda May*[2] *and Peter Haglund*[3], *(1)Chemistry, Umea University, Sweden, (2)HPC2N, Umea University, Sweden, (3)Umea University, Sweden*

The identification of chemicals in complex mixtures, such as environmental samples is a challenge due to the presence of both natural and anthropogenic compounds, at different level of concentrations. Separation is a key word to be able to detect low concentration chemicals in such mixtures. Ion mobility separation (IMS) has the ability to separate analytes in the gas phase according to their charge, shape and size in a carrier gas as they travel at different velocity in a drift cell. IMS experiments enable the determination of collision cross section (CCS) value that is a unique physicochemical properties of a molecule that can aid structural studies and also facilitates small molecule identification. However, the number of empirical CCS information available is limited, and prediction tools are needed. Prediction models already exist, mainly for metabolomics purposes, and little for environmental samples, where halogenated compounds are present, but not fully supported by existing prediction tools. The aim is to compare several machine learning prediction tools and a stochastic projection Approximation method (Monte Carlo simulations) with a set of 18 chemicals, including pesticides, pharmaceuticals (fenuron, tramadol, 4-Formylaminoantipyrine, trimethoprim, mirtazapine, metoprolol, sulfadimidine, azithromycin, bisoprolol, venlafaxine, clindamycin, climbazole, cycluron, terbutryn, DEET, candesartan, diclofenac and chloroxuron), for we have CCS values (acquired in an Agilent 6560 LC-IM-QTOF instrument). As isomeres can also be difficults to identify based on retention time and MS/MS only, another set of compounds was used for the CCS prediction. This set includes tris(1-chloropropyl) phosphate, tris(2-chloropropyl) phosphate, and tris(3-chloropropyl) phosphate, and tris(1,3-dichloropropyl) phosphate and tris(2,3-dichloropropyl)phosphate. The first results show that within the set of the 18 compounds, 12 compounds show a difference of CCS values (observed/predicted) below 5 %, 4 compounds between 5% and 10% and 2 compounds with a larger error, between 18% and 25% (azithromycin and bisoprolol, respectively) with the Monte Carlo simulations. With the prediction tool (MetCCS predictor), CCS predicted show less than 5% error for 15 compounds (including the bisoprolol), 2 compounds between 5 and 10%, and one compound (azithromycin) above 10 % (14%). Other prdiction tools need to be evaluated for environmental samples.

3.24.P-We239 Potential of Ion Mobility Separation in Improving GC-HRMS Screening in Environmental and Food Samples

Juan Vicente V Sancho Llopis[1], *David Izquierdo-Sandoval*[1], *David Fabregat-Safont*[1], *Leticia Lacalle-Bergeron*[1], *Felix hernandez Hernandez*[2] *and Tania Portoles*[1], *(1)Research Institute for Pesticides and Water (IUPA), University Jaume I, Spain, (2)University Jaume I, Castellón, Spain*

The coupling of ion mobility separation to high resolution mass spectrometry (IMS-HRMS) is an advanced tool for wide-scope screening of a large number of organic contaminants and residues in different applied fields. IMS-HRMS can be used in combination with Gas Chromatography (GC) with atmospheric pressure chemical ionization (APCI) source allowing for notably improve the reliability of (tentative) identifications in the monitoring of (semi)volatile compounds in complex matrices. First, the soft ionization promoted by APCI source designed for GC preserves the molecular ion and/or protonated molecule in mass spectra enabling an efficient, rapid, and sensitive wide-scope screening. Furthermore, IMS allows separating species of interest from co-eluting matrix interferences and/or resolving isomers based on their charge, shape, and size. The drift time (DT)-derived collision cross section (CCS) is a robust and matrix-independent parameter, comparable between instruments, of great help in the process of (tentative) identification of compounds detected in samples.

Mobility data for 264 GC-amenable compounds have been collected to build a CCS database, which has been applied to complex-matrix samples including fish feed extracts, surface waters, and different fruit and vegetable samples. The homemade library consisted of diverse families of compounds including pesticides, PAHs, PCBs, flame retardants, and emerging contaminants, such as insect repellents, musks, and UV filters among others. The data collected within this database comprises CCS values for molecular ions and/or protonated molecules and in-source fragments.

Selected examples are used to illustrate the benefits of including IMS in GC-ACPI-QTOF MS screening methodologies: a) The IMS DT alignment (±0.2ms) led to much cleaner spectra in comparison with the conventional HRMS spectra increasing the reliability of the analyte identification; b) The possibility to obtain independent fragmentation spectra at High Energy (HE) by using the appropriate IMS DT-alignment for different "precursors" ions (e.g. M+• and [M+H]+) when CCS differences between both ionized species are significant (e.g. > 2%); c) the inclusion of CCS deviation (e.g. < 2%) into the identification criteria is an extra value to enhance the confidence in the identification; this is particularly interesting in those cases when the mass accuracy criterion (mass error < 5 ppm) is not accomplished for the fragment ion.

3.24.P-We240 Prediction of Retention Time and Collision Cross Section for Different Adducts to Improve Non-target and Suspect Screening of Organic Micropollutants

Alberto Celma[1,2], *Richard Bade*[3,4], *Juan Vicente V Sancho Llopis*[5], *Felix hernandez Hernandez*[6], *Melissa Humphries*[7] *and Lubertus Bijlsma*[8], *(1)Swedish University of Agricultural Sciences (SLU), Sweden, (2)Research Institute for Pestidices and Water, University Jaume I, Castelló de la Plana, Spain, (3)Queensland Alliance for Environmental Health Sciences (QAEHS), University of Queensland, Australia, (4)University of South Australia, Adelaide, UniSA: Clinical and Health Sciences, Health and Biomedical Innovation, Australia, (5)Research Institute for Pesticides and Water (IUPA), University Jaume I, Spain, (6)University Jaume I, Castellón, Spain, (7)School of Mathematical Sciences, University of Adelaide, Australia, (8)University Jaume I, Spain*

Ultra-high performance liquid chromatography coupled to ion mobility separation and high-resolution mass spectrometry instruments are very valuable for the screening of emerging contaminants in the aquatic environment over the recent years.

However, when applying suspect or non-target approaches (i.e. when no reference standards are available) there is no information on retention time (RT) and collision cross section (CCS) values to facilitate identification. Thus, findings solely rely on the match between empirical and theoretical masses for (de)protonated molecules as well as fragment ions to result in MS2 stages. However, false positive tentative identifications could occur and candidates could also match the empirical observations. In this sense, *in-silico* prediction tools of RT and CCS can be of great utility to decrease the number of candidates to investigate as well as to gather more confidence in tentative identifications. In this work, Multiple Adaptive Regression Splines (MARS) was evaluated for the prediction of both RT and CCS. MARS prediction models were developed and validated using a database of 477 protonated molecules, 169 deprotonated molecules and 249 sodium adducts. The database was built using a Vion IMS QTOF instrument featuring a travelling wave IMS separation device. Multivariate and univariate models were evaluated showing a better fit for univariate models to the experimental data. The RT model ($R^2 = 0.855$) showed a deviation between predicted and experimental data of ± 2.32 min (95% confidence intervals). The deviation observed for CCS data of protonated molecules using the CCS_H model ($R^2 = 0.966$) was ± 4.05 % with 95% confidence intervals. The CCS_H model was also tested for the prediction of deprotonated molecules resulting in deviations below ± 5.86 % for 95% of the cases. Finally, a third model was developed for sodium adducts (CCS_{Na}, R^2=0.954) with a deviation below ± 5.25 % for 95% of the cases. The developed models have been incorporated in an open access and user-friendly online platform which represents a great advantage for third-party research laboratories for predicting both RT and CCS data. To the best of authors' knowledge, this is the first study developing RT and CCS predictors for the same instrumental system, as well as the first developed model to predict CCS data of sodium adducts.

3.24.P-We241 Advancing Towards the Use of Ion Mobility Separation Coupled to High Resolution Mass Spectrometry for the Analysis of Organic Micropollutants in Aquatic Samples

Alberto Celma[1]*, Lutz Ahrens*[2]*, Adrian Covaci*[3]*, Lidia Belova*[3]*, Felix hernandez Hernandez*[4]*, Foon Yin Lai*[2]*, Frank Menger*[1]*, Juan Vicente V Sancho Llopis*[5]*, Emma Schymanski*[6]*, Alexander Van Nuijs*[3]*, Karin Wiberg*[2] *and Lubertus Bijlsma*[5]*, (1)Swedish University of Agricultural Sciences (SLU), Sweden, (2)Department of Aquatic Sciences and Assessment, Swedish University of Agricultural Sciences (SLU), Sweden, (3)University of Antwerp, Belgium, (4)University Jaume I, Castellón, Spain, (5)University Jaume I, Spain, (6)University of Luxembourg, Luxembourg*

Ion mobility separation (IMS) coupled to high resolution mass spectrometry (IMS-HRMS) is a powerful tool for target, suspect and non-target analysis of organic micropollutants (OMPs) in complex environmental samples. In brief, IMS separates ionized compounds based on their mobility through an inert gas in the presence of an electric field. This separation mainly depends on the charge, shape, and size of the molecule. Consequently, IMS permits, in theory, the filtering of interfering species, such as isomeric or isobaric compounds. The implementation of IMS during the analysis of complex matrices permits to enhance the spectral quality compared to conventional HRMS configurations. In addition, IMS can provide an extra identification parameter for the confirmation of OMPs by calculating the collision cross section (CCS)value from the molecule's measured mobility. These values are independent from matrix and chromatographic separation. Thus, the development of freely available online databases of CCS values of organic molecules is of utmost importance for a proper establishment of IMS-HRMS as the routine approach for environmental screening analyses.We aim to highlight the main benefits of using IMS-HRMS instrumentation for the analysis of OMPs in complex environmental matrices. In this light, we present different studies towards the establishment of criteria for reporting identification confidence in aquatic samples, the resolution of isomeric/isobaric substances and the reduction of the false positive findings rate. Additionally, an evaluation of the spectral enhancement provided by IMS, as well as the intercomparability of CCS values between different instrumental set-ups, is shown.

3.24.P-We242 Semi-quantitative Non-Targeted Analysis for Emerging PFAS

James McCord[1]*, Shirley Pu*[2] *and Jon Sobus*[1]*, (1)U.S. Environmental Protection Agency, (2)ORISE Research Participant - USEPA*

Emerging chemical contaminants present a challenge for traditional chemical quantification as they lack reference standards; this is particularly relevant for per- and polyfluorinated alkyl substances (PFAS), which have a wide range of structural diversity and essentially zero available chemical reference data for novel species. Semi-quantitative estimates of chemical concentration can be made for such emerging contaminants using surrogate calibration curves based on related chemicals in the event that reference standards are not available. This is particularly useful when performing non-targeted analysis (NTA), where detection of diverse chemical species is a given, and the likelihood of having comprehensive reference data is low. The uncertainty of concentration estimates in NTA is influenced by NTA data processing, the choice of quantitative surrogate(s), and the mathematical models used to predict concentration from observed instrument abundances. Obtaining accurate concentration estimates is a priority, but bounding the accuracy of such estimates is a necessary step for interpreting the results in a risk-based context. We have compared the performance of semi-quantitative non-targeted analysis workflows in providing concentration estimates. Critically, these data processing approaches were selected to provide bounding confidence intervals for prediction. Model assessment was carried out using a set of 16 PFAS with available reference standards, including mass labeled internal standards, and an additional set of emerging PFAS with reference standards, but no widely available commercial source. Comparisons were made for quantitative accuracy between traditional targeted quantitative approaches and non-targeted data collection, as well as the underlying uncertainty. Estimation error and uncertainty were larger, but acceptable, for NTA derived data when reference standards were available for normalization. Semi-quantitative estimation of emerging contaminants using surrogate calibration with legacy compounds exhibited significant uncertainty, but the models were able to successfully bound the uncertainty using bootstrapped confidence intervals from the test set. Curation of the surrogate population used for concentration prediction and confidence bounding increases the accuracy and decreases the uncertainty of predictions, but development of a generalized approach for surrogate curation is ongoing.

3.24.P-We243 Simultaneous Electron and Chemical Ionization used for GC- and Real Time – MS Applications for Improved Non-Targeted Environmental Analysis

Marleen Vetter*, Sonja Klee and Steffen Braekling, TOFWERK AG, Switzerland*

A time of flight (TOF) mass spectrometer operating an electron ionization (EI) and a chemical ionization (CI) source simultaneously is presented for non-targeted environmental analysis. The ecTOF offers multiple setup options that provide the opportunity to use gas chromatographic as well as real time sampling. By coupling both ionization sources directly to one single gas chromatograph (GC), simultaneous structural as well as accurate mass molecular ion information is generated. Hence, target and suspect screening analysis as well as effective non-target analysis using GC-MS for environmental samples is improved considerably.

In addition, the ecTOF can employ real time CI-TOFMS sampling, which is well known for direct measurements of complex mixtures during rapid sample changes. The high resolution, accurate mass TOF mass spectrum continuously creates a full mass-range picture of the sample, gaining information that would otherwise be concealed in nominal mass spectrometry. Using the ecTOF, the real time CI-TOFMS measurements can be complemented by simultaneous GC-EI-TOF analysis of the same sample, allowing for effective separation and identification of isomers using divergent EI mass spectra in one singe analyzer.

Various experiments will be presented to depict the performance and highlight the advantages of the GC-ecTOF for non-targeted approaches, specifically for environmental contaminants such as pesticides, PCBs and phthalates. The potential of the ecTOF for real time monitoring is highlighted using an example of biomass burning processes, depicting the burning emissions in high time resolution. Parallel GC-EI-TOF measurements show isomer separation and its improved compound identification potential.

3.24.P-We244 Improved Monitoring and Non-target Screening of Indoor Air Samples Using TOF-MS Systems

Marleen Vetter*[1], Christina Hinterleitner[2], Luca Cappellin[3], Steffen Braekling[1] and Sonja Klee[1], (1)TOFWERK AG, Switzerland, (2)Department of Architektur, Holz und Bau, Berner Fachhochschule, Switzerland, (3)Department of Chemical Sciences, University of Padua, Italy*

Many people spend much of their time in indoor environments, for example at work, at home, or travelling in their car. In these indoor environments, thousands of volatile organic compounds (VOCs) may be present and may accumulate. The quality of indoor air is therefore of high importance as it can affect people's health, comfort, and work performance as well as potentially contaminate sensitive working environments. Hence, monitoring of indoor air has become increasingly important.

This presentation will highlight VOC emission measurements using ISO standard methods. These measurements are performed using a conventional quadrupole mass spectrometer (QMS) as well as a newly developed time of flight mass spectrometer operating an electron ionization and a chemical ionization source simultaneously (ecTOF). Both methods are initially assessed according to the ISO standard, where they are shown to fulfil the performance requirements regarding linearity, quantification limits, etc. Furthermore, a non-target approach to tentatively identify as many compounds as possible is employed for both. Here, compound identification of different indoor samples such as flooring or artificial leather using both systems was performed. The comparison showed that up to 31 % of compounds were misidentified using the conventional QMS system as shown by the additional chemical ionization information provided by the ecTOF. Next to increasing identification confidence, the ecTOF was also able to suggest tentative structures or sum formulas for up to 28 % of otherwise unidentified peaks.

In addition, measurements using a real time chemical ionization mass spectrometry (Vocus CI-TOF-MS) to detect VOCs of these materials is discussed. Compounds of interest as identified using the ISO methods were used for monitoring purposes. Due to the high sensitivity of the system, the analysis can be done within seconds, reducing the analysis time considerably. Furthermore, changes in concentration over time can be monitored and owing to the mobility of the Vocus, on-site and online monitoring becomes feasible for environmental monitoring of indoor environments.

In conclusion, this presentation will show the potential of new, state of the art instrumental setups for indoor air monitoring, characterization and non-target screening of environmental samples and their potential to improve upon existing standards and standard measurement technologies.

3.24.P-We245 Supramolecular Solvent-Based Extraction Method for the Determination of a Wide Range of Legacy and Emerging Environmental Contaminants in Indoor Dust

Paula Marcinekova*[1], Erika Martinelli[2], Lisa Melymuk[1], Pernilla Bohlin-Nizzetto[3] and Pawel Rostkowski[3], (1)Recetox, RECETOX, Masaryk University, Czech Republic, (2)Department of Chemistry "Giacomo Ciamician", Università di Bologna, Italy, (3)Norwegian Institute for Air Research (NILU), Norway*

Indoor environments are burdened with synthetic chemicals associated with consumer products, building materials and furnishing, personal care products and pharmaceuticals. These chemicals are detected in both gas and particulate phase of indoor environments and humans are exposed to them constantly. We have a good knowledge of some chemical pollutants that are typically detected in indoor dust; however, less is known about more novel/emerging contaminants such as UV-stabilizers, fragrances, chlorinated paraffins, dechloranes and more. State-of-the-art analytical tools for non-target screening of emerging contaminants are currently exploited in analytical laboratories worldwide and are rapidly developing. However, the methodology to determine multiple chemical classes in single samples is challenging. The objective of our study was to develop an efficient supramolecular solvent (SUPRAS) extraction method suitable for the extraction of a wide range of chemical pollutants in house dust. Ten house dust samples (composite dust) were collected, pooled together, and injected with multiple internal standards including flame retardants, plasticizers, bisphenols, current use pesticides, per- and polyfluorinated compounds, polyaromatic hydrocarbons (PAHs) and substituted PAHs and synthetic musks. Seven different mixtures of SUPRAS were investigated for extraction efficiency for a broad range of chemicals of interest. Liquid chromatography–mass spectrometry and gas chromatography–mass spectrometry were used for the detection of the targeted chemical classes. Based on calculated recoveries, SUPRAS composed of hexanol, tetrahydrofuran and Milli-Q in 1:2:7 volume ratio displayed the best extracting capability for a broad range of chemicals. The results show recoveries for the more volatile compounds at 40 to 60 % (PAHs, synthetic musks), while the less volatile compounds reach up to 90 % recovery. These recoveries are comparable with recoveries obtained by conventional extraction methods. However, a great advantage of the use of SUPRAS is its ability to extract different polarity compounds simultaneously while keeping a very low SUPRAS to sample ratio. As our preliminary results show, in addition to target analysis, SUPRAS extracts can be used in suspect screening and non-target analysis. This allows for the detection of an even broader range of chemicals, potentially exposing many new and unknown pollutants in the indoor environment.

3.24.P-We247 Linking Nucleic Acid Adductome to Environmental Contaminants
Giulia Martella[1], *Elena Gorokhova*[1], *Pedro F.M. Sousa*[2], *Natalia Y. Tretyakova*[3], *Zareen Khan*[1], *Brita Sundelin*[1] *and Hitesh V. Motwani*[1], *(1)Department of Environmental Science, Stockholm University, Sweden, (2)Department of Material and Environmental Chemistry, Stockholm University, Sweden, (3)Department of Medicinal Chemistry and Masonic Cancer Center, University of Minnesota, USA*
In polluted environments, biological effect assessment is based on biochemical or physiological changes caused by exposure to hazardous substances. However, finding ecologically relevant biomarkers related to chemical exposure is challenging, especially in wild populations, primarily because most biochemical responses are non-specific. In organisms inhabiting polluted environments, reproductive and developmental disorders can be driven by genome modifications, ultimately leading to population decline. DNA adductomics is an emerging -omics technique that includes screening and identifying chemical modifications of DNA. Recent advancements in HRMS analysis provide the scope for precise characterization of such structural modifications, i.e., the DNA adductome.
We propose that these modifications can be used to identify exposure effects at the genome level in biota, thus providing a proactive tool in biological effect monitoring. Using data on environmental contaminants (PAHs and trace metals) from the Baltic Sea sediments, we determined adductome profiles, identified specific adducts as biomarkers of the pollution status, and developed a workflow for environmental diagnostics.
Extracted and digested amphipod DNA was analyzed using LC-HRMS with a Full-MS/Data independent acquisition mode. The data processing employed a graphical user interface MATLAB program *nLossFinder,* available as open source, and based on the common neutral loss 116.0474 Da of deoxyribose. Nearly 100 putative adducts were found in the amphipods, which included markers for epigenetics (N^6-me-dA), oxidative stress (8-oxo-dG) and many unknown adducts. The DNA adducts were correlated to the contaminant concentrations, and a partial least square regression (PLSR) was used to identify influential adducts for the classification of the contaminated and reference sites. PLSR analysis showed that N^6-me-dA, the biomarker for epigenetic modifications, was one of the main predictors for classifying sites according to their contamination status.
Structural identification of these unknown adducts can aid in characterizing the effect of contaminants on the genome and searching sensitive biomarkers for environmental health assessment.

3.25.A Towards Harmonized Nano- And Microplastics Quantification: Reference Materials, Analytics and Improved Experimental Designs

3.25.A.T-01 Analytical Windows into the World of Microplastics - As Defined by Sampling and Analytical Constraints
Richard Cross, *UK Centre for Ecology & Hydrology (UKCEH), United Kingdom*
Whilst a standard definition of microplastics has yet to be agreed, taking into consideration the definition of a nanomaterial under the recommendation of the European Commission, microplastics may be considered as plastic particles smaller than 5 mm, but greater in size than 100 nm. This presents an analytical challenge for the detection and quantification of microplastics in complex environmental samples that may vary so greatly in size.
No single method can identify and quantify this diverse contaminant across the whole range of polymers, sizes and forms that are encompassed within the “microplastic universe”. Rather complimentary state-of-the-art techniques will be required, each of which has its own specific window into this universe. This “analytical window” is the operational space within the multiple dimensions that can describe microplastic material and must be defined every time we report on microplastic number concentrations from the field. Without defining the analytical window of a study, the longevity of any data produced is severely compromised. This is particularly pertinent for particle number concentrations, where even small shifts in the lower size limit of detection can result in orders of magnitude differences in total microplastic counts as larger plastics fragment into ever smaller particles.
In this presentation, we cover some of the fundamental principles that should be considered when attempting to quantify microplastics in the natural environment, including granularity in data as a function of sampling volume, sensitivity in detection as a function of particle size and quantifying repeatability and minimum QA/QC requirements. We will provide real examples of how to characterise the analytical window that operationally defines microplastics, using a case study of μ-FTIR, one of the most commonly employed techniques for chemically specific identification and quantification of microplastics in the environment.

3.25.A.T-02 Systematic Evaluation of Fragmentation of Five Common Synthetic Polymers: Influence of Photolysis, Temperature, and Relative Humidity on Fragment Size Distribution and Material Characteristics
Katherine Santizo[1], *Patrizia Pfohl*[1], *Wendel Wohlleben*[1], *Joana Marie Sipe*[2], *Mark Wiesner*[2], *Sam Harrison*[3], *Richard Cross*[3], *Gbotemi Adediran*[3], *Antonia Praetorius*[4], *Brandon Lopez*[2] *and Claus Svendsen*[3], *(1)BASF SE, Germany, (2)Duke University, USA, (3)UK Centre for Ecology & Hydrology (UKCEH), United Kingdom, (4)University of Amsterdam, Institute for Biodiversity*

and Ecosystem Dynamics, Netherlands
Stress on plastics from photolysis is commonly evaluated due to its potential to be a leading exposure pathway of plastics throughout their lifetime. Therefore, understanding the dynamics that lead to fragmentation and micro- and nanoplastics release from such exposure is necessary. This study focuses on systematically evaluating the influence of temperature and relative humidity during photolysis exposure on pristine microplastic powders and characterizing the powders at specified intervals. Five commonly used polymers are evaluated: PA-6, TPU, HIPS, LDPE and PP. Three exposure conditions all under ISO4892-2 are used with varying temperatures and relative humidity: (1) 90°C, 28%RH ("Kalahari protocol") (2) 65°C, 50%RH, (3) 65°C, 75%RH. Each polymer is evaluated at three exposure time points: 1000h, 1500h, and 2000h, corresponding to up to two years outdoor (at mid-European latitude). To evaluate the fragmentation, we use an adaptation of the NanoRelease protocol, ISO22293:2020. This allows the quantification of the smallest fragments, below 1 µm, thus allowing the observation of micro- to nano-plastic fragmentation. Material characteristics before and after aging are assessed by ATR-FTIR to measure Carbonyl Index (CI), DSC for crystallinity, and GPC for molar mass. Results indicate that each polymer's fragmentation dynamics varied based on time and exposure condition. For example, the LDPE showed high small particle fragments (< 2 µm) under all exposures. In specific, when exposed to high humidity the increase over time stayed on an upward trend over time. This is a clear distinction from the Kalahari method where the fragmentation values (< 2 µm) stayed relatively similar after 1000 hours with similar fragment counts at 1500 and 2000 hours. In contrast, TPU had steady fragmentation values when exposed to high humidity across all time points and showed more resistance to fragmentation under the Kalahari protocol with significant reduced small particle fragments. In addition, CI results varied with each exposure scenario for all the polymers tested with TPU and HIPS showing large changes in their values. Altogether, our current results show that temperature and relative humidity impact the fragmentation dynamics based on susceptibility of the polymers to each stress and will enable us to parametrize a model of fragmentation in different environmental compartments.

3.25.A.T-03 Microplastic Metrology: Creation and Characterization of Microplastic Reference Materials
Katherine Shaw[1], *Debra Ellisor*[1], *Raleigh Aiden Johnson*[2], *Rachel Sandquist*[3], *Marquesa Calderon*[2], *Meredith Evans Seeley*[1], *Rebecca Pugh*[1], *John R. Kucklick*[1] *and Jennifer Lynch*[1], *(1)National Institute of Standards and Technology (NIST), USA (2)Hawaii Pacific University Center for Marine Debris Research, USA (3)HPU Center for Marine Debris Research, USA*
Micro- and nanoplastics (MNP) are ubiquitous in the environment and have potential health effects on wildlife and humans. Plastic pollution analytical research has grown dramatically in the last 50 years, but methods in microplastic and nanoplastic research lack consistency and standardization. A commonly requested reference material (RM) is microplastic-sized particles of environmentally-relevant polymers and shapes. To meet this need, the National Institute of Standards and Technology (NIST) is creating an RM with multiple micro-size fractions. Furthermore, the lack of environmental RMs with verified microplastic quantities makes it difficult to validate analytical methods. Existing environmentally-collected NIST SRMs have been certified for organic and inorganic chemical pollutants, but until now, have not been examined for microplastics. Several NIST SRMs are good candidates to explore for microplastic certification including sediment, sludge, urban dust, soil, and bivalve tissue. Consumer goods were selected for creation of RMs as they are similar to plastics entering the environment from mismanaged waste and contain relevant plastic additives. Ten kg each of high density polyethylene milk jugs, polypropylene disposable cups, and polystyrene disposable knives were bought from retail manufacturers and cryomilled using a Palla VM-KT Vibrating cryomill at ≤ -150 °C in the NIST Cryogenic Reference Material Production Facility. This presentation will update the community on the status of the NIST RM creation and their many utilities. The second portion of this presentation will cover the potential of two existing NIST SRMs to serve as environmental RMs for microplastics. Two NIST reference materials, SRM 2782 Industrial Sludge and SRM 1941b Organics in Marine Sediment were analyzed for microplastics. An average of 0.72 ± 1.15 microplastics/g was found in SRM 1941b and 0.23 microplastics/gram in SRM 2782 (Figure 1). We expect the plastic and environmental reference materials to become valuable tools to validate and standardize analytical methods to quantify micro- and nanoplastics in the environment.

3.25.A.T-04 Granulometric Proxy-Based Geo-Spatial Prediction of Microplastic Inventories in Sediments
Kristina Enders[1], *Robin Lenz*[2], *Franziska Fischer*[2], *Klaus Schwarzer*[3], *Guntram Seiß*[4], *Dieter Fischer*[2] *and Matthias Labrenz*[5], *(1)IPF, Germany, (2)Leibniz Institute of Polymer Research, Germany, (3)Kiel University, Germany, (4)Bundesanstalt für Wasserbau, Germany, (5)Leibniz Institut für Ostseeforschung Warnemünde, Germany*
Sediments are likely the major storage of the microplastics (MP) legacy in the aquatic environment - being the place of continuous particle deposition. Yet, a reliable quantification of inventories is lacking, primarily for two reasons: data sets are limited and the natural variability in sediments is not accounted for. Key to a reliable quantification of sedimentary compartments is a sound normalisation that accounts for the hydrodynamic regime bias, the natural variability of the energetic conditions by which particles are sorted and distributed. While the lack of harmonisation of lab protocols has been frequently addressed, normalisation procedures of MP as part of data analysis harmonisation are unexplored.Former findings showed a co-occurrence of MP with other natural sedimentary particles and demonstrated their potential as part of normalisation procedures. The major scope of this study is to develop an empirical model approach for an accurate geo-spatial prediction of MP sediment inventories based on such identified granulometric proxies. However, in the investigated Schlei fjord the presence of geomorphological peculiarities, that is a narrowing strait, embayments, and the significant recent and continuous MP input from a WWTP, represent spatio-temporal discontinuities, that appear as deviations in the proxy continuum normalisation curve and challenge a simple prediction based on these proxies only. Parameters that solve the encountered challenges of spatio-temporal discontinuities were developed. Additionally, a mass-based model was set up that bases on particle measurements of all three dimension.

Based on a precursory MP data set (via µ-Raman and FTIR spectroscopy) and geospatial, hydrodynamic and sediment proxies generalized linear and tree-based (random forest) models were built to predict over 200 available granulometric proxy stations. Based on nested cross-validation results, the best performing model constellations was determined. Geo-spatial interpolation was applied to calculate the MP inventory.
Using granulometric proxy-based empirical models to quantify MP of entire geomorphological regions based on small-precursory data sets allows realistic assessments of MP inventories across different sedimentary systems. Estuarine environments are especially interesting with regard to anthopogenic land–based input into the aquatic systems and could potentially be used as leading indicators for changing MP inputs to the marine environment.

3.25.A.T-05 Microplastic Effects Tests Should use a Standard Heterogeneous Mixture: Multifarious Impacts among Sixteen Benthic Invertebrate Species Detected, Under Ecologically Relevant Conditions

Vera de Ruijter[1], *Matthias Hof*[1], *Petranta Kotorou*[1], *Jesse van Leeuwen*[2], *Martine J. van den Heuvel-Greve*[2], *Ivo Roessink*[3] *and Albert A. Koelmans*[1], *(1)Wageningen University & Research, Netherlands, (2)Wageningen Marine Research, Netherlands, (3)Wageningen Environmental Research (WUR), Netherlands*
Microplastic is a multidimensional contaminant and requires a risk assessment framework that takes into account all these dimensions, while only considering robust data. Therefore, effect tests should use a diverse, environmentally relevant microplastics (ERMP) standard material and meet high quality requirements. We provide seventeen chronic dose-effect relationships and effect thresholds for sixteen freshwater and marine benthic species exposed to ERMP. ERMP was made from plastic items from nature so that it represented the natural diversity of microplastics, in terms of size, shape and polymer type. The test design fulfilled twenty previously published quality assurance and quality control (QA/QC) criteria. Effect thresholds (EC_{10}) were found at ERMP concentrations of 0.11 ± 0.17 (*Gammarus pulex*, growth), 0.50 ± 0.37 (*Lumbriculus variegatus*, growth) and 1.90 ± 1.08 (*Lumbriculus variegatus*, reproduction) % sediment dry weight. A positive effect on survival was found for *Cerastoderma edule* and *Sphaerium corneum* with an EC_{10} of 0.021 ± 0.027 % and 7.67 ± 3.41 % sediment dry weight respectively. For the other species tested; *Hyalella azteca*, *Asellus aquaticus*, *Corbicula fluminalis*, *Potamopyrgus antipodarum*, *Tubifex spp.*, *Chironomus riparius*, *Alitta Virens*, *Limecola balthica*, *Corophium volutator*, *Arenicola marina*, *Porcellana platycheles*, and *Mytilus edulis*, no effects were detected up to the highest ERMP dose of 10% d.w. This work demonstrates that ecologically relevant effect thresholds can be measured for a contaminant as complex as microplastics, while meeting strict QA/QC criteria. Furthermore, we demonstrate that several lab-based single species effects thresholds of environmentally relevant microplastic particles occur at concentrations lower than those found in the environment.

3.25.B Towards Harmonized Nano- And Microplastics Quantification: Reference Materials, Analytics and Improved Experimental Designs

3.25.B.T-01 Improvements in Micro- and Nanoplastic Mass Detection by TED-GC/MS

Paul Eisentraut *and Korinna Altmann, Federal Institute for Materials Research and Testing (BAM), Germany*
Micro- and nanoplastics (MNP) remain a hot topic of public interest and an analytical challenge [1]. The thermo-analytical technique Thermo-Extraction-Desorption-Gaschromatography/Massspectrometry (TED-GC/MS) for measuring microplastic mass contents [2] and for estimating tire wear mass contents [3] in environmental samples was presented to the SETAC-community in 2018 [4].
This presentation describes method optimizations that have doubled the measurement speed, reduced limits of detection and allowed the implementation of additional QA measures. The applied optimizations made renewed validations necessary whose results are very promising.
Sample materials are heated in a thermogravimetric analyzer under N_2 atmosphere. The decomposition products are purged from the analyzer using a N_2 gas flow and transferred through a heated coupling device onto a solid phase consisting of polydimethylsiloxane. After the solid phase is loaded with the decomposition products, an auto-sampling robot transports the solid phase to a thermal desorption gas chromatograph mass spectrometer for further analysis. Polymer specific decomposition products allow to conclude on MNP-contents in the sample material. More details can be found in [2,3].
Materials were provided by BAM, BfG, Polymer Source and Sigma Aldrich.
Additional analytical runs performed for QA purposes decrease the overall measurement speed. The standard method protocol was hence improved, reducing the thermal range in which decomposition products are generated and sampled to 200-500 °C, reducing the length of the bakeout step and accelerating the GC-oven program. Finally, overlapping measurements were introduced allowing to perform the following thermal extraction while the GC-run of the former measurement is still in process.
For higher comparability between measurements, but also as a measure of quality assurance, inexpensive fivefold-deuterated polystyrene (PS) was used as an Internal standard. However, as some matrices can catalyze an H/D-exchange reaction very effectively [5], $^{13}C_6$-labelled PS was introduced as a replacement.
In comparison to the former standard method described in [2,3], most characteristics were retained (repeatability) or improved (LoD, linearity).
Besides MNP analysis, polymer aging, analysis of complex composite materials and of interactions between activated carbon and contaminants of pharmaceutical origin represent new research fields in which TED-GC/MS can contribute immensely.

3.25.B.T-02 Identification and Quantification of Microplastic in Environmental Samples by a Combined Method of Separation and Differential Scanning Calorimetry

Kathrin Harre[1], *Xhoen Gjashta*[2], *Maurice Hauffe*[3], *Lucas Kurzweg*[4], *Sven Schirrmeister*[5] *and Thomas Grischek*[2],

(1)Agriculture/Environment/Chemistry, University of Applied Sciences Dresden, Germany, (2)University of Applied Sciences Dresden, Germany, (3)Technical chemistry, University of Applied Sciences Dresden, Germany, (4)Chemical Engineering, University of Applied Sciences Dresden, Germany, (5)Fernwasserversorgung Elbaue-Ostharz, Germany
Microplastics in environmental compartments are a topic of serious concern. Time-consuming processes and analytical methods hamper not only the understanding of occurrence and fate of microplastics, but also the derivation of regulatory actions to monitor and minimise inputs in the environment. Therefore, the establishment of a fast, reliable, robust and cost-efficient method for environmental monitoring is required. Most of the common used methods do not fit all requirements. They are highly time-consuming, require high investments or may not give chemical confirmation of the polymer.
We present an approach for microplastic identification and quantification by a combination of separation and differential scanning calorimetry. Experimental data sets for the determination of LOQ for semi-crystalline and amorphous polymers as well as mixtures of polymers in an inert mineral matrix were generated. These data sets were evaluated by different regression methods. In addition to the regression according to DIN 32645, the two-factor regression was also included. The result shows that the two-parameter regression enables a clear identification and robust quantification. The LOQ of the overall process is thereby dependent on the choice of separation method. The method was applied to investigate sediment samples from the entire course of the Elbe River. These examples can be used to illustrate the influence of the separation method on the LOQ, but also the performance and limitations of the method.

3.25.B.T-03 The Integration of Further Analysis in a Standardized Biodegradability Test System Can Lead to Better Insights Into Microplastic Degradation
Eva-Maria Teggers[1,2,3]*, Boris Meisterjahn*[2]*, Markus Simon*[4]*, Dieter Hennecke*[5]*, Philipp Dalkmann*[6]*, Jonas Hardebusch*[2]*, Annika Jahnke*[3,7]*, Holger Egger*[8]*, Andreas Schäffer*[9]*, Werner Hoheisel*[10] *and Tim Feuerbach*[10]*, (1)Chempark Leverkusen, INVITE, Germany, (2)Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Germany, (3)RWTH Aachen University, Institute for Environmental Research, Germany, (4)Ecotoxicology, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Germany, (5)Ecological Chemistry, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Germany, (6)Environmental Safety, Bayer AG - Crop Science Division, Germany, (7)Department of Ecological Chemistry, Helmholtz Center for Environmental Research (UFZ), Germany, (8)Bayer AG, Research & Development, Crop Science, Insecticide Formulations, Germany, (9)Institute for Environmental Research, RWTH Aachen University, Germany, (10)INVITE, Germany*
Microplastics are solid plastic particles smaller than 5 mm. To improve product performance they are intentionally added e.g. in cosmetics, fertilizers, plant protection products, or paints. During application and use they enter the environment in various ways. Potential impacts on environmental and human health have raised concerns, therefore intentionally added microplastics are expected to be restricted by the European Union soon. Exempt from this restriction are biodegradable polymers. The proposed test methods to classify microplastics as biodegradable comprise several standardized test methods in a tiered approach. These proposed methods all target ultimate degradation (mineralization, i.e., organic C is converted to CO2 or O2 consumption) as defined biodegradation pass criterion. However, the overall degradation of the polymer is not only the result of the complete mineralization to CO2 but also other processes such as abiotic degradation (e.g., hydrolysis) or fragmentation (mechanical or biological) and moreover is dependent on several microplastic particle characteristics (shape, size and surface area).
The biodegradation of a polyurea capsule suspension was tested by performing a modified OECD 301B CO2-Evolution test. Since the polymeric component of the suspension comprised <1%, 14C-radiolabeling of the polymer was a pre-requisite to distinguishing the degradation to 14CO2 from other components of the suspension. Amongst others, the following modification was introduced: 50 ml aliquots of all replicates were passed through a sequential filtration at day 0, after 28 days and in the end (161 days) with filters consisting of four pore sizes. Thus, polymeric particles were separated by size and quantified by radioactivity measurements. With this approach we found out that the microcapsule suspension mostly consisted of particles larger than 12 µm (54% AR) or particles smaller than 0.2 µm (25% AR). Finally, the mineralization to 14CO2 could be attributed to the mineralization of components of all size fractions.
In addition, Liquid Chromatography-High Resolution Mass Spectrometry (LC-HRMS) analysis coupled with a radiodetector was performed to identify the majority of 14C-labeled molecules of the smallest size fraction, as 8% biodegradation was observed.

3.25.B.T-04 On the Potential of Analysing Biodegradability of Microplastics with Stable Isotope Raman Microspectroscopy
Kara Müller[1]*, Martin Elsner*[2] *and Natalia P. Ivleva*[2]*, (1)Technical University of Munich, Chair of Analytical Chemistry and Water Chemistry, Germany, (2)School of Natural Sciences (Dep. Chemistry), Technical University of Munich, Chair of Analytical Chemistry and Water Chemistry, Institute of Water Chemistry, Germany*
Biodegradable polymers are designed to reduce environmental plastic pollution, but it is of great importance to show their complete mineralization by microorganisms to avoid assimilation of inert micro- and nanoplastics in soils or waterbodies. Conventional methods either analyze the change of polymer properties during degradation (e.g., mass loss) or microbial activity in terms of O_2 consumption or CO_2 production. However, those methods lack a direct relation between plastic and microbes to see which species are responsible for the degradation and to determine the final fate of the polymers. Therefore, stable isotopes can be used to trace elements from the polymer into biodegradation products. With a Stable Isotope Raman Microspectroscopy (SIRM) approach, we want to monitor ^{13}C or D fluxes from labeled polymers into single microbial cells or vice versa, based on red-shifted Raman bands of heavier isotopes.
In a direct D-labeling approach, deuterated polylactic acid microplastic particles are incubated with *Sphingomonas koreensis*, which was isolated from an environmental sample and is able to produce carotenoids. Those pigments dominate the Raman spectra due to their resonance effect. Besides those carotenoid spectra, we can obtain full biomass spectra, which show Raman

bands of other cellular compounds after photo-bleaching. Depending on the cellular carotenoid concentration, we use two different strategies to determine the degree of deuteration: 1) CH vibrations are strongly red-shifted from 2990 to 2145 cm^{-1} (usually Raman silent region) in case of deuteration. Therefore, the peak area ratio CD/(CH+CD) can be used for quantification in the absence of dPLA signals and carotenoid overtones. 2) In the case of strong carotenoid signals (ν_1: C=C, ν_2:C-C stretching, ν_3: CH3 rocking), the overtone of their ν_3 Raman band overlaps with the CD signal and the peak ratio cannot be used. Instead, the difference between the band position of the ν_1 vibration (red-shifted signal for deuteration), and the ν_2 vibration (position independent from deuteration) is used to include an internal wavenumber correction.
We also work on a reverse labeling approach, where cells are initially labeled with cheaper ^{13}C-substrates (e.g., lactate-$^{13}C_3$) and then incubated with non-labeled polymers. Both approaches require statistically relevant reference data to define quantification models, which will be presented in this work together with the applicability of biodegradation experiments.

3.25.B.T-05 Differentiating Between Microplastics, Algae and Dissolved Organic Matter Using Single Particle ICP-TOFMS

***Lyndsey Hendriks**[1] and Denise M Mitrano[2], (1)TOFWERK AG, Switzerland, (2)Environmental Systems Science, ETH Zürich, Switzerland*

There is a diversity of analytical techniques to measure microplastics (MPs) in complex environmental matrices currently under development, and the selection of which approach to use often depends on the aim(s) of the research question and the experimental design. Researchers around the globe, as well as instrument manufacturers, are working to develop innovative approaches, tools, and technologies to help better characterize MPs and their impact on the environment and human health. Here we further broaden the suite of possible analytical techniques which can directly detect MPs in suspension while differentiating the carbon contained in MPs from other natural particles and dissolved organic matter (DOM). The work presented here makes use of a time-of-flight (TOF) based ICP-MS instrument operated in single-particle (sp) mode to record the signal spikes produced by individual MPs. Spherical polystyrene microspheres of 4 µm were used as model MPs for method validation. These MPs were detected by monitoring the ^{12}C-content in two different complex natural water systems, namely waters with environmentally relevant DOM concentrations (up to 20 mg/L) and in the presence of other carbon containing particles, such as algae cells. The strength of this development lies in the different types of analytical information that sp-ICP-TOFMS can provide from very simple measurements. Indeed, beside providing data on mass concentration (concentration of C per water volume) and particle number concentration (number of particles per water volume), this approach allows to unambiguously distinguish different C-containing species based on their multi-element fingerprint. Consequently, when MPs were suspended together with algae, distinct populations – MPs, single algae cells and heteroaggreates of MPs and algae - could be identified. Furthermore, elevated DOM concentrations did not impact the enumeration of particles in suspension. In summary, the method presented here allows for screening of MPs in aqueous suspensions in natural waters.

3.25.P Towards Harmonized Nano- And Microplastics Quantification: Reference Materials, Analytics and Improved Experimental Designs

3.25.P-We249 Quantifying Plastics in the Digestive Tract of Vertebrates: Development of a New Method Applied to Seabirds

***Florence Jeanne Nono Almeida**[1], Carole Leray[2], Magali Albignac[3], Marion Vittecoq[2], Alexandra ter Halle[3,4] and Karen D. McCoy[1], (1)CNRS / MIVEGEC, France, (2)Tour du Valat, (3)University of Toulouse, CNRS / IMRCP laboratory, France, (4)CNRS, France*

Plastics are now everywhere in our environment. As plastic production continues and waste accumulates, all species are exposed to this pollution to different degrees. Plastic ingestion may have a multitude of direct negative effects, from mortality due to obstruction to reductions in body condition due to nutritional deprivation. In addition, plastic ingestion can lead to adverse toxic effects because of additive chemicals or adhered contaminants that leach from the plastic and are absorbed by the organism. Thus, plastic ingestion can threaten population viability by reducing survival and/or breeding success and consequently, represents a major concern for conservation. Previous studies in vertebrates have mainly focused on macro and large microplastics (items larger than 1mm) and very little is known about the accumulation and impact of smaller microplastics in these animals, limiting our ability to evaluate the long-term impacts of this pollution. This gap is partially due to difficulties in measuring smaller microplastics in animals. To help fill this void, we have adapted a protocol, previously used on invertebrates, to measure macro and microplastics greater than 1.6µm in seabird tissues using pyrolysis gas chromatography - tandem mass spectrometry. Between 2019 and 2020, 38 yellow-legged gull (*Larus michahellis*) cadavers were opportunistically collected from several colonies in southern France. We evaluated two different methods for treating these samples and quantified both macro and microplastics separately in four different parts of the digestive tube. Our results show high inter-individual variation and differential accumulation of plastics – macro and micro – along the digestive tract. We hope that our method will become a standard that can be used for other vertebrates to better compare plastic ingestion among species and localities and to enable us to better evaluate the toxicity and population risks of accumulated plastics.

3.25.P-We250 Microplastics in Urban Freshwater: A Case Study in the city of Amsterdam

***Feride Öykü Sefiloglu**[1], Cleo Stratmann[2], Marthinus Brits[1], Lorenzo Scibetta[1], Martin van Velzen[1], Quinn Groenewoud[1], Dick Vethaak[3], Rachid Dris[4], Johnny Gasperi[5], Bruno Tassin[4] and Marja Lamoree[1], (1)A-Life, Vrije University Amsterdam, Netherlands, (2)Ecole Nationale des Ponts et Chaussées, France, (3)DELTARES, Netherlands, (4)LEESU, France, (5)Gustave Eiffel University, France*

The contamination of freshwaters with microplastics (MPs) has been globally established. From macro to nano-sizes, plastics enter aquatic ecosystems via direct sources such as discharges from wastewater treatment plants and drainage outlets and indirect sources such as atmospheric deposition, surface runoff, or human activities. In the environment, plastics undergo degradation and weathering processes depending on the physicochemical properties and environmental conditions [1]. Although the presence of MP in freshwater is an indubitable fact, the degree of MP pollution needs further investigation to understand the effects on the ecosystem scale and society. The aim of this study is to determine the MP abundances in the urban region of Amsterdam (The Netherlands) including a large network of canals and waterways, receiving treated wastewater from wastewater treatment plants, and an average annual rainfall of 844 mm. The sampling was done with a state-of-the-art in-situ volume-reduced sampling pump at 11 locations in the Amsterdam canal network in 2022. The qualification and quantification of the polymers for three size fractions (0.7-10 µm, 10-300 µm and 300µm-5mm) was accomplished in two laboratories at VUA (Amsterdam) and ENPC (Paris) with two complementary analysis methods using pyrolysis-gas chromatography-mass spectrometry (Py-GC-MS) and micro Fourier transform infrared (µ-FTIR) imaging.

3.25.P-We251 Microplastics as a Carrier of Selected Heavy Metals from Compost and Its Reduction in Concentration After Effective Separation

*George Kuttiparichel Varghese[1], **Dilraj S**[1] and Christain Zafiu[2], (1)National Institute of Technology Calicut, India, (2)University of Natural Resources and Life Sciences, Austria*

Microplastics(<5mm) are gaining importance as a carrier of heavy metals into the food webs and across different trophic levels. Compost is considered as one of the major sources of microplastics in soil environment. This study presents the results of analysis for selected heavy metals (Pb, Cu, and Zn) in three samples, i.e., plastic separated compost, hand-picked microplastics from compost and the microplastics separated from compost using chemicals. The compost for the study was collected from the compost plant of Kozhikode Corporation in Kerala, India. The chemical separation of microplastics adopted in this study includes density separation using zinc chloride(1.4–1.5g/cc) and oxidation using Fenton's reagent to remove the organic matter. The average number of microplastics in the compost sample was observed to be 840 items/kg. The three samples were digested using Aquaregia (3HCL:1HNO_3) and was filtered and diluted for the heavy metal analysis. The concentration of heavy metals in the three samples were analysed using the Flame Atomic Absorption Spectrometer. The results showed a reduction in concentration of heavy metals in the microplastics which are separated using chemicals compared to the hand-picked samples. This reduction in concentration points to the easy transfer of heavy metals to the soil when the compost is introduced in the soil for agriculture. This study shows that the assessment of heavy metals concentrations by the analyses on the microplastics which are chemically separated from compost leads to the underestimation of the ability of microplastics to carry heavy metals from compost to soil.

3.25.P-We252 The Release and Toxicity of Microfibers from Single-Use and Reusable Face Masks

***Yuyue Huang**, University of Southern Denmark, Denmark*

The COVID-19 pandemic has caused an unprecedented increase in face mask wearing as recommended by the World Health Organization (WHO) to prevent the spread of coronavirus. The increased production and use of single-use face masks during the pandemic has resulted in a significant increase in mask waste and a large number of used face masks has been found in the environment during and post-pandemic. Single-use face masks can fragment into micro- and nanoplastics which are of concern. Therefore, switching from single-use masks to reusable masks is one of the recommended solutions to reduce plastic waste. However, reusable face masks may also release plastic microfibers during recurrent use. This study aimed to 1) investigate the amount of microfibers released from both single-use and reusable plastic face masks under simulated environmental aqueous conditions, as well as under different washing procedures; 2) chemically characterize the released microfibers using micro-Raman Spectroscopy; 3) evaluate the toxicity of the released microfibers to zebrafish larvae. Up to over 500 microfibers can be released from one single-use face mask. The number of microfibers released from face masks varies largely from different brands and treatments. Hand washing and machine washing treatments release more microfibers than other treatments. Polypropylene fiber is dominant. Given the increasing use and disposal of face masks, the expected increasing release of polypropylene fibers and associated chemicals from face masks into the environment should not be overlooked.

3.25.P-We253 Spatiotemporal Distribution of Microplastics in Surface Water and Sediment of Jungnangcheon Tributary

***Dat THANH Pham** and Jung-Hwan Kwon, Korea University, Korea*

Microplastics (MPs) are of great public concerns for the ubiquitous and persistent occurrence in the aquatic environment. Less efforts have been made to monitor the MPs in fresh waters than those in seawaters, although rivers are now recognized to play a vital role in the transportation of MPs, particularly to marine environments. Variations in spatial scale (e.g., river reach, full watershed scale) and temporal scale (e.g., hourly sampling, repeated seasonal samplings) are factors influencing the MPs distribution and abundance. However, much is still unknown regarding their spatiotemporal distributions and links to potential sources. The accumulation or deposition of MPs in aquatic environment is also subjected to hydrodynamic processes. Therefore, the drivers of microplastic fluctuations, including seasonality, the role of resuspension of sediments, as well as the volume of precipitation and runoff, need to be thoroughly addressed. In this study, MPs spatiotemporal distribution in surface water and sediment of Jungnangcheon (South Korea) tributary were investigated using micro-Fourier-transform infrared spectroscopy (micro-FTIR) after appropriate isolation processes. Surface water and sediment samples from five sampling sites along 30 km of the river were collected monthly for a year. The results showed that there was no significant difference of MPs spatial distribution in both surface waters and sediments. Point sources such as sewage effluents may slightly contribute to the higher MPs abundances at some sites. Seasonally, average MPs abundance in water was highest and lowest in summer and winter. The MPs abundance in water in summer was significantly different from other seasons in two sampling sites, however, there was no significant difference in MPs in sediments between seasons. MPs abundance in water positively and strongly correlated with precipitation at most of the sites. MPs can be trapped in sediment during dry seasons and released to the surface water during wet seasons due to more extreme flows. MPs load was mainly transported by water column in the wet season. The results suggested that it is necessary to consider seasonal factors in analyzing the MPs distribution and transport in surface water.

3.25.P-We254 Effect of Biomolecules and Environmental Factors on the Aggregation of Colloidal Nanoplastic in Water
Demi Tristan Djajadi[1]*, Sascha Müller*[1,2]*, Lisbeth G. Thygesen*[1] *and Nicole R. Posth*[1]*, (1)Department of Geosciences and Natural Resource Management, University of Copenhagen, Denmark, (2)Department of Microbial Ecology, Lund University, Sweden*
Increasing micro- and nanoplastic (MNP) pollution in aquatic ecosystems can have severe consequences on the biota. Biomolecules are essential components of ecosystems, yet they seem to have been overlooked in studies to date. Studying the interaction of MNP with biomolecules is vital to gain better understanding of MNP transport in nature. Chitin is found in arthropods and fungi, and it is the second most abundant biomolecule on Earth, promoting its relevance for MNP-biomolecule interaction in the environment. Chitosan is derived from chitin, and its potential for water treatment and remediation has been studied earlier. However, the interaction of MNP with chitosan is still not well understood. This work explores the interaction of MNP with chitosan in the laboratory under environmentally relevant conditions reflecting fresh/groundwater, brackish water, and seawater. Polystyrene (PS) nanoparticles (NPs) with different surface modifications were used as model MNP and their interactions with chitosan in water at various concentrations, pH, salinity, and dissolved organic matter (DOM) content were studied during batch adsorption experiments. The aim was to identify conditions resulting in aggregation due to interaction between PS and chitosan. DLS-size and zeta potential of NPs were recorded during each experiment. Aggregation occurred only at particular chitosan concentrations, as low as 0.2% (w/w) dose of MNP. At high salinity aggregation occurred independently of chitosan concentrations. Higher chitosan concentrations were required to aggregate NPs at higher pH and DOM content, compared to lower pH and DOM content. The addition of carboxyl groups to the surface of PS to mimic UV photo-oxidation of plastic increased the stability of NPs even at high salinity. However, aggregation still occurred at particular chitosan concentrations. The zeta potential of PS NPs increased with chitosan concentration at low salinity, but aggregation occurred independently of the changes in zeta potential. At high salinity, the zeta potential approached 0 mV, which did not always cause aggregation. Thus, zeta potential alone might not be sufficient to study the interaction of MNP and biomolecules. Overall, this work showed that chitosan can impact MNP transport and has potential for remediation of polluted water.

3.25.P-We255 A Global Transect of The World's Oceans Monitoring Microplastics - A Citizen Science Collaboration
Alan Scarlett[1]*, Gina M Lintern*[2]*, Aaron D Copeland*[1] *and Kliti Grice*[1]*, (1)Curtin University, Bentley, Australia, (2)School of Molecular and Life Sciences, Curtin University, Bentley, Australia*
There have been numerous studies investigating possible effects of microplastics on biota, but what are environmentally realistic concentrations? Estimates of ocean microplastics concentrations are highly variable with offshore sampling stations typically recording much lower concentrations than coastal. Another issue that can complicate risk assessment is that of multiple collection protocols e.g., plankton net trawls versus direct filtration, which introduces high degrees of uncertainty when comparing one area of an ocean to another. An entire global transect of the World's Oceans using the same microplastic collection protocol provides a means of direct comparison and also gives insight into the degree of microplastic contamination in remote areas of the globe. However, such an undertaking would be immensely expensive for a scientific research voyage, but this is where Citizen Science can make a valuable contribution.
In this study, Western Australian Organic and Isotope and Geochemistry Centre (WA-OIGC) researchers at Curtin University collaborated with world-renowned, single-handed yachtsman Jon Sanders to quantify the numbers of microplastic particles present along a global transect starting/finishing in Fremantle, Western Australia, via Mauritius, South Africa, Virgin Islands and Panama Canal, using daily water filtration onto 43 µm aperture stainless steel filters. In particular, the study aimed to provide data for remote areas of the southern hemisphere for which very little data existed previously.
During the 46,100 km circumnavigation, approximately 115 L of seawater was pumped per day from an inlet in the hull, close to the bow of Yacht Perie Banou II. During stopovers in ports, the filters were couriered to the WA-OIGC laboratories for processing and analysed by Attenuated Total Reflectance Fourier-transform infrared spectroscopy (FTIR). The vast majority of the particles observed on the filters proved not to be plastic when analysed by FTIR. However, of the 177 filters collected and analysed, most contained microplastics. A mean count of 33 microplastics m^{-3} seawater was recorded across the entire global transect.
The study was the first global transect of microplastics in the oceans that utilized consistent sampling methods throughout. The data was comparable with other scientific surveys of remote areas of ocean and could act as a benchmark for future studies into microplastics in the oceans.

3.25.P-We256 Reactivity Evaluation between Microplastic Pretreatment Reagents and Ship Paint-Derived Microplastics
Taekhyun Kim[1,2]*, Soeun Eo*[1,2]*, Youna Cho*[2,3] *and Moonkoo Kim*[2,3]*, (1)Korea Institute of Ocean Science and Technology (KIOST), Korea, (2)University of Science and Technology, Korea, (3)Risk Assessment Research Center, Korea Institute of Ocean Science and Technology, Korea* As concerns about microplastic pollution in the marine environment are increasing, ship paint-derived microplastics are also gaining more attention. While microplastic pretreatment techniques for removing various organic matters contained in environmental samples are well established, the effects of existing pretreatment reagents on ship paint-derived microplastics, which are likely weaker and more brittle than common microplastics, have not been studied. Since ship paint-derived microplastics exist together with various hull-fouling organisms (e.g. bacteria, microorganisms, small invertebrates, algae,

fish eggs, etc.), it is more important to remove interfering organic matter through appropriate pretreatment technique before qualitative and quantitative evaluations.
Reactivity tests were conducted with three kinds of pretreatment reagents (10% KOH, 30% H_2O_2, Fenton's reagent) on nine types of ship paints (two types of primer as anticorrosive paint, two types of tie-coat as adhering agent between the primer and top-coat, and five types of top-coat as antifouling paint and deck paint). Each paint was pulverized into secondary microplastics using a mortar, under liquid nitrogen, and sieved through a 2 mm-sized mesh. After that, they were exposed to the pretreatment reagents for up to 7 days at 40°C and 60 rpm using a thermo shaker. After the exposure to pretreatment reagents, they were vacuum-filtered onto pre-weighed GF/F filter paper and washed with distilled water to stop further reaction. The microplastics on filter papers were dried at 40°C for 24 hours. The pretreated microplastics were compared to untreated control groups in weight and size variations on a microscope, and the changes in physicochemical characteristics were analyzed using Scanning Electron Microscope - Energy Dispersive X-ray Spectroscopy (SEM-EDS) and Fourier Transform Infrared Spectroscopy (FTIR).
For accurate qualitative and quantitative evaluation of ship paint-derived microplastics, the pretreatment reagent should not degrade the microplastic polymer. This study will contribute to more clearly identifying ship paint-derived microplastics by establishing an appropriate treatment method and thus to properly assessing the risk posed by ship-paint derived microplastic sources in the marine environment.

3.25.P-We257 Distinctions on Fragmentation and Degradation of Six Common Microplastics from Hydrolysis Condition Variations: Insight into pH, Salinity, and Enzyme Effects
Katherine Santizo[1]*, Patrizia Pfohl*[1]*, Wendel Wohlleben*[1]*, Joana Marie Sipe*[2]*, Mark Wiesner*[2]*, Richard Cross*[3]*, Gbotemi Adediran*[3]*, Sam Harrison*[3]*, Antonia Praetorius*[4]*, Brandon Lopez*[2] *and Claus Svendsen*[3]*, (1)BASF SE, Germany, (2)Duke University, USA, (3)UK Centre for Ecology & Hydrology (UKCEH), United Kingdom, (4)University of Amsterdam, Institute for Biodiversity and Ecosystem Dynamics, Netherlands*
It is known that mismanaged plastic waste often ends up in our water bodies (from rivers, lakes to ocean) and enter different stages of the water column from dispersion within the water body, sedimentation to the floors/beds, or floatation on the water surface. It has also been observed that plastic waste in the water bodies is fragmented and/or degraded. However, with the multitude of experimental conditions that can be explored there is a limitation of systematic approaches to comprehend the influence of water conditions on the fragmentation and degradation of polymers. Thus, this study focuses on evaluating the influence of temperature, pH, salinity, and enzymes on pristine microplastic powders and characterizing the powders at specified intervals. Six polymers are evaluated (PA-6, TPU, PLA, PET, LDPE, and PP) in various media (pH 4, pH 9, pH 7, artificial seawater, and enzymatic). The artificial seawater has an additional variation with experiments at 4°C and 22°C, both realistic, complemented by an accelerated aging at 65°C. The OECD Hydrolysis Guideline (OECD Test No. 111) was adapted with time intervals for observation at 5, 30, and 100 days for all but the enzymatic hydrolysis. To characterize the microplastics after hydrolysis multiple analytical methods were used including: an adapted NanoRelease protocol (ISO 22293:2020) to measure below 1 µm fragments, a particle counter providing fragment data from 1-190 µm, ATR-FTIR and GPC for chemical degradation, DSC for crystallinity, and DOC for the dissolved fraction. In addition, pH of the solution and mass of the powder was measured. Preliminary results show that PLA and PA-6 are the most susceptible to hydrolysis both exhibiting larger mass loss than the other polymers. In addition, PA-6 and TPU show larger amounts of particles in the 1-10 µm range after hydrolysis in the high temperature seawater. Furthermore, LDPE under seawater hydrolysis shows no decrease in hydrophobicity while under enzymatic hydrolysis it disperses within the water column showing an increase in hydrophilicity. Although, much of the plastic that enters water bodies is already weathered, this study provides a mechanistic approach to understand the behavior of microplastics under various hydrolysis conditions and will enable us to parametrize a model of fragmentation in different environmental compartments.

3.25.P-We258 Interaction Between Microplastics and Polycyclic Aromatic Hydrocarbons Under Sunlight Irradiation
Kazushi Noro[1] *and Yoshinori Yabuki*[2]*, (1)University of Shizuoka, Japan, (2)Research Institute of Environment, Agriculture, and Fisheries, Japan*
The fate of polycyclic aromatic hydrocarbons (PAHs) adsorbed on microplastics (MPs) remains unclear, although PAHs adsorb onto MPs and be transferred into organisms through accidental ingestion of MPs. The main degradation process for PAHs is photolysis, and the rate of photolysis of PAHs and the types of degradation products depend on the materials to which the PAHs are adsorbed. In addition, PAHs, which act as catalysts for photochemical reactions, may enhance the formation of secondary MPs due to degradation of plastic waste under the sunlight. In the present study targeting thirteen PAHs adsorbed with six polymer types of MPs (low-density polyethylene, high-density polyethylene (HDPE), polyethylene terephthalate (PET), polyacrylonitrile, polyvinyl chloride, and polystyrene), the half-lives of the PAHs photolysis ranged from 0.8 (anthracene on PET) to 212.8 (benzo[k]fluoranthene on HDPE) h and were longer than those in the aqueous phase (0.5 (anthracene) – 63.8 (chrysene)) h. Furthermore, we observed that coloration and surface degradation of polyethylene plates adsorbing PAHs under light irradiation, indicating that polyethylene plates adsorbed with PAHs became less tolerant to light. We demonstrate that the interaction between plastics and PAHs results in PAH longevity and accelerated MPs production, exacerbating marine environmental pollution by MPs and PAHs.

3.25.P-We259 Ecotoxicity of the Mixture of Microplastics, Nanoplastics, and Additives Produced from the Degradation of Fishing Nets
Edgar Dusacre[1,2]*, Christelle Clérendeau*[1]*, Sophie Lecomte*[3]*, Bénédicte Morin*[1]*, Fabienne Lagarde*[4]*, Miren Cajaraville*[5] *and Jérôme Cachot*[1]*, (1)EPOC, University of Bordeaux-CNRS, France, (2)Sciences and technologies, University of Bordeaux,*

France, (3)University of Bordeaux, France, (4)IMMM, Le Mans Université-CNRS, France, (5)CBET+, PIE, University of the Basque Country UPV/EHU, Spain
After more than 30 years of research on plastic pollution, data on sources and ecotoxicity are still fragmentary. Several studies have suggested that fishing gear is a major source of secondary micro-nanoplastics (MNPs) and additives. In this context, we focused our research on the ecotoxicity of leachates from the degradation of plastic fishing nets (FNs) during their life cycle, especially those used in the southeastern Bay of Biscay. For this, three gillnets made of polyamide (PA), one in-development gillnet made of bio-sourced and biodegradable polybutylene succinate (PBS), and one polyethylene (PE) trawl net were selected, both new and used ones. First, an artificial aging (AA) protocol based on UV irradiation and agitation was set up to characterize the degradation kinetics of FNs and quantify the released MNPs and additives. The ecotoxicity of leachates was investigated using the Microtox® (marine bacteria Aliivibrio fischeri), and fish larval behavior (freshwater medaka Oryzias latipes) bioassays. AA caused structural and morphological modifications of the polymers, revealed by FTIR-ATR, RAMAN, and SEM, and induced the release of MNPs into the water, quantified by Morphologically-Directed Raman Spectroscopy (MDRS). Contrary to what was expected, the produced particles were not only fibers but were mainly micro fragments below 100 µm. The degradation kinetics differed among FNs depending on the polymers. Results of the Microtox® and fish larval behavior bioassays revealed significant toxicity of some FNs' DMSO extracts. Toxicity depended on the polymeric matrix, the additives' composition, and the FNs' wear. These results raise concern about the toxicity of new ready-for-use bio-based FNs and highlights the possible major role of additives in the toxicity of plastic FNs. Experiments are underway to understand better these FNs' overall contribution to marine plastic pollution.

3.25.P-We260 Micro and Nanoplastics Detection in Small Living Organisms

Marisa Sarria Pereira de Passos[1]*, Andrea Barbaglia*[2] *and Andrea Valsesia*[3]*, (1)EU Commission JRC, Italy, (2)European Commission Joint Research Centre (JRC), (3)European Commission Joint Research Centre (JRC), Italy*
Nowadays, micro- and nanoplastic particles are found in a variety of environmental compartments. These can be taken by small organisms at the base of the food chain. Taking advantage of this behaviour, recent studies proposed these as bio-indicators of environmental plastic pollution. However, the application of conventional analytical methods on biological samples show many limitations. As an example, physical-chemical techniques based on pyrolysis have high detection limits, which could hide the amount of plastic collected by such accumulators. On the other hand, optical methods with chemical sensitivity, such as IR or Raman spectroscopy, allow detecting only larger particles or agglomeration of smaller ones. Moreover, a typical analysis usually requires a considerable amount of time. In this project, we are developing a new technique for detecting micro- and nanoplastics in small living organisms based on Hyper-Spectral Enhanced Dark Field microscopy. The setup microscope features a Cytoviva condenser enabling nanoparticle detection, and a wavelength selective optical filter for the hyper-spectral analysis of the scattered light, pixel by pixel. The acquired scattering spectra are then processed by a novel algorithm, based on the Mie model for scattering, which aims at identifying plastic particles from the sample background. This new method, tested onto phyto- and zooplankton species exposed to micro- and nanoplastics, features rapid sample analysis and sensitivity down to the single particle. Significantly, it results particularly effective in detecting particles with size between 100 nanometres and few microns, enabling additionally live particle tracking inside the microorganisms. Finally, it results cost-effective and convenient to be deployed in laboratories involved in plastic pollution research.

3.25.P-We261 Multi-Parameter Analysis of Nanoplastics: Taking Advantage of High Time Resolution Enabled by Stimulated Raman Scattering

Maximilian Huber[1]*, Liron Zada*[2]*, Freek Ariese*[2]*, Martin Elsner*[1] *and Natalia P. Ivleva*[1]*, (1)School of Natural Sciences (Dep. Chemistry), Technical University of Munich, Chair of Analytical Chemistry and Water Chemistry, Institute of Water Chemistry, Germany, (2)Department of Physics and Astronomy, Vrije Universiteit Amsterdam, Institute for Lasers, Life and Biophotonics/LaserLaB, Netherlands*
The characterization of nanoplastics, especially with regards to their toxicity, is still quite challenging since most analytical techniques can only deliver limited information on this complex analyte. Many different properties, like size, shape, concentration, and chemical composition, have to be considered for a proper characterization and potential risk assessment. To achieve this, it is necessary to use many different (hyphenated) techniques. A technique that can deliver multiple parameters - mainly size and chemical information - from one measurement is online-coupled field flow fractionation (FFF) – Raman microspectroscopy. However, this hyphenated technique still has some limitations, e.g., low sensitivity and dependency on optical trapping, and cannot deliver particle concentrations. For this reason, a coherent Raman technique, called stimulated Raman scattering (SRS), was tested for its potential hyphenation with FFF. This technique employs two different laser wavelengths. Their difference in frequency must match a vibrational transition of the analyte molecule to result in an enhanced signal. Thus, compared to spontaneous Raman, measurement times can be significantly reduced from 10 s to 60.5 µs. The detection of nanoplastics in suspension was achieved directly within the applied flow using a flow cell with either a reflective or a transparent base. Nanoplastics (PS, PE, PMMA) in a size range from <100 nm to 5 µm of spherical and irregular shape could be detected with this setup. In particular, due to the increased time resolution, individual signals per particle could be observed with this technique rather than a average sum signal for spontaneous Raman. Therefore, this method can be used to count particles and also (semi)quantify nanoplastics while also giving information on the material. For the (semi-)quantification a test calibration ranging from 42 mg/L to 500 mg/L was performed on different samples. A closer look at the peak shape of the individual signals reveals that not all detected particles were trapped in the focus of the laser. In case of untrapped particles the mean peak intensity and width can be used for size estimation. Overall, with this method (especially in hyphenation with FFF) a broad characterization of

nanoplastics is possible since information on size, concentration and chemical composition can be obtained within one measurement.

3.25.P-We262 Raman and Surface Enhanced Raman Spectroscopy to Detect Submicron- and Nanoplastics
Jessica Caldwell[1]*, Patricia Taladriz-Blanco*[2]*, Barbara Rothen-Rutishauser*[3] *and Alke Petri-Fink*[3]*, (1)BioNanomaterials, University of Fribourg, Adolphe Merkle Institute, Switzerland, (2)Water Quality, International Iberian Nanotechnology Laboratory, Portugal, (3)University of Fribourg, Switzerland*
The detection of submicron- (100 nm – 1 µm) and nanoplastics (< 100 nm) is of increasing interest within various scientific communities. While the particles are anticipated to be present within many different samples of interest (*e.g.* environmental systems such as rivers and oceans, or in beverages such as bottled water), their low estimated concentrations, small size, and organic composition make optimizing analytical techniques to study them in these sample matrices a challenging task. To that end, the work presented in this study focuses on the optimization of Raman Spectroscopy for the detection of submicron- and nanoplastic particles composed of polystyrene and poly(ethylene terephthalate). Traditional Raman Spectroscopy measurements were conducted to determine the limit of detection for the standard technique, and then Surface Enhanced Raman Scattering (SERS) substrates composed of gold nanoparticles were employed to improve upon the detection limits determined for Raman Spectroscopy alone. As a further proof of concept, these particles were spiked into true environmental fresh and saltwater collected from seas and rivers. Preliminary results indicate differences in analytical performance when nanoplastics are spiked into freshwater compared to nanoplastics that are spiked into saltwater. Furthermore, the size of the plastic particles as well as the type of plastic they are made of is shown to impact the limits of detection observed.

3.25.P-We263 Rapid Detection and Quantification of Micro-plastic Particles using MuScan® Technology
Michel Klerks*, Innosieve Diagnostics BV, Netherlands*
Current simple methods for micro-plastic detection often rely on manually viewing and counting micro-plastics in a sample under a microscope. More advanced techniques use Fourier-transform infrared spectroscopy (FT-IR), Raman spectrometry, and chromatography /mass spectrometry (GC/MS, ICP-MS). However, with these methods a reliable, objective quantification and determination of the size of micro-plastics in a larger sample volume is not possible or very cumbersome. As these advanced methods require large financial investments, need a high degree of expertise and are not easy to perform on-site, there is an urgent need for a more rapid, simple, and cost-effective methods.
We present the development of a fast on-site Solid Phase Cytometry-based method (the MuScan® method) that automatically analyses the number of micro-plastic particles (MNP) in a sample within one hour. The Muscan® method reliably detects, quantifies, and identifies micro-plastics, even down to 1 µm in size.
First a sample is filtered over an inert, optically flat silicon nitride microsieve membrane, herewith retaining all MNPs. Next the MNPs are stained using a fluorescent dye and subsequently the membrane is scanned using an automated LED-based optical scanning device, the MuScan. The total scanning time is only 3 minutes, during which an integrated data processing algorithm runs in the background. The raw data of each pixel area is analysed based on pre-set parameters. Based on fluorescent emission variations between different types of MNPs, a set of different MNPs can be identified. A summary report with counts and size distribution is achieved.
Using this methodology we evaluated different matrices like drinking water and packaged meat for occurrence of MNPs. The preliminary results from these studies will be presented.

3.25.P-We264 Rapid, automated analysis of microplastics direct on filters using laser direct infrared imaging and spectroscopy.
Darren Robey[1]*,* ***Wesam Alwan***[1] *and David Troiani*[2]*, (1)Agilent Technologies, Australia, (2)Agilent Technologies*
The presence of microplastics in the environment is gaining significant public interest. To study this, rapid, reliable, and harmonized characterization is essential. Technical hurdles in microplastics analysis stem from the number of particles to be analyzed in each sample which may range from few to many thousands. While visual microscopy has been used extensively, it may be prone to operator error and bias and is limited to larger particles. Vibrational spectroscopic techniques such as Raman and FTIR microscopy provide an alternative, however analysis time can be significant and more rapid and highly automated techniques are desirable.
The quantum cascade laser (QCL), is an alternative infra-red (IR) source that may assist to address this. In contrast to the FTIR approach, a QCL emits IR energy at specific and discrete wavelengths in a collimated beam with all the energy available and can quickly sweep the wavelength range for sub-second acquisition of spectra. Emitting at individual wavelengths, the QCL source can be combined with a single-point detector and rapid scanning optics allowing very fast discrete frequency scanning of large areas. Combined in this way, very fast, highly-automated workflows can be achieved.
Multifaceted sample preparation is a requirement of all spectroscopic techniques and filtration commonly forms the final step. Conducting microplastics analysis directly on this filter has become a common practice, however this has not previously been possible in the QCL system described as it relies on the use of an IR reflective substrate to perform a "transflection" (double pass transmission) measurement.
The aim of this study was to demonstrate that a suitable filter could function as an IR reflective substrate to achieve both adequate detection of particles on the surface and to obtain spectra suitable for spectral library matching. Achieving this goal eliminates additional sample preparation post filtration which itself reduces the potential for error from poor recovery or sample contamination. At the same time, the increased speed of analysis allows a greater number of samples being processed in a study.

3.25.P-We265 Micro- and Nanoplastic Particle Number and Mass-based Analysis on a Plastic-free Size-selective Two Stage Si Membrane Filtration Cascade

Paul-Tiberiu Miclea[1], *Korinna Altmann*[2], *Yosri Wiesner*[2] *and Christian Hagendorf*[3], *(1)Fraunhofer IMWS - Institute for Microstructure of Materials and Systems, Germany, (2)Federal Institute for Materials Research and Testing (BAM), Germany, (3)Fraunhofer CSP - Center for Silicon Photovoltaics, Germany*

A quantitative metrology and testing of microplastics requires representative methods for sampling, sample preparation and detection for all size ranges of micro- and nanoplastics (MNP). For this purpose, plastic-free filter materials have to be configured to allow a size selective analysis of MNP particles with different polymer types and integrate those into the analytical workflows. Analytical routines for particle sizes in the range of 10 - 1000 µm are nowadays quite well established. Current scientific efforts are focused on entering nano particle dimensions with diameters down to 10 nm. A major challenge lies in the availability of cascade filter setups spanning several orders of magnitude in a single filtration workflow with appropriate MNP analytic routines for both, particle and mass-oriented investigations.

In this work, we are implementing a well-defined microplastics test material for the development of a two-stage cascade filtration setup and subsequent application in MNP analytic workflow. The MNP test material is composed of a mixture of a polydisperse PET microplastic material mimicking environmentally particles and monodisperse PS spheres. The novel cascade filter system contains two filters made of microporous Si, thus realizing the required MNP size selectivity. In our experiments, we demonstrate the MNP size separation on Si filter substrates. Using the filters subsequently as analytical substrates, leads to an enhanced flexibility in the application of µ-Raman, scanning electron microscopy (SEM), atomic force microscopy (AFM) and even thermal extraction/desorption-gas chromatography/mass spectrometry (TED-GC/MS) instrumentations. We are able to analyse MNP properties, e.g. particle shape, size, spectroscopic fingerprints and mass - optical and chemical, both qualitatively and quantitatively afterwards on the same sample and filter in direct correlation.

Finally, requirements and limitations for a standardized plastics-free MNP filtration and analytic workflow will be discussed.

3.25.P-We266 Real-life Airborne Micro- and Nano-plastic Particles and Fibres on a Porous Membrane Filter System from a Textile Factory Suitable For Both: Vibrational and Mass Spectrometry

Paul-Tiberiu Miclea[1], *Korinna Altmann*[2], *Yosri Wiesner*[2] *and Emilia Visileanu*[3], *(1)Fraunhofer IMWS - Institute for Microstructure of Materials and Systems, Germany, (2)Federal Institute for Materials Research and Testing (BAM), Germany, (3)National Research and Development Institute for Textiles and Leather, Romania*

Quantitative metrology and testing of microplastic particles and fibres require a good representative method for sampling, sample preparation, and detection for all nano- and microplastics (NMP) size ranges. For this purpose, filter materials must be configured to allow a size-selective analysis of NMP particles and polymer types under ideally plastic-free conditions to be included in analytical workflows.

Analytical routes for microplastic particle sizes in the range of 10 to 1000 µm [1] are nowadays quite well established. Current scientific efforts are focused on entering nanoparticle dimensions under plastic-free conditions with diameters down to 10 nm. A major challenge lies in a suitable substrate for a combination of vibrational and mass spectrometry detection methods and the application of both methods on the same system.

In this work, we are implementing a real-life airborne NMP test material for the filtration workflow and subsequent NMP analytics. The NMP test material is collected in different textile factories. Using the filters subsequently as analytical substrates lead to enhanced flexibility in the application of µ-Raman, scanning electron microscopy (SEM), and atomic force microscopy (AFM) instrumentation. We are able to analyse NMP properties, e.g. particle shape, size, and spectroscopic fingerprints - optical and chemical, both qualitatively and quantitatively. Thermo extraction/desorption-gas chromatography/mass spectrometry (TED-GC/MS) can also be applied to the same filters and is used to identify the polymer types and quantify the mass of the material collected. Finally, requirements and limitations for a standardized filtration and vibrational and mass spectrometry workflow will be discussed.

3.25.P-We267 Advancing a Semi-Automated Polarized Light-Nile Red Method for Identifying Microplastics in Environmental Samples: From Proof-of-Concept to Protocol

Christine M Knauss[1], *Elizabeth North*[1] *and Christine Thompson*[2], *(1)University of Maryland Center for Environmental Science, USA (2)Stockton University*

Microplastic pollution can have harmful effects on the environment and human health depending on the type of plastic, particle size and shape, and exposure concentrations. However, the diversity of microplastics and associated particles in the environment makes the detection, identification, and quantification challenging and current methods to accurately detect and identify microplastics are time consuming and expensive. Because of these challenges, large data gaps exist for the fate, transport, and risks of microplastics. An accurate, fast, and low-cost method is needed to characterize microplastics in environmental samples to comprehensively understand microplastic abundance, fate and transport, and possible risks. One innovative method, combining polarized light microscopy with a semi-automated image capture system and fluorescent light microscopy, is inexpensive and can accurately detect a variety of microplastics with more reliability than either method individually. The objectives of this study are to set up a system with polarized and fluorescent light and a semi-automated image capture system on the same microscope, then develop a protocol to analyze environmental samples with this system. Known microplastics and unknown microparticles will be used to develop the detailed protocol for sample preparation, image capture, and image analysis, culminating in particle identification. Raman spectroscopy will be used to validate classification of samples processed using the new protocol. An overview of the protocol and preliminary data will be presented and discussed. If successful, this inexpensive, and high throughput method for bulk sample analysis will decrease the resources needed to analyze environmental samples and thus promote better understanding of microplastic presence, fate, and transport in different environments.

3.25.P-We268 The How to Guide: An Easy and Accessible Way to Calibrate Fluorescence Microscopes and Modify Raman Spectroscopes for Use with Nile Red Stained Microplastics

Anna Tuulikki Kukkola, *Liam Kelleher, Iseult Lynch, Greg Sambrook-Smith and Stefan Krause, University of Birmingham, United Kingdom*

In the field of microplastic (MP) research, there have been calls for reproducible and universally accessible and inexpensive methods, with low false positive and negative counts. The use of the Nile Red staining method has been put forward as a candidate, due to its low-cost and accessibility. However, not everything that fluoresces when stained with Nile Red should be counted as MP and setting up fluorescence of detection limits is imperative. We trialed several different microscope settings with known plastic types (n=13), as well as some common natural materials (e.g., sand, leaves etc.; n=5) for establishment of the fluorescence detection limits. Magnification and light intensities had different effects on distinct plastics and no clear trend was evident. By the usage of descriptive statistics, we identified the lowest pixel brightness cut-off limit whereby over 97% of plastics were detected and only 22% of rare false positives. Following the steps presented herein, fluorescence systems can be calibrated to increase comparability and transparency in microplastic research.

We also present guidelines for a cost-effective and simple modification to existing Raman spectroscopy systems to enable use in combination with the Nile Red staining in fluorescence mode to overcome the issue of potential false negatives as well. The false negatives are non-fluorescent particles unintentionally moved with suspected fluorescent MP onto a new filter when a sub-sample of suspected MPs are intended to be analysed with Raman spectroscopy or similar, when best-practise guidelines are followed. These particles are impossible to tell apart from the targeted fluorescent particles under bright-field but via Raman can identified as false-negatives.

The modifications took around 3 hours to complete on an existing Renishaw rm2000 system and the parts required cost £1,729 at time of purchase (2022, from Thorlabs). After installation, the plastic standards were visualized in the fluorescence mode, and a strong fluorescence signal from the plastics was detected, suggesting that with these relatively cheap modifications, it is possible to guide identification of MPs that can then be measured with Raman spectroscopy for polymer identification.

These modifications to the standard Nile Red staining protocol (establishment of pixel brightness limits and Raman for identification) will facilitate increased reproducibility, transparency, and simplicity of MP research.

3.25.P-We269 Automated Representative Quantitative Analysis of Microplastics down to 1 µm by Raman Microspectroscopy

Natalia P. Ivleva[1], *Christian Schwaferts*[2], *Oliver Jacob*[1] *and Alejandro Ramírez-Piñeiro*[1], *(1)School of Natural Sciences (Dep. Chemistry), Technical University of Munich, Chair of Analytical Chemistry and Water Chemistry, Institute of Water Chemistry, Germany, (2)Technical University of Munich, Chair of Analytical Chemistry and Water Chemistry, Institute of Water Chemistry, Germany*

Microplastics (MPs, synthetic polymer fragments in the size range 1 µm – 1 mm) are found in the environment all around the globe as well as in drinking water and food. Since more hazardous effects are expected from smaller MPs, reliable quantitative analysis is required. Here, Raman microspectroscopy (RM) is suitable for the chemical identification and quantification of MPs down to 1 µm (doi.org/10.1021/acs.chemrev.1c00178).

To ensure that the results are reliable and representative, a (very) high number of particles/fibers has to be analyzed, especially for small MPs. Therefore, automation of RM analysis becomes essential. Our open-source program *TUM-ParticleTyper* (doi.org/10.1371/journal.pone.0234766) enables the automated detection, quantification, and morphological characterization of (plastic) fragments in images of optical microscopy, followed by the automated RM-based identification of MPs and non-plastic fragments. This approach has been already successfully applied for the analysis of up to 7000 particles/fibers down to 10 µm, randomly selected on the entire filter (doi.org/10.1016/j.watres.2022.118549).

Since the number of particles (exponentially) increases with decreasing the particle size, it become nearly impossible to detect all particles down to 1 µm on the entire filter. Therefore, we proposed alternative strategy – random window subsampling, where the automated acquisition of optical image and localization of (MP) fragments are followed by RM measurements from window to window. We also introduced a bootstrap method, to provide an error quantification with confidence intervals from the available window data. Ultimately, we developed and implemented in *TUM-ParticleTyper 2* new measurement algorithm that computes confidence intervals *on-the-fly* during the analysis using bootstrap and, by checking whether given precision requirements are already met, automatically stops if an appropriate number of fragments is identified, thus improving time efficiency (doi.org/10.1007/s00216-021-03326-3). Furthermore, we implemented advanced image processing for better recognition and morphological characterization of small (MP) particles and fibers. In this presentation we will discuss our open-source program *TUM-ParticleTyper 2*, which enables automated representative analysis of MPs in the entire size range, with the focus on the program validation and applicability for the analysis of reference MPs (doi:10.3389/fchem.2020.00169) and environmental samples.

3.25.P-We270 Electrostatic Separation for a Comprehensive Microplastic Monitoring in River Sediments

Lucas Kurzweg[1], *Antonio Lancho*[2], *Maurice Hauffe*[3], *Jann Schneider*[4], *Marc-Peter Schmidt*[5] *and Kathrin Harre*[6], *(1)Chemical Engineering, University of Applied Sciences Dresden, Germany, (2)University of Applied Sciences, (3)technical chemistry, University of Applied Sciences Dresden, Germany, (4)University of Applied Sciences Dresden, Germany, (5)University of Applied Sciences Dresden, Germany, (6)Agriculture/Environment/Chemistry, University of Applied Sciences Dresden, Germany*

There are still no standardized processes, to address a comprehensive microplastic (MP) monitoring in real environmental scenarios. Such methods must process a high number of samples and large sample volumes time- and cost-efficiently. Especially for sediment samples, current methods lack representative sample volumes and masses. We want to introduce electrostatic separation (ES) as a method to overcome this problem. We applied ES to different particulate matrices such as quartz sand and various river sediments. Thus, we were able to derive a feasible working range of this method. Moreover, a comparison of recovery rates for different sample sizes, MP types and, contents was carried out. Nine different particulate matrices were used to investigate the particle size dependency of ES. Quartz sand samples (Cemex AG, Dresden, Germany) with a mass of 100 g and 1000 g were spiked with 75 mg of MP low-density polyethylene (LD-PE), polyethylene therephthalate (PET) and polycaprolactone (PCL; total MP mass per sample: 225 mg) in a size range of 63-200 µm. Additionally, 1000 g of quartz sand were spiked with different contents of LD-PE. MP quantification was carried out by differential scanning calorimetrie (DSC). Our results show a great potential of ES to enrich samples of quartz sand with an average particle size above 200 µm. Even small contents of finer particles seem not to have an influence on the separation result. MP was successfully separated form quartz sand by ES. The recoveries are in a moderate range for all MP types (50 to 100 %). In the range of 10 to 80 mg LD-PE per kilogram sand no significant differences of the recovery were found. The average recovery was 90 ± 8%. The theoretical limit of quantification was determined as 2.3 mg MP in 1 kg sediment. We conclude that ES can facilitate a fast and reliable extraction of MP from particulate matrices. The application of ES and DSC for MP analysis in river sediments shows a very high potential to address comprehensive monitoring time- and cost-efficiently. However, further research is required to address smaller particle sizes and more polymer types.

3.25.P-We271 Optimising µFTIR Analysis Measurments Time and Quality with Artificial Intelligence
***Thibault Schowing**, IICT, HEIG-VD, Switzerland*
Today, microplastics are ubiquitous and can be found from the highest mountains to human embryo. These plastic microparticles are present but their quantity, sizes and composition remain poorly charted. FTIR (Fourier Transform InfraRed) microspectroscopy is among the non-destructive procedures allowing to characterize both aspect and composition of these particles using the advantages of microscopy imaging and spectrum identification. The characterization of microplastics with µFTIR microscopy involves, as a first stage, detecting and selecting particles from microscopic images for which an infrared absorption spectrum will be further measured and computed. This step is currently performed with the assistance of a proprietary, instrument built-in tool that shows low flexibility and biased performance on a quantitative and qualitative point of view.
Using Artificial Intelligence (AI), more exactly machine learning, to accelerate this step has entailed two main challenges. First, the proposed AI solution must have the ability to interact tightly with the instrument to process incoming images and to highlight in it a set of candidate particles. To adress this challenge, we adopted GEPARD, a publicly-available software developed for a subset of Raman and µFTIR instruments.
The second challenge is the amount of high-quality annotated data that is required to satisfactorily train AI-based detection models. We have addressed this by means of a semi-supervised learning approach. Starting with a few available unannotated images and using data-augmentation technics to feed an available industry level freeware for the annotation of microscopic images, we were able to create a synthetic ground truth of thousands of annotated images, with each particle clearly labelled on each image. On the base of such annotated data, we were then able to train an AI-based predictive model, compatible with GEPARD, allowing us to rapidly detect particles on the instrument images, potentially saving precious time with respect to the current process.

3.25.P-We272 Harmonizing and Expanding Py-GC/MS for the Analysis of Environmental Plastics
***Meredith Evans Seeley** and Jennifer Lynch, National Institute of Standards and Technology (NIST), USA*
The chemical analysis of micro and nanoplastics in complex matrices is a priority for human and environmental health research. Spectroscopic techniques (e.g., Fourier transform infrared or Raman spectroscopy) are commonly employed to identify a particle’s polymer type, but require size and density approximations to estimate mass-based concentration. Mass-based estimates of, for example, body burden are increasingly requested for environmental risk assessment. Further, spectroscopic techniques require extensive sample preparation to isolate individual particles and are not applicable to particles below 1 um, limiting sample throughput and analysis of nanoplastics.   rolysis – gas chromatography/mass spectrometry (Py-GC/MS) is uniquely suitable for the mass-based analysis of plastics as it employs high-temperature thermal degradation of large polymers to generate GC/MS amenable marker compounds (often, a monomer or the polymer). Researchers have used such marker pyrolysates to identify polymer type, as well as quantify polymer concentration using external standards. Uniquely, Py-GC/MS may also detect additive content at low (i.e., thermal desorption) temperatures, but little work has demonstrated the ability to quantify additives in plastics and the polymer simultaneously. We reviewed the application of Py-GC/MS for analysis of micro and nanoplastics in environmental samples, ultimately synthesizing recommendations for future harmonization and possible avenues for method expansion. This begins with sample and calibrant preparation, including which type(s) of preparation are required for different matrices and how they affect quantitation, including a synopsis of limits of detection reachable using these different approaches. The unique requirements for emerging nanoplastics work are highlighted. Toward improving quantification, recommendations for isotopically-labeled standards are included. The merits and pitfalls of different Py-GC/MS thermal programs (e.g., flash or double-shot) are highlighted, including their capacity to qualify polymer additive content. Further, aspects of Py-GC/MS that have not been previously employed for the analysis of environmental plastics will be proposed (e.g., semi-quantification of oxidation in weathered plastics). In total, this poster will open the floor to discuss the timely harmonization and improvement of Py-GC/MS approaches in the environmental plastics field.

3.25.P-We273 Establishing Spectral Library of Ship Paint-Derived Microplastics by Fourier Transform Infrared Spectroscopy (FTIR) and Scanning Electron Microscope - Energy Dispersive X-ray Spectroscopy (SEM-EDS)
Taekhyun Kim[1,2]*, Soeun Eo*[1,2]*, Dongju Shin*[3,4] *and Moonkoo Kim*[2,3]*, (1)Korea Institute of Ocean Science and Technology (KIOST), Korea, (2)University of Science and Technology, Korea, (3)Risk Assessment Research Center, Korea Institute of Ocean Science and Technology, Korea, (4)Department of Marine Environmental Science, Korea University of Science and Technology, Korea*
Although the International Union for Conservation of Nature (IUCN) and the International Maritime Organization (IMO) identified marine coatings as potential sources of microplastics, there are not enough studies reporting the status of microplastic pollution derived from ship paints. Qualitative and quantitative evaluations are possible only after the chemical and material property data of ship paint-derived microplastics are well accumulated, such as polymer types and elemental compositions.
To establish a spectral library of ship paint-derived microplastics, a total of nine types of representative ship paints (two types of primer as anticorrosive paint, two types of tie-coat as adhering agent between the primer and top-coat, and five types of top-coat as antifouling paint and deck paint) were selected according to their functions and working mechanisms. Each dried paint was pulverized into secondary microplastics using a mortar under liquid nitrogen and sieved through a 2 mm-sized mesh to simulate environmental samples. The FTIR spectrum of the secondary microplastics was measured and the spectral information on the absorption peaks, their appearance, corresponding functional groups with mode of vibrations, as well as the fingerprint of specific constituents, was reported in this presentation. When blind samples were analyzed after library construction, they showed an average matching rate of 96.0% or more with the established library spectrum. In addition, the external characteristics and constituent element information of secondary microplastics were analyzed by using SEM and EDS. As a result of observing the external image through SEM, it was found that copper chunks were embedded in some antifouling top-coats. In addition to C and O, which are the most dominant elements in all types of ship paint-derived microplastics, Mg and Si were clearly detected in primers; Si, Ti, and Ba in tie-coat; Cu, Zn, Fe, and Ca in antifouling top-coat; Mg, Si, Ca, Fe, and Ba in epoxy based top-coat; and Ca and Ti in urethane based top-coat. Their relative compositions were unique among different types of paint-derived microplastics.
Establishing a library on the polymer type by FTIR, external features by SEM, and elemental compositions by EDS will contribute to clearly identifying ship paint-derived microplastics in environmental samples, and thus to better quantitative analysis required for risk assessment.

3.25.P-We274 How Precisely can we Analyse Very Small Microplastic Particles?
Oliver Jacob*, Alejandro Ramírez-Piñeiro, Martin Elsner and Natalia P. Ivleva, School of Natural Sciences (Dep. Chemistry), Technical University of Munich, Chair of Analytical Chemistry and Water Chemistry, Institute of Water Chemistry, Germany*
When considering their presence in environmental samples, the number of microplastic particles (MP, polymer fragments from 1 µm to 1 mm diameter) [10.1021/acs.est.8b05297] is expected to increase exponentially towards smaller sizes. The precision of an analytical method that aims for fast results in this size range is therefore of great concern. *TUM-ParticleTyper* [10.1371/journal.pone.0234766], an open-source software that detects objects as small as 10 µm in dark-field images of particles deposited on a filter, has now been further developed and extended by the Random Window Subsampling (RWS) approach [10.1007/s00216-021-03326-3] to enable the analysis across the entire MP size range, whereby particle identification is performed automatically by Raman microspectroscopy (RM). Here, we report on the precision of this procedure estimated for the particle size range 1 µm—50 µm.
Suspended microplastic particles were generated [10.3389/fchem.2020.00169], including three polymer types (PS, PET, PLA). Particles of a sample were separated out using a Au-coated polycarbonate filter (APC GmbH, pore size 0.8 µm). On the filter loaded this way, five repetitive measurements were conducted by applying a fully automated procedure supported by the in house developed software *TUM-ParticleTyper 2* (average duration 21 h). Particle detection and Raman measurements (532 nm, 3.5 mW, 40 × 0.5 s per particle, 100 × magnification, N. A. 0.9) were hereby started iteratively, until the given minimum precision requirements were met. The results, obtained under consistent conditions, give $(5.35 \pm 1.29)\cdot 10^5$ plastic particles (2.132 × SD). Each identified between 660 and 840 plastic particles by covering about 0.15 % of the total filter surface, followed by extrapolation. Here, a relative error of 24 % is achieved within 21 h of measurement time per result. Uncertainty can also be estimated on the basis of a single result as calculated from bootstrap samples of RWS, considering only the quantification of particles made of certain materials (plastic types in this case). The uncertainty of each extrapolated result was between $0.43\cdot 10^5$ and $0.57\cdot 10^5$ plastic particles (CL 90%). As the selection is not limited to plastic types, the procedure is also generally applicable for universal particle analysis beyond MP. These results provide a first indication of the random variation to be expected as the general methodology of microplastic analysis is extended to smaller particle sizes (> 1 µm).

3.25.P-We275 Investigation of Airborne Microplastics and Heavy Metals Interaction in Coastal Environment: Application of SEM + SEM EDS, Raman, and LIBS-MS Instrumentation
Precious Onyinyechi Odika*, School of Environment, Geography and Geosciences, University of Portsmouth, United Kingdom*
Microplastics (MPs) are classified as plastic particles with a size range ≤ 5mm in diameter. Pollution by MPs is gaining more attention given its potential cause of toxic accumulation in the food chain, which can pose risk to humans and animals. Of concern also is their ability to adsorb and transport heavy metals (HMs). Heavy metal adsorption by MPs can be affected by the formation of biofilms, and the ageing processes and types of MPs. Although some studies have identified MPs as potential vectors of heavy metals, the adsorption mechanism in the complex natural environment where many heavy metals coexist is yet to be fully investigated. Understanding the chemical interactions between airborne MPs and HMs will improve the present knowledge on the ecological effects and on the toxicity of MPs at environmentally realistic concentrations, their weathering pattern and risk

implications. This ongoing PhD study will develop some much needed instrumentation and methodological techniques and standards for airborne MPs research; sampling, analysis, assessment, interpretation, monitoring and management. It will involve a combination of field and laboratory activities, and the use of Deployable Particulate Sampler (DPS), SEM + SEM EDS, Micro-Raman and LIBS-MS analytical techniques. We will investigate the chemical interactions of different polymer types of MPs with toxic chemicals under various climatic and weathering conditions and their potential resistance level. Specifically, there will be a regional and seasonal comparative analysis of heavy metals transport and adsorption by MPs in the coastal areas of Portsmouth in the UK and Lagos in Nigeria, West Africa. There will be a comparative evaluation of experimental approach versus active method. In addition, simulations and modelling of exposure assessment will be done to predict possible human health and environmental risk from potential airborne MPs pollutants. The regional comparative study will help to evaluate climatic and or geographical sensitivity in the characterisation of MPs with respect to toxic chemical adsorption, desorption and transport. It will contribute to designing global airborne MPs instrumentation development framework and quantitative measurements for global air quality monitoring and management.

3.25.P-We276 Identification of Micro- and Nano-plastics Using Raman Spectroscopy Coupled with Confocal Microscopy
Mathilde Falcou-Prefol[1,2]*, Maaike Vercauteren*[3]*, Gert Nuyts*[4]*, Colin Janssen*[5]*, Ronny Blust*[6]*, Jana Asselman*[7] *and Raewyn M. Town*[6]*, (1)Ghentoxlab, Ghent University, Belgium, (2)ECOSPHERE, University of Antwerp, Belgium, (3)GhEnToxLab, Ghent University, Belgium, (4)University of Antwerp, Belgium, (5)Laboratory for Environmental Toxicology (GhEnToxLab), Ghent University, Belgium, (6)ECOSPHERE, University of Antwerpen, Belgium, (7)Blue Growth Research Lab, Ghent University, Belgium*
Plastic pollution is ubiquitous and persistent in the aquatic environment where a mixture of plastic particles is found. Environmental plastic particles are heterogeneous in terms of both physical and chemical properties. Nanoplastics (dimensions < 1 µm; NP) are expected to be widely present in the environment, but there is a paucity of reliable data on the concentration and distribution of small microplastics (dimensions < 10 µm; sMP) and NP in environmental matrices notably because of sampling and analytical challenges. Accordingly, there are knowledge gaps in understanding their effects and interactions with biota under environmentally relevant exposure conditions. The current lack of relevant and standardized methods for quantification of sMP and NP precludes the development of robust environmental risk assessment strategies.
Chemical identification and quantification of plastic particles is possible using vibrational spectroscopy such as Raman spectroscopy coupled with confocal microscopy. It enables chemical characterization and counting of particles with dimensions between 1 and 10 µm and also eventually particles with dimensions in the sub-micron range. At first, laboratory-based samples using two different stages (pristine and aged) of polyethylene were used. To enhance environmental relevance, comprise milled plastic particles with a variety of morphologies and broad size distribution were used. Then, the complexity of the samples will be increased to test the method on a mixture of milled particles with sizes smaller than 10 µm. The strategy will be further tested and optimised for environmental samples after relevant sample preparation.
This work focuses on the detection and characterization of small microplastics and nanoplastics using Raman microspectroscopy to be allow the determine the concentration and distribution of these particles in environmental matrices. The results will facilitate determination of realistic concentration input values for further ecotoxicological studies regarding plastic particles with size smaller than 10 µm. Our work will thus yield environmentally relevant sMP and NP exposure data thereby enabling consistent risk assessment.

3.25.P-We277 Combining Polymer-specific Binding Peptides and Asymmetric Flow-Field Fractionation Analytics to Tag and Detect Nanoplastics in Mussel's Haemolymph Circulating Cells
Marisa Sarria Pereira de Passos[1]*, Cloe Desmet*[2]*, Dora Mehn*[2]*, Vanessa Modesto*[3]*, Nicoletta Riccardi*[4]*, Maximilian Nöth*[5]*, Tetiana Kurkina*[5]*, Francisca Contreras Leiva*[5]*, Ulrich Schwaneberg*[5] *and Douglas Gilliland*[2]*, (1)EU Commission JRC, Italy, (2)European Commission Joint Research Centre, Italy, (3)IRSA CNR Verbania: Instituto di Ricerca sulle Acque, Consiglio Nazionale delle Ricerche, Italy, (4)Water Research Institute - Italian National Research Council IRSA-CNR, Italy, (5)RWTH Aachen University, Germany*
Bivalve mollusc's haemolymph is one ecologically relevant biomatrix that can be extracted non-invasively to assess the presence of nanoplastics. It constitutes the first line of defence against the entry of external alien material and therefore pertinent to indicate the health status of specimens and populations in natural ecosystems. Haemocytes play a key role on the innate immunity, transporting nutrients, respiratory gases, enzymes, metabolic wastes and toxicants throughout tissues. Induction of functional or stress responses and apoptotic processes on these circulating cells occur particularly fast, and thus makes them worthy of study to evaluate their suitability for aquatic biomonitoring programs.
Tagging and detection of unmodified nanoplastics is technically challenging due to the lack of analytical methods, which can reliably distinguish polymeric particulates from other non-polymeric particulates. An often-cited solution is to dope or stain the nanoplastics with optical markers prior to analysis, but this could be a source of artefacts if marker molecules leach from plastic particles or if interactions are not sufficiently specific towards the targeted polymeric materials. Furthermore, this labelling strategy adds an additional step since, prior to their use in testing, any unbound marker molecules have to be efficiently separated from the polymer without further disrupting their binding to the nanoparticles.
Flow Field Fractionation techniques allow efficient separation of liquid dispersed particulates from free molecular species while also permitting size-fractionation across the size-range from a few nanometers to micrometers. Since these methods can use simple aqueous dispersions as the mobile phase, including those mimicking the physiological conditions, size separation by Flow Field Fractionation techniques is therefore compatible with any biomolecular species as peptides and proteins, which may be associated with the polymer particles.

In this work, Asymmetric Flow-field Fractionation coupled to different on-line detectors (UV-vis, fluorescent and dynamic light scattering) was investigated as a mean to size-separate and detect nanoplastics in complex biomatrices (mussels haemolymph), which have been incubated and tagged with polymer-specific biomolecular species fused with a fluorescent protein. Results evaluating the binding specificity of different polymer-specific binding peptides are presented and discussed.

3.25.P-We278 Fluorescent Micro- and Nanoplastics for the Optimization of Analytical Pathways in Various Biological Systems

Jessica Caldwell[1]*, Barbara Rothen-Rutishauser*[2] *and Alke Petri-Fink*[2]*, (1)BioNanomaterials, University of Fribourg, Adolphe Merkle Institute, Switzerland, (2)University of Fribourg, Switzerland*

Within the past decade, research focused on attempting to understand the interaction of micro- (1 µm – 5 mm), submicron- (100 nm – 1 µm), and nanoplastics (< 100 nm) with humans or various animals has been of increasing interest. These studies seek to determine if any interactions which may occur will have adverse impacts. However, with this growing interest has come a growing need to optimize sample preparation and analytical protocols that facilitate detection of plastic particles in such complex biological systems. In an effort to address this need, our study focuses on the creation of micro- and nanoplastic particles with and without a fluorescent label to use as a foundation for optimizing sample analysis. Microplastic particles of poly(ethylene terephthalate) and polypropylene with sizes < 300 µm were prepared and used to develop a protocol that facilitated the use of correlative light, electron microscopy with Raman Spectroscopy to detect the microplastics after their ingestion by medusa of the jellyfish *Cassiopea andromeda*. Finally, the microplastic particles could be used as a stock material to create nanoplastic particles with average sizes near 75 nm. As a proof-of-concept, these nanoplastics were utilized in *in-vitro* experiments aimed at mimicking potential interactions with cell types relevant to the human gastrointestinal system. Uptake by two different cell types; human colon (colorectal adenocarcinoma) cell line Caco-2 and mouse monocyte/macrophage cell line J774A.1; could be observed.

3.25.P-We279 Production and Analysis Methods for Pristine and Degraded Microplastic and Nanoplastic Reference Materials

Andy Booth, PhD[1]*, Bettie Cormier*[2]*, Martin Wagner*[2]*, Matthias Gerace*[2]*, Kjersti Almås*[3]*, Jérémie Parot*[3]*, Christelle Denonville*[3]*, Stefania Piarulli*[3] *and Lisbet Sorensen*[3]*, (1)Climate and Environment, SINTEF, Norway, (2)Norwegian University of Science & Technology, Norway, (3)SINTEF, Norway*

Most microplastic (MP) and nanoplastic (NP) environmental fate and hazard assessments utilise spherical, monodisperse polymer particles that do not represent the continuum of partially degraded, irregular-shaped MPs in the natural environment. As such, there is a strong need for environmentally relevant test and reference materials (TRMs). Cryomilling approaches can readily generate bulk amounts of MP TRMs >100 µm, but only negligible amounts of TRMs below this size and into the nanoscale (generally <<0.1% by mass). New methods need to be developed for the production of small MP (sMP; 1-100 µm) and NP (<1 µm). In the current study, pristine polypropylene (PP), polyethylene (PE, HDPE and LDPE), polyethylene terephthalate (PET), polystyrene (PS) and Polytetrafluoroethylene (PTFE) pellets were cryomilled and sieved to produce core stocks of TRMs <100 µm in size. Characterisation by a Morphology G3 particle size and shape image analyser showed that all TRMs had a mean particle size of ~100 µm by volume and 0.5-2 µm by particle number, indicating high numbers of sMP and NP, but representing a very low mass. Cryomilled PET, PE and PS were selected for use in the development of a secondary TRM production step that combined UVC ozonation to partially UV degrade the surface of the particles, followed by probe sonication to promote further fragmentation. At the same time, a hyphenated field flow fractionation (FFF) and pyrolysis GC-MS workflow was developed for the mass-based quantification of sMP and NPs of defined size fractions. This involved the use of solvent extraction of the particles from aqueous dispersions prior to analysis and quantification. The approach was able to extract ~100% of sMP and ~80% of NP from aqueous dispersion and quantification limits were identified as ~0.1 ng, ~1 ng and ~1 µg for PET, PE and PS respectively. Morphology G3 was used to quantify the number of sMP, while nanotracking analysis was used to quantify the size distribution and number of NPs. Results suggested that the UVC ozonation and probe sonication strongly increased the quantity of sMP and NP, with mass fraction increases of 30x (PS), 15x (PET) and 6x (PE), respectively. However, this still represented µg quantities being produced from mg quantities of stock material. The results suggest that environmentally relevant sMP and NP TRMs can be produced, but the method requires optimisation to generate quantities suitable for use in environmental fate and effects studies.

3.25.P-We280 Key Challenges and Limitations to Characterizing and Quantifying Environmental and Human Health Risks to Micro- and Nanoplastic Particles: Reference Materials Urgently Required

Todd Gouin*, TG Environmental Research, United Kingdom*

Micro- and nanoplastic particle (MNP) research is at a nascent stage, with numerous studies observing a need to adopt robust quality assurance / quality control (QA/QC) practices regarding sample collection, analysis and effects testing. Good QA/QC is needed to support the reliability and relevance of data generated, which further supports comparability across studies and which further strengthens the ability to perform a risk assessment. It is generally understood that an important element of QA/QC protocol relates to a demonstrated understanding of the characteristics of the stressor under investigation. Th development and application of sampling and analytical methods, for instance, relies on the use of analytical standards, which are used to quantify the efficacy of the sampling and analytical method, such as in the reporting of recovery efficiencies or in the use of quantifying calibration curves. At present, there are no readily available standardized MNP reference materials or methods. In an effort to address this urgent research need, a multi-stakeholder workshop was held during May 2022 in Atlanta, aimed at exploring opportunities to support the generation of a suite of environmentally relevant standard reference MNP materials for use to support the validation of sampling, preparation, and analytical protocols. MNP reference materials would encompass different resins, morphologies, and sizes to represent in some degree the particle variability present in the environment. Standard materials would serve a variety of needs, but would be particularly valuable in supporting the adoption of good QA/QC practices for both environmental monitoring and effects testing, thus helping to strengthen the quality and reliability of data to support risk-based decisions. This presentation will summarize key output from the workshop, including a summary of the various approaches currently used to generate and weather MNP, their strengths and weaknesses and recommendations regarding best practices for use of MNP reference materials for supporting both analytical method development and effects testing.

3.25.P-We281 Untangling Environmental Ageing Processes of (Micro)Plastic Toward the Creation of Realistic Reference Materials

Gilberto Binda, *Rachel Hurley and Luca Nizzetto, Norwegian Institute for Water Research (NIVA), Norway*

The creation of reference materials mimicking the properties of environmental plastics is needed to improve assessment of environmental risk and harmonization of analytical methods. The study of ageing processes is therefore gaining interest of researchers, but the effects of different processes determining ageing (i.e., physical, chemical and biological factors) are still only understood to a limited degree. Here we propose the test of multiple ageing stressors on (micro)plastic specimens to observe how different processes affect (micro)plastic properties. Three different plastic objects composed by polyethylene (PE), polypropylene (PP) and polylactic acid (PLA) were tested. These materials were aged using 3 factors: ultraviolet (UV) irradiation to simulate photoinduced oxidation, the incubation with a mixed algae inoculum to simulate biofouling and both treatments performed sequentially. Changes in surface characteristics were assessed by Fourier-transform infrared spectroscopy, scanning electron microscopy, and water contact angle. Moreover, biofilm growth on plastic fragments was analyzed by chlorophyll fluorescence and optical microscopy. UV radiation caused a significant increase in the density of oxidized groups (i.e., hydroxyl and carbonyl) and increased the surface wettability of PP and PE, while only slightly affecting the surface properties of PLA. Biofouling too, strongly affected surface alterations, regardless of the polymer type and previous ageing process. All biofouled samples present (i) specific infrared bands of new surface functional groups (e.g., amides and polysaccharides), (ii) the diffuse presence of algal biofilm on the plastic surface, and (iii) a significant decrease in surface hydrophobicity. The monitoring of biofilm growth showed that the surface properties of plastic affect cellular attachment and growth rates, whereby hydrophobic samples (i.e., pristine PP and PE) present faster colonization by algae and more abundant biofilm on their fragments. This suggests that chemical and biological alterations are strongly affecting plastic features and that these processes should be considered to foster realistic and reliable reference materials.

3.25.P-We282 Production and Characterisation of Environmentally Relevant Microplastic Reference Materials for Agricultural Soils

Rachel Hurley[1], *Sarmite Kernchen[2], Gilberto Binda[1], Sabrina Carroccio[3], Chiara Consolaro[1], Martin G.J. Löder[2], Christian Laforsch[4], Pierfrancesco Cerruti[3], Demetres Briassoulis[5] and Luca Nizzetto[1,6], (1)Norwegian Institute for Water Research, Norway, (2)University of Bayreuth, Germany, (3)Institute for Polymers, Composites and Biomaterials, National Research Council of Italy, Italy, (4)University of Bayreuth, Animal Ecology I, Germany, (5)Agricultural University of Athens, Greece, (6)RECETOX, Masaryk University, Czech Republic*

Soil environments, particularly in agricultural settings, are often contaminated with microplastics. Agricultural plastics, such as mulching films, are used in close or direct contact with soils and there is growing evidence demonstrating that they represent a potential source of microplastics. These particles, especially those derived from films composed of conventional non-degradable polymer materials, may accumulate in soils, leading to increasingly high concentrations over time. There is a demand to undertake fate and effects studies to understand the behaviour and impacts of this contamination. Yet, there is a lack of reference materials available for this purpose.

Microplastic reference materials can be defined as standardised and well-characterised batches of particles available for use in scientific testing. Their scarcity in this context is related to several challenges in producing environmentally relevant particles, which has been highlighted as an important requirement for microplastic reference materials. This includes challenges in generating microplastic particles from relevant source materials and obtaining environmentally relevant particle typologies (e.g. size, shape, surface properties). There is also lack of consensus or guidelines regarding the necessary particle and material characterisation. This poster presents an overview of batches of microplastic reference materials produced from environmentally relevant source materials, including results of a thorough characterisation of the microplastic particles generated. Advances in micronising agricultural mulching films are described. This includes an emphasis on the efforts made to generate sufficiently large batches of reference materials that can be used across multiple experiments and by several research groups, therefore facilitating harmonisation of fate and effects testing. This work represents an ongoing activity to develop new typologies of microplastic particles from different source materials to supply environmentally relevant microplastics for scientific experimentation.

3.25.P-We283 Generation and Characterization of Cryomilled Micro- and Nanoplastics

Bryan J. Harper[1], *Campbell J. McColley[2], Stacey L Harper[1] and Jeffrey A. Nason[2], (1)Environmental & Molecular Toxicology, Oregon State University, USA (2)School of Chemical, Biological and Environmental Engineering, Oregon State University, USA*

There is a critical need to generate environmentally relevant Microplastics (MPs) and nanoplastics (NPs) to better investigate MP behavior in laboratory settings. Environmental MPs are heterogenous in size and shape unlike monodisperse and uniform microspheres commonly used. Cryogenic grinding, or cryomilling, was successfully utilized to transform polystyrene (PS) bulk material into heterogenous micro and nano fragments. Fourier-Transform Infrared (FTIR) spectroscopy confirmed that this approach did not alter polymer surface chemistry. The number of milling cycles (time of milling) and frequency of grinding (intensity of milling) were varied to investigate the role cryomilling parameters had on generated MP characteristics. The resulting particle size distributions and surface area of these varied cryomilled samples were measured and compared. Coulter Counter and Nanoparticle Tracking Analysis (NTA) were employed to measure the particle size distributions at the micro and nanoparticle size ranges, respectively. Microspheres were used to determine what camera settings yielded more accurate sizing and to reduce bias in the NTA analysis. Increasing milling cycles generally increased the number of smaller particles. As PS was cryomilled, small nanosized fragments broke off from larger MPs. As the number of NPs increase over time, the diameter of larger MPs decreases. The number of milling cycles was observed to more consistently impact the size distributions of fragments compared to the frequency of milling. This study offers both cryomilling analysis and recommendations to generate and make use of these MP/NPs in more environmentally relevant work.

3.25.P-We284 Synthesis and Characterisation of Polystyrene Particles with Silver Nanoparticle Core for Environmental Fate Studies

Jan Koeser[1] *and Martin Hoppe*[2]*, (1)Federal Institute for Geosciences and Natural Resources, Germany, (2)Federal Institute for Geosciences and Natural Resources, Germany*

Recently, research efforts have increased to understand the fate and impact of plastics in the soil environment. Due to the background of natural organic matter in the environment, the quantification of polymers in environmental matrices is challenging. Therefore, the use of well-characterised model particles is mandatory to assess the fate of nanoplastics in soil. The quantification and localisation of these particles are alleviated by doping with metals with very low natural background in the environment, e.g. palladium (Pd) or silver (Ag). In this work, we follow Mitrano et al. and synthesise polystyrene particles (PS-P) in the range of up to 300 nm doped with Ag as tracer material. This synthesis uses the well-characterised and commercially available reference silver nanomaterial NM-300K as precursor. The silver nanomaterial was coated with a thick shell of polystyrene following the work of Braconnot et al. to prevent Ag release from the particles and ensure that the particle surface properties match polystyrene, which is mandatory to investigate the PS-P interactions in environmental matrices. We use only the essential educts NM-300K, styrene, divinylbenzene and $K_2S_2O_8$ to exclude effects from comonomers, other additives, or contamination from reducing agents in environmental fate studies. The synthesised particles were characterised by light scattering methods and electron microscopy. The particles' Ag content and the potential Ag release were analysed by inductively coupled plasma optical emission and mass spectrometry after aqua regia digestion. The silver nanomaterial with the nominal diameter of 15 nm was successfully coated with a symmetric polystyrene shell with a thickness of approx. 130 nm. Stability experiments show excellent colloidal stability with a zeta potential of approx. -40 mV and a stable hydrodynamic diameter of approx. 260 nm. Under light acidic conditions, the chemical stability of the particles was satisfactory with a very low Ag release. This implied the good applicability of the synthesised particles for environmental fate studies.

3.25.P-We285 Artificially Aged Nanoplastics Models for Laboratory Testing

Gabriella Schirinzi[1]*,* ***Francesco Fumagalli***[2]*, Dora Mehn*[2]*, Douglas Gilliland*[2]*, Justin Gorham*[3]*, Jennifer Lynch*[3]*, Katherine Shaw*[3]*, Li-Piin Sung*[3]*, Eric S. Windsor*[3]*, John M. Pettibone*[3]*, Valentina Tolardo*[4]*, Despina Fragouli*[5]*, Andrea Valsesia*[2] *and Sabrina Gioria*[2]*, (1)European Commission, Italy, (2)European Commission Joint Research Centre, Italy, (3)National Institute of Standards and Technology (NIST), USA (4)Istituto Italiano di Tecnologia, Italy, (5)Istituto Italiano Di Tecnologia, Italy*

Reference particle models are essential to obtain an accurate perspective of how environmental nanoplastics behave in natural systems and to generate data on their environmental fate and impact on living organisms. However, although the current available models are particularly important for filling the initial knowledge gaps on nanoplastics, they do not demonstrate enough diversity and/or accuracy to represent the actual heterogeneity of the physical and chemical properties of environmental nanoplastics.

In this framework, the Joint Research Centre (JRC) and the National Institute of Standards and Technology (NIST) are collaborating on a challenging project, which aims to identify a novel strategy for the production of aged nanoplastics. These new test materials are specifically designed to become environmentally relevant models. To reproduce in a controllable fashion both morphological and surface chemistry characteristics of nanoparticles distributions different top-down synthesis approaches are investigated. The model particulate is synthetized (i) via mechanical abrasion (cryomilling) of artificially aged plastic specimens (heat and UV exposure) and (ii) via laser ablation of plastic targets in chemically reactive liquid environment. The pros and cons of two approaches are compared and discussed from the synthesis and the surface chemistry point of view. The objective of this investigation is to obtain nanoplastics, with a reasonable throughput, which mimic naturally weathered ones in size distribution, morphology and surface chemistry.

The scalable production of these nanoplastics is investigated to make them available to stakeholders. This test material will have applications for the development of new analytical methodology to detect nanoplastics, to better understand their role in carrying other pollutants and increase knowledge related to their behaviour and fate in the environment.

3.25.P-We286 Fabrication of Controlled Microplastic Materials for Pulmonary Toxicity Studies

Eric Auyang[1]*, Mengzheng Ouyang*[2]*, Joseph M Levermore*[1]*, Timothy W Gant*[3] *and Stephanie Wright*[1]*, (1)School of Public Health, Imperial College London, United Kingdom, (2)Department of Earth Science & Engineering, Imperial College London, United Kingdom, (3)Radiation, Chemical and Environment Directorate, UKHSA, Harwell Science Campus, United Kingdom*

Microplastic (MP) particles and fibres can be produced from the breakdown of larger plastics and their presence in ambient air requires research into potential toxicity following inhalation. The majority of recent toxicological studies primarily use commercially available polystyrene beads which are not representative of the range of microplastics which occur in the environment. To address this, a methodology has been developed to create MP particles and fibres of a respirable size (<5 µm) and irregular shape for use in pulmonary toxicity studies which will help answer questions about how physiochemical properties influence toxicity. Polyethylene terephthalate (PET) (Sigma), polyamide 6,6 (PA6,6) (Sigma), and polystyrene (PS) (GoodFellow) were chosen as the test polymers. PET, PA6,6, and PS were dissolved in hexafluoro-2-isopropanol, formic acid, and tetrahydrofuran respectively. Precipitation was performed through the addition of ethanol under probe ultrasonication. Particles were passed through a 5 µm sieve and centrifuged to remove over- and undersized particles. Fibres were fabricated through electrospinning of the same plastic solutions, a process using an electrical gradient to extrude polymer fibres with a diameter of 1-2 µm. Cryotome slicing was then performed to yield fibres with an aspect ratio >3. Both MP types were washed several times to remove residual solvent and other potential contaminants and left to dry. Size distribution was performed through a combination of SEM (Zeiss LEO 1525), and Dynamic Light Scattering (Zetasizer Pro), and fabricated particles were found to all have an aerodynamic diameter of <5 µm. Pyrolysis- Two-Dimensional Gas Chromatography Mass Spectrometry (MS), inductively coupled plasma MS, and Limulus Amebocyte Lysate assays were performed to test for methodological artefacts that may interfere with *in vitro* studies. This simple method for the fabrication of pristine MPs provides a resource to ask fundamental questions about how shape, size, and polymer chemistry influence pulmonary MP toxicity. These techniques can be adopted by the wider MP community to investigate more MP physicochemical properties than those commercially available. Preliminary *in vitro* toxicity studies using fabricated PS particles and fibres caused no significant decrease in cell viability after 24 hours of exposure at doses 3.125-100 µg/mL. This will be supplemented by a comprehensive screen of all fabricated MPs in a macrophage-like cell line.

3.25.P-We287 Controlling Contamination: A Comparison of Control Data Analysis Methods
Amanda Dawson[1]*, Marina Santana*[2]*, Joost LD Nelis*[1] *and Cherie Motti*[3]*, (1)CSIRO, Australia, (2)AIMS@JCU, James Cook University & Australian Institute of Marine Science, Australia, (3)Australian Institute of Marine Science, Australia*
After more than a decade of research, the harmonisation of methods has become an international priority in the field of environmental monitoring for microplastics (MPs). This harmonisation has focused predominantly on extraction and isolation methods, identification of MPs and, more recently reporting. However, there is currently no consensus on how the data generated from controls and blanks are used to correct the sample data. Common approaches used in microplastics studies include a) No correction; b) Subtraction; c) Subtraction of mean; d) Subtraction of LOD/LOQ; e) Spectra similarity; or f) Statistical analysis. This study evaluated 51 different data correction strategies based on variations of the 6 approaches listed above to determine the most suitable for application to MP datasets. These methods were tested on a dummy dataset which comprised of real background contamination collected from in situ laboratory analysis. Of the 51 data methods tested, only 7 managed to remove on average 95% of the contaminant data. Data correction methods based on total subtraction were unable to remove even 50% of the dataset, and hence are not recommended for use to correct MP datasets. All methods based on average subtraction, LOD/LOQ and spectra similarity were successful at removing at least 50% of the data. We recommend using the LOD/LOQ method combined with spectra similarity to remove known contaminants within MP datasets. However, the spectra similarity method relies on all items being analysed spectrally. Therefore, if all items are not spectrally characterised, the LOD/LOQ method without a spectra similarity step was also found to be acceptable.

3.25.P-We288 Interlaboratory Study on the Analysis of Microplastics
Ike van der Veen[1]*, Bert Van Bavel*[2] *and Steven Crum*[3]*, (1)Vrije University Amsterdam, Netherlands, (2)Norwegian Institute for Water Research (NIVA), Norway, (3)WEPAL-QUASIMEME, Netherlands*
Within the European quality Controlled Harmonization Assuring Reproducible Monitoring and assessment of plastic pollution (EUROqCHARM) project an interlaboratory comparison study (ILS) has been organised for the analyses of MP in environmental matrices. The aims of the study were to assess the variance between laboratories performing MP analyses, to assess the different methods used for MP analyses, and to assess the performance on the different type of methods used. With the overall aim of the study to move forward to validate and harmonize various methods.
The ILS focused on the analyses of MP in environmental realistic contaminated test materials. The samples included 'soda' tablets simulating water samples with the different polymers in the size region of 50-299 µm, and three sediment and sand samples.
98 laboratories subscribed to the study of which 67 submitted data. Most those laboratories reported on the number of particles (81-87%, depending on the matrix), and only 17-21% reported on the mass of MPs (i.e., mg/tablet or mg/kg). A diversity of methods was used for the extraction and analyses of MP.
Since only a small number of participants report on mass, most of the results on mass were insufficient to be able to perform any statistics on. For the reporting on number of particles, the variation (expressed as relative standard deviation (RSD)) in results was 51-130%, showing that the performance on MP analyses did not improve compared to previous ILS even though the identity of the polymers was known on forehand.
This high variation shows that there is a need for harmonization of methods for MP analyses, and a need for training in order to achieve a better agreement between laboratories performing MP analyses in environmental matrices.

3.25.P-We289 Value for Money: A Cost-effectiveness Analysis of Microplastic Sampling and Analytics
Nelle Siele Meyers[1]*, Gert Everaert*[2]*, Colin Janssen*[3] *and Bavo De Witte*[4]*, (1)Ocean and Human Health, Flanders Marine Institute (VLIZ), Belgium, (2)Ocean & Human health, Flanders Marine Institute (VLIZ), Belgium, (3)Laboratory for Environmental Toxicology (GhEnToxLab), Ghent University, Belgium, (4)Flanders Research Institute for Agriculture, Fisheries and Food (ILVO), Belgium*
The quest for increasingly small microplastic particles, together with their potential impact on ecosystems has expedited the

development of microplastic research in recent years. A wide range of sampling procedures, sample processing steps and sample analysis techniques, both manual and automated, have been established. Despite this progress, this diversification of techniques impedes cross-study comparability and can be confusing for reseachers. Many of the currently applied procedures are also perceived as expensive. Unanswered questions concerning MP abundance, composition, distribution and fate in the marine environment emphasize the need for standardised and reliable monitoring procedures to comply with the Marine Strategy Framework Directive (MSFD).
In our study, which was performed within the JPI Oceans Andromeda project, we performed a cost-effectiveness analysis (CEA) of frequently used methods for microplastic analysis in seawater on a European scale. Data was collected through an online survey consisting of 97 questions related to sample acquisition, sample processing, and sample analysis of preset scenarios. In these scenarios, seawater samples were defined with specific information on microplastic load and composition, microplastic size range, and suspended particulate matter concentration. Total working hours, personnel costs, sector of employment, European marine region of employment, and equipment costs/depreciation/usage were also included in the survey. The survey was performed during autumn 2022 and was spread to experts in the field through personal contacts in various European microplastics expert groups. Following the survey, key outcomes were discussed during two different workshops held with microplastics researchers and with policy makers. Their opinions and perspectives were then used to write up recommendations.
The survey allowed us to compare relative costs and outcomes of different methods based on real experiences of experts in the field. Obtained results allow to gain insight on which workflows provide the greatest value for money for seawater samples, as well as on key elements to which the CEA outcome is sensitive. By providing concrete and useful recommendations of monitoring strategies in terms of cost-effectivity, we want to support reseachers, policy makers and other stakeholders when choosing between different microplastic workflows during future monitoring campaigns in the scope of the MSFD.

3.25.P-We290 Microplastic Analytical Proficiency Testing: Using Immobilised Particles to Improve Experimental Designs
Robin Lenz[1]*, Kristina Enders*[2]*, Julia Muche*[1]*, Elisavet Kanaki*[1]*, Eva C. Vizsolyi*[3]*, Martin G.J. Löder*[3]*, Christian Laforsch*[4]*, Gabriele Eder*[5]*, Matthias Labrenz*[6] *and Dieter Fischer*[1]*, (1)Leibniz Institute of Polymer Research, Germany, (2)IPF, Germany, (3)University of Bayreuth, Germany, (4)University of Bayreuth, Animal Ecology I, Germany, (5)Österreichisches Forschungsinstitut für Chemie und Technik, Austria, (6)Leibniz Institut für Ostseeforschung Warnemünde, Germany*
Interlaboratory calibrations (ILCs), or ring trials, are important procedures to compare and validate the analytical proficiencies of different microplastic (MP) laboratories, techniques or instruments. Conducting an ILC, conventionally involves the preparation of artificial test samples. Every participant will obtain and measure an individual sample and report the result for comparison. There is a variety of published experimental designs for the preparation of the test sample either repetitively, or by splitting a common stock sample. However, especially when the tested material involves particles in the lower micrometer size ranges (here termed small microplastics, sMP, e.g. ~1 to 100 µm), an independent validation of the MP quantities in each replicate is not possible: the only techniques available to quantify them would be those that are supposed to be evaluated by the ILC itself. We introduce the idea of immobilised MP samples and demonstrate their implementation for ILCs. The conceptual difference to suspended ILC designs is that the same sample, in the same constitution, gets measured by every participant instead of individual replica.
The presented implementation is based on cryo-milled and sieved irregular MP particles (nominal sizes of 10 – 70 µm), which are filtered and arrested on silicon and aluminium oxide filters: two kinds microspectroscopic filter materials frequently used for MP quantification. Prior to filtration the particle suspension is mixed with a liquid inorganic binder which leads to an immobilisation of the particles after curing that can withstand flushing with running water or compressed air.
The intended effect of the switch from a design of repeated replica to a to a single immobilised sample is to exclude error terms from an ILC which are a) non-controllable, and b) specific to the ILC itself, thus not informative about the proficiencies in measurements of real world samples.
Preliminary results suggest that in a comparison between a conventional state-of-the-art suspended ILC design and one using a immobilisation, the relative standard deviation of the results reported by the participants was higher in the former by a factor of 6 to 7.
We also discuss other fields of application for the concept of immobilised MP particles: it has already been utilised for sMP purification method evaluations, but also MP sample storability, and correlative microscopy could benefit from the idea.

3.25.P-We291 Platinum Vaporization-deposition Coated Polycarbonate Membranes For Comprehensive, Multimodal, and Correlative Microscopic Analysis of Micro-and Nanoplastics and Other Environmental Particles
Karin Mattsson[1]*, Mats Hagberg*[2] *and Martin Hassellöv*[3]*, (1)Department of Marine Sciences, University of Gothenburg, Sweden, (2)Chalmers University of Technology, Sweden, (3)University of Gothenburg, Sweden*
Anthropogenic particles, including microplastics, are sampled from many matrixes, including the environment such as water, sediment, and air. However, there are no standard methods for sampling particles in the environment; thereby, many different approaches are used for both single particle and ensemble distribution or bulk chemical analyses.
For microplastics, the most commonly used sampling techniques are bulk sampling, i.e., the entire sample volume is collected and not reduced during the sampling, or volume-reduced sampling, i.e., the sample is reduced while collected, such as through filtration. In both cases, the particles of interest will end up on filters. The filters are then analyzed visually and spectroscopically. For particles larger than 300 mm, the quality of the filters is not as crucial as for smaller-sized particles. The size distribution of particles collected in the environment shows a higher abundance of particles within the smaller-sized classes. Because of their small size, high abundance of particles, and a potential biased impact from the operator, automated analysis are required. For automated analysis, the filters' surface has to be unstructured and smooth and have good optical contrast, low Raman, and

fluorescence signal, especially in the range of polymer bands. If Scanning Electron Microscopy (SEM) analysis is desired, the conductivity of the filter and particles is important, especially under high vacuum conditions. The filters should also not be affected by high pressure from the filtration, treatments to reduce organic matter, and have a defined pore size and pore distributions and not be fragile. Preferable many filters made of the same material but with different pore sizes can be used during the sampling of particles. Subsequently, the filters would be put through the analysis pipeline with one or another mode of micro-spectroscopy or even correlative microscopy workflows.
We aimed to develop filters made of the same material and have a defined and practical pore distribution, available in many pore sizes and with a circular diameter of 47 mm and 25 mm. Moreover, the membranes must be able to handle high pressure, filtrate a large volume of solutions, withstand chemical or enzymatic treatments, low background signal from filters that do not interfere with the polymeric fingerprint as well as good properties in SEM with various detectors and performing good in different imaging modes of light microscopy (LM).

3.25.P-We292 Characterization of Microplastics in Drinking Water Using Micro-ftir: Method Validation
***Vitor Vale Cardoso**[1], Rodrigo Cordeiro[2], Rui N Carneiro Eng.[1] and Cristina CM Almeida[2], (1)Laboratory, Empresa Portuguesa das Águas Livres, Portugal, (2)iMed.UL, Faculdade de Farmácia da Universidade de Lisboa, Portugal*
The term 'microplastics' (MP) commonly refers to solid and insoluble plastic particles of small dimensions, usually smaller than 5 mm (and without a specific lower limit). It is also common to distinguish between primary and secondary microplastics. Regardless of their classification, MP contamination is an environmental issue of increasing concern.
Water suppliers using surface water as a raw water resource are likely to be affected by the potential presence of MP particles. As investigated in many studies, larger particles are retained during depth filtration, bank filtration, artificial recharge, underground passage, and membrane filtration. Data on the occurrence of very small microplastic particles in freshwater systems and their behavior during water treatment still need to be included at this stage. There must be comprehensive studies on microplastics in raw water resources, their behavior during drinking water treatment, and their potential occurrence in drinking water.
The need for harmonized methods, reference material, and thus comparative data is one of the biggest challenges regarding determining MP in the environment. Therefore, efforts must be taken to evade these challenges, mainly in drinking water. Destructive techniques such as pyrolysis-gas chromatography-mass spectrometry (Pyr-GC-MS) have been employed in the chemical identification of microplastics, but no information on shape or size of particles can be collected. Non-destructive techniques such as optical microscopy, scanning electron microscopy, SEM, and fluorescence microscopy have been employed for the quantification of microplastics.
Nevertheless, these techniques cannot allow the identification of the polymer composition of these particles. Micro-FTIR (Fourier Transform Infrared Spectroscopy) is a well-known technique that combines infrared spectroscopy with an optical microscopy approach; it is a non-destructive and reproducible technique.
The novelty of our study is to develop and optimize an analytical method for the quantification and the simultaneous identification via Micro-FTIR of different MP, which is present in drinking water.
Regarding the optimization and validation method, several parameters were evaluated, namely: i) sampling method; ii) sample size; iii) sample processing and storage; iv) laboratory preparation; v) clean air conditions; vi) negative controls; vii) positive controls; viii) sample treatment; ix) polymer identification.

3.25.P-We293 Taking Plastic Particle Extraction to the Next Level: Development of an Extraction Process for Nanoplastics from Compost and Sample Preparation for AFM Analysis
***Patrizia Pfohl**, Svetlana Guriyanova, Christian Roth, Sebastian Mueller and Wendel Wohlleben, BASF SE, Germany*
Microplastics are ubiquitous in the environment and several extraction processes for micrometer-sized particles from complex environmental matrices have been reported during the last years. Raman/IR and fluorescence microscopy techniques with fluorescent labelling are the most common techniques for counting extracted particles but have limited size detection ranges. So far, little is known about the fragmentation and degradation of microplastics into secondary nanoplastics under environmental conditions, mostly due to the lack of reliable nanoplastic extraction protocols for complex environmental matrices and analytical methods needed for quantification and identification.
We present preliminary results on an extraction process developed for nanoplastics from compost, which is based on deagglomeration and a sieving cascade to isolate coarser fractions from the nanoplastics, which are then enriched by a density-driven process adapted from the harvesting of mitochondria in cell biology. To test the extraction efficiency during method development we used spherical fluorescent polystyrene (PS) beads (0.91 µm). This model polymer particle was also beneficial for the AFM study. We could easily differentiate the polymer and compost particles by morphology and adjust the filtration and application parameter. The premise for accurate differentiation of nanoplastics from remaining compost and quantification is a homogeneous particle sub-monolayer on the substrate used for AFM analysis. In the stepwise approach to real-world samples, we then applied the optimized extraction process also on pristine and UV-aged polyamide (PA) nanoplastics, which are polydisperse, non-spherical, and surface-aged. The AFM material contrast, mapping of mechanical properties or adhesion can be used for the differentiation purpose. The developed extraction process, the controls and substrates finally shall enable AFM-nanoIR, to differentiate particles of natural origin from those with synthetic polymer composition, but also SEM cathode luminescence is an option to resolve both chemical composition and particle size.

3.25.P-We294 Enabling Technology for Routine Microplastics Sampling and Analysis: Autonomous Marine Drones and High-Throughput Hyperspectral Imaging
***Andrea Faltynkova**[1], Catherine E. Deschênes[2], Artur P Zolich[2], Tor Arne Johansen[2], Geir Johnsen[2] and Martin Wagner[2],*

(1)Biology, Norwegian University of Science & Technology (NTNU), Norway, (2)Norwegian University of Science & Technology (NTNU), Norway
Monitoring the occurrence of microplastics (MP) in the environment is critical to 1) understand exposure for risk analysis of ecosystems, 2) elucidate transport processes, and 3) to monitor the effectiveness of pollution reduction measures. Current MP sampling and analysis techniques do not allow high sample throughput due to bottlenecks in both sample collection and sample analysis. We conducted a proof-of-concept study on the west coast of Norway to assess the viability of combining rapid marine drone-enabled sampling with high throughput short-wave-infrared hyperspectral imaging (HSI) analysis of MP. We propose a workflow for surface water sampling of MP which uses an uncrewed surface vehicle (USV) to collect triplicate manta-net samples simultaneously and in a repeatable fashion. Using HSI, we demonstrate the capacity to analyze multiple MP samples (down to 500 µm particle diameter) in a short time frame (20 x 47 mm Ø filters/h). A multivariate model rapidly classifies hyperspectral datacubes to obtain particle number, polymer type and size/morphological data in one step. The tools and techniques used in this framework can increase the scalability of sampling MP in aquatic environments. Further development of this framework could enable routine analysis of important ecosystems affected by plastic pollution.

3.25.P-We295 A Novel Method for Density Separation Followed by Quantitative 1H-Nuclear Magnetic Resonance Spectroscopy for the Determination of Microplastics in Marine Sediments
*Javier Lopez-Vazquez[1], Rosa Montes[2], Victor M Sanchez-Pedregal[1], José Benito Quintana[1] and **Rosario Rodil**[1], (1)Universidade de Santiago de Compostela, Spain, (2)University of Santiago de Compostela, Spain*
Microplastics (MPs), defined as plastic particles smaller than 5 mm, are considered a new class of persistent environmental pollutants. MPs have been found in almost every compartment affected by human interaction but are of particular concern in the marine environment as a major sink of those pollutants. The determination of MPs in the marine environment, particularly sediments and sand, is very laborious. Separation of MPs from other particles is typically conducted in costly large density separators. Then, determination is most often performed by infrared (IR) or Raman spectroscopy, or by pyrolytic methods. Consequently, the development of reliable, simpler, and cost-effective analytical methods is necessary to better assess their distribution in the marine environment at a larger scale.
Therefore, the aim of this study was to develop a method for the separation, identification, and quantification of MPs from aquatic sediments. With that purpose, a density separation using a novel small-scale separation setup made of glass was developed. Thus, it was tested for the separation of sediments (100 g) with spiked with different MPs (polyethylene, polystyrene, polypropylene, polyvinyl chloride and polyethylene terephthalate) at two environmentally realistic concentration levels (2 and 20 mg). The density separation was done with 1.6 g/cm^3 zinc chloride solutions. The trueness of the method was calculated by a gravimetric method and quantitative ^{1}H Nuclear Magnetic Resonance spectroscopy (qNMR) for polyethylene terephthalate, polyvinyl chloride and low-density polyethylene, producing recoveries higher than 81% in all cases. Moreover, the combination with qNMR led to limits of quantification below 0.01 ng/g for these three polymers. Finally, the developed method was applied to a few samples of beach sediments from different sites of the Galician coast (Norwest of Spain) where concentrations of polyethylene terephthalate and low-density polyethylene ranged from 62 to 186 ng/g and 82 to 100 ng/g, respectively.

3.25.P-We296 Investigation of Polymer Type and Particle Size on Microplastic Enrichment from Sediment Samples
***Maurice Hauffe**, technical chemistry, University of Applied Sciences Dresden, Germany*
Microplastics represent an increasing environmental problem, which is more and more in the focus of the society and politics. To develop strategies and solutions for the targeted prevention of microplastics and for environmental protection, reliable environmental monitoring is very important. For an analysis of environmental samples, an enrichment of microplastic from these samples is absolutely necessary. Without an enrichment of the samples, the limits of detection and quantification cannot be guaranteed. Two things are critical in the enrichment processes. First, no microplastics should be lost in the process. Secondly, the environmental matrix must be separated. The higher the degree of the separated matrix, the simpler and more reliable is the final microplastic analysis. Various factors of the sample itself and during separation are responsible for the success of the enrichment process. In this work, two different polymers in different particle sizes were investigated during electrostatic and density separation. These were the two semi-crystalline thermoplastic polymers LD-PE and PET. These represent two completely different polymers due to their density difference and chemical structure. The polymers were classified into the five fractions < 63 µm, 63 - 125 µm, 125 - 250 µm and 500 - 2000 µm by cryogenic milling and sieving. All particle fractions investigated were tested in a sand well suited for separation with regard to separation success. The success of the processing of the samples was evaluated by the degree of separation on sediment and by a DSC analysis and the calculated recovery rates of the particles.
It was found that small and large particles show difficulties in separation. Particles that are too small can be easily lost in electrostatic separation. Particles that are too large are difficult to analyze in the fractions due to sample inhomogeneities. This leads to large value fluctuations and uncertainties in the results. With the particles of medium size, good separations and recoveries can be obtained. Between polymer types, it was observed that the measurement uncertainty for PET is greater than that for LD-PE. The enrichment of the samples with LD-PE was higher than the enrichment of the PET samples. In addition, it was found that multiple separation in electrostatic separation results in a loss of microplastics.

3.25.P-We297 Is Polypropylene Relevant for Microplastic Analysis?
***Maren Meurer**, Yosri Wiesner, Tassilo Waniek, Anja Geburtig and Korinna Altmann, Federal Institute for Materials Research and Testing, Germany*
Nowadays, in every terrestrial and aquatic ecosystem, even in the remotest areas, small residues of plastics, the so called microplastic (MP) can be found. MPs are particles with a size of 1-1000 µm (ISO/TR 21960:2020), mainly containing synthetic

polymers like polyethylene (PE), polypropylene (PP), polystyrene (PS) or polyethylene terephthalate (PET). Even styrene-butadiene rubber (SBR) as an indication for tire wear is included due to similar particle formation. To understand the MPs consequences to the environment, it is of high priority to capture its extent of contamination. It is surprising that in the analysis of polymer masses in environmental samples, PE, PS and SBR are often detected, but only small amounts of PP, although this is the second most commonly produced standard plastic and many MP particles originate from carelessly disposed packaging materials. This presentation provides hypotheses about the reasons of rare PP identification and mass quantification in environmental samples. Different investigations of pristine PP and representative environmental samples, including the pre-treatment by Accelerated Solvent Extraction (ASE) or with density separation followed by the thermal extraction / desorption gas chromatography-mass spectrometry (TED-GC/MS) are presented. The results are discussed according to the material properties and a possible degradation mechanism under different weathering conditions which indicate less stability under relevant storage conditions.

3.25.P-We298 Considering Both Effect Sizes and Test Concentrations Improves Conclusions Drawn from Meta-analyses in Ecotoxicology

*Ana Leticia Antonio Vital[1] and **Magdalena M. Mair**[2], (1)Junior Research Group Statistical Ecotoxicology, University of Bayreuth, Germany, (2)Statistical Ecotoxicology, University of Bayreuth, Germany*

The amount of microplastic (MP) particles in the environment is rising, and several studies on the toxic effects of MP particles on biota have been published in the last few years. However, whether MP represents a general risk for ecosystems and which MP traits are associated with adverse effects remains uncertain. Individual studies provide evidence that, for example, MP size, shape, and the presence of an eco-corona may directly affect toxicity. However, there is still much controversy surrounding whether these patterns are generalized for different species, MP trait combinations, and endpoints. To reach more broad conclusions, it is thus necessary to aggregate the available information from different studies in combined analyses. Meta-analyses are a way of quantitatively agregating results from previous studies. Although meta-analyses have become more broadly used in ecotoxicology, they often focus on the presence/absence of effects (i.e., using concepts based on p-values such as NOEC/LOEC) rather than looking directly at concentration-dependent effect sizes (i.e., dose/concentration-response relationships). We use an example dataset on toxic effects of micro- and nanoplastic particles on *Daphnia* spp. and theoretical considerations to investigate the importance of incorporating concentration-dependent effect relationships in ecotoxicological meta-analyses. To this end, we compare the information we can gain when applying three different meta-analytical approaches: (1) grouping of test concentrations into concentrations leading to significant and non-significant results, (2) looking directly at effect sizes without taking concentration into account (forest plots) and (3) investigating effect sizes in a concentration-dependent manner (regression approach). As concentration is usually a confounder in environmental toxicity studies, we argue that taking both effect sizes and test concentrations into account in ecotoxicological meta-analyses is beneficial to draw reliable conclusions.

3.25.V Towards Harmonized Nano- And Microplastics Quantification: Reference Materials, Analytics and Improved Experimental Designs

3.25.V-01 Microplastics Are Hidden in Sediments: A Case Study from a Natural Protected Area of Guatemala

***Carlos Mazariegos**[1], Sonia Munoz[1] and Jaclyn Canas-Carrell[2], (1)Environmental Toxicology, Texas Tech University, USA (2)Dept. of Environmental Toxicology, Texas Tech University, USA* Microplastics (MPS) are an emerging problem for this century threatening human health and the environment. MPS are cosmopolitan particles, however undeveloped countries are more vulnerable to MPS pollution due to their lack of environmental rules, waste management, and indiscriminate consumption of every type of plastic material. Guatemala has three protected areas on the south coast intended to support biodiversity and natural services for communities. The Reserva Natural de Usos Multiples Monterrico is recognized for having biodiversity including mangroves, fish, birds, and flora. The area is economically important for small-scale fisheries. However, little is known about MPS contamination in water, sediments, fauna, and flora in this area. Thus, the purpose of this study was to assess MPS accumulation and distribution in sediments from the Reserva Natural de Usos Multiples Monterrico. Sediments were collected using a trawl from six places along the estuarine system classified as non-populated and populated. Then, MPS were separated by using 1- and 5-mm steel sieves. Finally, MPS were counted, classified according to shape, and identified using an infrared spectroscopy technique (MPS polymer identification is ongoing). 344 MPS were registered, and film and fragments were the predominant shapes found. No differences were detected between non-populated and populated sites ($p>0.05$). Results from this work will allow an understanding of MPS accumulation and distribution in sediments from an important protected area of Guatemala. Additionally, the information might be useful for stakeholders to inform the advances of the UN's sustainable development goal number 14: life below water.

3.25.V-02 Size Limitations on the Data-driven Identification of Microplastic Using FD-FLIM

***Maximilian Wohlschläger**[1], Nina Simone Leiter[1], Simon David Jakob Oster[2], Martin Versen[1], Martin G.J. Löder[3] and Christian Laforsch[4], (1)Rosenheim Technical University of Applied Sciences, Germany, (2)University Bayreuth, Germany, (3)University of Bayreuth, Germany, (4)University of Bayreuth, Animal Ecology I, Germany*

Currently, a fast and reliable ecological risk assessment is time-consuming due to the challenging purification which has to be done to analyze the microplastic (MP) samples taken from the environment using the established analytical methods. Thus, an urgent need exists concerning a fast and reliable identification of plastic-type, shape and size. Recent studies on Frequency-Domain Fluorescence Lifetime Imaging Microscopy (FD-FLIM) show high potential to quickly identify the plastic type, shape and size and differentiate plastics from environmental materials. However, it has yet to be tested down to which size MP samples

can be identified using FD-FLIM. To determine the identification limitations, LDPE, PET, PP and PS spiked with 0.012 wt% of fluoresceine are prepared in 1000 x 1000 x 20 µm down to 125 x 125 x 20 µm quadratic particles. Six particles of each size are placed next to each other on microscope slides and sealed with coverslips. The experimental setup consists of a modulated laser, an FD-FLIM camera, a microscope (objective: x20, imaging field: 0.28 mm x 0.28 mm), and two optical filters. Twelve FD-FLIM measurements are done on 1 mm particle of spiked LDPE, PET, PP, and PS MP particles and evaluated by Gaussian analysis. The resulting expectation value and standard deviation of the FLTs serve as thresholds. Combined with an image processing algorithm consisting of gaussian blur, binarization and erosion, we set the minimum detectable particle size to 125 µm. With this, identifying the plastic type, shape, and size was possible for 6/6 images of the 125 µm particles from LDPE, PP and PS and 3/6 images from ABS. However, comparing the results of the FLT of the fluorescein-spiked particles with the FLTs of pure PET and PP, a decrease in FLT is obtained for PET (-1.2 ns) and PP (-0.5 ns), while the FLTs of LDPE and PS are within one standard deviation of the FLT of the pure LDPE and PS.
In conclusion, fast and reliable identification of the plastic type, shape and size is possible down to a size of 125 µm. Hence, further studies with particles smaller than 125 µm must be conducted to set a detection limit. Nevertheless, the additive concentration impacted two plastic types, which may lead to difficulties in the identification. Therefore, a heuristic model has to be investigated to determine how plastic containing different additive concentrations can be identified by their characteristic FLT.

3.25.V-03 Analytical Alternatives to Detect and Quantify Nanoplastics in Complex Environmental Matrices

Patricia Taladriz-Blanco[1]*, Ana Castanheira*[2]*, Monica Quarato*[2]*, Alexandre Chicharo*[3]*, Sara Abalde-Cela*[3]*, Begoña Espina*[4] *and Laura Rodriguez-Lorenzo*[2]*, (1)Water Quality, International Iberian Nanotechnology Laboratory, Portugal, (2)Water Quality Group, International Iberian Nanotechnology Laboratory (INL), Portugal, (3)Medical Devices Group, International Iberian Nanotechnology Laboratory (INL), Portugal, (4)International Iberian Nanotechnology Laboratory, Portugal*

Detecting and quantifying nanoplastic particles (< 1000 nm) at environmentally relevant concentrations (ng/L - ug/L) using conventional analytical techniques such as Raman and Infrared spectroscopy (IR) or Fluorescence microscopy (FM) represents one of the biggest challenges for this research field. The main challenge relies on the instrument size, which for confocal Raman is ≥ 0.25 um (lateral), FM is > 1 um and FTIR > 2-5 um. Additional challenges related to their low concentration in natural environments, the complexity of the sample matrices, their ubiquity, and their inherent physicochemical properties raise the need to develop and standardise analytical methods for nanoplastic particles. Herein, we describe the work done in our research group on developing different approaches based on Surface-Enhanced Raman Spectroscopy (SERS), Nanoparticle Tracking Analysis (NTA), and electron microscopy (SEM and TEM) to fulfil the existing gap in analytical techniques to detect and quantify nanoplastic particles.

3.25.V-04 Nanoparticle Tracking Analysis to Quantify Nanoplastics in Complex Environmental Matrices

Ana Castanheira[1]*, Monica Quarato*[1]*, Begoña Espina*[2]*, Laura Rodriguez-Lorenzo*[1] *and* ***Patricia Taladriz-Blanco***[3]*, (1)Water Quality Group, International Iberian Nanotechnology Laboratory (INL), Portugal, (2)International Iberian Nanotechnology Laboratory, Portugal, (3)Water Quality, International Iberian Nanotechnology Laboratory, Portugal*

Detecting and quantifying nanoplastic particles (< 1000 nm) at environmentally relevant concentrations (ng/L - ug/L) using conventional analytical techniques represents one of the biggest challenges for this research field. Often, a pre-treatment step, including pre-concentration and removal of undesirable material, is required. Cloud point extraction (CPE), using a non-ionic surfactant such as Triton-X, has been shown to successfully separate and concentrate nanoplastics in complex environments. Nanoparticle tracking analysis (NTA) relies on scattering properties and is used to quantify and calculate nanoparticle size (distribution). Compared to dynamic light scattering, NTA has the advantage that the results are calculated as number-weighted; therefore, size values are less biased by the presence of aggregates or larger nanoparticles. NTA is a non-destructive technique, representing a promising tool for analysing nanoplastic particles compared to the mainly used Pyrolysis Gas Chromatography-Mass Spectrometry. Herein, we show the combination of CPE and NTA to successfully quantify and characterise nanoplastics (100 and 200 nm – Polystyrene) in natural fresh and salt waters. 50 nm – gold and 100 nm – silver nanoparticles were used as a control due to the better optical properties compared to nanoplastics for a defined size.

3.25.V-05 Surface Enhanced Raman Scattering for Rapid Monitoring of Microplastics

Qihang Xu[1]*,* ***Zhugen Yang***[2] *and Pablo Campo Moreno*[3]*, (1)Cranfield University, United Kingdom, (2)School of Water, Energy and Environment, Cranfield University, United Kingdom, (3)Cranfield University, United Kingdom*

Given the current circumstances of widespread use of plastic products and lack of means to deal with them, microplastics (MPs), as an emerging contaminant, has become a global concern. Many studies have demonstrated that microplastics can be found in numerous environmental samples. The widespread distribution of microplastics poses a threat to the biological community, but the toxicology of microplastics has not been adequately studied. The most commonly used methods for chemical and physical identification of microplastics are Fourier transform infrared spectroscopy (FTIR) and Raman. However, these two methods are limited by poor spatial resolution, which is 20 µm and 5 µm respectively. Surface-enhanced Raman scattering (SERS) can significantly enhance the weak Raman signal, thus making it a promising tool for microplastics detection at a low concentration. In this work, gold nanoparticles (AuNPs) and silver nanoparticles (AgNPs) are employed as enhancement substrate to enhance the Raman signal of microplastics. The experimental conditions were optimized to achieve better analytical performance, including the size of the nanoparticles, the amount of addition, the ionic strength of the solution and the ratio of nanoparticles to microplastic particles. To investigate the effect of AuNP size on Raman signal enhancement, three size AuNPs are tested. To determine the appropriate amount of gold nanoparticles for microplastics, different amounts of the gold nanoparticles were tested. Results show that AuNPs can significantly enhance the Raman signal of microplastics. A strong relationship between the size of

AuNPs and the enhancement performance is identified in this work. This platform has the potential to be a more sensitive microplastic detection approach and serve as a new tool for rapid monitoring the spatial and temporal distribution, toxicity, and environmental exposure of microplastics.

Track 4: Ecological and Human Health Risk Assessment of Chemicals, Mixtures and Stressors and Risk Mitigation Strategies

4.01 Advances in Environmental Risk Assessment of Chemicals

4.01.T-01 National Risk Trends Based on Pesticide Sale Data in Germany - A Comparison of Five Indicators

***Jörn Strassemeyer**, Silke Dachbrodt-Saydeh and Hella Kehlenbeck, Julius Kühn-Institute Federal Research Centre for Cultivated Plants (JKI), Germany*

The reduction of environmental and health risks from the use of pesticides in agriculture is a corner stone of the recent European Farm-to-Fork Strategy of the European Commission, calling for a 50% reduction in the amount and risks of pesticides by 2030. EU policies like the Sustainable Use Directive (Directive 128/2009/EC) already demand the implementation of National Action Plans to reduce environmental risks from pesticide use.

To monitor the ubiquitous efforts towards risk reduction, a robust assessment and indicator system is required. Thus, comprehensive and transparent indicators are needed to capture, on national level, the heterogeneity of active ingredients in terms of their potential impact on the environment and human health. The Harmonized Risk Indicator (HRI) was developed as a harmonized approach for all EU Member States to assess the risk trends on national level and EU level to represent the risk caused by pesticide applications. Such an approach requires EU-wide availability of the necessary data as well as an appropriate degree of complexity in the calculation of the indicator. To meet these requirements, the COM has adopted the HRI, which combines the hazard classification under Regulation 1107/2009 with the sales statistics.

To reflect the risk trend of AIs, the assessment must take into account their intrinsic properties and specific toxicity values. Several existing risk indicators follow this approach. Numerical values are assigned according to the various AI properties and toxicity end points and added for several AI properties to produce an AI-specific weighting factor that reflects toxicity to humans and the environment, as well as environmental fate. The Environmental Impact Quotient and Toxic Load Indicator were developed based on such an approach. In Denmark, the Pesticide Load Indicator, has been used to estimate risk at national and regional levels and to calculate pesticide taxes. In Sweden, the Pesticide Risk Indicator was developed to map long-term risk trends at the national level.

To compare the trend development of the different indicators, we calculate all indicators with the German sales data and present the results in the Pesticide-Trend Database Explorer (https://sf.julius-kuehn.de/pesticide-dbx/), a transparent online tool for flexible evaluations of the indicators regarding the base line period, the weighting factors and the different AI groups. Based on these results simple improvement of the HRI are discussed.

4.01.T-02 Validating Predicted No Effect Concentrations (PNECs) in the Field

***Oliver Weisner**[1], Kristina Hitzfeld[1], Saskia Knillmann[1], Alexandra Müller[1], Jörn Wogram[1] and Matthias Liess[2], (1)German Environment Agency, Germany, (2)Department of System Ecotoxicology, Helmholtz Centre for Environmental Research (UFZ), Germany*

Both the derivation of predicted environmental concentrations (PECs) and predicted no effect concentrations (PNECs) used in the environmental risk assessment of chemicals rely on various models and assumptions. Particularly for PNECs, a validation of these models and assumptions in the field is pending and challenging as targeted post-authorisation monitoring is scarce and specific ecolgoical effects are largely masked by other influences. In this exemplary assessment we aim to answer the questions what steps enable a validation of PNECs, whether the PNECs for pesticides we monitored were adequate and of what use such a field-based validation can be. On the basis of a large stream monitoring data set of >100 small streams we linked chemical (75 pesticides in >800 water samples) with biological measurements (invertebrate communities) to validate the PNECs of primarily invertebrate-toxic pesticides in surface waters.

We identified five general steps to be performed to validate PNECs with field data: 1) Measure environmental eposure adequately. 2) Assess a suitable ecological response. 3) Link dose and response. 4) Define a protecion. 5) Integrate unvertainty. Referring to our case study, we were able to link the ecological effects observed reflected by the invertebrate-based and pesticide-specific SPEcies At Risk ($SPEAR_{pesticides}$) indicator to the maximum single pesticide-related factor of PNEC-exceedance measured using a linear correlation ($R^2 = 0.44$, $p < 0.001$). We found that, in the average stream subjected to various chemical and environmental stressors, peak concentrations equalling the PNEC were already associated with a $SPEAR_{pesticides}$ that did not comply with the previously defined protection goal.

Our analysis questions the established principles, data requirements and assessment factors according to which pesticide PNECs for surface waters specifically and PNECs in general are derived. The use of this field-based validation and respective consequences for pesticide regulation are to be discussed.

4.01.T-03 Development of Analytical Frameworks to Assess the Risks Posed to Soil by Emerging Contaminants

***Federica Persico**[1], Frederic Coulon[2], Melissa Ladyman[1] and Tracey Temple[1], (1)Cranfield University, United Kingdom, (2)School of Water, Energy and Environment, Cranfield University, United Kingdom*

Many unregulated contaminants, often termed Emerging Contaminants (ECs), are globally released on soil creating potential risks, especially when undetected leading to significant impact on environmental receptors. The UK ministry of Defence plays an important role in soil protection as the biggest holder of Sites of Special Scientific Interest (SSSI) in the UK as well as being an active polluter in these protected areas through essential training activities. Therefore, improved methods for early identification of emerging contamination are needed to avoid long term environmental impacts and costly remediation. This research has contributed to the development of a soil analytical framework to facilitate early identification of the deleterious effects of ECs and chemicals of military concern. Two different scenarios were considered, firstly, when there is a significant body of ecotoxicological data available for a specific contaminant in the literature and secondly, when ecotoxicological data is not available.
Firstly, a hazard-base scale was developed and designed to categorise chemicals into low, medium, and high environmental hazards to provide an early indicator for soil degradation at low-cost. This research showed that for the contaminants of interest (e.g., hexahydro-1,3,5-trinitro-1,3,5-triazine, trinitrotoluene, perfluoroalkyl, polyfluoroalkyl and Cypermethrin) the low-level hazard values were lower than expected when compared to Soil Screening Values (SSVs) and Ecological Soil Screening Levels (Eco-SSL). This means the contaminants are likely to have a negative impact on the soil at lower concentrations.
Secondly, Insensitive High Explosive (IHE) compositions were identified as lacking data and so soil mesocosms were carried out to define the long-term consequences on soil. Field experiments were used to quantify IHE residue deposition concentrations from a standard 155 mm artillery shell, which was then used to estimate low, medium, and high contaminant concentration for soil mesocosm studies. Mesocosms were used to quantify the impact on soil using indicators identified through literature review. Specifically, this work showed that the frequent use of IHE filled munitions on training ranges influence the quality of the soil even when low quantities of energetic residue are deposited. Results from this work are a first step towards a more comprehensive soil analytical framework development providing early identification tools for soil protection.

4.01.T-04 Effect of PAC (PAH & Polar-PAC) Availability on Terrestrial Organisms' Ecotoxicity

***Imane Aabbar**, Interdisciplinary Laboratory of Continental Environments, France*

Historically contaminated sites have gained attention in recent decades. Some of them, e.g., former coking plants are contaminated by polycyclic aromatic compounds including PAHs and polar-PACs (O/N/S-PACs). The exposure of terrestrial organisms to freshly contaminated soil with PAC demonstrated significant toxicity towards organisms. However, for some soils sampled from historically contaminated sites exhibiting a higher PAC content, tests performed on earthworms have shown a limited impact on mortality rates.
Based on studies, in historically contaminated sites, PAC (bio)availability is generally limited. This phenomenon known as "aging" is a main factor to consider in the evaluation of toxicity risk in soil contaminated by PAC.
In fact, for a refined estimation of the environmental risk and understanding of the impact of the PAC (bio)availability on toxicity, it's necessary to combine a complete chemical characterization (total content and available fraction of PACs) and biological expositions.
This work aims to evaluate the toxicity of two aged coking plant soils by running bioassays on invertebrates and plants. The toxicity of these soils (low PAC availability) will be compared with the same soils previously treated (heating) to increase their PAC availability.
A pre-heating treatment was carried out to increase PAC availability, then the soil was extracted with dichloromethane (DCM) and the PACs (i.e., PAHs and O/N/S PACs) were quantified by GC-MS. As a second step, ecotoxicity tests were performed through limit assays using acute bioassays. The purpose of this step is to evaluate the earthworm viability rate and seed development of plants (seedling emergence and growth) and to highlight the importance of taking into account the availability factor.
Results of this study showed that soils with identical physico-chemical properties but exhibiting contrasted levels of PAC availability induced different ecotoxic responses of terrestrial organisms, an increased availability leading to a much higher toxicity. These results pointed out the importance of considering the contamination availability parameter in risk assessment and not only the total contaminant concentration.

4.01.T-05 Chronic Toxicity and Bioacumulation Testing of Heterocyclic Polyaromatic Hydrocarbons with *Daphnia magna* – Controlling Exposure with Passive Dosing

***Goksu Celik**[1], Stefan Stolte[2] and Marta Markiewicz[2], (1)Institute of Water Chemistry, Technical University Dresden, Germany, (2)Institute of Water Chemistry, Technical University Dresden, Germany*

Heterocyclic polyaromatic hydrocarbons (heterocyclic PAHs) substituted with sulphur, nitrogen, or oxygen heteroatoms are often released along with their homocyclic equivalents but are often present in higher concentrations due to their higher polarity. Heterocyclic PAH are often toxic and persistent in the aquatic environment and can pose a threat to aquatic life. Nevertheless, reliable toxicity data, especially for chronic exposure, are still very limited. Given the "difficult" nature of heterocyclic PAHs, i.e., poor water solubility and high hydrophobicity, conducting toxicity test using standard approaches is very challenging and not always meaningful. Compound losses often occur, e.g., through sorption during the test, resulting in an unstable exposure. Passive dosing can overcome these challenges by maintaining a defined and stable exposure during the test. Although passive dosing method was used efficiently for short-term toxicity testing, its applicability for long-term toxicity tests (21-days), where the exposure medium has to be renewed and test organisms have to be fed, was so far not performed. In this study, we employed the passive dosing method in the chronic toxicity test with *Daphnia magna* to assess heterocyclic PAHs. To maximize the information output, the chronic toxicity test simultaneously served as an uptake phase of the bioaccumulation test, which was subsequently followed by the depuration phase. The adaptability and effectiveness of using this method in routine toxicity testing is critically debated.

4.01.P Advances in Environmental Risk Assessment of Chemicals

4.01.P-Mo261 A Pulsed Exposure Approach to Investigate Chronic Fish Developmental Stage Mortality and Its Relevance for Risk Assessment

***Richard John Maunder*[1]*, David Fazakerley[1], Alastair J Lyes[1], Marion Gagniarre[2], Thomas Fruhmann[3] and Seamus Taylor[4], (1)Scymaris, United Kingdom, (2)ADAMA Agricultural Solutions, France, (3)Nufarm, Austria, (4)ADAMA Agricultural Solutions, United Kingdom*

The chronic toxicity of pesticides to fish is typically evaluated using standard methods e.g., OECD 210, Fish, Early Life Stage toxicity (FELS). In addition, OPPTS 850.1500 guidance describes the method to conduct the fish life cycle (FLC) test that can be used to detect adverse effects on development, growth and reproduction over an entire life cycle. In some cases, effect endpoints reported in FELS and FLC studies can be inconsistent and further investigation of development growth stage effects may be justified.

In this case, we will present findings from a real example where development growth stage specific effects were reported from a FLC study that were inconsistent with findings from other chronic fish studies with the same test substance.

We intend to share lessons learned of the practicalities in delivering a chronic fish GLP study using pulse exposure scenarios to different life stages. This includes using both semi-static and flow-through exposures, and the brief use of a prophylactic egg fungicide. We will also present findings from supporting chemical analysis to characterise the exposure pulses and present recommendations for the consideration of fish developmental stage toxicity in pesticide regulatory risk assessment.

4.01.P-Mo262 Graphical Matching of Exposure Profiles in Pulsed Exposure Toxicity Tests to Predicted Environmental Concentrations – A Helpful Tool in Higher-Tier Aquatic Pesticide Risk Assessments

*Dietmar Warnecke, Alexander Singer, André Dabrunz, **Oliver Jakoby** and Dominic Englert, RIFCON, Hirschberg, Germany*

Following the current EFSA Aquatic Guidance Document (AGD), the risks for aquatic organisms can inter alia be refined by performing pulsed (peak) exposure tests or mesocosm studies in the tiered risk assessment scheme. The endpoints of these studies (NOEC, EC_x) can be used together with an assessment factor to define a regulatory acceptable concentration (RAC). In risk assessments, this RAC is compared to the maximum predicted environmental concentration (PEC_{max}). However, the question whether the exposure in higher-tier studies covers the predicted exposure profiles (e.g. FOCUS scenarios) has gained considerable relevance in recent years.

The reason is that environmental exposure is temporally variable in aquatic environments, with peak exposures after application due to drift, followed by run-off or drainage events to respective water bodies. The shape of this temporal exposure profile influences uptake and effect of compounds. Consecutive exposure peaks might be ecotoxicologically dependent leading to an accumulation of internal concentrations and possibly additive effects. To demonstrate that exposure regimes in higher-tier studies adequately cover predicted consecutive environmental exposure peaks in a worst-case scenario, a comparison of the exposure profile in the higher-tier study to the predicted exposure profile is required. However, due to the variety of exposure scenarios included in the FOCUS model, a single worst-case scenario often cannot be identified.

We present a practical tool programmed in statistics software "R", which expands EPAT functionality to compare the time course of exposure profiles of higher-tier experiments with predicted exposure profiles from FOCUS scenarios. In brief, we illustrate the three application steps: (1) Using a moving time window to scan the predicted exposure profile for critically high exposure peaks; (2) Exposure profiles of the higher-tier study are graphically overlaid to the environmentally predicted profiles; (3) Both exposure patterns are compared visually by the user.

The outcome of this approach supports the definition of the regulatory acceptable profile (RAP). Advances, shortcomings, and potential further adaptations of the approach are discussed.

4.01.P-Mo263 Heterogeneity in Biological Assemblages and Exposure in Chemical Risk Assessment: Exploring Capabilities and Challenges in Methodology with Two Landscape-Scale Case Studies

***Christopher M Holmes*[1]*, Lorraine Maltby[2], Paul Sweeney[3], Pernille Thorbek[4], Jens C. Otte[4] and Stuart Marshall[5], (1)Applied Analysis Solutions, (2)University of Sheffield, United Kingdom, (3)Syngenta, United Kingdom, (4)BASF SE, Germany, (5)Consultant, United Kingdom*

Chemical exposure concentrations and the composition of ecological species vary in space and time, resulting in landscape-scale heterogeneity. Current regulatory, prospective chemical risk assessment frameworks do not directly address this heterogeneity because they assume that reasonably worst-case chemical exposure concentrations co-occur (spatially and temporally) with species that are the most sensitive to the chemical's toxicity. Whilst these approaches aim to be protective, a more precise understanding of when and where chemical exposure and species sensitivity co-occur enables risk assessments to be better tailored and applied mitigation to be more efficient. We used two aquatic case studies covering different spatial and temporal resolution to explore how geo-referenced data and spatial tools might be used to account for landscape heterogeneity of chemical exposure and ecological assemblages in prospective risk assessment. Each case study followed a stepwise approach: i) estimate and establish spatial chemical exposure distributions using local environmental information and environmental fate models; ii) derive toxicity thresholds for different taxonomic groups and determine geo-referenced distributions of exposure-toxicity ratios, i.e., potential risk; and iii) overlay risk data with the ecological status of biomonitoring sites to determine if relationships exist. We focus on demonstrating whether the integration of relevant data and potential approaches is feasible rather than making comprehensive and refined risk assessments of specific chemicals. The case studies indicate that geo-referenced predicted environmental concentration estimations can be achieved with available data, models and tools but establishing the distribution of species assemblages is reliant on the availability of a few sources of biomonitoring data and tools. Linking large sets of geo-referenced exposure and biomonitoring data is feasible but assessment of risk will often be limited by the availability of ecotoxicity data. The studies highlight the important influence that choices for aggregating data and for the selection of statistical metrics have on assessing and interpreting risk at different spatial scales and patterns of distribution within the landscape. Finally, we discuss approaches and development needs that could help to address environmental heterogeneity in chemical risk assessment.

4.01.P-Mo264 If The 95th Percentile Risk Quotient of a Substance in Surface Waters in a Country Is Above 1 Is It Always a Country-wide Risk?
***Iain A Wilson**, Adam Peters and Graham Merrington, wca environment, United Kingdom*
When more than 5 % of sites within a country have a risk quotient (RQ) above 1 for a substance in many jurisdictions this is concluded to be a country-wide risk. In the European Union if there are 4 or more countries meeting this criteria it is subsequently concluded that the substance is a continent wide risk. During the evaluation of the criteria there is, typically, no consideration of the location or characteristics of sites that are exceeding the RQ threshold of 1.
The aim of this poster is to highlight that the location of the exceeding sites should also be accounted for when using this metric. Local, or regional, risks may incorrectly be assigned as nationwide risks if the spatial extent is not considered. This could then potentially lead to a substance being concluded as a continental-wide risk when the exceedances are located in specific regions of specific countries. This is of particular importance for natural occurring substances that will be greatly impacted by natural geologic factors.
This poster will use examples where the metric does show that the substance does pose a nation-wide risk due to greater than 5 % of sites having an RQ above 1 as well as examples of where although greater than 5 % of sites are exceedances, they are all (or predominantly) limited to a specific area. Through these examples it can be shown that the 5 % of sites exceeding criteria is not in itself a poor estimate of risk, but that it should not be used in isolation to determine the risk of a substance within a country.

4.01.P-Mo265 Mechanism-based Prioritization of Chemicals using ToxCast™ Database: A Case Study with Priority Existing Chemicals under K-REACH
***Donghyeon Kim**, Jaeseong Jeong and Jinhee Choi, School of Environmental Engineering, University of Seoul, Seoul, Korea*
A new chemical regulation in Korea, the Act on Registration and Evaluation of Chemicals (K-REACH) came into force on January 1, 2015. However, the toxicity data required to register and evaluate the chemicals is insufficient. Use of high-throughput in vitro bioactivity data in setting prioritization of chemicals provide a new feasibility to inform mechanism-based screening. Herein, we conducted a systematic analysis on 510 chemicals, priority existing chemicals regulated under K-REACH, using 949 ToxCast bioassays with intended target genes to identify the potential toxicity mechanism of the chemicals. First, we computed a comprehensive hit-call data matrix contained 298984 chemical-gene integrations. Based on the reactiveness to the chemicals, we selected top 20 bioassays whose intended target genes' families were CYP, oxidoreductase, transporter, nuclear receptor, steroid hormone, GPCR, DNA binding. We also selected top 20 chemicals based on the reactiveness to the bioassays. They are mainly in consumer products including colorant, surfactant, and detergent. Further, using set analyzer tool provided in Comparative Toxicogenomics Database (CTD), we investigated the enriched pathways and diseases of intended target genes active with top 20 chemicals. The enrichment analysis showed these genes may play diverse roles in cell differentiation/development, proliferation, and metabolism and induce various diseases including pathologic processes (MESH:D010335), cardiovascular diseases (MESH:D002318), skin and connective tissue diseases (MESH:D017437), and chemically-induced disorders (MESH:D064419). Our result demonstrates that ToxCast™ bioassay data can be used for mechanism-based chemical categorization. Further study on chemical prioritization using adverse outcome pathway (AOP) by predicting in vitro target gene activity data in ToxCast is in progress.

4.01.P-Mo266 High-Content Screening of Polycyclic Aromatic Hydrocarbons (PAHs) by the Cell Painting Assay: Harnessing Cell Phenotypes for the Risk Assessment of Chemicals
***Andi Alijagic**[1], Oleksandr Kotlyar[2], Nikolai Scherbak[2], Maria Larsson[2] and Magnus Engwall[2], (1)Örebro University, Sweden, (2)School of Science and Technology, Orebro University, Sweden*
Polycyclic aromatic hydrocarbons (PAHs) are widespread across the globe mainly due to long-term anthropogenic sources of pollution. The inherent properties of PAHs such as hydrophobicity, and thermostability have made them highly persistent in the environment. PAHs have been found highly toxic, mutagenic, carcinogenic, and teratogenic to various life forms. Even though hundreds of PAHs exist, risk assessments of PAHs in contaminated environmental samples are usually based on instrumental quantification of a small number of individual PAHs. The next-generation blueprint of toxicology at the U.S. Environmental Protection Agency (EPA), (i.e., USEPA CompTox Blueprint), advocates the use of nontargeted, high-throughput profiling assays for initial characterization of the biological activity of environmental chemicals, including PAHs. Such profiling assays should be capable of being deployed in a high-throughput, concentration-response screening format; and provide high-content data that can be used to identify potency thresholds for perturbation of cellular biology and provide information on putative mechanisms of toxicity. Cell Painting is high-throughput and high-content phenotypic profiling assay that reveals impact of perturbation(s) on eight broadly relevant cell compartments, including nucleus, actin/Golgi/plasma membrane, mitochondria, endoplasmic reticulum, and RNA/nucleoli. In this study, we have exposed human osteosarcoma U-2 OS cells to 20 native, alkylated, oxygenated and OH-PAHs for 24 h using a range of concentrations. Afterwards, cells were fixed, stained following the Cell

Painting protocol and imaged on a high-throughput imaging platform InCell 2200 HTS system (GE Healthcare). Image processing was performed via CellProfiler software (v. 4.2.1; www.cellprofiler.org) using a combination of cell segmentation and defining of cellular compartments. CellProfiler measured ~3.200 morphological features of single cells related to size, granularity, shape, texture, intensity, radial distribution etc. For example, following the exposure we have observed a number of PAH-specific phenotypic profiles, including cytoskeleton alterations, mitochondrial feature changes and micronucleus formation. Employing Cell Painting to study PAHs toxicity, will provide efficient high-throughput *in vitro* methodologies needed to group and prioritize PAHs based on the potency thresholds.

4.01.P-Mo267 Screening the Effects of Coumaphos, an Organophosphate Pesticide on Freshwater Planarian Through Standardized and Reproducible Quantitative Approaches

Lucia Rejo[1]*, Jean-Michel Malgouyres*[2]*, Elsa Bonnafé*[2] *and Caroline Vignet*[2]*, (1)Biology, INU Champollion, University of Albi, France, (2)Centre Universitaire JeanFranÁois Champollion Albi France, France*

Environmental pollution is a worldwide issue. Pesticides are widely used in agriculture and exposure to some can result in adverse effect on the nervous system of animals, especially on non-target organisms. In ecotoxicology, the adoption of the 3Rs rule - reduce, refine, replace - aiming to limit the use of vertebrate animals in scientific research, has precipitated the development of new models using invertebrate organisms for bioassays.

Freshwater planarian, an invertebrate flatworm, have shown to be a promising alternative model to assess chemicals that may end up in aquatic environment. They are worldwide distributed, easy to collect and to maintain in lab. Their small size allows medium to high-throughput *in vivo* screening of toxicity. Planarian can enable the evaluation of toxicity of chemicals on many levels: 1) they are non-target organism; 2) almost all species are endemic to their geographical location; 3) they are good indicators of chemical risk on the aquatic ecosystem; 4) their nervous system share the same neuronal subpopulations and neurotransmitters as the mammalian brain, making them potential screening tools for predicting pollutant toxicity for mammals.

Using a standardized, reproducible quantitative protocol, we assessed the effect of Coumaphos, an organophosphate pesticide on freshwater planarians.

Planarian were screened for mortality over a 24 h period. Effects of sublethal concentrations of Coumaphos were screened through quantitative assessment of multiple behaviour. Endpoints measured includes exploratory behaviour and response to light stress. These tests have shown to be reliable and repeatable for toxicological screening in lab. Coumaphos has never been tested on planarians, nevertheless planarians were more sensitive to Coumaphos than the aquatic arthropod *Artemia salina* with 24h LC_{50} of 2.56µM and 585µM (21.23mg/L), respectively (Sánchez-Fortún et al., 1995). As it has been demonstrated for other aquatic organisms, exposure to increasing concentrations of Coumaphos results in significant impairment of planarian locomotion, but did not impair response to light stimulation. In planarians, locomotion is a mix of muscular contractions controlled by the cholinergic system, and ciliary beating. Thus a conservation of the negative effect of the organophosphate pesticide on planarian's brain could explain the observed locomotion impairment.

4.01.P-Mo268 Determining the Toxicity of Organic Compounds on the Nematode *Caenorhabditis elegans* based on Aqueous Concentrations

Sebastian Hoess[1]*, Roger van Egmond*[2] *and David Sanders*[3]*, (1)Ecossa, Germany, (2)Unilever, United Kingdom, (3)Safety & Environmental Assurance Centre, Unilever, United Kingdom*

Caenorhabditis elegans is used as a test organism for assessing the toxicity of chemicals in aqueous medium. In the test system, however, chemicals can absorb to the bacterial food source, which reduces the freely dissolved concentrations of the tested compounds. This makes it difficult to compare the toxicity to other test organisms when comparing based on total or nominal concentrations. In this study, *C. elegans* was exposed to seven organic chemicals with varying hydrophobicity, thus also different affinities to bind to the food of *C. elegans*. Measured concentrations of the dissolved aqueous and the bacterial-bound fraction, allowed the calculation of binding constants (K_b), that were comparable to literature data of hydrophobic chemicals and correlated well with their hydrophobicity, expressed as log K_{OW}. The chronic toxicity of the various compounds on *C. elegans'* reproduction, based on their aqueous concentration, was weakly related to their log K_{OW}, as not all tested substances could unequivocally be classified as narcotic chemicals. The analysis of toxicity on a chemical activity basis suggested baseline toxicity of most compounds, with some chemicals less inert or even specifically acting when comparing to a *C. elegans* specific baseline toxicity model. Compared to the toxicity for *Daphnia magna*, good correspondence of these two test systems in terms of the toxicity ranking of the seven tested chemicals was found, although *C. elegans* showed to be slightly less susceptible. It could be shown that aqueous concentrations in the nematode test system corresponded very well with freely dissolved concentrations that were modelled using partitioning coefficients for food bacteria K_b, hydrophobicity constants (K_{OW}) or a simple mass-balance model from nominal concentrations. This offers the possibility to estimate freely dissolved concentrations of chemicals from nominal concentrations, making routine testing of chemicals more accurate.

4.01.P-Mo269 Nematode Community of a Natural Grassland Responds Sensitively to the Broad-spectrum Fungicide Mancozeb in Soil Microcosms

Sebastian Hoess[1]*, Johannes Helder*[2]*, Jennifer Asekunowo*[3] *and Nicola Reiff*[1]*, (1)Ecossa, Germany, (2)Laboratory of Nematology, Wageningen University & Research, Netherlands, (3)Eurofins Agroscience Services EAG Laboratories, Germany*

Fungicides make up the largest part of the total pesticide use, with the dithiocarbamate mancozeb being widely applied as a non-systemic contact pesticide to protect a wide range of field crops against fungal diseases. Although nematodes are key drivers of soil functioning, data on effects of fungicides, and especially mancozeb, on these non-target organisms are scarce. Therefore, the effects of mancozeb on a soil nematode community from a natural grassland was assessed in small-scale soil microcosms.

Nematodes were exposed to mancozeb-spiked soil in six nominal concentrations (7 – 133 mg/kg dry soil) and analyzed after 14, 56 and 84 days in terms of densities, genus composition and functional traits. As this fungicide is known to quickly degrade in soils (DT50 < 1 day), mancozeb concentrations were analyzed for all sampling occasions. Chemical analysis revealed considerably lower measured concentrations as compared to the aimed nominal soil concentrations at the begin of the exposure (1 to 18 mg/kg dry soil), suggesting a fast degradation during the spiking process. Nevertheless, the native nematode community responded sensitively to the fungicide mancozeb, revealing lower NOEC and EC10 values than reported for other soil invertebrates such as springtails and earthworms. Using the EC10 for the most sensitive nematode community endpoint (% predators and omnivores: 1.2 mg/kg dry soil), the risk assessment exhibited a toxicity exposure ratio of 0.66 and thus a high risk of mancozeb for soil nematodes. Keeping in mind their abundance and their central roles in soil food web functioning, the demonstrated sensitivity to a widely applied fungicide underscores the relevance of the inclusion of nematodes into routine risk assessment programs for pesticides.

4.01.P-Mo270 All of a Flutter: Heart-rate Effects in Response to Diclofenac in Adult (Female) *Moina macrocopa* Strauss 1820

*Paul Mosnier[1], **Thomas McCloughlin**[2] and Fiona Regan[1], (1)Water Institute, Dublin City University, Ireland, (2)Dublin City University, Ireland*

The European Union has taken steps to highlight pharmaceutical pollution in the aquatic environment. Successive 'watchlists' have targeted an increasingly diverse range of pharmaceuticals found in ground, drinking, influent & effluent waste- waters. One such compound is 'diclofenac' (2-[2-(2,6-dichloroanilino)phenyl]acetic acid; CAS ID: 15307-86-5)(DCF). DCF was listed in European Commission Decision 2015/495 on March 20, 2015 in the water watchlist under the Water Framework Directive (WFD). The WFD is a mechanism for obtaining high-quality European Union-wide monitoring data on potential water pollutants for the purpose of determining the risk they pose and thus whether Environmental Quality Standards (EQS) should be set for them at EU level. According to the EQS Directive (article 8b), this list should be updated every 2 years.

Therefore, rather than detecting the presence of, and recording the levels of DCF in waters, it is incumbent upon researchers in the field to determine specific effects on living organisms. To ascertain in the first instance, a gross metabolic effect as a result of the presence of DCF in water in which organisms live we investigated the relationship between concentrations of DCF and the heart-rate of adult (female) *Moina macrocopa* Strauss 1820. *Macrocopa* is a homologue of *Daphnia* spp., and consists of two sub-species - one prevalent in the Americas, and the other in Eurasia - and the classic heart-rate protocol applies well to this species. The *M. macrocopa* were acutely exposed to environmentally relevant DCF concentrations and were studied using the classical 'heart-rate' protocol as is well known for *Daphnia* spp. as an intended non-lethal method of investigation.

M. macrocopa were observed *in vivo* in cavity slides under short spans under a microscope with a smart-phone attachment. Recordings were taken of the heart-rate and on slowing to an easily observable rate, beats were counted using a hand counter. The chronic effects of the pharmaceutical were then established by observing organ function and we report the effect of DCF on the rate and rhythm of the crustacean 'heart' as a function of overall life processes. This work is part of a larger project examining the acute and chronic effects of a range of aquatic pharmaceuticals on a range of macroinvertebrates.

4.01.P-Mo271 Ecotoxicity of Water-Soluble Synthetic Film

***Norihisa Tatarazako**[1], Yukiyo Okazaki[1], Yusuke Muramatsu[2] and Nobuyoshi Yoshimura[2], (1)Ehime University, Japan, (2)Advanced Polymers, Osaka R &D Center, R&D Transformation Div., Mitsubishi Chemical Corporation, Japan*

Water-soluble synthetic film and polymer (WSSP) are used in industrial, food, household and biomedical fields, but their impact in the aquatic environment and effects to aquatic organisms are still unclear.

To clarify their impact to aquatic environment, two grades of water-soluble films (Hi-Selon™ from Mitsubishi Chemical Corporation) made from polyvinyl alcohol which is one of the typical WSSPs and used as water-soluble packaging of liquid detergent, and 5 kinds of additives in those films were investigated by acute and extended-acute toxicity test using water flea (*D. magna*). And fry of medaka (*O. latipes*) were used in acute toxicity test.

As the result, no acute toxicity was observed with both *D. magna* and *O. latipes* even at a concentration of 1000 mg/L which is 10 times higher than the maximum concentration commonly used in toxicity test. In an additional experiment of acute toxicity test with *D. magna* under 100 times higher concentration, the swimming inhibition was observed. This result is considered probably due to the physical (viscosity/osmotic pressure) effects of the substance.

Although some of the additives showed weak toxic effects on *D. magna*, the amount of the additives contained in the film were less than 1% by weight. Their dissolutions from the film into the environment is expected to be too small, thus their impact is thought to be negligible.

Based on our current understanding, it is thought that water-soluble film Hi-Selon™ is ecologically safe.

4.01.P-Mo273 Ecotoxicity of Hydroquinone on Non-target Soil and Water organisms

*Antonio Valenzuela, Diego Ballestero, Cristina Gan-Oria, Guillermo Lorca, Natalia Ferrando Lázaro, Elisa Langa and **M Rosa Pino**, Universidad San Jorge, Spain*

Hydroquinone (HQ) is a metabolite of benzene that is ubiquitous in the environment due to its use in industrial activities and as a human topical treatment. It is present in many natural sources, such as various plants, and can also be produced by chemical synthesis. Industrially, it can be used as a stabilizer in paints or varnishes, as a colorant and as a developing agent in photography. As a cosmetic formulation, it is used to treat hyperpigmentation, although the safety of exposure is still unclear.

The aim of this study was to determine the ecotoxicological effects of HQ. *Allium cepa* and *Eisenia foetida* were used as biological indicators of terrestrial environments, while *Daphnia magna* and *Vibrio fischeri* were used as indicators of aquatic environments.
A cepa was exposed to 0.03, 0.3, 3, 30, and 300 µg/mL of the compound and the impact on root inhibition was measured after a 72 hours incubation as an endpoint. HQ showed phytotoxic effects with EC_{50} values = 7.631 (6.720-8.676) µg/mL.
Adult individuals of *E. foetida* were placed for 14 days in soil containing 0.2, 2, 20, 200, and 2000 mg/Kg of HQ. After the exposure time, the number of dead worms was measured, resulting in an LC_{50} higher than 140 mg/Kg.
The acute toxicity of HQ in *D. magna* was studied by exposing these aquatic invertebrates to 0.01, 0.1, 0.5, 1 and 2 µg/mL and measuring their mobility after 24 hours, showing a value of EC_{50}=0.142 (0.104-0.204) µg/mL.
V. fischeri was exposed to 0.1, 1, 10, 100 and 1000 µg/mL of HQ and the percentage loss of fluorescence emission was measured resulting in a EC_{50} of 1.446 (1.155-1.796) µg/mL.
HQ has ecotoxicity effects on both aquatic and terrestrial biomarkers, with the invertebrate *D. magna* being particularly sensitive to it. However, from the point of view of environmental relevance, the doses at which HQ exhibits toxicity on these biomarkers are unlikely to be reached in both aquatic and terrestrial environments.

4.01.P-Mo274 Sediment-Water Chironomid Toxicity Test – Experiences Using a Flow-Through Device
***Markus Simon**, Ecotoxicology, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Germany*
For Environmental Risk Assessments in the frame of several legislations, toxicity tests with sediment dwellers have to be conducted. Internationally accepted OECD guidelines exist for *Lumbriculus* (OECD 225) and *Chironomus* (OECD 218/219). All test designs represent sediment-water compartments. Even when the standard test design is static without water renewal, semi-static or flow-through systems are accepted in exceptional cases (e.g., if water quality becomes inappropriate for the chironomids). Such exceptional cases could also be unstable substances, or precipitating metal salts in spiked water test designs. Despite of most other aquatic or sediment dwelling standard test organisms applied in ecotoxicity tests, chironomids show a holometabolous life cycle starting from a larvae living in and on the sediment surface and ending as a midge, emerging from a pupae at the water surface. Test vessels in chronic tests looking for emergence rate, therefore have to be sealed with emergence traps. This, and the circumstance that the chironomids are inserted as first instar larvae into the overlying water makes the application of a flow-through test system challenging. Additionally, food availability – in most cases a fish food suspension applied via overlying water – could be limited depending on the water exchange rate, affecting the survival rate.
The aim was to perform valid 28-day Sediment-Water Chironomid tests according to OECD 218/219 in a flow-through test system. An adapted flow-through test system developed for *Daphnia* Reproduction Tests was used. First results obtained that the test system ensure remaining of all larvae and pupae in the vessels but problems can arise regarding survival rate when frequently applying fish food suspension as food source. Results for test designs applying more frequently fish food suspension or plant material incorporated into the sediment before test start are currently running and tests comparing the influence of static test design versus flow-through test design on effect concentrations are outstanding.

4.01.P-Mo275 Sediment-Water Hyalella Reproduction Test: Challenges Using Plant Material as Food Source
***Markus Simon**, Ecotoxicology, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Germany*
For Environmental Risk Assessments in the frame of several legislations, toxicity tests with sediment dwellers have to be conducted. Some legislations offer the chance to reduce an assessment factor when results for three different species are provided. Internationally accepted guidelines exist for *Lumbriculus* (OECD 225), *Chironomus* (OECD 218/219) and *Hyalella* (ASTM E1706). All test designs represent sediment-water compartments. However, according to the OECD and ASTM guidelines, there are two serious differences regarding the feeding regimes for strongly adsorbing substances.
According to the OECD guidelines, ingestion of contaminated food may be a significant exposure route and therefore, the use of food added to the sediment before application of the test substance may be considered. In such a case, finely ground plant material added to the formulated sediment before test substance application must be used instead of frequently applied fish-food suspension via the overyling water. According to the ASTM E1706 guideline, such a fedding regime is not considered. Independent from the test substance properties, always food suspensions have to be applied frequently via the overlying water. This may be one reasons why the OECD currently develops an own sediment-water Hyalella guideline considering different feeding regimes. An international ring test is announced for 2023 and 2024. However, one problem regarding a change in food source and quality could be a reduced survival rate, growth and maybe a total lack of reproduction within the test duration of six weeks. So far, no guideline, ring test or research project published regarding adverse effects of chemicals on *Hyalella* development and reproduction in a sediment-water test system used plant material as the only food source.
In this project we aim to perform valid modified sediment-water *Hyhallea azteca* reproduction tests following ASTM E1706 in a flow-through test system using finely ground plant material as the only food source. First results obtained that problems can arise regarding i) fungal growth on the sediment surface and ii) surpassing the threshold value for survival rate. Results for effects on reproduction are outstanding and further tests regarding the origin for the problems (composition of artificial sediment, overlying water quality, food source (species used for plant material), temperature, static/flow-through test system) are currently running.

4.01.P-Mo276 Modified Collembola Test for Granular Formulations
***Ricardo Petersen**[1], Tiago Luz[2,3], Rita Tentúgal[3], Márcia Bessa[4], Camila Campello[4], José Paulo Sousa[4] and Stephanie Fritz[5], (1)ERM - Environmental Resources Management, Portugal, (2)Department Life Sciences, University of Coimbra, Centre for Functional Ecology, Portugal, (3)Cloverstrategy, Instituto Pedro Nunes, Portugal, (4)University of Coimbra, Centre for Functional Ecology, Portugal, (5)R&ra, Sumitomo Chemical Agro Europe SAS, France*

Plant protection products (PPPs) are currently an essential part of modern agriculture, providing tools for pest and disease control while improving crop yield. Soil organisms are one of the most diverse and abundant communities in agricultural fields and surrounding areas, being non-target organisms of concern regarding potential exposure to PPPs and its consequences. The risk assessment scheme for PPPs for soil macro- and meso-fauna is currently based on Tier 1 laboratory tests with standard species representative of key organism groups (including the *Folsomia candida* reproduction test) and, when an unacceptable risk is found, higher tier tests must be conducted based on field studies. However, improving realism of exposure conditions in Tier 1 tests may provide additional information possibly making higher tier testing unnecessary in the environmental risk assessment of certain PPPs.
To provide an additional option for laboratory testing under more realistic exposure conditions, a methodology was developed for testing the toxicity of granular formulations to *Folsomia candida*. To better mimic field exposure conditions, the method departs from the standard laboratory test methodology adopted in collembolan reproduction tests by using modified test units measuring 17 cm width x 140 cm length x 15 cm height, and an organism density of 0.33 collembolans/cm^2. The method simulates the field exposure by applying the granules in rows and following application depths mimicking the actual agricultural practice. This strategy allows to evaluate the effect of a granulated pesticide in the density, distribution and reproduction of collembolans in the soil after 28 days of exposure. The developed method and some results on population densities and data of a positive control with boric acid will be presented.
The possibility of manipulating different factors like row width application, inter-row spacing, application depth, population density and different modes of sampling, is one of the advantages the present approach. Furthermore, the possibility of simulating artificial rain or even conducting the entire study under natural conditions may also improve the realism of this approach when compared to laboratory Tier 1 tests. This study design can be easily adapted to not only other Collembola species but also other soil organisms, like earthworms.

4.01.P-Mo277 Malformations in Tadpole Tails, 'Kinked-Tailed'
Klaus Weber[1], *Laura Polledo Ruiz*[1] *and Jeffrey C. Wolf*[2], *(1)AnaPath, Switzerland, (2)EPL, USA*
In studies performed with the African clawed frog (Xenopus laevis), a high percentage of the tadpoles (even controls) may present curved "kinked" tails. This condition is occasionally referred as to scoliosis because of the sideways curvature. But scoliosis is associated with a spine, whereas tadpoles carry a fibrous elastic cord, occasionally with notochord cells in the tail. Basically, the kink tail is related to metamorphosis. Tadpoles do not lose their tails, they absorb them. Kink tails are associated with focal apoptosis or even segmental necrosis. Several traumatic conditions, water temperature, UVB-radiation or genetical background may influence the incidence. The presentation summarizes the facts. Other tail and limb findings are discussed and their pathogenesis in relation to endocrine disorders is shown.

4.01.P-Mo278 Mefenpyr Diethyl- an Emerging Safener and its Co-Herbicide, Fenoxaprop-P-ethyl, How Safe?
Oluwabunmi Femi-Oloye[1] *and John Giesy*[2], *(1)Toxicology Center, Canada, (2)University of Saskatchewan, Canada*
Mefenpyr diethyl, a safener used with active ingredients of Fenoxaprop-P-ethyl herbicide in its formulation and considered inert, has been found in surface water. The potential threats that this safener could cause to non-target aquatic organisms are not yet known, and therefore, the need to study the potential toxicity of these compounds on various endpoints in zebrafish embryos. Acute and chronic studies were conducted on this model organism, with the acute studies targeting mortality and hatchability in zebrafish embryos. The chronic study targeted growth and survival in zebrafish larvae. All methods follow the OECD regulations with slight modification in some instances. Results for MEF alone from the acute studies showed that zebrafish treated with the lower concentrations had no lethal effect, and Zebrafish embryos hatched within the third and fourth day. However, the organisms treated with higher concentrations died in the yolk sac. Results from the mixture of safener and herbicide showed that some percentage of protection was conferred on the organism by MEF against its co-herbicide, FEN, but there were various deformities. These results support the notion that exposure determines toxicity and that the not so studied emerging safeners can cause varying effects from toxicity to lethality and should be monitored and regulated. To understand how these compounds work, we are conducting experiments to understand their mode of action in these organisms, and the results will be presented.

4.01.P-Mo279 Central Composite Rotatable Design Applicability in Ecotoxicological Studies: A Case Study with Aquaculture Drugs and Organic Matter Enrichment Effects on Sea Urchins
Davide Asnicar[1], *Lauren Jonah*[2], *Dounia Hamoutene*[2] *and Benjamin Patrick de Jourdan*[1], *(1)Huntsman Marine Science Centre, Canada, (2)Saint Andrews Biological Station, Fisheries and Oceans Canada, Canada*
In Canada, the salmon aquaculture industry is a major economic activity. For fish health control and management, the use of ten drugs and two pesticides in 75% of the facilities between 2016 and 2018 has been reported by science advice documents of Fisheries and Oceans Canada. In-feed products like Emamectin benzoate (EMB), and Oxytetracycline (OTC) enter the marine environment accumulating in sediments, potentially remaining bioavailable to non-target organisms from months to years. Organic matter (OM) content in sediment may affect compounds' toxicity, bioavailability, and degradation. For example, the degradation product of EMB (Desmethyl-EMB) has been detected in aquaculture sites, with one study reporting more toxicity than the parent compound. Despite the regular usage of chemicals in Canadian aquaculture, there are still knowledge gaps regarding environmental fate and effects of mixtures of contaminants on non-target organisms.
In this study, we applied a Central Composite Rotatable Design (CCRD), in long-term exposure of the adult green sea urchin (*Strongylocentrotus droebachiensis*). This species was selected as it plays key ecological and economical roles in coastal ecosystems, is a sensitive organism, and is widely used in ecotoxicological studies.

The sediment concentration ranges of EMB and OTC used in the study were selected based on measurements from more than 400 stations surrounding aquaculture sites across Canada. OM content varies greatly across sites as a result of fish waste and natural geographic conditions. For the CCRD we employed five levels of the three factors: combining environmentally relevant scenarios of EMB (from 0 to 34 ng/g), OTC (0-340 ng/g), and OM (0-10%), for a total of 36 experimental units. The most environmentally common conditions were addressed and included in the design.
We assessed the effect of contaminant mixtures on adult sea urchins' behavior, immunology, physiology, and reproduction, as well as tracked the formation and fate of Desmethyl-EMB under different OTC and OM% conditions.
The data generated in this project will provide an understanding of hazards posed by environmentally relevant concentrations of these compounds and will serve to document potential synergistic/antagonistic effects when establishing environmental quality standards or monitoring thresholds.

4.01.P-Mo280 Proposal for Critical Appraisal Tools for the Evaluation of Ecotoxicology Studies
__Joost Lahr__[1], Gertie Arts[2], Sabine Duquesne[3], Vanessa Mazerolles[4], Caroline Moermond[5], Frank de Jong[5], Jozef van der Steen[6], Urwa Alalouni[3], Elise Baujard[4], Sanne van den Berg[7], Bas Buddendorf[8], Melvin Faber[5], Karin Mahieu[5], Mark Montforts[5], Els Smit[5], Klaus Swarowsky[3], Pierre-François Chaton[9], Jérémy Foldrin[4], Sébastien Lambin[4] and Silvia Pieper[3], (1)Environmental Quality, National Institute for Public Health and the Environment (RIVM), Netherlands, (2)Environmental Risk Assessment, Wageningen University & Research, Netherlands, (3)German Environment Agency (UBA), Germany, (4)French Agency for Food, Environment and Occupational Health & Safety (ANSES), France, (5)National Institute for Public Health and the Environment (RIVM), Netherlands, (6)AlveusAB, Netherlands, (7)Wageningen University & Research, Netherlands, (8)Environmental Risk Assessment, Wageningen Environmental Research (WUR), Netherlands, (9)European Food Safety Authority (EFSA), Italy
According to the European Regulation (EC) No 1107/2009, pesticide active substances to be approved shall not pose unacceptable effects for human health, animal health and the environment. For this purpose, applicants must submit a dossier, containing a data package including ecotoxicity studies in line with the EU data requirements. The evaluation of such studies, particularly when a standard test guideline is not available, may be challenging and result in inconsistent outcomes.
The scope of the work was to develop Critical Appraisal Tools (CATs) to support the evaluation of the following seven types of non-standard higher tier ecotoxicity studies submitted with these dossiers. Aquatic organisms: Modified exposure studies (tier 2), Mesocosm studies (tier 3). Bees: Honeybee brood test (feeding and tent test version). Non-target arthropods other than bees: Extended laboratory studies, Aged residue studies, Field studies. Residue decline studies and related kinetics (currently relevant for birds and mammals risk assessment): Field studies.
CATs provide a structured and transparent approach to assess the internal and external validity (i.e., reliability and relevance) of individual studies. The work included a systematic literature review of existing CATs and study evaluation methods in ecotoxicology and environmental risk assessment. Based on this review, it was decided to base the CATs to be developed on the CRED approach (Criteria for Reporting and Evaluating Ecotoxicity Data) for evaluating reliability and relevance of studies.
The CATs consist of MS-Excel spreadsheets with criteria and scoring tables, accompanied by handbooks with detailed instructions for appraising the individual criteria. A method for evaluating the overall validity of these ecotoxicity studies, based on both a (semi-) quantitative scoring system and expert judgement, is also proposed.
The adoption of common appraisal tools will enhance the harmonisation and transparency of the study evaluations performed by the experts in the area of ecotoxicology and it is expected that it will increase the trust of the scientific assessments conducted by National competent authorities of member states of the European Union and the European Food Safety Authority (EFSA).

4.01.P-Mo281 The Importance of Confidence Limits for Ecotoxicological Endpoints
Zoe Leanne Parker-Crosse[1], Ellie Welch[2], Marie Brown[1], Katie Smith[1] and __Nadine S Taylor__[1], (1)Cambridge Environmental Assessments (CEA), United Kingdom, (2)Aquatic Ecotoxicology, Cambridge Environmental Assessments (CEA), United Kingdom
In Europe, Tier I ecotoxicity tests using standard species are a regulatory risk assessment requirement for all chemicals prior to commercial use. The most common statistical endpoints used in acute and chronic ecotoxicological studies are Effect Concentration (EC_x) values. These describe the concentration at which 'x' percent of the test organisms are affected, for any given parameter. For example, an EC_{50} value for mortality would be the calculated concentration where 50% of all test organisms had died.
In recent years, there has been a requirement for the provision of both EC_{10} and EC_{20} values in addition to the traditional EC_{50} values. Therefore, older study data is routinely re-analysed to generate these values to be submitted to the regulatory authorities for current environmental risk assessments.
These re-analyses should also include an assessment of the reliability of each endpoint. This is usually carried out by investigating the corresponding confidence limits. Although confidence limits are a key indicator of the reliability of the data, they can sometimes be overlooked, or their importance misunderstood.
We provide an overview on the current guidance for calculating EC_x values, and their confidence limits, to provide an insight on how confidence limits can be used to identify a reliable EC_x endpoint. We will also highlight the standard species accepted endpoints detailed in the OECD test guidelines.

4.01.P-Mo282 The Species Sensitivity Distribution Approach as a Tool for Deriving Safe Threshold Values for Data-Rich Endocrine-Active Substances in the Regulatory Practice: Case Study on Bisphenol A
__Michael Bunge__[1], Margaret E. McArdle[2], Ellen M. Mihaich[3] and Patrick Van Sprang[4], (1)Covestro, Germany, (2)Exponent, (3)ER2, USA, (4)ARCHE Consulting, Belgium

Toxicological thresholds exist for endocrine-active chemicals that are consistent with the fundamentals of ligand-receptor interaction, such as affinity, efficacy, potency, and mass action. For Bisphenol A (BPA), safe thresholds have been derived from species-specific toxicity data representing phylogenetically diverse organisms that cover all trophic levels; the available aquatic toxicity data for BPA allow for the calculation of effects concentrations that are based on exposure-response relationships. We used Species Sensitivity Distribution (SSD) approaches to derive Predicted No Effect Concentrations (PNECs) for BPA using a chronic freshwater toxicity dataset including ED-relevant endpoints that met well-defined criteria for data relevance, reliability and adequacy (*e.g.*, Klimisch scores of 1 or 2). Where appropriate, EC_{10} instead of no observed effect concentration (NOEC) values were used as recommended by OECD (2006) and ECHA (2008). We developed both non-parametric and parametric SSDs by fitting the chronic toxicity data to different distributions using regulatory accepted tools, such as the ETx-, MosaicSSD- and the SSDTool-software, and a fitting tool designed by ARCHE. When minimizing the statistical uncertainties around the 5th percentile estimate ($HC_{5\text{-}50\%}$) and considering the goodness-of-fit statistics as recommended by ECHA guidelines, the Weibull distribution was the best fitting distribution for the chronic freshwater toxicity dataset and resulted in an $HC_{5\text{-}50\%}$ of 46.8 μg BPA/L. The normal distribution from the more commonly used ETx tool also provided a well-fit SSD with an $HC_{5\text{-}50\%}$ of 45.2 μg BPA/L. Comparing these $HC_{5\text{-}50\%}$ values with the individual NOEC/EC_{10} values from our robust toxicity dataset of 18 species from 15 taxonomic groups results in only one NOEC (25 μg BPA/L) from a study with the mollusk *Marisa cornuarietis* that is below the $HC_{5\text{-}50\%}$ values. However, applying an assessment factor (AF) of 2, which is recommended based on the available information to derive the aquatic PNEC, results in a freshwater PNEC for BPA of 23.4 μg/L using the Weibull distribution or 22.6 μg/L using the ETx tool. Therefore, these PNECs are protective for all species included in this robust chronic freshwater dataset. Our approach demonstrates that statistical extrapolations like SSDs can be used as a tool in the regulatory practice for deriving safe threshold values for data-rich, potentially endocrine-active substances.

4.01.P-Mo283 Assessing Acute Ecological Risks of Selenium to Freshwater Organisms by Species Sensitivity Distributions
Chi-Ying Hsieh[1] *and Guang-Ya Wu*[2]*, (1)National Pingtung University of Science and Technology, Taiwan, (2)Department of Environmental Science and Engineering, National Pingtung University of Science and Technology, Taiwan*
Selenium (Se) pollution is a worldwide phenomenon and is associated with a broad spectrum of human activities, ranging from agriculture to high technology industry processes. The growing interest in selenium toxicity is attributed to the thin line between nutritional value and toxic concentrations. Taiwan's selenium effluent criterion concentration is set at 0.5 mg/L, but this value is higher than the most recommended threshold water quality criterion for the protection of aquatic life of 5 µg/L from conferences. Furthermore, Se emissions are unavoidable in industrialized Taiwan, therefore, we are very interested in protecting the narrow threshold of Taiwan's aquatic environment. In this study, based on species sensitivity distributions (SSD) calculated the acute concentration (HC_5) to 5% of species from exposure to selenium. The aquatic species used by SSD are mainly the toxicity test species announced by Taiwan, including algae, invertebrates and vertebrates. The results of this study are helpful in obtaining the PNEC (prediction of no-effect concentrations) and HC_5 values of selenium in the water environment, which are rarely discussed but are very important for understanding the environmental management limits of pollutants. The sensitivity of the biota exposed to selenium is, from low to high: *Pseudorasbora parva* > *Cyprinus carpio* > *Chlorella vulgaris* > *Chironomus riparius* > *Neocaridina denticulata* > *Pseudokirchneriella subcapitata* > *Daphnia magna* > *Hyalella azteca*, showing that vertebrates and algae are less affected. In this study, the HC_5 of selenium was 0.311 mg/L and the PNEC value was 0.0622 mg/L. In comparison to the HC_5 of selenium was decreased to 0.114 mg/L and the PNEC value was 0.0228 mg/L. The number of species and the composition of the species greatly influenced the estimation of HC_5. Ecological risk assessment usually uses the risk quotient (RQ) method, which is the ratio of a predicted environmental concentration (PEC) to a non-effect concentration PNEC, so the larger the PNEC value, the lower the risk. Our research revealed that the risk quotients calculated using laboratory exposure for Se were 0.0305-0.0864, respectively, indicating very low ecological risks. not selected from the database. We believed that the description of local ecological risks is more appropriate than that revealed in database.

4.01.P-Mo284 Development of a chronic OTNE Species Sensitivity Distribution
Aurelia Lapczynski[1]*, Jared Bozich*[2] *and Kristin A Connors*[3]*, (1)Research Institute for Fragrance Materials, USA, (2)International Flavors and Fragrances, (3)Procter & Gamble*
Octahydro-tetramethyl-naphthalenyl-ethanone (OTNE) is high volume fragrance ingredient found in cleaning and personal care products, among other applications. A chronic Species Sensitivity Distribution (SSD) was generated to reduce the uncertainty in the OTNE hazard assessment. Species were selected to adhere to SSD criterion for taxonomic diversity. A total of 11 chronic ecotoxicity studies were completed including 3 species of algae (including green, blue-green, and diatom species), 1 aquatic macrophyte, 5 invertebrates (including an amphipod and insect), and 2 fish. The OTNE chronic data were fitted to a log-logistical function from which the HC_5 ($SSD_{0.05}$) and 95% confidence intervals were calculated. The quality of the dataset and the sensitivity and stability of the SSD were validated using recommended criteria and conventional statistical procedures. These included "leave-one-out" and "add-one-in" statistical simulations using hypothetical data. These evaluations demonstrated that the chronic toxicity data were highly ordered, and strongly adhered to statistical assumptions.

4.01.P-Mo285 Towards the Development of Fragrance Specific Ecological Threshold of Toxicological Concern (ecoTTC)
Aurelia Lapczynski[1]*, Jared Bozich*[2] *and Kristin A Connors*[3]*, (1)Research Institute for Fragrance Materials, USA, (2)International Flavors and Fragrances, (3)Procter & Gamble*
Threshold for Toxicological Concern, or TTC, is a well-established and regulatory accepted concept in human safety to rapidly screen and assess data poor compounds and mixtures. TTCs are used to establish a de minimis exposure concentration, below which negligible risk is expected. The use of TTCs has been accepted in regulatory safety frameworks for human safety endpoints

and is leveraged by RIFM (Research Institute for Fragrance Materials) to screen fragrance materials in human health safety assessments (e.g., skin endpoints). Efforts are underway to develop an analogous ecological TTC (ecoTTC) approach using distributions of Predicted No Effect Concentration (PNEC) values. The objective of this project is to examine the applicability of the ecoTTC approach for fragrance specific materials. The EnviroTox database was specifically built to support the development and creation of ecoTTCs. This database contains over 4200+ chemicals and over 80,000 aquatic toxicity results. All information was collected from publicly available sources and has not been independently verified for quality. The RIFM proprietary environmental hazard database was explored to further augment the chemical domain of EnviroTox for chemical domains relevant for fragrance ingredients. A fragrance ingredient database was constructed using the robust, high quality ecotoxicity data from the proprietary RIFM database. Unlike the EnviroTox database, all experimental results from the RIFM database were manually reviewed and curated. Studies were assessed for accuracy, data quality, and validity of test methodology. After manual review, 421 acute invert, algae, and fish studies were identified and 48 chronic invert, and fish studies were identified as relevant for ecoTTC development. In effort to create tailored fragrance specific ecoTTC, chemical-class and/or mode of action-specific ecoTTCs will be explored. It is anticipated that the fragrance-specific ecoTTC will update RIFM environmental risk assessment framework to minimize unnecessary animal testing without compromising safety.

4.01.P-Mo286 Data-driven Decision Making Using Advanced High-throughput Environmental Risk Assessment of Fragrance Materials

Aurelia Lapczynski[1]*, Heather Summers*[2] *and Christopher Stevens*[2]*, (1)Research Institute for Fragrance Materials, USA, (2)Integral Consulting*

For the last 20 years, the Research Institute for Fragrance Materials (RIFM) has conducted environmental risk screening and assessments to evaluate the environmental safety of more than 3,000 fragrance materials manufactured and used by its members. Though the RIFM Environmental Framework (Salvito et al. 2002. Environ. Toxicol. Chem., 21: 1301-1308) is an effective tool, in light of rapid growth in global use of fragrance materials, RIFM has updated the framework to expand its geographic scope and to incorporate recent advances in environmental exposure science and ecological hazard characterization. In this presentation we describe the updated Framework, detailing its expanded geographies, real-time access to the most current population and hydrological data, estimated environmental exposure using waste water treatment plant simulation models and biodegradation, material categorization based on mode of action (MoA), application of an MoA-based ecological threshold of concern, and streamlined execution. The tool’s methods and outcomes are illustrated through a proof-of-concept exercise. The updated Framework is an enhanced risk assessment tool that enables RIFM and users and suppliers of fragrance materials to perform timely assessments of thousands of fragrance materials to maintain a high degree of environmental protection and support science-based decisions related to product formulations.

4.01.P-Mo287 Risk Assessment of Organic Micropollutant Mixtures based on 5-Year Monitoring Data of Public Wastewater Treatment Plants in Flanders, Belgium

Warich Leekitratanapisan *and Karel De Schamphelaere, Ghent University, GhEnToxLab, Belgium*

Organic micropollutants (OMPs) are widespread in surface water, which raises concerns about potential risks to aquatic wildlife. One of the main sources of OMPs is effluents of public wastewater treatment plants (WWTPs). In Flanders, Belgium, most of the public WWTPs operate using primary and secondary treatment, which can hardly degrade many of these OMPs. Environmental risk assessment (ERA) is an approach to identify and prioritize problematic OMPs and WWTPs to improve water quality management. In this study, we received a 5-year monitoring database of OMPs from the Flemish Environment Agency (VMM) from 2017-2021, which provides information on measured environmental concentrations. The approaches for ERA included PNEC-based regulatory risk quotients (RQ-PNEC) and toxic units (TUs) for three biological quality elements (BQEs), which are algae (TUalg), crustaceans (TUcrust) and fish (TUfish). 104 OMPs have been detected in concentrations ranging from 4.9 ng/L to 360 µg/L. Based on the RQ-PNEC approach, the predicted environmental risks were mainly driven by the anti-inflammatory drug diclofenac, the anticonvulsant carbamazepine, the herbicide diflufenican, and the X-ray contrast agent iopromide. Herbicides (diuron, terbutylazine, metolachlor) dominate mixture toxicity to algae, whereastoxicity to crustaceans mainly originated from contributions of diclofenac and terbutylazine. For fish, the highest TUs are exhibited by the fungicide carbendazim. Pharmaceuticals and pesticides are two major groups of OMPs in these WWTP effluents posing an environmental risk to aquatic organisms. 94%, 53%, 83%, and 11% WWTP effluents were at high risk of mixture effects with the summation of RQs-PNEC, TUalg, TUcrust, and TUfish exceeding 10, respectively. Additionally, the sum of RQs and TUs of three BQEs appeared to remain constant in the majority of the WWTPs during the most recent 5 years of monitoring. Our calculations suggest that Flanders’public WWTPs need tertiary treatment steps to remove OMPs. Ozonation could be one technology to be implemented to reduce residual toxicity and risks posed by WWTP effluent.

4.01.P-Mo288 Evaluation of the Water Quality of the Cachoeira River, Sc, Brazil

Carlos H.L. Soares[1]*, Ivana Eunice Baptista*[2] *and Grasiane Andrietti*[2]*, (1)Biochemistry, Universidade Federal de Santa Catarina, Brazil, (2)Biochemistry, Federal University of Santa Catarina, Brazil*

The Cachoeira River is the main water resource that crosses a central area of Joinville. In addition to its historical importance in the colonization of the city, this watercourse is responsible for diluting and transporting all kinds of waste. About 50% of the municipality's population resides and, at the same time, promotes your activities at the Cachoeira watershed. Joinville, is characterized by being the main industrial hub in the state, leading the GDP of Santa Catarina. Among the main activities are the textile, metal-mechanical, machinery and equipment, electrical material, auto parts, plastic and furniture industries. The history of surface water degradation at the Cachoeira by industrial and domestic effluents, gives conditions of low quality to this basin. The objective of this research was to characterize chronic and acute ecotoxicity, using bioindicators such as *Daphnia magna*, *Danio rerio*, *Desmodesmus subspicatus*, physical chemical analysis, quantification of heavy metals and arsenic in the Cachoeira's river. The results obtained indicate that there is a high load of organic contamination by domestic effluents, as well as the introduction of heavy metals, pharmaceutical drugs, illicit drugs and metabolites in the water of the Cachoeira River. The results of the ecotoxicological evaluation showed lethal toxic effects for *Danio rerio*, with the coagulation of eggs, for *Daphnia magna* with the reduction of neonates and decreased longevity, and for *Desmodesmus subspicatus* it was found a tendency to reduce the growth of algae in relation to the control. Therefore, the Cachoeira river does not meet the criteria considered by the current legislation, in several points and parameters.

4.01.P-Mo289 Site-Specific Soil Ecological Risk Assessment on Metal Contaminated Site Based on TRIAD Approach
***Dokyung Kim**, Tae-Yang Lee, Haemi Kim, Sun-Hwa Nam, Jin Il Kwak, Lia Kim, Sang A Kim, An Sanghee and Youn-Joo An, Konkuk University, Korea*
A TRIAD approach was officially released by International Standard Organization in 2017 as a tool for site-specific soil ecological risk assessment (SERA). The TRIAD approach quantifies the ecological risk of complex contaminants in contaminated site by considering ecotoxicological and ecological factors along with chemical factors. Finally, based on the three line-of-evidences (LoEs), the integrated risk (IR) is calculated as a number between 0 and 1. This study tried to apply the TRIAD approach to metal contaminated site in Korea by estimating the chemical-LoE (Chem-LoE), ecotoxicological-LoE (etox-LoE), and ecological-LoE (eco-LoE). The IR for five cells in site including the reference cell (R) was calculated. The IR of each cell was identified as 0.701, 0.758, 0.840, and 0.429, respectively, confirming a worrisome risk in more than three cells. Among various items used in this study, the extractable concentrations, collembola bioassay, and vegetation survey were found as the best represent item the IR value in each LoE. This study evaluated the applicability of the TRIAD approach via various bioassays and presented reasonable items. Our results can be helpful to select cost-effective bioassay in site-specific SERA based on TRIAD approach.

4.01.P-Mo290 Approach for Environmental Hazard Assessment through Zebrafish Cell Line and Biomaterials
*Indong Jun[1], Juyong Yoon[2] and **Chang Seon Ryu**[2], (1)KIST Europe Forschungsgesellschaft, Germany, (2)KIST Europe, Germany*
Numerous methods are being introduced for three-dimensional (3D) cell culture to reduce unnecessary animal experiments. In this study, we present the unique 3D culture platform that featured bioinspired fragments of electrospun nanofibers and aquatic cell lines to compensate for the shortcoming of the current cell spheroid generation technique. Here, it is shown how bioinspired fragments of electrospun nanofibers in 3D zebrafish liver cell culture promote improved functions related to liver and reproduction through spheroid-based in vitro assays, such as whole transcriptome sequencing and reproductive toxicity testing. In addition, it has been demonstrated that the optimized properties of the bioinspired fragments of electrospun nanofiber used in 3D spheroid culture exhibit reproductive toxicity results similar to those of Fish Embryo Acute Toxicity (FET, OECD TG 236) for environmental endocrine-disrupting chemicals exposures (17β-Estradiol (E2), 4-hydroxytamoxifen (4-HT), and bisphenol compounds (BPA and BPFL)). As a closer analog of in vivo conditions responded during exposure to potentially hazardous chemicals, the straightforward culture model introduced in this study shows promise as an alternative tool that can be used to further our understanding of the eco-environmental assessment model. More importantly, this finding can support ongoing development and refinement of the in vitro 3D culture system to accomplish the 3Rs principles (Replacement, Reduction, and Refinement) for alternatives to animal testing.

4.01.P-Mo291 Burden of Disease Assessment for Non-ferrous Metal Industry Air Emissions at a Local Scale
***Joonas Koivisto**[1], Lorenzo Marotti[2], Violaine Verougstraete[2] and Patrick Van Sprang[1], (1)ARCHE Consulting, Belgium, (2)Eurometaux, Belgium*
A source/sector specific health impact assessment allows to identify cost-efficient mitigation methods to reduce the air pollution health burden. The source/sector health loss can be quantified by using the Burden of Disease (BoD) concept. The BoD assessment is performed by calculating Disability Adjusted Life Years (DALYs), which combines years of life lost due to premature mortality (YLLs) and years of healthy life lost due to disability (YLDs). BoD assessment is used to estimate the benefits of target emission objectives compared to the currently prevailing situation [1,2]. However, the European Commission revision proposal of the ambient air quality directives lacks examining the relation between emission source/sector and health impact. In this study, the BoD concept was applied to quantify health impacts of the non-ferrous metal (NFM) industry air emissions.
The NFM factory emissions were collected for years 2019 and 2020 from the European Pollutant Release and Transfer Register. An aggregated emission evaluation was performed by using emission weighted stack properties. Gaussian plume dispersion modelling was performed for an area of 1,600 km^2 [3]. The population was set at 800,000 (500 persons/km^2). Exposure response functions considered: Particulate Matter (PM), SO_2, NO_X, CO, Ni, Co, Sb, Cr, Cd, As, and Pb, C_6H_6, BaP, dioxins, naphthalene, PCBs, tetrachloroethylene, trichloroethylene and dichloromethane.
Cumulative emissions accounted to 0.51 Mt and 0.55 Mt for the years 2019 and 2020, respectively. The emissions consisted of 90% CO, 6.8% NO_X, 2.1% SO_X, 1.1% non-methane volatile organic compounds and 0.5% other pollutants. The calculated average annual ground level concentration was 72.2 μg/m^3 at the model area. Calculated DALYs were 1,430 and 1,446 DALYs for years 2019 and 2020, respectively. 96% of the overall DALY burden was covered by NO_X, $PM_{2.5}$, and $PM_{2.5\text{-}10}$. Metals contribution to DALYs was below 0.015% in total. The NFM-industry disease burden including YLD and YLL is 0.04% of YLLs by $PM_{2.5}$ pollution in EU-27 in 2019 (4,097,900 YLLs as estimated by the European Environmental Agency [EEA]).

This study shows that the NFM-industry potential to reduce air pollution human health effects is limited compared to other emission categories. A similar impact assessment should be performed for the key emission categories as specified by EEA to identify cost-efficient mitigation methods and to provide evidence for impactful regulatory decision making.

4.01.P-Mo292 Formation of Disinfection By-products (DBPs) in Laboratory Disinfection Simulations Under Different Experimental Conditions

***Michael Huben**[1], Muhammad Usman[2], Volker Linnemann[3] and Stefan Hahn[4], (1)Ecological Chemistry, Fraunhofer IME - Institute for Molecular Biology and Applied Ecology, Germany, (2)Institute of Environmental Engineering, Germany, (3)Institute of Environmental Engineering, RWTH Aachen University, Germany, (4)Fraunhofer ITEM - Institute for Toxicology and Experimental Medicine, Germany*

Disinfectants are widely used biocidal products with broad scopes of applications including such different fields as (drinking) water, health care, food processing or construction industry. Among the active ingredients used, highly reactive substances like chlorine, peroxides or ozone are common. During their application, numerous disinfection by-products (DBPs) are formed, especially if organic matter is present. The intended use determines possible releases of the formed DBPs into the environment. The authorisation of biocidal products is regulated by the EU Biocides Regulation 528/2012 which also requires the assessment of possible DBPs. The existing “Guidance on Disinfection By-Products” is limited to halogen-containing biocidal active substances and selected product types and includes only general scientific strategies for the risk assessment of DBPs. On this basis a harmonized environmental risk assessment (ERA) of biocidal products and their DBPs within the EU is questionable.

To fill this regulatory gap and develop a feasible regulatory toolkit, the German Environment Agency (Umweltbundesamt, UBA) launched a research project for the consideration of DBPs within the environmental risk assessment of biocidal products (FKZ 3718 65 403 0).

An important part of the project were laboratory simulations of disinfection applications including the analysis for a selection of approx. 60 DBPs. The disinfection simulations were performed using two matrix compositions one focusing on disinfection uses in swimming pools and one containing organic matter that can be generally expected for disinfection uses across the regarded product types (PTs) 1-5, 11 and 12. Simulations were performed for uses in aqueous solutions and on hard surfaces. An elaborate dataset was generated by application of four different biocidal active substances (a.s.) and the variation of different experimental parameters. Significant differences with respect to DBP formation were observed not only for the different biocidal a.s. but also for the two different matrices and the uses in solution and on surface. Key results of the laboratory simulations which give some implications for simulations testing within the ERA of DBPs, will be presented.

4.01.P-Mo293 Development of Simultaneous Determination Method for Urinary Metabolites of 10 Volatile Organic Compounds and Pyrethroid Insecticide

***Sunhey Jung**[1], Na-Youn Park[1] and Younglim Kho[2], (1)Eulji University, Korea, (2)Health, Environment & Safety, Eulji University, Korea*

Volatile organic compounds (VOCs) are liquid and gaseous organic compounds with low boiling points that easily evaporate into the atmosphere, and are mainly used in food packaging, paint, and chemical synthesis, and are easily exposed to the indoor or ambient environment. Pyrethroid insecticides are made by artificial synthesis and account for most of the insecticides used in households. These chemicals are metabolized in the body and excreted through urine and simultaneous determination method has not yet been studied. This study aimed to establish a simultaneous analysis method for 11 metabolites of VOCs and pyrethroid insecticides in human urine.

The target compounds were 10 metabolites (2-methyl hippuric acid, 3 and 4-methyl hippuric acid, mandelic acid, phenylglyoxylic acid, trans, trans-muconic acid, N-acetyl-S-(benzyl)-L-cysteine, N-acetyl-S-(3,4-dihydroxybutyl)-L-cysteine, N-acetyl-S-(2-carbamoylethyl)-L-cysteine, N-acetyl-S-(N-methylcarbamoyl)-L-cysteine) for VOCs and 3-phenoxybenzoic acid for pyrethroid insecticides. Solid phase extraction (SPE) with a cartridge (HLB 96-Well Plate, 30 µm/30mg, Oasis) was used for urine sample preparation. Targeted compounds were separated on a C18 column (ACME, 2.1x100mm, 1.9µm) with mobile phase A (0.1% acetic acid in water) and B (0.1% acetic acid in acetonitrile). Instrumental anlaysis was performed by UPLC-MS/MS.

As a results method validation, the accuracies of the established analysis method were range from 82.3 to115.7%, the precisions were less than 20%, and coefficient of determination(r^2) was over 0.995 for all 11 types, showing good linearity, which is judged to be suitable for the analysis of metabolites of VOCs and pyrethroid pesticides in urine simultaneously.

4.01.P-Mo294 Urinary Concentration of Phthalates and Alternative Plasticizer Metabolites in 799 Korean People

*Na-Youn Park[1], **JinYeong Heo**[1], Kyungho Choi[2], Younglim Kho[3], Sunhey Jung[1] and Ji-Soo Lee[1], (1)Eulji University, Korea, (2)School of Public Health, Seoul National University of Science and Technology, Korea, (3)Health, Environment & Safety, Eulji University, Korea*

Phthalates are commonly used as plasticizers in various industries because of their excellent properties of softening plastics. Phthalate has been reported to cause endocrine disorders. Therefore, alternative plasticizers with chemical structures similar to phthalates have been developed and used. However, alternative plasticizers have also been reported to cause endocrine disorders. The purpose of this study was to measure the exposure in human samples to various plasticizers, including several alternative plasticizers for which human exposure assessments have rarely been conducted.

We extracted 799 urine samples among standard human urine samples collected by the Ministry of Food and Drug Safety in Korea in 2016. The selected urine samples were prepared by solid phase extraction, and 38 metabolites of phthalates and alternative plasticizers were analyzed using liquid chromatography-tandem mass spectrometry (TQ 5500+, AB SCIEX).

As a result, 20 compounds showed a detection rate over 70% among 38 target compounds (11 metabolites of phthalates and 9 metabolites of alternative plasticizers). Excluding compounds with a detection rate of less than 70%, the geometric mean (GM) ranged from 0.11 ng/ml for OH-MINCH to 21.70 ng/ml for MnBP. When the samples were classified by sex, most of the GM concentrations of metabolites of plasticizers showed higher in male's urine samples (*n*=411) than in female's urine (*n*=388) except MEP, cx-MEPA and 5cx-MEPTP.

Differences in urine concentrations of phthalates and alternative plasticizers by gender are likely due to differences in lifestyle and behavioral factors. We found that the urinary concentrations of metabolites of plasticizers are higher in children than that of adults, and which was consistent with previous studies. In this study, various plasticizer metabolites were measured in urine. This is the first study to analyze various alternative plasticizers in human samples representing Koreans. Among alternative plasticizers, many metabolites such as DEHTP, DEHA and DINCH were detected.

4.01.P-Mo295 Spatial Temporal Analysis and Risk Assessment of Organic Micropollutants in Western Kenya

ISAAC Cheruiyot Tanui[1]*, Faith Kandie*[1]*, Werner Brack*[2]*, Martin Krauss*[3] *and Ambrose Kiprop*[4]*, (1)Helmholtz Center for Environmental Research (UFZ), Germany, (2)Department of Effect Directed Analysis, Helmholtz Center for Environmental Research (UFZ), Germany, (3)Department of Effect-Directed Analysis, Helmholtz Center for Environmental Research (UFZ), Germany, (4)Moi University, Kenya*

More than three hundred and fifty thousand (350,000) of chemicals are in daily use for improving the quality of life. However, their occurrence as individual chemical or as a cocktail of chemical mixtures in the environment causes pollution and detrimental effects to organisms. Such kind of chemicals include the often-used organic micropollutants like the pharmaceuticals, pesticides, endocrine disrupting compounds (EDCs), non-prescriptive drugs, personal care products, hormones, steroids, disinfection by-products, and flame retardants among others. Their co-occurrence can result in additive, antagonistic, or synergistic ecotoxicological effects. Their toxicity towards organisms is a function of time, exposure concentration, toxicodynamic and toxicokinetic processes. In this study, we conducted a spatial-temporal analysis and risk assessment of organic micropollutants in twenty-five sites within five rivers located in different regions of western Kenya, where we identified and prioritized compounds based on risk assessment approaches (Toxic unit, Hazard Unit and RQ) on standard test organisms (Fish, Crustacea and algae). Our study was conducted for one year and covered four seasons which are experienced in Kenya, (Two rainy and two dry seasons). The two rainy seasons are experienced between March to May and also between October and November while dry seasons are between June and September and December to February. Our results provide for the first time a broader overview on the contamination of water bodies in western Kenya with mixtures of organic contaminants of emerging concern. The results also play a critical role on a bigger project on the linkage between water contamination and the abundance of host snails of the tropical disease schistosomiasis via toxic effects on competitors and predators supporting the insensitive snail.

4.01.V Advances in Environmental Risk Assessment of Chemicals

4.01.V-01 Are Existing Bioconcentration Models for Earthworms Able to Account for Inter-Species Differences in Pesticide Uptake from Soil?

Jun Li[1]*, Mark Hodson*[2]*, Colin Brown*[2] *and Roman Ashauer*[3]*, (1)Department of Environment and Geography, University of York, United Kingdom, (2)University of York, United Kingdom, (3)Syngenta Crop Protection, Switzerland*

Earthworms are important ecosystem engineers and as such are commonly included in risk assessment of pesticides in terrestrial environments (SANCO, 2002) and of secondary poisoning via the terrestrial food chain (TGD, 2003). If lower-tier risk assessments indicate potential for effects of pesticides on earthworms, field trials are required to assess impacts more realistically. Modelling approaches that predict internal concentrations of compounds in earthworms from bulk soil or soil porewater concentrations could provide a cost- and time-effective alternative to field testing for characterising the risk of pesticides to earthworms and via secondary poisoning. Several equilibrium partitioning (EP) and dynamic mechanistic models have been developed to predict bioconcentration of organic chemicals in earthworms. EP models assume that the main route of exposure for earthworms is uptake from soil porewater through the skin, and that differences in bioconcentration between earthworm species are negligible. To investigate how existing models perform for different earthworm species, we conducted kinetic uptake and elimination experiments for the earthworms *Eisenia fetida*, *Aporrectodea caliginosa* and *Lumbricus terrestris* which have varying body size and lipid content, in five contrasting soils, and for five pesticides (lenacil, flutriafol, dieldrin, hexachlorobenzene and p,p'-DDT). Measured bioconcentration factors (BCF) were comparable across earthworm species (within a factor of 1.8 on average) for hydrophilic pesticides due to the similar water content of earthworm species. For hydrophobic pesticides, BCF varied between species by an average factor of 4.0, but normalisation of BCF values to earthworm lipid content and specific surface area significantly reduced this to a factor of 1.8. The best performing EP model was that of Belfroid *et al.* (1993), but it still provided poor predictions for *L. terrestris* (NSE= -0.38). This model also overestimated internal concentrations of lenacil for all three earthworm species by up to two orders of magnitude. Existing EP models cannot be generalised to predict bioconcentration across earthworm species. Refined EP models are required separately for hydrophilic and hydrophobic pesticides, incorporating additional soil, and earthworm terms in addition to Log Kow to account for the influence of these characteristics on bioconcentration. Further model evaluation and refinement for dynamic bioconcentration models are ongoing.

4.02 Antimicrobials in the Environment – A Threat to Environmental and Human Health?

4.02.T-01 Dawning of a New ERA: Environmental Risk Assessment of Selection for Antimicrobial Resistance

Aimee Kaye Murray[1]*, William Gaze*[1]*, Neil A. R. Gow*[2]*, Alwyn Hart*[3]*, Wiebke Schmidt*[4]*, Jason Snape*[5]*, Isobel C. Stanton*[1,6]*, Emily*

Stevenson[7], Jane Usher[2], Adilia Warris[2], Helen Wilkinson[8] and Lihong Zhang[1], (1)University of Exeter, United Kingdom, (2)University of Exeter, MRC Centre for Medical Mycology, United Kingdom, (3)Environment Agency, (4)Chief Scientist's Group, Environment Agency (England), United Kingdom, (5)Astrazeneca UK, United Kingdom, (6)UK Centre for Ecology & Hydrology (UKCEH), United Kingdom, (7)Medical School, University of Exeter, United Kingdom, (8)Environment Agency (England), United Kingdom
Antibiotics, antifungals, antimicrobials and other compounds have the potential to directly select or indirectly co-select for antimicrobial resistance. These environmental contaminants are released from a variety of sources, resulting in huge concentration gradients of antimicrobials through different environments. However, a growing body of research has demonstrated that very low concentrations of antibiotics can select for antimicrobial resistance. Therefore, environmental pollution may be directly contributing to the rise of the 'silent pandemic' of AMR, one of the greatest threats to human and animal health, the global economy and global food security.
Currently, environmental risk assessments (ERAs) performed for antimicrobials do not utilise data from experiments that determined the concentration at which an antimicrobial selects for resistance. This has been shown to be orders of magnitude lower than inhibitory, or 'toxic' concentrations in some cases. ERAs using data derived from ecotoxicological experiments may therefore not be protective against antimicrobial resistance selection.
This presentation will outline some of the experimental approaches used to date to determine selective concentrations of antibiotics, the most well studied type of antimicrobial in terms of minimal selective concentrations, and the risk these antibiotics pose in different environments. Antifungals remain unstudied in terms of their minimal selective concentrations, despite being a major contributor to the global burden of antimicrobial resistance. Consideration will therefore be given to how the methods used for antibiotics may be transferred (or not) to studying minimal selective concentrations of antifungals. Finally, issues unique to ERA of antimicrobial resistance will be proposed and outlined in a potential framework to streamline adaption of a new ERA for antimicrobials that considers selection for AMR. These recommendations may help stem the tide of antimicrobial resistance by contributing to the development of environmental quality standards for antimicrobials, when supported by sufficient data.

4.02.T-02 First Steps Towards an Environmental Surveillance for Antimicrobial Resistance (AMR)
***Wiebke Schmidt**[1], Jonathan Warren[2], Collette Allen[3], Purvi Mali[2], Elizabeth Johnson[3], Katie Hopkins[3], Ian Martin[4], Alison Mather[5], Caroline Willis[3] and Alwyn Hart[2], (1)Chief Scientist's Group, Environment Agency (England), United Kingdom, (2)Environment Agency, (3)UK Health Security Agency, United Kingdom, (4)Environment Agency (England), United Kingdom, (5)Quadram Institute*
Traditionally, antimicrobials are associated with the clinical use of antibiotics in the protection of human and animal health, but antimicrobials are also used for crop protection. We know that the presence and pathways of antimicrobial substances and resistant organisms are not limited to the intended spaces (e.g., hospital, farmyard) and can enter our environment. For example, antifungals are spread across large, farmed areas at effect concentrations or antibiotics excreted by patients enter into the sewage system and ultimately into water environment. Thus, we need to understand the role that the environment plays in the development, maintenance and transport of antimicrobial resistance (AMR) and the impact of AMR on environmental ecosystems.
Globally, organisations including the World Health Organisation, United Nations Environment Programme and the UK Government have identified and called for a need for surveillance of antimicrobial resistance in the environment to sit alongside the surveillance carried out in clinical and veterinary settings. However, having recognised the need for environmental surveillance there are multiple challenges in deciding what this should entail.
The Environment Agency, UK Health Security Agency and Department for Environment, Food and Rural Affairs are piloting how to deliver AMR surveillance in the environment in England, UK. We will present results how we conducted sampling across different environmental matrices, with a focus on three river catchments in England. In addition to presenting results from our river catchment works, we shall showcase results from other areas, such as presenting detected concentrations of clinical antifungals in biosolids in England as well as results from using shellfish as bioindicators for coastal waters. Our pilot work also considers practical considerations, such as site access, resource requirements and usage of results that need to be taken into account for the development of a future environmental AMR surveillance programme.

4.02.T-03 Terrestrial Risk of Antibiotic Resistance in Slurry or Manure Amended Soils
***Felicity C T Elder**[1], Alex J O'Neill[2], Lisa Collins[2] and Laura Carter[3], (1)Geography, University of Leeds, United Kingdom, (2)University of Leeds, United Kingdom, (3)School of Geography, University of Leeds, United Kingdom*
Antibiotic resistance (ABR) is a current and very real global health and economic threat, as antibiotics are fundamental in both healthcare and food production. There is increasing concern that the presence of antibiotics in the environment may select for the evolution and dissemination of antibiotic resistance. Currently there are no regulatory guidelines that take these risks into account, and while there is ongoing work to address this within aquatic environments, terrestrial systems have been somewhat overlooked, mainly due to our focus on wastewater treatment plant effluent as the main source of antibiotics within the environment. There is an increasing push within agriculture to move away from chemical-based fertilisers and towards the use of organic soil amendments such as slurry, manure or sludge, in order to improve soil health. However, these organic soil amendments have been shown to contain antibiotics and other pharmaceuticals alongside antibiotic resistant bacteria posing a potential risk to the environment, livestock and humans through the proliferation and spread of ABR. Using current knowledge on the fate of antibiotics within soil and mathematical models to enable an assessment of risk of ABR, this presentation puts forward a novel framework for assessing the terrestrial risk of antibiotic resistance through the use of farmyard manure as fertilisers, alongside experiment data to show the potential for predicted pore water concentrations to select for oxytetracycline resistance.

4.02.T-04 Presence and Dissemination of Antibiotic Resistance in Agricultural Soil Supplemented with Sewage Sludge

Marta Jaskulak[1], *Katarzyna Zorena*[2], *Saeid Rostami*[3], *Damian Lech*[2], *Maciej Winczewski*[2], *Jakub Krajnik*[2] *and Franck Vandenbulcke*[3], *(1)Czestochowa University of Technology, France, (2)Medical University of Gdansk, Poland, (3)University of Lille, France*

For the last 20 years in EU-15 countries, the sewage sludge produced by wastewater treatment plants (WWTPs) has increased from 6.5 million tDM (dry matter) up to 9.5 million tDM (2000-2020). Applying sewage sludge (SS) to agricultural soil can improve the soil fertility, allows to recycle this biowaste and helps to meet crop nutritional needs. However, SS may contain various unregulated emerging contaminants, as well as mobile genetic elements (MGEs) and antibiotic resistance genes (ARGs), increasing the danger of the spread of antibiotic resistance. We looked at how applying thermally dried anaerobically digested SS affected the physical, chemical, and microbiological characteristics of the soil, and (ii) the relative abundance of 96 ARGs and 10 MGE-genes in the soil. Three factors—the dose of application, the technology of sludge treatment, and the amount of time since the last treatment—were different for each of the SS-amended agricultural fields from which soil samples were collected. ARGs and MGE-genes were both more abundant in soils fertilized with sewage sludge relative to non-amended soils in SS-amended soils, particularly in more recent SS applications and in soils supplemented by SS repeatedly thorough the last 5 years. The relative abundance of ARGs and MGE-genes was positively linked with some physicochemical factors, such as cation exchange capacity, nitrogen and phosphorus content. The primary explanation for the distribution pattern of ARGs and MGE-genes was the application of sewage sludge. We concluded that adding thermally dried anaerobically digested sewage sludge to agricultural soils without any additional treatments can enhance the chance of antibiotic resistance spreading. Much future research needed for the development of innovative treatments and technologies for SS to reduce the risk of further emergence and spread of ARGs and MGE-genes in SS-amended agricultural soils and afterwards, in crops. Until then, SS should be applied in agricultural soils with caution.

4.02.T-05 Assessing the Chemical Complexity of Discharge into the Environment from Antimicrobial Manufacturing Hubs in India

Kaniz Fatema Chowdhury[1], *Kgato P Selwe*[2], *Brett Sallach*[3], *Rebecca H Hall*[4], *Alan McNally*[4] *and Laura Carter*[1], *(1)School of Geography, University of Leeds, United Kingdom, (2)Chemistry, University of York, United Kingdom, (3)University of York, United Kingdom, (4)University of Birmingham, United Kingdom*

Our current understanding of the presence of antimicrobial resistance (AMR) drivers in the environment has been driven by a targeted approach to chemical identification, whereby potential drivers of AMR may be missed. To understand the complexity of chemical contaminants released into the environment following pharmaceutical manufacturing activities, we carried out a non-targeted approach using high-resolution mass spectrometry to identify antimicrobials and other chemical contaminants in environmental samples across two sites known as antimicrobial manufacturing hubs in India. Compound discovery software was used for data analysis, where existing libraries (m/z cloud and Norman mass list) were used for compound annotation. Suspect lists were also created from information regarding the known product formulations from antimicrobial industries in the local sampling area. A workflow was used to clean the data and included steps to remove chemicals identified with no name and a delta mass > 5 ppm. Peak area (< 50,000 removed) and peak rating (< 5 removed) were then assessed. n the initial screening, at level 5 confidence, the hit list consisted of 4914 compounds identified in samples of wastewater influent, effluent and river water (upstream and downstream). In total, 458 chemicals were annotated to L3 Schmanski confidence, of which 57 chemicals were confirmed as L2 confidence following a spectral library match with m/z cloud. Of the chemicals annotated as L2, sulfamethazine, methicilin and metampicilin antibiotics were found repeatedly in samples from Bhiwadi, Rajasthan and Dera Bassi, River Ghaggar. In addition, almost all collected samples contained beta blockers, antidepressants and illegal drugs. Chemicals were still detected within the effluent following wastewater treatment suggesting that current treatment options are ineffective and are contributing to the direct release of AMR drivers into the receiving environment. Most importantly, it demands further investigation into the impact of these ubiquitous contaminants on human and environmental health and highlights that environments surrounding manufacturing facilities contain a complex cocktail of chemicals beyond just active antimicrobial ingredients.

4.02.P Antimicrobials in the Environment – A Threat to Environmental and Human Health?

4.02.P-Mo296 Veterinary Antibiotics in the Soil Environment: Earthworm *Dendrobaena veneta* Responsetoo Tetracycline Exposure

Jurate Zaltauskaite[1], *Diana Miškelytė*[2], *Gintare Sujetoviene*[3], *Austra Dikšaitytė*[3], *Irena Januskaitiene*[3] *and Giedrė Kacienė*[3], *(1) Lithuanian Energy Institute, Lithuania, (2) Lithuania, (3)Vytautas Magnus University, Lithuania*

Antibiotics have received growing attention in recent years as emerging aquatic and terrestrial contaminants. Animal manure, slurry or sewage sludge land application are the main routes for veterinary antibiotics to enter the soil environment. Tetracyclines are among the antibiotics most used in veterinary resulting in their wide distribution in the environment. However antibiotic effects on soil dwelling organisms are still poorly understood. Earthworms *Dendrobaena veneta* were exposed to 1-500 mg/kg of tetracycline for 56 days. Mortality, body weight, cocoon production and biochemical responses including the activity of catalase (CAT), superoxide dismutase (SOD), glutathione reductase (GR), gluthathione-S-transferase (GST) and malondialdehyde (MDA) were examined. Tetracycline reduced *D. veneta* survival, weight growth, and impaired antioxidant enzymes system. Data on *D. veneta* response to tetracycline will be presented.

4.02.P-Mo297 Effects of Tetracycline on Physiological and Enzymatic Defense Response in Lichen *Evernia prunastri*

*Gintare Sujetoviene[1], **Diana Miškelytė**[1], Austra Dikšaitytė[1], Irena Januskaitiene[1], Giedrė Kacienė[1], Jurate Zaltauskaite[2] and Martynas Jasas[1], (1)Vytautas Magnus University, Lithuania, (2)Lithuanian Energy Institute, Lithuania*

Tetracycline antibiotics are one of the main groups of antibiotics widely used in veterinary medicine, human medicine, and agriculture, with significant environmental concerns including ecological risks. The impact of tetracycline on physiological parameters (integrity of cell membranes, membrane lipid peroxidation, chlorophyll content, photosynthetic efficiency) and enzymatic activity of lichens was determined. Lichens *Evernia prunastri* were exposed to different concentrations: 0, 10, 50, 250, 500 µg/L. The lichens were incubating with tetracycline solutions for 2 h (simulating a single pollution episode) maintaining a constant 10/1 w/v ratio. The results of the experiment showed that exposure affected the lichen membrane damage as indicated by increase in conductivity. The potential photosystem II efficiency (F_v/F_m) was susceptible to the impact of antibiotic. The results of the study supplemented the knowledge on the effects of pollution on organisms, such as veterinary antibiotics, on lichens and provided a better understanding of the mechanisms of toxicity.

4.02.P-Mo298 Pre–COVID-19 Occurrence of Antimicrobials, ARB, and ARGs in Hospital Wastewaters and Adjacent Surface Waters in Sri Lanka

***Keerthi S. Guruge**[1], Yukino A Tamamura[1], Prasun Goswami[1], Rumi Tanoue[2], K. B. S. N. Jinadasa[3], Kei Nomiyama[2] and Tatsuya Kunisue[2], (1)National Institute of Animal Health-NARO, Japan, (2)Ehime University, Japan, (3)University of Peradeniya, Sri Lanka*

In this study, the concentrations of 25 antimicrobials, the resistance of *Escherichia coli* (*E. coli*) strains in response to the selection pressure imposed by 15 antimicrobials, and enrichment of 20 antimicrobial resistance genes (ARGs) in *E. coli* isolated from hospital wastewaters and surface waters were investigated during the pre–COVID-19 period, from 2016 to 2018. In hospital wastewaters, clarithromycin (18,800 ng/L) was detected at the highest concentration followed by sulfamethoxazole (15,300 ng/L) and sulfapyridine (14,120 ng/L). The maximum concentrations for personal care products (PCPs) such as triclocarban, triclosan and methyl paraben were detected at 363 ng/L, 77 ng/L and 468 ng/L, respectively, in the hospital wastewaters. Approximately 80% of the *E. coli* isolates were resistant against the tested antimicrobial agents. Approximately 61% of the examined isolates were categorized as multidrug-resistant bacteria. The overall abundance of phenotypes that were resistant toward drugs was in the following order: β-lactams, tetracycline, quinolones, sulfamethoxazole/trimethoprim, aminoglycosides, and chloramphenicol. The data showed that the *E. coli* isolates frequently harbored *bla*TEM, *bla*CTX-M, tetA, qnrS, and sul2. These results indicated that some PCPs were significantly associated with the presence of several resistant phenotypes and resistance genes, implying their role in co-association with multidrug resistance. Statistical analysis also indicated a disparity specific to the site, treatment, and year in the data describing the prevalence of antimicrobial-resistant bacteria (ARB) and ARGs and their release into downstream waters. This valuable information on pre–COVID-19 abundance of antimicrobial, ARB and ARGs can be compared with the With/Post-Covid-19 occurrence of them in Sri Lanka.

4.02.P-Mo299 Impact of Thermal Hydrolysis on Abundance of Antibiotic Resistance Genes During Anaerobic Digestion of Sewage Sludge

***Young Mo KIM**, Department of Civil and Environmental Engineering, Hanyang University, Korea*

The effects of recuperative thickening (RT) and thermal hydrolysis during anaerobic digestion (AD) on AD performance, microbial communities and reduction of antibiotic resistance genes (ARGs) were investigated. Compared to the results in conventional AD (Phase I), biogas production increased slightly (10%) through RT (Phase II) but increased (63%) via RT with a digestate treatment system (DTS, thermal hydrolysis of thickened digestate) during AD (Phase III). Meanwhile, the three different operating conditions further influenced microbial community structures as well as efficiencies in reducing ARGs: The abundance of hydrolytic bacteria in Phase II and the abundance of acidogenic bacteria in Phase III increased, and 64.3% and 47.4% of the total sum of the relative abundance of ARGs in the substrate were removed in Phases II and III, respectively. Thus, RT-AD with DTS could represent a promising process for improved AD performance, but requires additional refinements to further reduce concentrations of residual ARGs in digestate.

4.02.P-Mo300 Characterizing Antimicrobial Resistance Across Australia

*Jake O'Brien[1], Aimee Kaye Murray[2], **Leah Clarke**[1], Kevin Thomas[3] and William Gaze[2], (1)Queensland Alliance for Environmental Health Sciences (QAEHS), University of Queensland, Australia, (2)University of Exeter, United Kingdom, (3)University of Queensland, Australia*

Antimicrobial resistance (AMR) looming threat to public health world-wide. Resistant bacteria can be found in clinical settings and throughout the natural environment. When antibiotics and antimicrobial compounds are consumed by humans or animals, they do not completely break down during metabolism and are excreted into the environment - whether that be via wastewater treatment plants, animal manure, aquaculture reservoirs, and water bodies.

The objective is to characterize antibiotic resistance in wastewater using both analytical chemistry and sequencing techniques. To facilitate this, wastewater samples have been collected and preserved from over 100 wastewater treatment plants across Australia since 2016. Importantly, area specific demographics have also been collected for each of the wastewater catchments in order to provide a socioeconomic dimension to the data.

4.02.P-Mo301 Certifying the Responsible Manufacture of Antibiotics

***Joan G. Tell**[1] and Daniel Caldwell[2], (1)MSD, (2)Johnson & Johnson*

The AMR Industry Alliance (the Alliance) brings together the leading biotech, diagnostic, generic and research-based pharmaceutical companies around the shared goal of curbing antimicrobial resistance in the world. Alliance companies are committed to contribute to and measure their efforts in fighting AMR across four key areas: research, appropriate use, access and manufacturing and the environment. In 2018, AMR Alliance generic and research-based pharmaceutical companies agreed on a framework that promotes responsible antibiotic manufacturing and derived Predicted No-Effect Concentrations (PNECs) for antibiotics in surface water that would be protective of ecological receptors and also limit the spread of resistance from manufacturing sites. Since 2018, the Alliance has conducted additional environmental tests on antibiotics, provided guidance to manufacturers on best practices, set default values to use in the absence of data and are furthering the science via targeted research grants.   w, with the help of the British Standards Institute, the Alliance has developed a **standard and certification scheme** that encompasses all the necessary elements of responsible manufacturing of antibiotics in a protective and transparent manner. Th certification scheme will provide a level of assurance for the general public, regulators and procurers that the antibiotics they use and purchase are made in a manner that is safe for the environment and minimizes the contribution of manufacturing to the spread of resistance.

4.02.P-Mo302 Detection of Antimicrobials in Common Effluent Treatment Plant Wastewater and Receiving Water Body

Arhama Tufail Ahd Ansari*, Ayush Ransingh, Pradnya Vernekar and Suparna Mukherji, Environmental Science and Engineering Department, IIT Bombay, India*

In recent times, a large quantity of antibiotics is being administered to humans and animals for treating diseases and infections. This has increased the production of antimicrobials and the generation of antimicrobial-containing effluents. In India, various drug and pharmaceutical industries send their effluent to common effluent treatment plants (CETPs), where wastewater from various types of industries is treated together. In the present study, antimicrobials in CETP influent, effluent, and samples from the receiving water body were analyzed using solid-phase extraction followed by LCMS-MS using concentration factors 100, and 500, respectively. The antibiotics detected in both influent and effluent wastewater samples from the CETP included cefalexin, netilmicin, enrofloxacin, erythromycin, azithromycin, and sulfamethazine. Some of the antibiotics were detected only in the effluent samples. Several of the antibiotics detected in the effluent samples were also found in the water samples from the receiving water body. Along with antibiotics, other antimicrobial compounds, such as antifungals and antivirals, were also detected in the CETP treatment plant and the receiving water body.

4.02.P-Mo303 Investigating the Effects of Aminoglycoside Antibiotic Plant Protection Products on Complex Microbial Communities

Laura May Murray[1]*, Lihong Zhang*[1]*, Jason Snape*[2]*, William Gaze*[1] *and Aimee Kaye Murray*[1]*, (1)University of Exeter, United Kingdom, (2)Astrazeneca UK, United Kingdom*

Crop production utilises the application of plant protection products (PPPs), including antibiotics, to crops and soils in many countries. This targets bacterial crop pathogens but results in both target and non-target organisms being exposed to concentrations of antibiotic up to hundreds of mg/L. Bacterial exposure to antibiotic PPPs may result in the development and spread of antibiotic resistance genes (ARGs) between environmentally and clinically relevant bacteria. This project considers how use of antibiotic PPPs contributes to the burden of antibiotic resistance (ABR) via a novel comparison of different antibiotics belonging to the same class, which are crop-specific (kasugamycin) or used both clinically, and as PPPs (streptomycin and gentamycin).

Lowest observed effect concentrations (LOECs) for a reduction in growth of a complex bacterial community were determined for streptomycin (2mg/L), gentamicin (0.25mg/L) and kasugamycin (50mg/L) using over-night growth experiments. LOECs informed the concentration range for seven-day evolution experiments. QPCR was performed on extracted DNA from evolved communities to determine *intI1*/16S rRNA prevalence. Metagenomic sequencing was conducted and analysed to determine changes in community composition (MetaPhlAn2) or relative abundance of ARGs (ARGs-OAP).

Streptomycin and gentamycin significantly increased *intI1* prevalence at concentrations orders of magnitude lower than application concentration. Increases in specific ARG classes (e.g. aminoglycosides & beta-lactams) were also observed. Species richness also decreased with increasing antibiotic concentration. Kasugamycin did not significantly increase *intI1*, nor strongly select for ARG classes even at its application concentration of 100mg/L. Kasugamycin as a crop-specific antibiotic, is less well researched than the others, therefore resistance genes may not have been characterised. We aim to carry out functional metagenomics to identify novel kasugamycin resistance genes.

Results provide information on the effects of different PPPs on microbial communities, contributing to understanding ABR from a “One Health” perspective. Results demonstrate that antibiotics of the same class may have different selective capabilities, necessitating further studies on AMR selection at the level of the individual antibiotic rather than class level.

4.02.P-Mo304 Validation of the SELECT Assay as a Method to Facilitate Risk Assessment for Antimicrobial Resistance

Alejandra Bouzas Monroy[1]*, Ville Friman*[2]*, John Wilkinson*[3] *and Alistair B.A. Boxall*[4]*, (1)Environment, University of York, United Kingdom, (2)Biology, University of York, United Kingdom, (3)Environment and Geography, University of York, United Kingdom, (4)University of York, United Kingdom*

Antimicrobials are widely used to treat humans and animals and during their manufacture, use and disposal it is inevitable that they will be released to the natural environment. Residues of antibiotics have the potential to select for antimicrobial resistance (AMR) in bacteria and contribute to the global AMR crisis. It is therefore critical that concentrations of antimicrobials in the environment are managed but to achieve this it will be necessary to derive safe target concentrations. Recently, the ‘SELection End points in Communities of bacTeria’ (SELECT) method was proposed as a simple approach to derive safe concentrations of antimicrobials in the environment (Murray et al. 2020). However, to date, this approach has not been independently evaluated and assessed. In this study, we used SELECT, culture-based assays, and qPCR-based assays to determine 'safe' concentrations of 14 antimicrobials (azithromycin, cefotaxime, chloramphenicol, ciprofloxacin, clarithromycin, erythromycin, gentamicin, trimethoprim, metronidazole, sulfamethoxazole, sulfadiazine, lincomycin, tetracycline, and tylosin) in the environment. Bacterial communities from a range of influent samples obtained from plants with a variety of treatment system types and sizes were exposed to a range of concentrations of each antimicrobial using the different assay approaches. Results for the different bacterial communities and the different assay types were then compared to understand the performance of the SELECT assay.

4.02.P-Mo305 Impacts of Human-use Antifungals on Symbiotic Soil Fungi in the Agro-Environment
Emily Durant[1]*, Katie Field*[1]*, Sara Moeskjær*[1]*, J Brett Sallach*[2] *and Laura Carter*[3]*, (1)Plants, Photosynthesis and Soil, School of Biosciences, University of Sheffield, United Kingdom, (2)Department of Environment & Geography, University of York, United Kingdom, (3)School of Geography, University of Leeds, United Kingdom*
To sustainably meet the future food demands of a growing human population, regenerative or circular farming practices must be implemented. Central to these is preservation and exploitation of beneficial soil microbes, such as arbuscular mycorrhizal fungi (AMF), to improve soil structure, increased access to soil nutrients, and enhanced stress protection in crops. As the production of artificial fertilizers rely on finite natural resources, sustainable crop production should aim to maximise the potential benefits of crop-AMF interactions. Irrigation using wastewater and biosolids can also reduce the application of artificial fertilizers, thereby improving sustainability of crop production. However, this increasingly common practice also represents a pathway for man-made chemicals to enter agricultural soils. Emerging pharmaceutical contaminants exist in soils at concentrations ranging from ng/kg – µg/kg and have manifested in sub-lethal effects on plants. Here, we focus on human-use antifungal azoles, bioactive pharmaceuticals that retain their biological potency when present in soil. The inadvertent introduction of human-use antifungal azoles to agricultural soils could negatively impact many aspects of soil health, including abundance, structure, and function of AMF. These near-ubiquitous symbiotic soil fungi are critical components of soil health through their contributions to soil nutrient cycling and plant nutrition, but the effects of antifungal azoles on AMF are unknown. We tracked carbon for nutrient exchange between AMF and two host crops, spring onion and lettuce, in the presence of environmentally relevant concentrations of antifungal azoles. We found that azoles greatly reduced AMF density in the soil and colonization of crop roots. AMF function was also significantly altered, with reduced fungal-acquired phosphorus allocation to host plants and reduced plant carbon allocation to AMF in both species tested when azoles were present. Our results suggest that the presence of human-use antifungal azoles in soils negatively affect the function of AMF with potential subsequent impacts on plant and soil health. While the need for greater sustainability in future farming practices is clear, our research shows there can be significant, albeit unintended, impacts on the soil ecosystem of circular agricultural practices. As such, wastewater treatment processes must be improved to remove the emerging threat of human-use pharmaceuticals.

4.02.P-Mo306 Cell and Tissue Level Effects of Sulfamethazine and Tetracycline in the Earthworm *Eisenia fetida*
Erik Urionabarrenetxea[1]*, Nerea Garcia-Velasco*[1]*, Ainhoa Ugarte*[1]*,* ***Manuel Soto***[2]*, Ane Arrizabalaga*[1]*, Beñat Zaldibar*[1] *and Camila Fatima Rutkoski*[3]*, (1)University of the Basque Country (UPV/EHU), Spain, (2)Plentzia Marine Station, University of the Basque Country (UPV/EHU), Spain, (3)Universidade Regional de Blumenau*
Sulfamethazine and Tetracycline are two common antimicrobial compounds widely used in health services and cattle industry. Therefore, it is not unexpected finding relatively relevant concentrations of both substances in soils due to uncontrolled disposals or other careless management policies. Although broadly used, the information of the effects exerted by these compounds in a soil key species such as earthworms is still scarce. In the present work, earthworms (*Eisenia fetida*) were exposed to three different sulfamethazine and tetracycline concentrations (10, 100 and 1000 mg / Kg soil dw) to determine how these compounds may alter earthworm health status using cell and tissue level biomarkers including enzyme activity measurements, histochemical and histopathological alterations. Preliminary results indicated that after 14 days of exposure even though none of the antimicrobials induced earthworm death or significant weight loss, some cell levels changes were observed. Thus, a trend to increase of riboflavin concentration of the coelomic fluid was observed under the exposure of both compounds even at low concentrations (10 mg / Kg soil dw). On the other hand, also a trend to decrease the height of the epithelium of the digestive tract was observed. This trend was more marked in earthworms exposed to sulfamethazine than in those exposed to tetracycline although in the latter a decrease of digestive tract irregularities and concomitant decrease of soil contact surface was detected. Similarly, the mucous secretion of the earthworm integument presented different response patterns according to the antimicrobial. In the case of the sulfamethazine an increased volume density of mucocytes was measured while no clear trend was observed in tetracycline exposed earthworms. Overall, it can be concluded that some effects were observed at cell and tissue level after exposure to antimicrobials but these changes did not induce more significant alterations in terms of individual mortality or weight loss after 14 days of exposure.

4.02.P-Mo307 Effects of Legacy and Emerging Antimicrobial Compounds to Early Life Stages of Rainbow Trout (*Oncorhynchus mykiss*)
Mawuli Amekor[1]*, Evan Kohlman*[1]*, Catherine Roberts*[1]*, Alper James Alcaraz*[1]*, Niteesh Jain*[1]*,* ***Markus Brinkmann***[1,2,3]*, Markus Hecker*[1,2] *and Natacha S Hogan*[1,4]*, (1)Toxicology Centre, University of Saskatchewan, Canada, (2)School of Environment and Sustainability, University of Saskatchewan, Canada, (3)Global Institute of Water Security, University of Saskatchewan, Canada, (4)Dept Animal and Poultry Science, University of Saskatchewan, Canada*
Products with antimicrobial properties can be released with wastewater effluent and enter freshwater systems, where they might pose a risk to the health of aquatic organisms. While the effects of legacy antimicrobial compounds, such as triclosan (TCS), are well-studied, less is known about the toxicity of emerging alternative antimicrobials. This study aimed to evaluate and compare

the effects of TCS and two commonly used and high-volume antimicrobials, chloroxylenol (PCMX) and methylisothiazolinone (MIT), on early-life stage rainbow trout (*Oncorhynchus mykiss*). Embryos were exposed from hatch until 28 days post-hatch (dph) to TCS, PCMX, and MIT separately at nominal concentrations of 0.38 – 400 µg/L. After 96 h exposure (4 dph), whole embryos were sub-sampled and pooled per concentration to assess transcriptomic responses using a novel standardized reduced transcriptome qPCR array (EcoToxChip) specific to rainbow trout. The remaining individuals were carried through the 28-day exposure, during which mortality along with sublethal developmental responses (e.g., presence of edema and spinal curvature, time to swim-up) were recorded. At study termination, individuals were weighed, length recorded, and samples were preserved for histology of key tissues (liver, gills, intestine). Water was sampled throughout the experiment to confirm exposure concentrations. There was a reduction in survivability and increased incidence of developmental abnormalities (primarily edema and jaw deformity) in fish exposed to TCS and PCMX at the higher exposure concentrations as compared to MIT. Reduced transcriptome profiling using the EcoToxChip is pending, but this broader evaluation of gene expression is anticipated to reveal additional mode(s) of action for these compounds. This research will provide information on the biological effects of antimicrobials on an ecologically relevant fish species and provide data to inform risk assessment of these compounds in Canadian freshwater systems.

4.02.P-Mo308 Potential of the microalgae, *Chlorella sorokiniana*, in the Removal of Nutrients and Antimicrobials in Wastewater Treatment

Ornrumpha Sethanunt[1]*, James PJ Chong*[1]*, Thierry Tonon*[1] *and J Brett Sallach*[2]*, (1)Department of Biology, University of York, United Kingdom, (2)Department of Environment & Geography, University of York, United Kingdom*

Access to clean water is a global priority as well as a focus of the UN SDGs. An increasing number of frequently detected contaminants in the aquatic environment include pharmaceutical contaminants (antimicrobials), which represents a significant risk to human and environmental health and the spread of antimicrobial resistance.

Microalgae represent a potential new direction in sustainable water treatment with application in the bioeconomy and circular economic systems. These organisms offer the opportunity to provide “bioremediation” as they utilise excess nutrients in wastewater for growth and offer the ability to decompose organic pollutants or accumulate these compounds in their biomass. Algae can remove dissolved nutrients in the form of NH_4^+, NO_3^-, PO_4^{3-}, and COD. Pollutants removal in this system is facilitated through several mechanisms, such as photodegradation, bioadsorption, and biodegradation.

In this experiment, *C. sorokiniana* (*CS*) was used to measure the removal of a mixture of 10 antimicrobials, selected based on environmental risk assessment using modelled wastewater concentrations derived from annual mass prescription data available through the NHS in the UK. The selected antimicrobials had a risk quotient > 1 calculated by the ratio between PEC and PNEC. Experimental antimicrobials concentrations were prepared according to the calculated PEC values.

Four different batches of the experiment were designed to examine the growth effect of the algae cells of treatment compared to the control over 19 days. Abiotic controls were conducted to determine the mechanism involved in the elimination of antimicrobials.

The achieved results from the experiment showed that *CS* was effective in eliminating antimicrobials > 85 % in the β-lactam class. Photodegradation also contributed to the highest removal of tetracycline class at 75 %.

Analysis of the biodegradation mechanism revealed a direct effect on the increased cellular concentration of algae suggesting the utilization of antimicrobials as a carbon source for algal growth and the β-lactam class had the highest removal (83 %). The effect on dissolved nutrients elimination was also studied. The NH_4^+, NO_3^-, PO_4^{3-}, and COD demonstrated increased removals over controls at 88, 22, 100, and 10 %, respectively.

The results of the study confirmed the ability of *CS* to bioadsorb, and potentially biodegrade antimicrobials while also effectively reducing key nutrient loadings including NH_4^+, NO_3^-, PO_4^{3-}, and COD.

4.02.P-Mo309 Impacts of Three Antimicrobials on Early-Life Stage Rainbow Trout Gut Microbiome

Phillip Ankley*, Alper James Alcaraz, Catherine Roberts, Mawuli Amekor, Markus Hecker, Markus Brinkmann and Natacha S Hogan, Toxicology Centre, University of Saskatchewan, Canada*

Antimicrobials are contaminants of emerging concern as they are continuously discharged via wastewater effluent in urban environments and their pseudo-persistence may negatively affect organisms in the receiving ecosystem, including fish. In particular, antimicrobials may alter fish gut microbiomes which serve central roles in the overall condition of hosts and therefore could have important implications for the health of host fishes. This study assessed the impacts of three antimicrobials on early-life stage rainbow trout gut microbiome. Embryos were exposed from hatch to 28 days post-hatch to six graded concentrations of triclosan (TCS), methylisothiazolinone (MIT), and chloroxylenol (PCMX). Excised whole gut was collected and 16S rDNA amplicon sequencing of gut microbiome was applied to investigate responses to antimicrobials. Gut microbiome was dominated by phyla Proteobacteria and Bacteroidota and genera *Aeromonas* and *Pseudomonas*. Significant changes in Shannon diversity were observed in TCS-exposed fish, with PCMX-exposed fish indicating a marginal response. Differences in community composition were shown for TCS, with slight changes being observed for MIT. Fourteen genera correlated with nominal concentrations of TCS, while PCMX and MIT each have a single genus significantly correlated. TCS overall had the largest impact on exposed fish gut microbiome, followed by PCMX and MIT. Future steps include assessing the functional response of the gut microbiome to antimicrobials using predictive bioinformatics tools and assessment of antimicrobials on rainbow trout gut cell line (RTgutGC) to assess possible direct impacts of the chemicals on intestinal tissue. Results of this study provide insights into the potential effects of emerging antimicrobials on alevin rainbow trout gut microbiome with implications on physiological health status of the host.

4.02.P-Mo310 Characterisation of Antimicrobial Resistance in Wastewater Treatment Biosolids

Charlotte Head[1], *Jonathan Brett Sallach*[2] *and James PJ Chong*[3], *(1)Department of Environment and Geography, University of York, United Kingdom, (2)University of York, United Kingdom, (3)Department of Biology, University of York*

Antimicrobial resistance (AMR) is a global public-health crisis, threatening lives worldwide. AMR poses a difficult challenge since both exposure to antimicrobials and transfer of antimicrobial resistance genes (ARGs) contribute to its spread. Wastewater treatment plants (WWTPs) and their by-products are hotspots of AMR and reservoirs for antimicrobial compounds and ARGs. As WWTPs receive the unmetabolised portion of antimicrobials excreted by a population, the mixture of antimicrobial compounds and subsequent ARGs throughout is complex.

The by-products of wastewater treatment, namely biosolids and effluent are likely to contain the aforementioned complex mixture, and these by-products are often released, or reused within the surrounding environment, serving as a pathway for contaminant exposure. Biosolids, once separated from the liquid stream of wastewater through centrifugation, are usually dried or dewatered before reuse within the agricultural industry as organic fertilisers or soil conditioners.

Previous work has tentatively identified 119 different ARGs and 23 antimicrobial parent compounds from samples taken from Naburn WWTP on a snapshot day in 2020. Methods included screening with SmartChip™ HT-qPCR for ARG identification and high-resolution LC-MS/MS, coupled with a custom workflow developed within Thermo CompoundDiscoverer for chemical analysis. Associations between major antibiotic classes including aminoglycosides, beta-lactams and tetracyclines and their subsequent resistance genes were determined. These results provide new insights into the dynamics of AMR within a critical hotspot in wastewater treatment.

Further study investigating the fate of these ARGs and antimicrobial compounds was conducted over the 28-day air-drying period for biosolids. Samples were collected from 6 different spatial points within the ~200 T biosolid pile twice a week, for four weeks. ARG and chemical analysis provide insight into the dynamics of these pollutants and the ability to evaluate biosolid drying as a process meant to reduce their environmental exposure. Results show that trends in contaminant loading over time are compound and gene specific and enable data to inform pollution management options aimed to reduce the environmental burden of antimicrobials and antimicrobial resistance.

4.02.P-Mo311 Quaternary Ammonium Disinfectants in Livestock Farms and Human Wastewater Treatment Systems – a Driver of Antimicrobial Resistance?

Sophie Lennartz[1], *Sanjana Balachandran*[2], *Osas Elizabeth Aigbekaen*[2], *Alexandra Jahraus*[2], *Jan Siemens*[1], *Stefanie P. Glaeser*[2] *and Ines Mulder*[1], *(1)Institute of Soil Science and Soil Conservation, Justus Liebig University Giessen, Germany, (2)Institute of Applied Micobiology, Justus Liebig University Giessen, Germany*

Quaternary ammonium compounds (QACs) are cationic high-production volume disinfectants and surfactants applied e.g., in hospitals, industry, households and agriculture. As effective broad-spectrum antimicrobials, QAC residues remaining in the environment at sub-inhibitory concentrations could contribute to spreading antimicrobial resistance via co- or cross-resistance mechanisms. This may have been amplified by globally increased disinfectant use during the SARS-CoV-2-pandemic. While wastewater treatment plants (WWTPs) are known emission sources of QACs and hot spots for antimicrobial resistance propagation, comparatively little is known about the use and effects of QACs in agricultural systems. The aims of this study were therefore firstly, to compare the extent of QAC pollution and QAC-tolerance in potentially pathogenic bacteria between livestock farms and human WWTPs and secondly, to investigate how raised disinfectant use during the SARS-CoV-2 pandemic affected QAC concentrations and the abundance of QAC-tolerant bacteria.

Four German livestock farms and three WWTPs were investigated including two farms and one WWTP studied before and after the onset of the pandemic. Manure/slurry and anaerobic digestates of on-farm biogas plants, untreated wastewater, activated sludge, dewatered sludge and treated wastewater (effluent) were studied. Using matrix-specific solid-phase extraction and liquid chromatography-tandem mass spectrometry, 22 different QACs were quantified including alkyltrimethyl, benzylalkyl and dialkyldimethyl ammonium compounds with chain lengths between 8-18 C atoms. QAC-tolerant potentially pathogenic bacteria were cultured on QAC-supplemented agar and their minimal inhibitory concentrations for two QACs and the multidrug resistance (MDR) status were determined.

Our analyses revealed much higher QAC concentrations in WWTPs compared to manure and biogas plant digestates of livestock farms. Although QACs were largely removed from wastewater, they persisted at levels of 2-200 $\mu g\ g^{-1}$ in the treated sewage sludge and at 0-400 $ng\ g^{-1}$ in biogas plant digestates. The effect of the pandemic was most obvious in dewatered sewage sludge, where concentrations of most QACs increased two- to threefold, but hardly notable in wastewater or farm manure/slurry. The correlation to QAC- tolerance and the MDR status is currently investigated. This study helps to re-assess the ecological and human health risks of QACs in the context of antimicrobial resistance.

4.02.P-Mo312 Effects of the Systemic Fungicide Fluopyram on Aquatic Leaf-Shredders and Microbial Decomposers

Marina Arias[1], ***Alexander Feckler***[1], *Michele Meyer*[1,2], *Sara Isabel Bastos Goncalves*[1], *Johannes Raths*[3], *Juliane Hollender*[3] *and Mirco Bundschuh*[4], *(1)iES Landau, Germany, (2)Department of River Ecology, Helmholtz Centre for Environmental Research UFZ, Germany, (3)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (4)iES Landau, Institute for Environmental Sciences, University of Kaiserslautern-Landau (RPTU), Germany*

Leaf litter decomposition is an important energy-providing process for heterotrophic stream organisms. Invertebrate shredders mainly drive this process, together with microbial decomposers (i.e., bacteria and fungi). Fungicides might affect decomposition, impairing both shredders and microbial communities. The aim of the present study was to assess how fluopyram affects leaf-associated microbial decomposers and the shredder *Gammarus fossarum* directly by water exposure, indirectly by food exposure, and by the combination of both pathways.

Therefore, *Alnus glutinosa* leaves were conditioned by a field-collected microbial community in the presence and in absence of fluopyram (150 µg/L). We used a 2x2-factorial design, where individuals of *G. fossarum* were exposed to fluopyram directly through the water phase (150 µg/L), indirectly by feeding them with exposed leaves, and in combination of both pathways over 21 days (n=40). Fluopyram effects on microbial decomposers were assessed by quantifying bacterial and fungal operon copies via quantitative real-time PCR. The feeding and excretion rates of *G. fossarum* were assessed every 7 days and growth was assessed at the end of the exposure. Fluopyram concentrations associated with the conditioned leaf material and *G. fossarum* were determined at the end of the conditioning phase and the experiment, respectively.
Results showed that fluopyram non-significantly affected the microbial community by increasing the fungal (~43%) and bacterial (~41%) abundance on leaves, likely accompanied by a shift in the fungal community composition towards more tolerant species that are rejected by shredders, as shown in a previous study. At the same time, fluopyram accumulated in *G. fossarum* through water exposure (5100 µg/kg dw) and the combination of both pathways (5000 µg/kg dw), while showing ~15-fold lower accumulation through feeding exposure only (320 µg/kg dw). Despite these changes at the microbial level and partially high fungicide body burdens, fluopyram did not significantly affect consumption, excretion, assimilation rates, or growth of *G. fossarum* ($p>0.05$). Although we did not find effects on the feeding behavior or growth of *G. fossarum*, the effects on the microbial community and the high body burden through the water phase and combined exposure point to the potential for long-term effects in freshwater shredder communities that should be studied in further detail.

4.02.P-Mo313 Monitoring of AMR in Environmental Compartments: Considerations from a Regulatory Perspective
Kathi Westphal Settele[1]*, Jens Schönfeld*[2]*, Patrick Schröder*[1] *and Thomas U. Berendonk*[3]*, (1)Pharmaceuticals, German Environment Agency (UBA), Germany, (2)German Environment Agency (UBA), Germany, (3)Institute of Hydrobiology, Technical University Dresden, Germany*
Following the One Health approach the environment has been recognised as a crucial sector in the development and spread of antimicrobial resistance (AMR). Monitoring or surveillance schemes for AMR and antibiotic use have been developed and implemented most notably in clinical and animal husbandry, but a systematic monitoring for AMR in the environmental compartments e.g., surface and ground water, soil, manure or digestates is still missing. Existing monitoring systems of the health sectors primarily rely on cultivation of pathogens and certain bacterial indicator species of interest. However, these approaches seem to not be directly applicable to the monitoring of antibiotic resistant bacteria or antibiotic resistance genes (ARGs) in the environment.
This is the case, because the majority of environmental bacteria are not cultivable using standard methods. In principle, applying cultivation independent methods like e.g. quantitative PCR (qPCR) allow for the detection and quantification of individual ARGs. Although high-throughput qPCR systems are available which allow measurements of the abundances of a large number of ARGs simultaneously, they still are not yet ready for implementation in routine monitoring, mainly due to high expenditure. To address the regulatory requirement of feasibility, there is a need for priorisation of ARGs to select a manageable number of highly relevant qPCR targets for standard monitoring of AMR in the environment.
As a first step to develop efficient monitoring strategies in the future, data on present abundances and prevalence of virtually all ARGs occurring in natural environments are gathered to establish background levels of ARGs. In a second step, we present the prerequisites necessary to design efficient monitoring strategies and propose a condensed list of ARGs which are highly relevant for distinct environmental compartments, from a regulatory perspective. The priorisation criteria comprise e.g., consumption of the antibiotic for humans and animals, selective concentration, and status as critically important antibiotic.
Hereby, we aim at adding regulatory considerations to achieve both, the aggregation of AMR reference data for the majority of environmental compartments as well as a proposed set of ARGs to be used for environmental AMR monitoring.

4.02.P-Mo314 MSC ok? – Experimental vs. Calculated Minimum Selective Concentrations (MSCs) for the Assessment of AMR in the Environment
Patrick Schröder[1]*, Uli Klümper*[2]*, Dirk Jungmann*[2]*, Jens Schönfeld*[3]*, David Kneis*[2]*, Kathi Westphal Settele*[1] *and Thomas U. Berendonk*[2]*, (1)Pharmaceuticals, German Environment Agency (UBA), Germany, (2)Institute of Hydrobiology, Technical University Dresden, Germany, (3)German Environment Agency (UBA), Germany*
This project aims to close the methodological gap of assessing the risk regarding the spread of antimicrobial resistance (AMR) in the environment within the authorisation of medicinal products. Different approaches are discussed for the computational derivation of so called MSC values (Minimum Selective Concentration) as the basis for their assessment. In these computational approaches, MSC values are calculated from publicly available MIC values (Minimum Inhibitory Concentration). However, so far it has not been experimentally determined which of the approaches is most realistic. Therefore, the aim of this project is to verify the approaches and to subsequently identify the most suitable computational approach for the risk assessment by comparing calculated and experimentally generated MSC values. For this purpose, MSC values will be experimentally determined for an unprecedented number of antibiotics in combination with five environmental bacterial species, respectively. Preliminary data on these comparisons are presented.
Isogenic strains differing exclusively in their fluorescence profile (encoding mScarlet or YFP) were designed from an environmental *Sphingomonas sp.* isolate. The MIC for this strain was first determined for more than twenty antibiotics using a broth-microdilution-assay. Thereafter, the mScarlet encoding strain was allowed to acquire naturally occurring resistance genes for each of the antibiotics through horizontal gene transfer in liquid mating assays with environmental microbial communities originating from soils or wastewater in- and effluents. Then, the resulting resistant strain was grown in competition with the susceptible isogenic strain encoding YFP across a gradient of the corresponding antibiotic. By recording both fluorescence signals

the growth rates of the resistant strain relative to its susceptible counterpart were determined. The MSC corresponds to the tested antibiotic concentration at which the growth rates of the strains are identical.
The experimentally and computationally determined MSC values were then compared for each antibiotic to determine whether existing computational approaches could correctly predict MSC values for environmentally acquired resistances. Finally, the most appropriate computational approach should serve as the basis for developing methodological guidance on how to assess the risk of AMR development and spread in the environment within the authorisation procedure of medicinal products.

4.02.P-Mo315 Detection of Multidrug-Resistant Staphylococcus spp. Bound to Plastic Substrates in Surface Water
Ifra Ferheen *and Roberto Spurio, School of Biosciences and Veterinary Medicine, University of Camerino, Italy*
The large and often inappropriate use of conventional drugs in human and veterinary medicine has led to a progressive spread of antibiotic-resistant strains including some important Multiple-drug resistant organisms like MDR Staphylococcus spp. In the context of the spread of antibiotic resistance genes (ARGs) and the role of the environmental sector is underestimated in planning prevention action in One health respective. Furthermore, plastic can become the vehicle for transferring pathogenic microorganisms to other ecosystems, and play a vital role in spreading infections. The current research focuses on implementing the knowledge on the role of aquatic ecosystems in transmitting multi-drug resistant Staphylococcus spp and studying its capability of adhering to surfaces submerged in a caldera-type lake of central Italy.
In the late summer of 2021, Artificial Plastic Substrates (APSs) were used to sampling pathogens spread on to aquatic ecosystem. A comparative analysis of the microbial community residing in raw water and colonizing on APS was performed to investigate plastic's potential role in amplifying and spreading pathogenic bacteria, particularly Staphylococcus spp. Antibiotic susceptibility was performed using the Kirby-Bauer disk diffusion assay: Tetracycline (TET 30 µg), Gentamycin (GEN 10 µg), Meropenem (MEM 10 µg), Imipenem (IMP 10 µg), Sulfamethoxazole (SXM 25 µg), Ceftazidime (CAZ 30 µg) and Erythromycin (ERY 15 µg). Eight ARGs belonging to three different antibiotic classes; tetracycline (tetA, tetB, tetM, tetW), sulfonamide (sul1, sul2, sul3), β-lactamase (mecA), and two genes for class 1 integrons (intI1 and intI1-V) were investigated by molecular tools. esults. Result . Different types of plastic polymers diaplay different adhesion surface for bacterial colonization; Staphylococcus strains were resistant to almost all tested antibiotics. Resistance percentage of isolated strains was as following, TET(80%), MEM(64%), OXA (84%), GEN(88%), CEF (80%), ERY (96%), SMX (92%). Antibiotic resistance genes were found in the isolated strains of Staphylococcus with the following percentages: tetA (63%), tetB (86%), tetW (81%), sul1 (31%), sul2 (40%), mecA (100%), intl1 (50%). In conclusion, Considering complex interactions, symbiotic behavior, rising resistance, and infection rates of Staphylococcus spp., its colonization on the plastic surface should be strictly monitored to address public health concerns.

4.02.P-Mo316 Mind the Gap: Regulation of Antimicrobial Substances Used in Biocidal Products and Cosmetics
Diana Kättström[1]*, Anna Beronius*[2]*, Christina Rudén*[3] *and Marlene Ågerstrand*[3]*, (1)Department of Environmental Science, Stockholm University, Sweden, (2)Karolinska Institutet, Sweden, (3)Stockholm University, Sweden*
Antimicrobial substances are chemicals that can eradicate or slow down the growth of unwanted microorganisms. Upon exposure to antimicrobial substances, the microorganisms are able to rapidly adjust to the new environmental conditions, which may lead to the development of antimicrobial resistance. In EU, different uses of antimicrobial substances may fall under different regulations, each with its own aim, scope and data requirements. Antimicrobial substances used as biocidal active substances in biocidal products fall under the Biocidal Products Regulation (EC) 528/2012. When the same substances are used as preservatives in cosmetic products, Cosmetic Product Regulation (EC) 1223/2009 applies. Both uses involve evaluation and authorization prior entering the EU market, however, different requirements apply. This creates a regulatory inconsistency which may result in unintentional release of hazardous substances into the environment.
We investigated how the regulation of biocidal active substances and cosmetic preservatives focusing on aims, scope, information requirements, and risk assessment procedures. Neither environmental data nor environmental risk assessment were required for approval of cosmetic preservatives. In contrast, environmental data and risk assessment for both the active substance and one representative product would be required for the approval of the same substance if used as a biocidal active substance. The approval of the cosmetic preservatives was not time-limited and once the substance was approved, there was no obligation to update the information on properties, even if such information became available. We also examined the environmental classification of approved cosmetic preservatives under the Classification, Labelling and Packaging Regulation (CLP), and their regulatory status under REACH and the Biocidal Products Regulations. Half of the approved cosmetic preservatives were environmentally hazardous according to classification under the CLP. Some were not approved as biocidal active substances due to the environmental risks and no longer manufactured or imported by the European chemical industry. Despite that, they retained their status as approved cosmetic preservatives. Inconsistencies such as those described above compromise the high level of protection of the environment, and by extension the human health, that EU chemicals legislation aims at.

4.02.P-Mo317 Predicting Selection for Antimicrobial Resistance in UK Wastewater and Aquatic Environments: Ciprofloxacin Poses a Significant Risk
Laura May Murray[1]*, April Hayes*[1]*, Isobel C. Stanton*[1,2]*, Lihong Zhang*[1]*, Jason Snape*[3]*, William Gaze*[1] *and Aimee Kaye Murray*[1]*, (1)University of Exeter, United Kingdom, (2)UK Centre for Ecology & Hydrology (UKCEH), United Kingdom, (3)Astrazeneca UK, United Kingdom*
The environment acts as a reservoir of antimicrobial resistance (AMR) genes that can be transferred to clinically relevant bacteria. It is increasingly recognised as an important factor in the evolution, dissemination, and transmission of AMR. Antibiotics have been shown to select for AMR at concentrations comparable to those found in the environment. Despite these concerns, they are

released into the environment via wastewater, and this release is not regulated. Further research is required to determine if this release poses a risk that requires mitigation.
To investigate risk of selection for AMR in UK wastewaters, we used measured environmental concentration (MEC) data collected by UK water industry research (UKWIR) in England and Wales 2015-2018. The database contained MECs for four antibiotics: ciprofloxacin, azithromycin, clarithromycin, and erythromycin. We used these data to determine where MECs exceeded minimal selective concentration (MSC) thresholds. There are several methods used to determine MSCs of antibiotics. We used thresholds determined by evolution experiments with a complex sewage community which incorporates community interactions and bacteria likely to be found in wastewater. We also applied a dilution factor of 10 to effluent MECs, to predict concentrations of antibiotics in surface waters.
Results show that selection for AMR by ciprofloxacin is likely to occur routinely in the wastewaters of England and Wales (2015-2018). Wastewater treatment reduced the risk posed by ciprofloxacin significantly, but not completely, with almost 45 % of effluent MECs exceeding a medium selection risk (risk quotient (RQ) ≥ 1). Additionally, risk was still present in predicted surface waters. We investigated this further to look for seasonal and geographical trends. Although seasonal and geographical differences were observed, instances of high risk (RQ ≥ 10) in effluent were present at least once across all seasons, and medium risk was present in all geographical locations. Conversely, lower risks were posed by the macrolides (azithromycin, clarithromycin, and erythromycin) and no RQs > 1 were found.
Our data demonstrate risk of selection for AMR is present in UK waste waters and some receiving waters. Further action is needed to prevent selection for AMR, with environmental quality standards for some antibiotics likely required in the future.

4.02.P-Mo318 Antifungal Exposure and Resistance Development: Defining Minimal Selective Antifungal Concentrations and Testing Methodologies

Emily Stevenson[1], *William Gaze*[2], *Neil A. R. Gow*[3], *Alwyn Hart*[4], *Wiebke Schmidt*[5], *Jane Usher*[3], *Adilia Warris*[3], *Helen Wilkinson*[6] *and Aimee Kaye Murray*[2], *(1)Medical School, University of Exeter, United Kingdom, (2)University of Exeter, United Kingdom, (3)University of Exeter, MRC Centre for Medical Mycology, United Kingdom, (4)Environment Agency, (5)Chief Scientist's Group, Environment Agency (England), United Kingdom, (6)Environment Agency (England), United Kingdom*
Antifungal resistance (AFR) represents a significant, global threat to human health, associated with high mortality rates, absence of effective surveillance systems and with few alternative treatment options available. AFR within the clinic is well documented, though the environment is increasingly recognised to play a role in the evolution and spread of AFR. Diverse fungal communities have been discovered across a wide range of environmental compartments. These communities may be regularly exposed to antifungals from the direct application of effect concentrations of fungicides to agricultural crops and the incomplete removal of pharmaceutical antifungals in wastewater treatment systems, potentially increasing AFR selection risk. At present, environmental risk assessment guidelines do not require assessment of antifungal agents in terms of their ability to drive AFR development, nor are there established experimental tools to determine antifungal selective concentrations. Without data to interpret the selective risk of antifungals, our ability to effectively inform safe environmental thresholds is severely limited. This work aimed to summarise the current understanding of selection for AFR and to compare this with selection for antibacterial resistance. The findings allowed the identification of potential methods to generate antifungal selective concentration data. Data generated by such methods can be considered in the development of regulatory guidelines that aim to reduce selection for AFR in the environment.

4.02.P-Mo319 Microplastics as Vectors of Antimicrobial Resistance in Aquatic Systems

Emily Stevenson[1], *Angus Buckling*[2], *Matthew Cole*[3], *Penelope Lindeque*[3] *and Aimee Kaye Murray*[2], *(1)Medical School, University of Exeter, United Kingdom, (2)University of Exeter, United Kingdom, (3)Plymouth Marine Laboratory, United Kingdom*
Antimicrobial resistance (AMR) is one of the greatest threats to modern society, with the environment recognised to play an important role in the emergence, evolution and spread of AMR. Microplastics are the most prevalent type of plastic pollutant, and frequently co-exist in different environments alongside AMR bacteria, human or animal pathogens, antibiotic resistance genes and antimicrobial residues. Upon entering the environment, microplastics become rapidly colonised by phylogenetically diverse biofilms, also known as 'the Plastisphere'. It is proposed that Plastisphere communities support and enrich distinct, pathogenic and/or AMR communities in comparison to free-living counterparts or communities or those adhered to natural or inert substrates. Due to this, there are concerns that plastic particles may enrich and disseminate AMR pathogens in aquatic systems, potentially increasing human and animal exposure. Using both culture- and molecular-based methods, this research investigated and compared biofilm and free-living bacterial communities following incubation of environmentally aged microplastics and natural or inert substrate controls with a natural sewage community. Selective agar plating and qPCR for 16S rRNA and *intI1* were used to calculate phenotypic resistance prevalence of faecal coliforms and a community wide measure of resistance prevalence, respectively. A pre-described multiplex colony PCR was adopted to identify *Escherichia coli* pathotypes and generate pathotype prevalence within particle and free-living communities. This work identified that surfaces may promote the attachment of AMR bacteria and pathogens, but that the type of surface matters when selecting for these communities. These data will help to develop our understanding of the wider implications of these pollutants on human, animal and ecosystem health.

4.02.P-Mo320 Antimicrobial Residues in Poultry Litter: A Study of its Occurrence in Farms with Different Production Management and Evaluation of a Simple Waste Composting Process

Lucas Leonel Alonso[1], *Natalia S. Podio*[2], *Irma I. Bernigaud*[3], *Natalia S. Almada*[3], *Juan M. Gange*[3] *and Daniel Alberto Wunderlin*[2], *(1)UNLP-CONICET, Argentina, (2)Instituto de Ciencia y Tecnología de Alimentos Córdoba (ICYTAC), CONICET*

and Department of Organic Chemistry, Argentina, (3)Instituto Nacional de Tecnología Agropecuaria (INTA), Argentina
In recent years, poultry litter (PL) has gained value under the circular economy perspective due to its advantages as an agricultural fertilizer. However, the use of antimicrobials (AMB)implies the intake of these compounds, which can result in the excretion of up to 90% of the parent compound. The presence of AMB in animal manure poses a risk to both terrestrial and aquatic environments, including the potential spread of microbial resistances among the environmental microbiome. Given the worldwide magnitude of poultry production, and in accordance with the One Health perspective, it is relevant to generate baseline information that contributes to the characterization of the potential risks that this practice may entail to human health. Thus, we analysed the presence of AMB in PL from farms with different management practices. Besides, we performed a typical *in situ* composting process in the studied farms (15 days of stacking with a turning after 7 days). So, we had representative samples to verify the spread of the AMB after PL composting. Considering the complexity of the matrix, different extraction methods were tested, based on: (1) ultrasound and solid-phase extraction or (2) salt-assisted solvent extraction, including 5 different solvents and salts. The optimized method consisted of extraction at pH = 7, using acetonitrile and NaCl. Thereinafter, PL samples from 19 farms were analyzed (n= 3) by UHPLC-QqQ (Waters). Twenty out of 23 studied AMB were detected throughout studied samples at levels ranging from 0.001 mg/kg to 25.3 mg/kg (Sulfamethoxazole). Fluoroquinolones and tylosin were the most frequently AMBs detected, whit ionophores presenting the highest concentrations. Farms that restricted the use of AMB in feed presented less occurrence and load of these compounds in PL. Moreover, we observed that the natural heat, occurring during compost production, lead to a reduction of ca. 50% from the starting concentration in 9 AMB Our current results highlight the relevance of AMB surveillance in PL residue before deciding its use for composting, manure addition, etc. Finally, reducing the use of AMB into feed and veterinary practices helps with a sustainable use of PL during composting, which may help to reduce the load of these compounds in compost, helping with a sustainable re-use of PL.

4.02.P-Mo321 Removal of Intracellular and Extracellular Antibiotic Resistant Genes (ARGs) by Ultraviolet Light in Different Water Matrices

***Rominder Pal Singh Suri**, Civil & Environmental Engineering, Temple University*
Antibiotic resistant bacteria (ARB) and antibiotic resistance genes (ARG) have been recognized as emerging contaminants of concern. ARGs are known to be persistent and have been detected widely in wastewater effluents worldwide. UV disinfection is gaining implementation at wastewater treatment plants, and could also be used for the removal of ARGs. In this study, different types and forms of ARGs (chromosomal, plasmids; intracellular and extracellular) from different resistant *E. coli's* were evaluated by UV and UV/H_2O_2 process as a function of water matrices. The degradation profile of extracellular-ARGs (e-ARGs) showed 1-4 log reductions (90-99.99% removal) during UV treatment. UV-mediated e-ARG degradation strongly depends on the number of active sites and ARG types. The intracellular-ARGs (i-ARGs) showed similar degradation rates as compared to e-ARGs for UV in phosphate buffer saline (PBS). During UV/H_2O_2 treatment, •OH radicals showed improved degradation for some e-ARGs (1.2-5 logs). However, this advanced oxidation process showed minimal contribution for i-ARG degradation (1-2.4 logs), due to scavenging of •OH radicals by the cellular components in PBS. In contrast to the PBS, the wastewater matrix moderately enhanced degradation, possibly due to the generation of reactive species from effluent organic matter. For the plasmid degradation, conformational differences of the supercoiled structures showed 1.2-2.8 times slower degradation rates than chromosomal ARGs. In addition, the fate of free residual ARGs (*f-ARGs*) and their degradation kinetics were tracked to monitor the correlation between ARB inactivation and subsequent AMR dissemination risk. Overall, these results can be useful for better assessing UV and UV/H_2O_2 based treatment processes for the effective removal of ARGs from water and wastewater.

4.02.V Antimicrobials in the Environment – A Threat to Environmental and Human Health?

4.02.V-01 Effects of Erythromycin and Roxithromycin on River Periphyton: Structure, Functions and Metabolic Pathways

***Ning Ding**[1] and Jiahua Guo[2], (1)Northwest University, China, (2)College of Urban and Environmental Sciences, Northwest University, China*
Macrolide antibiotics have been frequently detected in surface waters worldwide, posing a threat to the aquatic microbes. While several studies have evaluated the ecotoxicological effects of macrolides on single algal and bacterial strains, these results without consideration of the species interaction in the aquatic microbial community cannot be realistically extrapolated to the field. The aim of this study is therefore to evaluate the effects of two macrolides (erythromycin and roxithromycin) on the structure, photosynthetic process, and carbon utilization capacity, as well as the antibiotic metabolic pathways in river periphyton. The colonized periphyton was exposed to the graded concentration (0 µg/L (control), 0.5 µg/L (low), 5 µg/L (medium), 50 µg/L (high)) of ERY and ROX, respectively, for 7 d exposure. Here, ERY and ROX at high level altered the community composition by primarily reducing the relative abundance of Chlorophyta in the eukaryotic community, and the Shannon and Simpson diversity index of prokaryotes were lowered, though similar effects were seldomly detected in the low and medium groups.
In contrast with the unchanged carbon utilization capacity, the PS II reaction center involved in the periphytic photosynthesis was significantly inhibited by macrolides exposure. In addition, both antibiotics had been degraded effectively by periphyton, with the removal rate of 51.63% to 66.87% and 41.85% to 48.27% for ERY and ROX, respectively, where side chain and ring cleavage were the main degradation pathways. Overall, this study provides an insight into the structural and functional toxicity and degradation process of macrolides in river periphyton.

4.02.V-02 Metagenomic Analysis Reveals the Spatio-Temporal Shifts of Microbial Community in an Urban River System Contaminated by Macrolide Antibiotics

Jiahua Guo, *College of Urban and Environmental Sciences, Northwest University, China*
Macrolide antibiotics have been frequently detected in surface waters worldwide, posing a threat to the aquatic microbes. While several studies have evaluated the ecotoxicological effects of macrolides on single bacterial strains, it remains undetermined whether the abundance and biodiversity of bacterial community is negatively linked the occurrence of macrolides in the environment. The aim of this study is therefore to investigate the spatio-temporal distribution of macrolide residues in Zao River (Xi'an city, China), known as an urban river receiving reclaimed water discharged from a Wastewater Treatment Plant, and their potential effects on the aquatic microbial community. Here, the sampling campaign including 20 sites was conducted in dry (Dec, 2021), normal (April, 2022), and wet seasons (Aug, 2022). The levels of five macrolides, including azithromycin (AZI), roxithromycin (ROX), erythromycin (ERY), clarithromycin (CLA), and anhydro erythromycin (ERY-H_2O) were measured by HPLC-MS/MS coupled with solid-phase extraction. The composition of aquatic microbial community was characterized by metagenomic analysis of the filtered river water. Overall, five macrolides have been detected in Zao river with the concentration of AZI (0 - 1359 ng/L), ERY (0 - 236 ng/L), ROX (0 - 690 ng/L), CLA (0 - 76 ng/L), and ERY-H_2O (0 to 24 ng/L). Furthermore, the seasonal shifts of macrolide residues are as follows: Dry season > Wet season > Normal season, and the levels were gradually reduced from the outlet to the lower reaches of the river. The redundancy analysis (RDA) between the microbial Operational Taxonomic Unit (OTUs) at species level and macrolide residues indicated that the abundance of bacteria was negatively impacted by the antibiotic residues, including *Opitutae bacterium*, *Verrucomicrobia bacterium*, *Flavobacteriales bacterium*, *Rhodospirillaceae bacterium CCH5-H10*, and *Rhizobiales bacterium KCTC 52945*, in three seasons. In addition, *Chloroflexi bacterium* and *Acidobacteria bacterium* were positively correlated with macrolides in dry and normal seasons, whereas the trend was opposite in wet season. The network analysis is also performed to explore the correlation among antibiotic residues, antibiotic resistance genes, and the structure of microbial community. Overall, this study gains an insight into the distribution characteristics of macrolide antibiotics and their interaction with the aquatic microbial community in an urban river receiving reclaimed water.

4.03.P Biogeochemistry, Ecotoxicology, and Life Cycle of Critical Raw Materials

4.03.P-Tu338 Are Seaweeds Suitable Indicators to Assess Spatiotemporal Patterns in Critical Elements Concentrations? An Insight on the Use of Seaweeds as Biomonitors in Norwegian coastal Areas

Stefania Piarulli[1], Achillefs Zervos[2], Sara Cvetkovics[3], Tomasz Ciesielski[4], Silje Forbord[1], Juliane Annemieke Riedel[5], Bjørn Henrik Hansen[1] and ***Julia Farkas***[1]*, (1)SINTEF, Norway, (2)Chemistry, Norwegian University of Science & Technology (NTNU), Norway, (3)3Department of Functional Aquatic Ecotoxicology, University of Kaiserslautern-Landau (RPTU), Germany, (4)Department of Biology, Norwegian University of Science & Technology (NTNU), Norway, (5)Nord University, Norway*
Rising critical element (including metals and rare earth elements plus yttrium, REY) production and use can also lead to an increasing release into the environment, therefore monitoring the concentrations of these elements in the marine environment is crucial to assess the related environmental risk. Seaweeds are, due to their high abundance, widespread distribution, sessile nature and the capacity to bioconcentrate elements considered as suitable organisms for biomonitoring of element/metal pollution. The aim of the study was to assess the suitability of brown seaweeds as biomonitoring organisms to detect spatiotemporal and source-related contamination patterns of technology critical element concentrations in the Norwegian coastal environment. We also assessed the suitability of two biomonitoring approaches through two case studies. In Case study 1 we applied passive biomonitoring using different species of naturally growing seaweeds specimens and in Case study 2 we used active biomonitoring, using cultivated specimens of a single seaweed species (*Saccharina latissima*) deployed at specific monitoring sites. Element concentrations were determined using ICP-MS on freeze dried seaweeds tissue samples. Relationships between element accumulation, and presence of local point-sources, environmental and biological parameters were evaluated. Results from Case study 1 indicated spatial and species-specific differences in REY concentration according to the sampling site, with seaweeds (specially *Fucus* spp. and *Saccharina latissima*) sampled in proximity to potential anthropogenic point-sources having the highest REY concentrations. Findings from Case study 2 showed a high spatiotemporal variability in element concentrations, with different elements (or element groups) exhibiting specific trends. REY behaved as a coherent group, showing similar spatiotemporal trends with accumulation being most pronounced in a freshwater impacted site. Other investigated elements exhibited various spatiotemporal trends according to different biotic and abiotic drivers. Our findings indicate that (either natural or cultivated) seaweeds can act as useful biomonitoring organisms for assessing spatiotemporal variation of the bioavailable dissolved element fraction as well as to assess the presence of local anthropogenic element sources. Furthermore, species-specific difference in element uptake and accumulation patterns exists and need to be considered for future use of biomonitoring.

4.03.P-Tu339 Fate and Biological Effects of Rare Earth Element mixtures in a Model Freshwater Food Web

Nicolas Lachaux[1]*, Laura Junique[1], Simon Devin[1], Sébastien Cambier[2], Benedicte Sohm[1], Amelie Chatel[3], Laurence Poirier[4], Sandrine Pain-Devin[1], Elisabeth Maria Gross[1] and Laure Giamberini[1], (1)Liec Cnrs Umr 7360, University of Lorraine, France, (2)Luxembourg Institute of Science and Technology (LIST), Luxembourg, (3)Université Catholique de l'Ouest, France, (4)Nantes University, France*
The growing uses of rare earth elements (REE) led to increasing releases of anthropogenic REE in freshwater systems from effluents of mining, industrial, medical, wastewater treatment plant (WWTP) activities, which raise concern about their environmental risk. The lack of environmental realism in REE ecotoxicological studies implies a limited extrapolation of the results to natural ecosystems. The objectives of this study was to i) assess REE mixture (Nd+Gd+Yb) fate and biological effects in more realistic conditions reproducing environmental scenarios of REE contamination: WWTP effluents and industrial/mining

activities, set at 15 and 1500 µg L^{-1} total REE concentration, respectively, ii) compare the fate, bioaccumulation and toxicity of Gd in its chloride form (GdCl) and MRI contrast-agent (GdCA), iii) assess the potential REE trophic transfer.
We reproduced a freshwater food web in indoor mesocosms using the primary producers *Myriophyllum spicatum, Raphidocelis subcapitata* and *Chlorella vulgaris*, the primary consumers *Corbicula fluminea* and *Daphnia magna* and the secondary consumer *Danio rerio*. After 28 days of exposure, we measured a battery of biomarkers including growth, behaviour, oxidative stress, cellular damages, elemental homeostasis, photosynthetic pigments on *C. fluminea*, *D. rerio* and *M. spicatum.* In addition, REE were quantified in the medium and in the organisms.
The results showed that species from all trophic levels accumulated significant concentrations of Nd, Gd and Yb. REE bioaccumulation was not influenced by food contamination and decreased with increasing trophic level demonstrating the limited trophic transfer of REE. Exposed bivalves and fish showed increased activities of GST, LDH and CSP-3 activities suggesting a stress and potential tissue damages. Osmoregulation was disturbed in exposed bivalves with an inhibition of $Na^{+}K^{+}$-ATPase activity in *C. fluminea*. *M. spicatum* growth was inhibited and photosynthetic pigment contents decreased at the highest tested concentration. GdCA had an opposite fate compared to GdCl with a lower bioaccumulation and a different internal distribution in *C. fluminea* and *D. rerio*.
Overall, this study showed that current effluents from mining, industrial and WWTP activities are of concern because they contain high concentrations of REE that can be accumulated and induce toxic effects on species belonging to different trophic levels, especially primary producers.

4.03.P-Tu340 Bioavailability and Effects of Different Forms of Gadolinium in Three Fish Species
***Julia Farkas**[1], Juliane Annemieke Riedel[2], Stefania Piarulli[1], Ailin Østerås[3], Frida Fossum[3], Florence Kermen[3], Trond Nordtug[1], Pal A Olsvik[2], Christian Sonne[4], Páll Leiffson[5], Tørris Sandsæter[6], Arne Malzahn[1], Bjørn Munro Jenssen[6], Tomasz Ciesielski[6] and Bjørn Henrik Hansen[1], (1)SINTEF, Norway, (2)Nord University, Norway, (3)Norwegian University of Science & Technology (NTNU), Norway, (4)Bioscience, Aarhus University, Denmark, (5)University of Copenhagen, Denmark, (6)Department of Biology, Norwegian University of Science & Technology (NTNU), Norway*
Gadolinium is one of the rare earth elements (REY), and is, amongst others used as contrast agent for magnetic resonance imaging (MRI) diagnostics. Due to toxic properties of Gd^{3+} Gd-based contrast agents (GBCAs) are administered as Gd-chelates. GBCAs are not retained in wastewater treatment plants and are thus released into the aquatic environment where Gd can be detected as micropollutant in rivers, groundwater, and coastal waters. Gd emissions from MRI imaging are substantial and are estimated to several tons annually. However, knowledge on the effects of Gd on aquatic organisms is still scarce. In the Elementary project we studied effects of inorganic Gd ($GdCl_3$) and GBCAs on three fish species: embryos and larvae of zebrafish (*Danio rerio*), embryos and larvae of Atlantic cod (*Gadus morhua*) and juvenile lumpfish (*Cyclopterus lumpus*).
Our results show that, while Gd is bioavailable in both forms, $GdCl_3$ is taken up to a larger extend in early live stages of fish. $GdCl_3$ exposure did have negative effects on both zebrafish and cod larvae. However, effects were more pronounced in cod, where we found early hatching, an increase in mortality and deformation rates as well as lacking pigmentation following exposure to (nominally) 300 and 3000 µg/L Gd equalling approximately 130 µg/L of dissolved Gd as analysed by ICP-MS. In contrast, these concentrations did not affect survival or development in zebrafish, showing a lower sensitivity in comparison to cod. We did, however, find effects on neural activity in form of a decrease of pERK and tERK in the brain of zebrafish exposed to $GdCl_3$ at high concentrations. In contrast, GBCA caused a slight increase in neural activity.
In lumpfish, exposure to low concentrations of $GdCl_3$ and GBCA did not cause mortality or obvious behavioural changes. Similarly, no significant effects on body mass and the determined blood parameters. Uptake, organ distribution and effects are analysed.
Results of our study show that free Gd can affect early life stages fish, and show a greater sensitivity of cod compared to zebrafish. Our findings highlight that effects of chemicals can be overlooked in standard toxicity tests, and that a more in-depth investigation, also including potentially exposed non-standard species can be advisable. While we did not observe effects of the tested GBCA, data on GBCAs stability in the marine environment are scarce and await further studies to determine environmental fate and potential effects.

4.03.P-Tu341 Deep-Sea Mining as an Emerging Stressor in Deep-Sea Environments: Case Studies Using Hyperbaric Chambers for Hazard and Risk Assessment
***Bárbara Marlene Pinheiro**[1,2], Rithielli Marassi[3], Adriana Oliveira[1,3], Susana Barros[3], Nélson Alves[1,3], Hugo Morais[1,3], Marta Ribeiro[3], Miguel Caetano[3,4], Joana Raimundo[3,4], Filipe Castro[1,3], João Coimbra[3], Teresa Neuparth[3] and Miguel M. Santos[1,3], (1)Department of Biology, Faculty of Sciences of the University of Porto (FCUP), Portugal, (2)Porto University, Portugal, (3)University of Porto, Interdisciplinary Centre of Marine and Environmental Research, Portugal, (4)Portuguese Institute for Sea and Atmosphere (IPMA), Portugal*
The deep-sea, the largest biome on Earth, despite its remoteness is subjected to anthropogenic stressors. These stressors include, among others, deep-sea mining, an emerging threat to deep-sea environments. Deep-sea mining is being looked at with renewed interest due to the increased need for minerals and rare earth elements that are depleting land-based deposits because of technological advances, mainly in green energy. Deep-sea mining will release sediment plumes, clouds of resuspended particles, considered one of the most extensive and immediate effects of mining as they can travel hundreds of kilometers across the water column.
To study the potential effects of suspended sediments, we used two model species, the *Mytilus galloprovincialis* mussel and the *Spisula solida* clam, exposed for 96h in a hyperbaric chamber to different size classes of sediments (63-125;125-250;250-500um) in a mixture with different concentrations (1,2 and 4g/L) at increasing pressures (up to 50Bar). We analyzed the filtration rate

(FR) and oxidative stress biomarkers in juvenile mussels and adult clams. The FR decreased in all conditions and significant changes were observed in all tested biomarkers, which were concentration and pressure dependent. We also studied the effects of the different size classes of sediment separately by exposing juvenile mussels to the different sizes of sediments at 1g/L and 4Bar. The FR, molecular and biochemical endpoints were analyzed. The FR decreased significantly for all sizes with a more pronounced effect in the smaller particles. Significant changes were found in all tested biomarkers and gene expression was altered in some genes related to oxidative stress (catalase and actin).
Sediments affected the organisms at all levels, with a more pronounced effect for the smallest particles. As these particles are known to have high dispersion capacities, particular attention should be given to their release as a by-product of mining. These findings will help to fill knowledge gaps in the effects of suspended particles in deep-sea environments, contribute to hazard and risk assessment of deep-sea mining and to the establishment of frameworks to mitigate the negative effects of this stressor in sensitive habitats.

4.03.P-Tu342 Potential Future Ecotoxicological Problems in Soil Irrigation by Gadolinium Pollution
Ana Romero Freire[1], *Manuel Sierra Aragón*[1] *and Hao Qiu*[2], *(1)Department of Soil Science and Agricultural Chemistry, University of Granada, Spain, (2)School of Environmental Science and Engineering, Shanghai Jiao Tong University, China*
Rare earth elements use has increased in the last decades in multiple anthropogenic activities from green energy and medical technologies to telecommunications. However, due to until the end of last century they had never been characterized as essential or toxic for living organisms, the current understanding on the concentration, behaviour and possible ecological effects of almost all REEs is limited, and no regulatory information has been settled. One of the most frequently detected anthropogenic REE is gadolinium (Gd), the occurrence of Gd anomalies is highly correlated with the use of this metal in medical applications, especially in densely populated areas. For example, it was reported that the release of Gd in Germany, related to biomedical purpose, was ca. 12t Gd per year. Since Gd cannot be removed by common sewage treatment technologies, we expect that it will be easily increase their accumulation in irrigated soils. Therefore, the aims of the present study are to (1) perform a preliminary ecotoxicological risk assessment for Gd in soils; and (2) assess the potential trophic movement of Gd in a crop irrigated with water enriched in this element. For this study soils with contrasting properties, will be spiked with different Gd concentrations (from 0 to 4000 mg kg^{-1}) and short-term ecotoxicological assays with lettuce, due to is a well-known laboratory model and an irrigated crop, will be performed. According to the EC values obtained in the ecotoxicological test, and the concentrations of Gd in water rivers of the city of Granada, potential Gd content in irrigated waters will be selected. Different soils will be irrigated and incubated for at least 4 weeks. After that, a lettuce plantation will be culture (28 d) and irrigated weekly with Gd enriched water, to check the toxic effect and potential Gd accumulation and translocation in plants. Our results will shed light on the effect of use waters with anthropogenic Gd in irrigating crops and if the continuous discharge of this element in aquatic systems could lead to plant detriment and, finally, pass Gd through the trophic chain.

4.03.P-Tu343 Evaluation of the Effects of a Mixture of REE ol Gene Expression of *Daphnia magna*
Kahina Mehennaoui[1,2], *Jeremy Delaunay*[1], *Sébastien Cambier*[1], *Arno Gutleb*[1], *Laure Giamberini*[2], *Tommaso Serchi*[1] *and Benedicte Sohm*[2], *(1)Luxembourg Institute of Science and Technology (LIST), Luxembourg, (2)University of Lorraine (LIEC), CNRS, France*
Rare earth elements (REE) are considered as technology critical elements. Compared to trace elements with well-documented environmental impacts, REE remain less studied, and their toxicity mechanisms are not fully understood. A transcriptomic approach through a targeted gene expression method was used to investigate REE effects on *Daphnia magna* at sub-lethal concentrations. A set of stress-related genes was selected to assess the effects of a mixture of REE on *D. magna* juveniles.
