ABSTRACT BOOK

SETAC EUROPE 34TH ANNUAL MEETING

5–9 MAY 2024 | SEVILLE, SPAIN

SCIENCE-BASED SOLUTIONS IN TIMES OF CRISIS: INTEGRATING SCIENCE AND POLICY FOR ENVIRONMENTAL CHALLENGES.

Abstract Book

SETAC Europe 34th Annual Meeting

Table of Contents

This book compiles the abstracts from the 34th annual meeting of the Society of Environmental Toxicology and Chemistry – Europe (SETAC Europe), conducted from 5–9 May 2024 in Seville, Spain.

The abstracts are reproduced as submitted by the author and accepted by the scientific committee. They appear in order of abstract code and alphabetical order per presentation type. The poster spotlight abstracts are included in the list of poster abstracts. The presenting author of each abstract is highlighted in bold.

The information in this abstract book reflects the status of the abstracts as was on 29 April 2024.

PRINT ISSN 2309-8031 - ONLINE ISSN 2310-3043 © 2024

Society of Environmental Toxicology and Chemistry Europe (SETAC Europe)

About SETAC

In the 1970s, no forum existed for interdisciplinary communication among environmental scientists, biologists, chemists, toxicologists, managers, engineers or others interested in environmental issues. The Society of Environmental Toxicology and Chemistry (SETAC) was founded in North America in 1979 to fill the void and quickly saw dynamic growth in the Society's membership, meeting attendance and publications.

A unique strength of SETAC is its commitment to balance the scientific interests of government, academia and business. The Society by-laws mandate equal representation from these three sectors for officers of the World Council and Geographic Unit Boards of Directors and Councils, and in the composition of committees and other society activities. The proportion of members from each of the three sectors has remained nearly equal over the years.

The Society is concerned about global environmental issues. Its members are committed to Environmental Quality Through Science®, timely and effective communication of research, and interactions among professionals so that enhanced knowledge and increased personal exchanges occur. Therefore, SETAC publishes two globally esteemed scientific journals and convenes annual meetings around the world, showcasing cutting-edge science in poster and platform presentations. Because of its multidisciplinary approach, the scope of the science of SETAC is broader in concept and application than that of many other societies.

SETAC's growth is reflected in the founding of Geographic Units around the world. SETAC Europe was established in 1989 as an independent organisation, followed by SETAC Asia-Pacific in 1997 and SETAC Latin America in 1999. In 2002, the four existing organisations joined together under the governance of the SETAC World Council. SETAC Africa is the most recent Geographic Unit, which was adopted in 2012. As evidence of international acceptance of the SETAC model and of the great interest at the local level, regional chapters and branches have emerged in a number of countries.

SETAC publishes two journals, *Environmental Toxicology and Chemistry* (ET&C) and *Integrated Environmental Assessment and Management* (IEAM). ET&C is dedicated to furthering scientific knowledge and disseminating information on environmental toxicology and chemistry, including the application of these sciences to risk assessment. Integrated Environmental Assessment and Management focuses on the application of science in environmental decision-making, regulation and management, including aspects of policy and law, and the development of scientifically sound approaches to environmental problem solving. Together, these journals provide a forum for professionals in academia, business, government and other segments of society involved in the use, protection and management of the environment for the enhancement of ecological health and human welfare.

SETAC books provide timely in-depth reviews and critical appraisals on scientific subjects relevant to understanding a wide range of contemporary topics pertaining to the environment. These include any aspect of environmental chemistry, toxicology, risk assessment, risk management or environmental policy.

SETAC has two administrative offices, in Pensacola, Florida, USA, established in 1992, and in Brussels, Belgium, established in 1993.

Environmental Quality Through Science®

Track 1. Environmental and Human Toxicology: From Molecules to Organisms, from Omics to in Vivo

1.01 Advancing the Use of Effect-Based Approaches for Water Quality Assessment

1.01.T-01 Use of estrogen receptor cell bioassays to evaluate dietary and aqueous exposure routes to determine the cause of widespread intersex in Largemouth Bass in a waste-water dominated stream.

Victoria McGruer[1], William Ota[2], Alvine C Mehinto[3], Charles S. Wong[3], Wayne Lao[3], Kali Krishnan[1], Brian Yacoub[1], Kurt E Anderson[2] and ***Daniel Schlenk[1]***, *(1)Environmental Sciences, University of California Riverside (UC Riverside), (2)Evolution, Ecology, and Organismal Biology, University of California Riverside (UC Riverside), (3)Southern California Coastal Water Research Project (SCCWRP)*

The Santa Ana River flows within the largest river basin in southern California, home to over 5 million residents. Due to upstream dams and dry climate, the surface flow is dominated by wastewater effluent most of the year, with more than 93 million gallons of effluent discharged into the river daily. The continuous input of treated effluent raises concern for protecting native fish within the river, such as the federally threatened Santa Ana sucker (*Catostomus santaanae*). Previous work in the Santa Ana River demonstrated that the estrogenic activity of water samples collected downstream of wastewater treatment plants (WWTPs) did not significantly differ compared to other sampling sites along the river. However, a 2019 survey of Largemouth bass (*Micropterus salmoides*) found that the percent of fish with the visible presence of both testes and ovaries increased with proximity to a WWTP outflow (Adjusted R-squared: 0.854, p-value: 0.015). In order to determine the contribution of dietary exposure to estrogenic substances, water, sediment, periphyton, and macroinvertebrates, were sampled and chemical and Estrogen-Receptor Bioassays were conducted on extracts. Histological analysis of Male Largemouth bass testes found that males at all sites displayed the presence of ova-testes ranging from 33-67% presence depending on the site. However, Intersex prevalence was not statistically different between sites (Chi-square test, $p = 0.7$). Chemical analysis found that the estrogens 17b-estradiol (E2) and estrone (E1) were detected at three and four of the six river sites, respectively. Comparisons of analytical chemistry with ER-Bioassays indicated significant correlation with an r-value of 0.58 ($p < 0.0015$). Evaluations of extracts of periphyton and macrofauna did not have detected estrogenic activity nor E1 or E2. These data suggest dietary exposure may not be responsible for the widespread intersex observed in fish of the SAR.

1.01.T-02 Chemical mixtures : Additivity and beyond

David Spurgeon[1], *Stephen James Short[2], Alex Robinson[1], Claire Badder[1], Sylvain Bart[3] and Peter Kille[4], (1)UK Centre for Ecology & Hydrology (UKCEH), United Kingdom, (2)Pollution, UK Centre for Ecology & Hydrology (UKCEH), United Kingdom, (3)Ministère de l'Écologie, du Développement durable, des Transports et du Logement, France, (4)Cardiff University, United Kingdom*

Semi-quantitative and untargeted screening methods mean it is now more tractable to detect and measure a wider range of chemicals present in the environment. The Environment Agency use semi-quantitative GC-MS and LC-MS methods to measure >1,000 chemicals in groundwater and surface water samples collected from across England and Wales. These measurements indicate that in any given sample, up to 100 chemicals may be detected. The risks to aquatic ecosystems from these mixtures can be assessed by comparing measured concentrations to hazard values derived from toxicity tests. Such analyses indicate that, as expected, risk increases with the number of detectable compounds. However in the vast majority of cases, much of the risk (>80%) is due to ≤ 5 of the chemicals present. This analysis assumes, as a default, that the chemicals work additively. What if this is not the case? Experimental studies have shown cases of both antagonism and synergism in the joint toxicity of chemical pairs. A meta-analysis indicated that such non-additive cases represent about 20% of all mixture studies. Interactions occur at even higher frequency between pesticides, with azole fungicides often one of the two chemicals in these non-additive mixtures. The capacity of these fungicides to inhibit cytochrome P450 enzymes, likely contributes to these cases of synergism, with species with a low CYP P450 diversity particularly affected by such interactions (i.e. such species show more frequent and larger magnitude synergism when exposed to a chemical mixture that include an azole). If this synergism potential is included in the risk assessment for surface water for chemical mixture effects, then the number of locations at risk can be greatly increased.

1.01.T-03 Can we use a biosensor to detect water pollution in real-time? Results of a pilot study in the Venice lagoon

Roberta Carafa[1], ***Elisabetta Canuti[2]***, *Jordi Sierra[3], Ana Garcia[1], Sara Draganova[1], Sebastiano Carrer[4], Saurav Kumar[5], Vikas Kumar[6], Austoni Martina[7], Teresa Lettieri[8] and Montserrat Real[1], (1)AECOM, Spain, (2)European Commission - Joint Research Centre (JRC), Belgium, (3)Enginyeria Química, Universitat Rovira i Virgili, Spain, (4)Thetis, Italy, (5)Pere Virgili Health Research Institute (IISPV), Spain, (6)Universitat Rovira i Virgili, Spain, (7)CNR-Water Research Institute IRSA, Italy, (8)European Commission - Joint Research Centre (JRC), Italy*

In 2021, 214 million tons of chemicals hazardous to health were produced (4% more than in 2020; 1% more than in 2019), along with 85 million tons of chemicals hazardous to the environment (6% more compared with 2020; 2% more than in 2019) (EUROSTAT). A fraction of these chemicals reaches surface, ground, and marine waters in complex mixtures through different emission sources: industry, WWTPs, diffuse sources (leaching and runoff in agricultural fields, air deposition, etc.). In this challenging context, the European Commission adopted a proposal to review and modify the Water Framework Directive in 2022, in line with the objectives of the European Green Deal and the Zero Pollution Action Plan. To address these new stringent water quality requirements, we have developed a new monitoring device, called WATERSCAN that continuously tests water quality using a biosensor. WATERSCAN applies real-time PAM (Pulse Amplitude Modulated) fluorometry to detect changes in functional indicators of microbial biofilms exposed to a constant water flow and includes a local clean reference. The device also included passive samplers POCIS (Polar Organic Chemical Integrative Samplers), specific for polar organic compounds, Diffusive Gradient in Thin film (DGT), for trace metals and a novel passive sampler to determine chemotaxonomical phytoplankton composition. The prototype, protected by a patent, has been tested in the field. Here are the results of the pilot study conducted at the Arsenale of the Venice lagoon from 17/7/23 to 27/7/23. First results indicate that the device can operate with minimal maintenance and provides highly sensitive results with a constant water flow during several days. Significant differences were detected between monitoring and reference chambers indicating possible water contamination events, in line with the results of passive sampling. A local reference was essential to discriminate significant divergences in PAM signals, especially during and after a storm event. The analysis of chlorophyll-a content indicates higher concentrations in the inflow compared to the outflow. This pattern is more pronounced during the afternoon, aligning with the day/night cycle of phytoplankton. HPLC and microscopy analysis confirm that colonization of the biofilm by external species is reduced to a minimal colonization by diatoms. Future developments will include the implementation of a standard monospecific biofilm to reduce variability in results.

1.01.T-04 Increasing the Acceptance of Effect-Based Methods for Surface Water Quality Assessment – Results of an Interdisciplinary Workshop

Rita Triebskorn[1], Matthias Oetken[2], Cornelia Kienle[3], Andrea Sundermann[4], Jochen Kuckelkorn[5] and ***Gerd Maack**[6]*, *(1)University of Tuebingen, Germany, (2)Aquatic Ecotoxicology, Goethe University Frankfurt, Germany, (3)Ecotox Centre, Switzerland, (4)River Ecology and Conservation, Senckenberg Research Institute and Natural History Museum Frankfurt, Germany, (5)Section Toxicology of Drinking Water and Swimming Pool Water, German Environment Agency (UBA), Germany, (6)German Environment Agency (UBA), Germany*

Several Effect-Based Methods (EBM) are currently available to characterise water pollution. However, they are only partially represented in the relevant regulations for assessing water quality in Europe. In many of them, EBM are not accepted, often not even mentioned. The main reason identified was the lack of regulatory acceptance. Chemical analysis is often seen as simpler, more accurate and safer, and also as a competitor rather than an explanatory tool to explain the observed effects. Lack of knowledge about EBM, including its advantages such as higher sensitivity or integration of mixture effects, is another potential reason. Further reasons are doubts about the robustness of the data and their (ecological) relevance. Lack of standards for the individual assays and of experience of the regulatory laboratories, are potential reasons for the missing acceptance and establishment in water management practice or regulation. To overcome this problem the participants of a workshop, organised by the Association of German Engineers (VDI) and the North Rhine-Westphalia Office of Nature, Environment and Consumer Protection (LANUV) suggested several measures: (i) Intensive communication is needed not only between the scientific community and the authorities involved, but also between the EU and the respective national administrations, (ii) implementation of EBM in the respective guidance documents, (iii) the advantages, but also the differences, of EBM compared to standard analytical methods should be better explained to government and policy makers. (iv) interlaboratory comparisons are needed to standardise technical procedures such as sample preparation and extraction as well as EBM, (v) for the results of EBM to be admissible in court, the derivation of toxicity thresholds/ effect-based trigger values must be scientifically robust and accepted by regulatory authorities, (vi) the assays and the organisms used in these assays need to be available in sufficient quantity and quality. In addition, (vii) EBM-related data should not only be published in peer-reviewed scientific journals, but also in journals relevant to government, water management professionals and the private sector. Also (viii) competence centres for co-ordinating existing initiatives should be stablished. As a first step towards an EU-wide application, the current proposal to amend the Water Framework Directive proposes to include EBM to assess the presence of estrogenic hormones in water bodies.

1.01.T-05 Daphnia magna behavioural responses. An emerging novel tool for effect direct analyses of neuro-active substances in waste water treated effluents

***Irene Romero**[1]*, *Cristian Gómez-Canela[2] and Carlos Barata Dr[3], (1)Department of Analytical and Applied Chemistry, Department of Analytical and Applied Chemistry, School of Engineering, Institut Químic de Sarrià-Universitat Ramon Llull, Spain, (2)School of Engineering, Institut Químic de Sarrià-Universitat Ramon Llull, Spain, (3)Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain*

Behavioral responses in non-animal species, such as *Daphnia magna* and zebrafish embryos, are increasingly used as sublethal toxicological endpoints for assessing neurodevelopmental and neuro-disruptive effects of toxic contaminants. However, their reliability in detecting neuro-active compounds in real-world field situations remains unclear. In the present study, we present the we present the outcomes of a battery of seven behavioral responses in D. magna, along with neurotransmitters and related metabolites, employed to identify neuro-active contaminants present in wastewater-treated effluent discharges from three rivers in southeastern (SE) Spain. The investigated rivers include Llobregat and Besós, located within the Barcelona urban area and receiving a mix of industrial and domestic effluents, and the Onyar river in Girona, primarily affected by agricultural activities. Our sampling involved collecting water samples from wastewater treatment plant (WWTP) effluent discharges, upstream and downstream locations, on two occasions. Contaminants from these samples were extracted and pre-concentrated using solid phase extraction (SPE) cartridges , and tested at concentrations enriched by factors of x2, 5, 10 and x20 fold. Analysis of contaminants was performed using liquid chromatography coupled to tandem mass spectrometry (LC-MS/MS). Of the 48 water samples analyzed at increased concentrations, 43 showed impacts on at least one of the measured responses. Specifically, Llobregat, Besos and Onyar rivers, respectively, affected 24, 19 and 2 *D. magna* responses. The extracts concentrated x20 fold accounted for 67% of the detected effects, clearly indicating a concentration-dependent response. Additionally, WWTP discharges had a pronounced impact on the studied rivers, contributing to 88%of the observed

effects. Finally, the use of chemometric and bioinformatic tools helped to identify potential neuro-active contaminants and understanding their modes of action.
This study was supported by the grants TED2021-130845B-C31, TED2021-130845B-C31, PID2020-113371RB-C21 and PID2020-113371RB-C22 funded by MCIN/AEI/ 10.13039/501100011033 and by the NextGenerationEU/PRTR.

1.01.P Advancing the Use of Effect-Based Approaches for Water Quality Assessment

1.01.P-We001 Application of a bioassay battery to assess water quality in 15 Swiss watercourses

***Cornelia Kienle**, Nadine Bramaz, Andrea Schifferli, Daniel Olbrich, Anne-Sophie Voisin, Inge Werner, Etienne Vermeirssen and Benoit J.D. Ferrari, Swiss Centre for Applied Ecotoxicology, Switzerland*

Effect-based methods such as ecotoxicological bioassays and biomarkers are promising for assessing water quality. As screening tools and early indicators, they provide an important bridge between exposure (i.e. the chemicals present and the associated risks to aquatic organisms) and the effects on organisms in the environment and enable the assessment of mixtures of contaminants in environmental samples, especially because not all substances present can be measured. The Ecotox Centre has carried out an extensive monitoring study with the aim of extending the assessment of water quality using a selection of effect-based methods. To this end, water quality was assessed at sites with extensive, agricultural or agricultural-urban land use using a comprehensive bioassay battery of largely standardised water and sediment bioassays. Molecular biomarkers in young brown trout were used in streams in extensively and agriculturally used areas. Together with measurements of abiotic parameters and chemical analyses, a comprehensive picture of the influences can be obtained. The current presentation provides an overview on the results of the aquatic bioassays.
Fourteen largely standardised *in vitro* and *in vivo* bioassays were used with different cell lines, algae, aquatic invertebrates (ostracods and water fleas) and fish embryos and larvae. The risk to aquatic life was assessed using effect-based, bioassay-specific thresholds. Potentially problematic sites were identified. Results of this effect-based risk assessment were also compared with the mixture risk assessment based on chemical measurements. Sites with agricultural-urban land use showed the strongest effects, followed by sites with agricultural land use and sites with extensive land use. Bioassays that showed the most exceedances of effect-based thresholds were reporter gene tests for pollutant perception and oxidative stress as well as the combined algae test (endpoint growth) and acute toxicity tests using fish embryos and a fish cell line. The comparison with established assessment methods based on chemical analytical data has shown that these effect-based methods complement each other and the chemical analysis and thus improve the detection of ecotoxicological risks. Results presented here will be used to propose suitable test batteries adapted to the sources of pollution in Switzerland.

1.01.P-We002 How land-use influences aquatic ecotoxicity

***Delia Lara Hof**[1], Thomas Bing[2], Klaus Peter Ebke[3], Gustav Glock[1], Sebastian Heß[4], Jörg Oehlmann[1], Andrea Sundermann[5] and Matthias Oetken[1], (1)Aquatic Ecotoxicology, Goethe University Frankfurt, Germany, (2)MESOCOSM GmbH - Institute for Water Protection, Germany, (3)MESOCOSM GmbH, Institut für Gewässerschutz, Germany, (4)Department of River Ecology and Conservation, Senckenberg Research Institute and Natural History Museum Frankfurt, Germany, (5)River Ecology and Conservation, Senckenberg Research Institute and Natural History Museum Frankfurt, Germany*

A major stressor complex to aquatic ecosystems is the steady increase of micropollutants over the last decades. Micropollutants are particularly problematic for the environment because they can cause toxic effects even at very low concentrations. They have the potential to affect both the environment and human health as they are often ubiquitous and persistent. Micropollutants are anthropogenical organic trace substances and comprise, for example, pharmaceuticals, pesticides, biocides and a wide range of household and personal care products and therefore have multiple pathways into the environment. In this study field samples were analysed using different *in vivo* and *in vitro* effect-based methods (EBM). The overall aim was to attribute the measured effects of the different EBMs to specific pollutant sources. This knowledge should allow a more targeted prior test selection for the evaluation of field samples.

30 water and sediment samples from three different streams in the heavily anthropogenically impacted southern Rhine-Main area were analysed. All samples were tested *in vitro* for their endocrine and dioxin-like activity, mutagenicity, baseline toxicity and oxidative stress. For *in vivo* assessment the snail *Potamopyrgus antipodarum*, the crustacean *Gammarus fossarum* and differend macrophytes were tested in chronic exposure. For all sampling sites the surrounding land use (arable land, forest, pasture, urban area) was recorded based on the Corine Land Cover 5 dataset and upsteam discharger of waste water treatment plants (WWTP) were identified. To evaluate the samples, the ecotoxicological effects were first compared with the main land use type. A PCA was then used to identify in more detail the main influencing factors at each sampling site and again compared with the results of the EBM. Overall, the selected test systems were well suited for an effect-based quality assessment of the rivers in general and thus for a first assessment of the hazard potential of existing pollutants. It was difficult to link the effects of a given EBM to one particular type of land use, as the causes of water pollution appear to be multi-causal. Agricultural pollutants may have been underestimated, as they are often not captured by grab samples. However, there were clear correlations between the effects of EBM and the proportion of the pollution load from upstream WWTP.

Acknowledgement This project is funded by the German Federal Environmental Foundation (DBU AZ 35663/01).

1.01.P-We003 Evaluation of disinfection by-products (DBPs) and related water sources using a panel of effect-based bioassays

Peter Alexander Behnisch[1], *Harrie Besselink*[1], *Jon Wullenweber*[2], *Anissa Grieb*[2] *and Mathias Ernst*[2], *(1)BioDetection Systems BV (BDS), Netherlands, (2)Technical University Hamburg, Germany*

Water systems worldwide are confronted with a complex mixture of thousands of known and unknown (unregulated) emerging compounds. Furthermore, water systems and treatment technologies face a major challenge and are under great pressure to deliver safe and affordable water services to a growing population. The SafeCREW project catalyzes innovations in several European water treatment sites through improved combinations of natural and engineered treatment systems. Water quality and treatment performance is generally assessed for a limited set of individual parameters, possibly resulting in an incomplete quality assessment. Room is now given in the Drinking Water Directive to develop a risk-based monitoring program. In the SafeCREW project we applied a comprehensive panel of human cell-based biological detection methods (i.e. CALUX® assay) to assess the impact of disinfection by-products (DBPs), related chemicals and chemical mixtures on a range of key types of toxicity pathways (e.g. cytotoxicity, genotoxicity, oxidative stress, endocrine effects, PAH and PFAS--like properties and obesity) in different model and real demonstration site waters. Such effect-based bioanalysis allows for detection of known/unregulated/unknown chemicals and to evaluate a safer risk assessment of total toxicity of water samples, including mixture effects. Most relevant DBPs were selected and tested by the CALUX panel to obtain relative potency factors (RPFs). For this first round of analyses, model and real water samples of natural organic matter (NOM) proxies for ground and surface water s were selected to evaluate the response of the innovative biotests on different disinfection methods. Additional water treatment using innovative treatment technologies (oxidation, advanced oxidation) improves water quality significantly as determined using panel of effect-based CALUX bioassays. Results from effect-based CALUX bioassays can be used for evaluation of efficiency of treatment technologies to remove bioactive substances. Our here applied effect-based trigger values (EBTs) for the assessment of water quality and implementation of effect-based bioassays in regulatory water frameworks for risk assessment is discussed. The here presented action plan for water treatment plant operators based on EBT, enhances the applicability of effect-based bioassay for assessment of water quality and regulatory acceptance.

1.01.P-We004 COMPLEMENTARY CHEMICAL SCREENING + BIOASSAY APPROACH FOR MONITORING WATER QUALITY: PRESENTATION OF A CASE STUDY

Jonathan Coulmin[1], *Berenice Ndaitwah*[2], *Mathilde Chachignon*[3], *Emilie Cocardon*[3], *Gaëla Leroy*[3], *Gaëlle Canteau*[3], *Laura Ashipala*[4] *and Thomas Honer*[2], *(1)Scientific & Technological Expertise Department, Veolia Group, France, (2)Windhoek Goreangab Operating Company, Namibia, (3)Scientific & Technological Expertise Department, VEOLIA Research & Innovation, France, (4)City of Windhoek Scientific Services Department, Namibia*

Today, the microbiological and chemical quality of drinking water is a major concern, particularly contaminants of emerging concern (CECs). The occurrence of these emerging pollutants in the environment has been a proven fact for several years now, but their impacts and risks, at the concentrations usually found in environmental matrices, are still poorly estimated.

The strategy put in place by VEOLIA Research and Innovation consists of carrying out parallel chemical and bioassays to monitor of various drinking water treatment processes as well as the resource:

- On one site, the implementation of two "semi-targeted" complementary chemical analysis protocols (SBSE-GC-HRMS and SPE-LC-HRMS) to the water samples. Next, a major data reprocessing operation is carried out, using in-house tools, to identify the substances present among almost 4,000 micropollutants.
- and other site, the implementation of analyses based on the biological activity or toxicity induced by any micropollutants present in the extract of the sample analyzed (effect-based monitoring, EBM). The 4 most relevant modes of action to monitor in drinking water supply according to the experts (GWRC) are: endocrine disruption, oxidative stress, xenobiotic metabolism and genotoxicity.

This paper presents the results of a case study. This combined Chemical Screening + Bioassay approach has been used to monitor the performance and evolution over time of various samples from the New Goreangab Reclamation Plant (Direct Potable Reuse Plant) in Windhoek, Namibia.

The results of chemical screening highlight that most of the micropollutants identified in raw water are Pharmaceuticals and Industrial contaminants and the removal performance of the whole treatment line is very good. The results of Bioessays highlight the decrease in toxicity during treatment, different levels of toxicity between the two campaigns and the presence of very low toxicity in the water produced (Estrogenic effect).

Water (even in the ressource) contains micropollutants, at a high or low level of concentration. For the moment, only targeted chemical analysis of certain micropollutants is regulated, Bioassays are not. This study shows how Chemical Screening and Effect-Based Monitoring are complementary for a better water quality risk assessment. Chemical analysis is still essential to understand which micropollutants are present in the samples, and the main advantage of EBM is to study their potential mixture effects on human health.

1.01.P-We005 Implementing effects-based monitoring strategy to assess water quality in California waterbodies

Alvine C Mehinto[1], *Victoria McGruer*[2], *Daniel Schlenk*[2] *and Keith Maruya*[1], *(1)Southern California Coastal Water Research Project (SCCWRP), (2)Environmental Sciences, University of California Riverside (UC Riverside)*

There is a growing interest in the application of cell-based bioassays to supplement chemical-by-chemical monitoring and assess the biological impacts of complex environmental mixtures. In recent years, California agencies have invested in the development and field evaluation of cell bioassays (e.g., estrogen receptor, aryl hydrocarbon receptor and glucocorticoid receptor assays) for water and sediment quality screening. This poster presentation will highlight the three-step approach we have employed to help facilitate the incorporation of cell bioassays in ambient monitoring programs in California. The first step focused on the development of performance-based criteria and data quality plan to ensure that all data reported meets minimum requirements. The second step focused on large scale application of cell bioassays and comparisons with other lines of evidence. This step was critical in demonstrating the added value of cell bioassay data. The third step focused on the development of a tiered interpretation framework with several cell bioassay thresholds (or effects-based triggers) associated with potential management actions.

1.01.P-We006 Effect-based assessment: Seasonal differences in streams

Delia Lara Hof[1]*, Thomas Bing*[2]*, Klaus Peter Ebke*[3]*, Sebastian Heß*[4]*, Jörg Oehlmann*[1]*, Andrea Sundermann*[5] *and Matthias Oetken*[1]*, (1)Aquatic Ecotoxicology, Goethe University Frankfurt, Germany, (2)MESOCOSM GmbH - Institute for Water Protection, Germany, (3)MESOCOSM GmbH, Institut für Gewässerschutz, Germany, (4)Department of River Ecology and Conservation, Senckenberg Research Institute and Natural History Museum Frankfurt, Germany, (5)River Ecology and Conservation, Senckenberg Research Institute and Natural History Museum Frankfurt, Germany*

The majority of aquatic ecosystems are now massively degraded as a consquence of various anthropogenic impacts, including pollution. Chemical analyses are often used to identify key stressors, but these selective testings represent only a fraction of the substances actually present in water bodies. However, for effective water management, the relevant pollutants need to be clearly identified. Effect-based methods (EBM) allow an integrative assessment of the pollutant effects of even complex mixtures as they occur in the environment, including potential interactions between substances. Therefore, they have the ability to bridge the gap between ecological condition and chemical pollution, thus providing a better understanding of the degraded status of water bodies. In this study different sites were sampled four times during the year and analysed via *in vitro* EBMs. The overall aim was to identify seasonal differences of the ecotoxicological activity in water samples. This knowledge should allow a more standardized evaluation of field samples.

A total of 15 water samples were collected in the southern Rhine-Main area. Due to various inputs and structural deficits, the water bodies there do not achieve a good ecological status as defined by the European Water Framework Directive (EU-WFD). Each site was sampled four times in 2021 (spring, summer, autumn, winter) and tested *in vitro* for endocrine and dioxin-like activity, mutagenicity and baseline toxicity. The effects found were first tested for differences in the time of sampling. Across all sites, no seasonal differences were found for the majority of the tests performed. However, the analysis of individual sampling sites showed site-specific seasonal variations in ecotoxicological effects. Therefore, different complex exposure scenarios are to be expected spatially and temporally, so that future ecotoxicological water assessments should consider not only factors such as a standardised sampling method, but also comparable sampling periods. For further evaluation, the effects were converted into a five-level system from "very good" to "poor" in order to determine an ecotoxicological water quality class for each sampling site.This was used to identify the causes of deficient water conditions, thereby helping to identify the reasons for the failure to achieve good ecological status.

Acknowledgement. The DECIDE project is funded by the German Federal Environmental Foundation (DBU AZ 35663/01).

1.01.P-We007 How Much Do Commonly Monitored Organic Contaminants Explain Species-Specific In Vitro Toxicity of Seawater?

Xintong Liu[1]*, Anqi Xiong*[2]*, Li Zhang*[3]*, Bo Liang*[4]*, Wenhua LIU*[4]*, James Kar-hei Fang*[3] *and Ling Jin*[3]*, (1)Hong Kong Polytechnic University, Hong Kong (China), (2)CEE, Hong Kong Polytechnic University, Hong Kong, (3)Hong Kong Polytechnic University, Hong Kong, (4)Shantou University*

The Indo-Pacific finless porpoise and Indo-Pacific humpback dolphin are iconic threatened marine mammals in Hong Kong. Chemical pollution is amongst the multiple stressors that impact their health. While there have been studies successively devoted to different groups of contaminants in the seawater where the porpoise and dolphin inhabit, it remains elusive to what extent these commonly monitored contaminants contribute to the overall toxicity of seawater and whether there is an imperative to resolve other contributing toxic pollutants. To fill this knowledge gap, we developed species-specific cell lines to assess the cytotoxicity of Hong Kong's marine water and employed mixture-toxicity modeling to determine the quantitative role of 32 chemicals previously detected thereof, including polycyclic aromatic hydrocarbons, polyfluoroalkyl substances, brominated flame retardants, organotins, ultraviolet filters, and algal toxins. These chemicals collectively accounted for a greater proportion of seawater cytotoxicity in the northern, eastern, central, and southern waters (25-43%) than in the western waters (6%). Consistent to this pattern, pectenotoxin-2, which is produced by *Dinophysis* spp. and the major driver of all the studied chemicals, explained 22-36% of seawater cytotoxicity in most of the waters except for the western waters (4%). In contrast, di-butyltin, one component of the antifouling agents in shipping activities, contributed consistently to seawater toxicity across the coastal waters (2-6%). These results pinpointed zone-specific focus in identification of marine pollutants potentially impacting the cetacean health (*e.g.,* more on anthropogenic chemicals in the western waters vs. more on natural biotoxins in the rest of the coastal waters) by suspect/non-target screening combined with artificial intelligence-facilitated toxicity profiling. Similar approaches should be directed towards chemical mixtures accumulated in the porpoise and dolphin. The development of effect-based trigger values for mixture effects should be prioritized as a tool for managing the overall risk of chemical cocktails in coastal waters to protect these threatened marine mammals.

1.01.P-We008 "Chemical characterization and genotoxic assesment of treated and untreated municipal wastewater from WWTPs of Las Palmas de Gran Canaria (Spain) and Mahdia (Tunisie) cities"

*Hedi BEN Mansour[1], **Ludovit Schreiber**[1], Maria Zoraida Sosa[2], Sergio Santana-Viera[3] and José Juan Santana-Rodríguez[1], (1)University of Las Palmas de Gran Canaria (ULPGC), Spain, (2)Chemistry Department, Universidad Las Palmas de Gran Canaria, Spain, (3)Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Barcelona, Spain*

The quality monitoring of municipal wastewater has an interesting role in sustainable development. In fact, wastewater treatment plants (WWTPs) constitute the main source of emerging pollutants which are released into the environment depending on their resistance to conventional treatments. These emerging and recalcitrant pollutants present a certainly environmental impact and risks to human health. A recent approach in environmental protection involves the toxicological assessment of effluents to complement the usual chemical evaluations. In our present work we effectued an comparative study between two WWTPs of Las Palmas de Gran Canaria (Spain) and Mahdia (Tunisie). Results indicated that the physicochemical analyzes carried out for parameters like COD, BOD, TSS, TOC, DOC, POC, MO, conductivity, turbidity, etc. showed that both the influent and the effluent of the WWTP of the Las Palmas de Gran Canaria seem to be more contaminated than those corresponding to WWTP in Mahdia which show lower values of the same parameters. However the genotoxic investigation carried out by the SOS chromotest with *E. coli* PQ37 in the presence and in the absence of the metabolic activation system (S-9) shows that the influent and effluent of wastewater treatment plants of Mahdia induced strongly genotoxic effect compared to those of Las Palmas de Gran Canaria. In fact, the IF is dose dependent and reaches a value of 5.32 with the highest concentration (well above the genotoxicity barrier of 1.5) in influent of the WWTP of Mahdia. This genotoxic effect decrease but remains greater than 1.5 at the effluent of the WWTP. We can conclude that the physicochemical parameters do not reflect the toxicity in the case of the effluent collected from WWTP in Las Palmas de Gran Canaria and that the genotoxic power of the influent and effluent of WWTP samples of Mahdia could be attributed to the presence of higher quantities of organic compounds cocktails which resist to the lagoon treatment system used. The genotoxic power of the tested wastewater treatment plants samples could be attributed partly to the presence of higher quantities of antibiotics which were detected in these samples and included in another of our works.

1.01.P-We009 Assessing Estrogenic Activity in Complex Environmental Matrices: The Impact of Organic Matter and Suspended Particulate Material on the Yeast Estrogen Screen

***Allan Argolo**, Giselle Gomes and Daniele Maia Bila, Departamento de Engenharia Sanitária e Meio Ambiente, Universidade do Estado do Rio de Janeiro - UERJ, Brazil*

The presence of estrogenic endocrine disruptors in aquatic environments has been a concern and bioassays are recommended tools for their monitoring. However, the physicochemical properties of contaminants and the environmental matrix features may influence the observed response. The present study aimed to assess this influence on the Yeast Estrogen Screen (YES) assay. Mixtures of 17β-estradiol (E2) and humic acid (HA) were evaluated through the Schild approach aiming to investigate the interactions between estrogens and dissolved organic matter (DOM). Moreover, environmental samples from municipal landfill leachate and wastewater treatment plant (WWTP) influents and effluents were screened for estrogenic and antiestrogenic activity at both dissolved and particulate (SPM) phases. Physicochemical characterization for solids and organic matter was also performed and a principal component analysis (PCA) was run, aiming to investigate global relationships between results and to probe if the assessed parameters were indicative of an estrogenic activity distribution. The HA test concentrations had strong apparent antagonistic effect and reduced the E2 response, even at low levels. Humic substances may not only reduce estrogen bioavailability, but also interfere with the assay mechanism through enzymatic inhibition thus masking the sample estrogenic potential. DOM-rich environmental samples may have their estrogenic potential underestimated by the YES assay and analogous methods. Landfill leachate had total E2-Equivalents (E2-Eq) in the range 1282–2591 ng L^{-1}, while WWTP samples were in the range 12.1–41.4 ng L^{-1} (influents) and up to 2.3 ng L^{-1} (effluents), respectively, so estrogenicity was reduced 92% in average by the treatment process. SPM phase was responsible for 33–100% of measured E2-Eq, though cytotoxicity was recurrently associated with particles >0.7 µm. Antiestrogenic activity was observed in both phases and might also have masked the estrogenicity of samples. Physicochemical parameters supported the interpretation of E2-Eq multiphase distribution, but no pattern was confirmed by the PCA and parameters were not determinant. In conclusion, the *in vitro* YES assay is subjected to factors intrinsic to the environmental sample that can influence on the measured estrogenic response. Therefore, results interpretation should be performed together with organic matter characterization parameters, cytotoxicity and antiestrogenic activity evaluation.

1.01.P-We010 Water fleas as a “canary in the coal mine” to early predict water pollution

*Emma Rowan[1], Anne Leung[1], Katie ORourke[1], Beatrice Engelmann[2], Rolf Altenburger[3], Ulrike Rolle-Kampczyk[2] and **Konstantinos Grintzalis**[4], (1)School of Biotechnology, Dublin City University (DCU), Ireland, (2)Molecular Systems Biology, Helmholtz Centre for Environmental Research (UFZ), Germany, (3)Department of Bioanalytical Ecotoxicology, Helmholtz Centre for Environmental Research (UFZ), Germany, (4)Dublin City University (DCU), Ireland*

The growing human population has a significant impact on the environment and the planet. Therefore, assessment of environmental exposure to toxic chemicals and their impact on biological systems is important. Currently traditional approaches focus on the detection of chemicals or monitoring the abundance of fauna and flora. However, these measurements are weak in terms of providing minimal detection of a fracture of possible contaminants in the environment, while they also fail to produce a diagnostic insight concerning the type of stressor. Furthermore, these methods cannot predict any future impact before ecological damage has occurred and this is reflected in the poor legislation in some cases of pollutants, which comes as a natural consequence of these approaches not being able to safeguard the environment. Moving away from traditional methods to monitor pollution, modern eco-toxicology is shifting towards the use of effect-based methods as key approaches to supplement and provide meaningful mechanistic insight for pollution assessment. Focusing on the freshwater ecosystem, daphnids, commonly known as water fleas, have acquired a central position in molecular ecology and ecotoxicology. Exposing daphnids in a series of pollutants and generating molecular fingerprints from their responses allows a more in depth understanding for the action of pollutants in non-target species. Expanding from acute to chronic and transgenerational exposures we are able to understand more on the impact of pollutants. Combining phenotypic endpoitns with holistic metabolomic approaches we defined the molecular changes of several chemicals and novel materials in the physiology of daphnids for individual and mixtures of stressors. Comparing these "signatures" with the ones obtained from actual water samples, we transformed daphnids as an equivalent to "a canary in the coal mine" to early predict pollution and provide new metrics for water quality.

1.01.P-We012 Biological activities of antidepressants and G protein-coupled receptors (GPCRs)-acting pharmaceuticals to monoamine transporters of human, fish, and water flea

Masaru Ihara[1]*, Mariko Ohno Ihara*[2]*, Han Zhang*[3] *and Minguang Han*[4]*, (1)Kochi University, Japan, (2)Agriculture and marine science, Kochi University, Japan, (3)Dalian University of Technology, China, (4)Kyoto University, Japan*

Over recent years, growing numbers of human pharmaceuticals have been detected in effluents of wastewater treatment plants (WWTPs) and river water. Antidepressants are one of most commonly detected human pharmaceuticals, and concern about their potential risks to aquatic species has been raised because they modulate neurotransmission in nervous systemn. Their target moleucules (i.e., monoamine transporers) are evolutionally well conserved from invertablate to human.
So far, we demonstrated that antidepressants could inhibit not only human but also zebrafish monoamine transporters[1),2)].
Several studies reported that antidepressants induce abnormal behaviors and alter the reproductions of invertebrates in vivo exposure test under the laboratory experimental setup (e.g., *Echinogammarus marinus*, snails, and clams). However, nobody has investigated the activity of antidepressants on the monoamine transporters of invertebrates.
In this study, we cloned SERT of water flea (*D. pulex*, WTN6) for the first time. We investigated by the in vitro assay whether SERT of water flea could be inhibited by antidepressants. We also cloned monoamine transporters of medaka and ayu fish (*Plecoglossus altivelis*), which is one of the important food fish in Japan.
As a result, antidepressants could inhibit not only human but also fish and water flea SERT. Interestingly, fish SERTs were strongly inhibited by antidepressant compared to human SERT.We also we applied the in vitro antidepressant assay to WWTP effluent extracts. All wastewater extracts showed reduction of APP uptake for not only human but also fish and water flea SERT. These results indicate that at least molecular level, fish and water flea could be more seriously affected by antidepressants in water environment than human.

1.01.P-We013 Application of gene expression biomarkers in brown trout, Salmo trutta, to assess water quality in 10 Swiss watercourses

Anne-Sophie Voisin*, Melanie Fasel, Cornelia Kienle, Rébecca Beauvais, Benoit J.D. Ferrari and Inge Werner, Swiss Centre for Applied Ecotoxicology, Switzerland*

Analysis of gene expression biomarkers in resident organisms represents a promising effect-based approach for water quality monitoring. It allows a sensitive and integrated detection of environmental pressures, including contamination with micropollutants. In this study, we used microfluidic qPCR for high-throughput analysis of 96 biomarker genes in brown trout. These genes were selected to detect the effects of micropollutants, in particular pesticides, and other stressors by reflecting a wide range of biological processes. The selection was based on scientific literature and databases (e.g. AOP-Wiki, Comparative Toxicogenomics Database, EcoToxChip) as well as previously established biomarkers (Ecotox Centre in collaboration with aQuaTox-Solutions GmbH). Biomarkers were measured in brain and liver tissue of juvenile brown trout from ten sites in Switzerland, including five sites with extensive land use and five sites with agricultural land use. Depending on the site, trout parr (less than one year old) and/or one year old trout were studied. In a parallel project carried out at the Ecotox Centre, water from the same sites was analysed by detailed chemical analysis and a battery of bioassays. The biomarker results show an influence of size and sex on the expression of specific genes in the liver and brain and the need to take these confounding factors into account when interpreting the responses. Accounting for these factors, we detected biological effects (e.g. oxidative stress, effects on the immune system, endocrine disruption, effects on metabolism) at several sites, with the majority of effects attributed to sites with agricultural land use. While the chemical analysis-based risk assessment indicated a risk to vertebrates at only one of the sites, which was concordant with the biomarker results, we observed biological effects at several other sites that warrant further investigation. Our study demonstrates the potential of biomarkers to provide complementary information to chemical analysis and bioassays for the identification of problematic sites, biological effects and stressors. To fully leverage the potential of biomarkers, future research and monitoring studies should aim to establish reference values that allow to distinguish between responses indicative of a stressed or healthy state. This study represents a step forward in the use of biomarkers for biomonitoring.

1.01.P-We014 The Adaptability of Fish Defense Mechanisms Against Anthrophogenic Environmental Pollution

Anna Koubová[1]*, Pavel Sauer*[2]*, Hana Kocour Kroupová*[2]*, Zuzana Toušová*[3]*, Maria Carolina de Sales RIbeiro*[4]*, Heike Smidt-Posthaus*[4]*, Klára Hilšerová*[3]*, Roman Grabic*[2] *and* ***Vladimír Žlábek***[2]*, (1)University of South Bohemia Ceske Budejovice, České Budějovice, Czech Republic, (2)University of South Bohemia in Ceske Budejovice, Faculty of Fisheries and Protection of Waters, Czech Republic, (3)RECETOX, Faculty of Science, Masaryk University, Czech Republic, (4)Centre of Fish and*

Wildlife Health, Department of Infectious Diseases and Pathobiology, University of Bern, Switzerland
Enhancing our comprehension of the adverse effects on aquatic fauna due to environmental pollution necessitates a holistic approach. Employing passive sampling and subsequently determining defense mechanisms, stress indicators, and other biological effects *in vitro* in fish and benthic invertebrates can unveil the organism capacity to respond and cope with contaminants released into streams by municipal wastewater. The knowledge of pollution impacts on fish and their associated food chains can clarify the processes that allow fish to adapt to chemical exposure. Biochemical responses and histological changes in the organism were monitored in brown trout (*Salmo trutta* m. *fario*) restocked up and downstream of the sewage treatment plant (STP). Passive samplers (Speedisks and Silicone rubber sheets) were deployed at both sites to simulate the potential trans-membrane uptake of micropollutants into the organisms. The activity of biomarkers of oxidative stress and the catalytic activity of enzymes from the cytochrome P450 group involved in transforming foreign substances in the organism were determined in selected fish tissues. The results showed gradual adaptability to environmental pollution during the tested season from spring to autumn. The increased level of vitellogenin in the blood plasma of males indicated the impact of pollution on the balance of the endocrine system. Minor histopathological changes did not result from water pollution level but rather from a time-dependent growth variability of the tested individuals arising from other environmental factors. *In vitro* testing revealed the presence of compounds inhibiting progesterone receptors in passive samplers and benthos (*Ephemera* and case-making caddisflies), both at the control site and the site burdened with discharges of wastewater but not in the fish tissues. The study contributed to determining the response and adaptability of fish defense mechanisms against anthropogenically introduced chemical pollution into the aquatic environment. Since the study uses a holistic approach, this research may be considered environmental biomonitoring. The research was supported by the Czech Science Foundation (project No. 20-04676X) and by the Ministry of Education, Youth and Sports of the Czech Republic – project "CENAKVA" (LM2018099).

1.01.P-We015 Exploring the Potential of a Byproduct from Essential Oil Distillation: Ecotoxicity of Lavandin Hydrolates

María Rosa Pino Otín[1]*, Antonio Valenzuela*[1]*, David Gimeno-Martinez Sr*[2]*, Elisa Langa*[3]*, Diego Ballestero*[1]*, Cristina Gan-Oria*[1]*, Mª Angeles Sanz-García*[2] *and Juliana Navarro*[2]*, (1)Universidad San Jorge, Spain, (2)Agrifood Research and Technology Centre of Aragon (CITA), Spain, (3)San Jorge University, Spain*

During essential oil steam distillation, a significant volume of condensed water, known as hydrolates, is produced. Traditionally considered waste, hydrolates are now recognized for their antioxidant, antibacterial, and antifungal activities. This study assesses the ecotoxicity of hydrolates from *Lavandula* x intermedia Emeric ex Loisel, Lavandin, specifically the 'Super' (LS) and 'Grosso' (LG) varieties. Bioindicators *Daphnia magna*, *Vibrio fisheri*, *Allium cepa*, and *Eisenia fetida* were employed.
Aerial plant parts were manually harvested, and steam distillation in a stainless-steel distiller produced 5L of each hydrolate. Hydrolate composition, including total polyphenols, flavonoids, and proanthocyanidins, was analyzed using spectrophotometric techniques. Coumarin was quantitatively analyzed by HPLC-DAD, and volatile fractions were examined by GC-MS.
The Grosso variety contained 32 compounds, while the Super variety had 14, both including the main lavandin oil components: linalool, linalyl acetate, camphor, 1,8-cineole, and borneol. Monoterpenes constituted 96.1% in Super and 86.4% in Grosso, mainly in oxygenated forms.
Both hydrolates showed high ecotoxicity to terrestrial and aquatic organisms. In descending order of toxicity: *D. magna* > *E. fetida* > *V. fisheri* > *A. cepa*.
D. magna and *E. fetida* were the most sensitive, exhibiting mortality at low hydrolate concentrations: LC_{50} = 0.23% for LG and 0.75% for LS in *D. magna*, and 0.82% and 0.84% for LG and LS, respectively, in *E. fetida*. *Vibrio fisheri* required slightly higher doses for luminescence loss: 1.60% and 1.07% for LG and LS. *A. cepa* root growth was inhibited at low hydrolate concentrations (EC_{50} = 3.44% and 2.60% for LG and LS, respectively).
Pronounced toxicity in both indicators highlights the importance of considering the ecotoxic potential of natural products, crucial as interest grows in using these substances in agri-food, pharmaceutical, or cosmetic applications.

1.01.P-We016 Improving the Ecotoxicity Assessment of Waste from Mirror Entries: Evaluating the Suitability of a Biotest Battery

Janina Blöcher[1]*, Karen Duis*[1]*, Stephan Jänsch*[1]*, Ralf Ketelhut*[2] *and Anja Coors*[1]*, (1)ECT Oekotoxikologie GmbH, Germany, (2)Stoffstromdesign Ralf Ketelhut, Germany*

The European List of Wastes (2000/532/EC) contains 'mirror entries', wastes that can depending on their properties be classified as hazardous (when displaying at least one of 15 hazard properties) or non-hazardous. The hazard property 'ecotoxic' (HP 14) is assessed with a calculation approach based on the content of hazardous substances or using ecotoxicity tests with the respective waste sample or its eluate. For the testing approach, guidance at EU level is so far lacking. In several EU member states including Germany, recommendations for the ecotoxicological characterisation of wastes have been developed. The aim of the present project was to verify the recommendations published in 2013 by the German Environment Agency (UBA) and to develop suggestions for their further development.

To verify the suitability of the recommended test battery, ten waste samples from three mirror entries (10 09 09*/10 09 10: flue-gas dust, 17 05 03*/17 05 04: soils and stones, 19 10 03*/19 10 04: fluff-light fraction and dust) were tested. Four of these wastes were classified as hazardous by their owners and six as non-hazardous. Waste sampling complied with the requirements of European (CEN/TR 15310) and German guidance (LAGA PN 98). Samples were sieved to a grain size of < 4 mm or, for the

Arthrobacter contact test, < 2 mm. The test battery consisted of three aquatic tests with waste eluate (acute daphnid test, algal growth test in microplates and luminescent bacteria test) and three terrestrial tests (earthworm avoidance test, growth test with higher plants and *Arthrobacter* contact test). Aquatic tests were repeated up to three times to evaluate reproducibility. According to the recommendations of UBA, a waste was classified as ecotoxic, if the EC_{50} determined in at least one of the six tests was ≤ 10% eluate or solid waste.

For the aquatic tests, several test runs always yielded very similar results leading to the same classification. Algae and daphnids were more sensitive than luminous bacteria, and the aquatic tests tended to be more sensitive than the terrestrial tests. According to the test results, most wastes classified as hazardous by their owners were ecotoxic (HP 14). However, most wastes which had been classified as non-hazardous by their owners, were also ecotoxic. Based on the results of the experimental work, suggestions were developed how to update and further advance the German 'Recommendations for the ecotoxicological characterisation of wastes'.

1.01.P-We017 The Road to Preliminary Identification of Techniques for Toxicity Monitoring and Chemical Key Environmental Issues

*Elvio D Amato[1], Danielle van Der Linde[1], **Gustavo Guerrero-Limon**[2], Markus Hjort[3], Renske P. J. Hoondert[1] and Eleni Vaiopoulou[4], (1)KWR Water Research Institute, Netherlands, (2)Water, Soil and Waste, Concawe, Belgium, (3)Concawe, Belgium, (4)CONCAWE*

The oil refining process requires substantial water volumes for several purposes, such as cooling, steam generation, and processing of raw materials. After usage, some of the remaining water volumes are discharged. Industrial emissions should be assessed using Best Available Techniques (BAT), the latter according to the Industrial Emissions Directive (IED; 2010/75/EU) that also establishes what kind of parameters and how they should be monitored. In the upcoming years the Best Available Techniques Reference Document and its BAT Conclusions will be revised. In addition to chemical parameters, this is expected to include also effect-based monitoring. We have previously described an array of bioassays deemed suitable for the monitoring of refinery effluents, that are based on well-established protocols by OECD and ISO guidelines. In this pilot project, we aim at developing a testing program with the purpose of assessing the practical implementation challenges with the proposed assays at a selection of European refineries, to be performed in combination with parallel assessment of emissions levels. This complex project requires the measurement of several chemical parameters and toxicological endpoints, for which different sampling approaches and sample handling are needed. The adequate preservation of the sample offers additional challenges given the relatively scarce availability of local laboratories that have the capabilities to screen the samples for the selected bioassays. Large scale projects as this highlight the need of coordinated efforts between stake-holders, industry, NGOs and others to achieve common goals. Staying innovative and making the best-informed decisions is crucial to success in the ever-evolving landscape of Directives and other regulations, thus, our pilot project provides important insights as how to tackle complex problems at once advancing water quality assessments.

1.01.P-We018 Strategies to address marginal and intermittent toxicity in effluent dominated systems.

***William L. Goodfellow**[1], Konrad Kulacki[2] and Alexandra Steele[3], (1)Ecological and Biological Sciences, Exponent, Inc., (2)Exponent, (3)Exponent Inc.*

As we continue to better manage water use within industrial facilities, effluent volumes can become reduced by water conservation. In these instances, chemical constituents in the wastewater maybe more concentrated, allowing more efficient treatment. However, less water may also be a concern for constituents that are recalcitrant to treatment. This issue is often magnified in effluent dominated receiving water systems. To overcome this limitation, as well as to account for the many effluents that contain mixtures of chemicals, whole effluent toxicity testing (WET) or whole effluent assessment (WEA) can more effectively determine whether effluent is toxic to aquatic organisms in its entirety, rather than by virtue of individual chemical components. Traditional WET or WEA methods use standard test species as fish, invertebrates, and algae as the analytical detectors to assess whether the effluents are unacceptably toxic even when the specific chemical composition is not immediately known. In effluent dominated systems, the regulatory trigger concentration can be at or nearly full-strength effluent. As a critical review, this paper will use case examples for the assessment of effluents to account for site-specific considerations of the discharge or receiving stream. One is faced with the challenge in effluent dominated systems to better understand if the results are due to effluent toxicity or whether the results are at least partially reflective of organism response variability. In these situations, the "but for question" needs to assess if the response in the effluent is due to chronic toxicity, or whether a necessary constituent that is present in the control water (or culture water) is missing in the effluent or does not provide the trace nutrients or food for adequate organisms' performance. This presentation will explore strategies to further evaluate effluents while employing novel assessment strategies, and still allowing the ability to resolve the specific chemical causing or contributing t the toxic effluent.

1.01.P-We019 Why emission control technologies matter – An environmental perspective of catalyst and electrostatic precipitator application in biomass-based energy supply and their impact on aquatic systems

***Marc Wollenweber**[1], Lisa Feikus[2], Jialiang Ma[3], Kamila Kluczek[3], Daniel Wohter[2], Manfred Möller[2], Manuel Garcia-Käufer[4], Alexander Vogel[5], Thomas Kraus[6], Sabrina Schiwy[7] and Henner Hollert[7], (1)Evolutionary Ecology & Environmental Toxicology (E³T), Goethe University Frankfurt, Germany, (2)RWTH Aachen University, Germany, (3)Goethe University Frankfurt, Germany, (4)University Medical Center Freiburg, (5)Goethe University Frankfurt, Institute for Atmospheric and Environmental Sciences, Germany, (6)Uniklinik RWTH Aachen, (7)Evolutionary ecology and environmental toxicology,*

Goethe University Frankfurt, Germany
The increasing use of wood in residential heating is a major concern due to its impact on human health and ecosystems. The increasing demand for renewable energy sources further exaggerates this isssue. To reduce the emissions from small-scale wood-fired heating appliances, the use of emission control technologies has become increasingly important. However, the efficiency of such technologies has been investigated mainly based on human health aspects, leading to significant neglect of ecotoxicological perspectives. In addition, the environmental risk assessment of atmospheric pollutants has focused primarily on particulate-associated toxicology, lacking effect data of the water-soluble fraction of wood smoke. Therefore, we applied two commercially available emission control technologies (ceramic foam catalyst (CAT) and electrostatic precipitator (ESP)) and investigated their impact on the acute (*Raphidocelis subcapitata*, *Daphnia magna*, and *Danio rerio*) and mechanism-specific toxicity (*in vitro* endocrine disruption, *in vitro* and *in vivo* EROD activity) of small-scale wood stove emissions. Beech wood was burned discontinuously in a small-scale wood stove, and water-soluble extracts of wood smoke (WSE) as well as organic extracts of deposited particulate matter (PME) were analyzed. Untreated WSE samples exerted pronounced acute toxicity to all investigated species (EC_{50}: 0.080–0.876 m³/l). Endocrine activity (estrogenicity and anti-androgenicity) was detected in PME but not clearly in WSE. A similar trend was observed for the investigation of EROD activity. As expected, CAT treatment resulted in high mitigation efficiencies, however, ESP operation did not clearly reduce the observed toxicity of the wood-burning emissions. Non-target chemical analysis combined with hierarchical cluster analysis confirmed these observations. The data strongly suggest a temperature-dependent efficiency of the ESP as a function of gas-to-particle conversion. In addition, ESP significantly reduced PM emissions, but resulted in the formation of very coarse PM (i.e., $PM_{>10}$). Overall, this study provides strong evidence that the use of CATs and, to a slightly lesser extent, ESPs in residential biomass heating appliances are promising measures to protect ecosystem health.

1.01.P-We021 Progressing Short-term Methods for Estimating Chronic Marine Toxicity for Regulatory Use in the North-East Atlantic Region.
Mathijs Smit, PhD[1], *Petra Baverbeck*[2], *Caroline Brown*[3], *Kevin Cailleaud*[4], *Tone Frost*[5], *Shona Knowles*[6], *Brid O'shea*[1], *Gustavo Guerrero-Limon*[7] *and Eleni Vaiopoulou*[8], *(1)Shell International, Netherlands, (2)SLB, (3)OEUK, (4)TOTALENERGIES, France, (5)Equinor AS, (6)EOSCA, (7)Water, Soil and Waste, Concawe, Belgium, (8)CONCAWE*
In the North-East Atlantic region, risk- and hazard assessment play an important role in the management and permitting of offshore chemicals, produced water and other wastewater discharges. Currently, assessments mostly rely on data from acute toxicity tests performed on a limited number of species. The application of acute tests potentially results in an overestimation of environmental risk due to the application of high assessment factors when deriving safe limits. Experience in some countries has shown that chronic toxicity testing can be an effective risk mitigating measure. However, due to their practical limitations and associated costs, chronic tests are not yet widely applied. There is a growing interest in the application of toxicity tests for the assessments of wastewater discharges both offshore and from land-based sites to coastal environments. Such tests might become essential to have appropriate and fit-for-purpose acute and chronic marine toxicity test protocols.

Under the umbrella of Offshore Energies UK (OEUK) a group of energy companies, chemical suppliers and industry associations have initiated a Joint Industry Project (JIP) that aims to pilot short-duration methods for estimating chronic marine toxicity tests for regulatory use in the North-East Atlantic region. The project aims to identify suitable methods for estimating chronic marine toxicity based on existing protocols and global practices and applicable to the management of both offshore and coastal discharges. The focus will be on protocols with short duration to reduce costs, optimize execution time and required logistics. Eventually the project aims to deliver a list of agreed and practical protocols that estimate chronic toxicity from which the endpoints are acceptable to all parties involved and includes tests that have been selected based on their availability and efficiency.

The project starts collecting and reviewing available short-term methods for estimating chronic toxicity. Selection of tests will be based on a comparison of available data on performance of such tests with the current acute tests. Piloting the methods on selected effluents and chemicals is foreseen within the project. The aim is to work with operators, chemical suppliers, testing laboratories, regulators, and their scientific advisors to develop a set of reliable short-term methods for marine chronic toxicity testing, ready for implementation upon project closure.

1.01.P-We022 Impacts of Anthropogenic Stressors on Feral Fish: Biomarker Response in Locally Adapted and Translocated Brown Trout along the Holtemme River, Germany
Tanja Reimann[1], *Fabian Weichert*[1], *Jörg Ahlheim*[2], *Werner Brack*[2], *Mario Brauns*[3], *Markus Brinkmann*[4], *Patrick Fink*[3], *Markus Hecker*[5], *Sarah Johann*[6], *Martin Krauss*[2], *Joachim Sturve*[7] *and Henner Hollert*[6], *(1)Evolutionary Ecology & Environmental Toxicology, Goethe University Frankfurt, Germany, (2)Department of Effect-Directed Analysis, Helmholtz Centre for Environmental Research (UFZ), Germany, (3)Department of River Ecology, Helmholtz Centre for Environmental Research (UFZ), Germany, (4)Toxicology Centre, University of Saskatchewan, Canada, (5)Toxicology Centre and School of the Environment and Sustainability, University of Saskatchewan, Canada, (6)Evolutionary ecology and environmental toxicology, Goethe University Frankfurt, Germany, (7)Biological and Environmental Sciences, University of Gothenburg, Sweden*
Water pollution has emerged as a global problem due to the continually growing number and quantity of chemicals used by society. Key sources of pollutants to aquatic ecosystems are point sources such as wastewater treatment plants (WWTPs), as well as diffuse sources such as runoff from urban areas and agriculture. The resulting exposure to complex pollutant mixtures

have the potential to induce significant ecological effects, which are often not well understood. *In situ* studies, considering realistic environmental exposure, are required to better characterize these ecological effects. This study aimed to investigate impacts of multiple chemical stressors on feral brown trout (*Salmo trutta*) by comparing biomarker response patterns of locally adapted and translocated individuals along the Holtemme River, Germany. While the upper reaches of the river are relatively unimpacted representing natural conditions, downstream areas are subjected to cumulative human impacts, accompanied by increased levels of chemical pollution. In brief, five groups of brown trout were exposed for 21 days at three sites along the river. Respectively, one fish group was caught and caged at all three sites (reference, urban and downstream of a WWTP) and represent the locally adapted fish. For translocation experiments, two additional groups were caught at the reference site and translocated to the anthropogenically impacted downstream sites (urban and downstream of the WWTP). For a better understanding of exposure impacts, multiple biomarkers in kidney were examined due to its role in excretion and metabolization of pollutants. The measured biomarkers are indicative for xenobiotic metabolism (glutathione *S*-transferase, benzyloxy-4-trifluoromethylcoumarin-O-debenzyloxylase and ethoxyresorufin-O-deethylase) and oxidative stress (glutathione reductase and catalase). Preliminary results indicated stronger alteration of enzyme activities in translocated fish compared to locally adapted. In contrast to locally adapted individuals, translocated fish experienced elevated levels of stress due to a changed environment. After molecular sex determination, only marginal differences in the effects between sexes were identified. At the location downstream of the WWTP, female fish exhibited increased enzyme activities, which may well be explained by sex-related variations in sensitivity to pollutants discharged from the WWTP.

1.01.PC Advancing the Use of Effect-Based Approaches for Water Quality Assessment

1.02 Alternatives to Animal Testing for Ecotoxicity Assessments: Exploring Approaches and Avenues for the Future

1.02.T-01 Importance of internal concentrations and toxicokinetics to classify modes of action of organic chemicals in the zebrafish embryo (Danio rerio)

Nico Grasse[1]*, Riccardo Massei, Dr*[2]*, Bettina Seiwert*[3]*, Beate Escher*[4]*, Stefan Scholz*[5]*, Thorsten Reemtsma*[1] *and Qiuguo Fu*[6]*, (1)Helmholtz Centre for Environmental Research (UFZ), Germany, (2)University of Antwerp, Belgium, (3)Department of Analytical Chemistry, Helmholtz Centre for Environmental Research (UFZ), Germany, (4)Department of Cell Toxicology, Helmholtz Centre for Environmental Research (UFZ), Germany, (5)Chemicals in the Environment Research Section, Helmholtz Centre for Environmental Research (UFZ), Germany, (6)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland*

There is a pressing demand to use new approach methodologies and powerful computational modeling approaches for chemical risk assessment. Environmental risk assessment at present is typically based on chemical exposure in water. Aqueous concentrations are only a proxy for the internal concentrations of a compound in the organism, which are the biologically effective doses and vital to know to interpret the toxic effects. There are various approaches available that predict the steady-state uptake of chemicals into the organisms and bioconcentration factors based on the physicochemical properties of the test compound. The zebrafish embryo (*Danio rerio*) has widely investigated to establish such predictive models and understand the mechanistic basis of the toxic effects of chemicals. However, these approaches are not the perfect predictors for internal concentrations as they do not consider specific toxicokinetic processes, e.g., biotransformation and active transport, which can substantially affect the bioconcentration of certain chemicals. Additionally, experimental internal concentration data are rare and most of them are only based on predicted bioconcentration factors and physicochemical properties of the chemical. Therefore, we measured steady-state concentrations of 61 polar and non-polar compounds by determining their internal concentrations in the ZFE after 96 hours of exposure at one sublethal exposure concentration and compared them to a mass-balance model (MBM). We found a close relationship with measured concentrations typically in the 1:1 range for 82 % of the study compounds. We identified 11 of 61 chemicals showing a significantly lower internal concentration than predicted. For some of these chemicals, various transformation products could be identified via UPLC-HRMS and their relative contribution to the total internal concentration indicates a significant transformation of the parental compound. In case of 7 of the 11 substances with internal concentration deviating from the model, biotransformation and/or specific transport had an influence on the classification of the specificity of the respective chemical, as this caused the membrane concentration to decline below the baseline toxicity range. This highlights the importance of toxicokinetics on the correct assessment of the specificity of the observed effect caused by a chemical.

1.02.T-02 Establishing a 24-Hour, Microplate-Based, Transcriptomics Assay for Rainbow Trout Embryos

Emily Boulanger, Hugo Marchand, Aylish Marshall, Krittika Mittal, Jessica Head and ***Niladri Basu****, McGill University, Canada*

There is interest in the development of early-life stage (ELS) tests with fish embryo models that are high-throughput and can generate transcriptomics point of departure (tPOD) values. The objective of this study was to establish a high-throughput toxicity test for larval fish that could simultaneously generate tPOD values, and basic mortality data. We based our pilot method on recent efforts by U.S. EPA researchers to establish a larval fathead minnow high throughput transcriptomics assay. Briefly, rainbow trout alevins (1-2 day post-hatch) were placed in individual wells (24-well plates) and exposed for 24 hr to 12 different concentrations of OECD 249 test chemicals (and other chemicals of interest), including a negative control (fish water or 0.5% DMSO) for 24 hours. Test concentrations were based on a tapered design which included an LC50 push zone (10- and 100-fold higher than estimated LC50 from the U.S. EPA EcoTox database), transcriptomics point of departure (tPOD) zone (six concentrations below the LC50 range on a half log10 basis), and baseline zone (10- and 100-fold lower concentrations).

Using this design, the exposure for 3,4-dichloroaniline was: 1000, 320, 100, 32, 10, 3.2, 1, 0.32, 0.1, 0.032 and 0.01 mg/L (covering 7 orders of magnitudes). Presently, we have tested 25 distinct chemicals using this design. LC50 values have been generated for 3,4-dichloroaniline (58.5 mg/L), copper sulfate (0.3-0.8 mg/L), glyphosate (150 mg/L), malathion (0.6 mg/L), acetaldehyde (41.2 mg/L), 4-fluoroaniline (243 mg/L), ethanol (18.2 g/L), 6-PPD quinone (5.6 ug/L), aniline (1026 mg/L), pentachlorophenol (0.6 mg/L), lindane (3.4 mg/L), 4,6-dinitro-o-cresol (0.3 mg/L), dimethyl sulfoxide (6.5%), caffeine (153.2 mg/l), sodium dodecyl sulfate (14.5 mg/L), methylmercury (0.5 mg/L), ethinylestradiol (>100 ng/L), thiamethoxam (>300 mg/L), permethrin (>3 mg/L), allyl alcohol (>30 mg/L), dibutyl phthalate (>300 mg/L), metformin (>10000 mg/L) and guanylurea (>5000 mg/L); preliminary LC50 values are provided in parentheses. Repeated studies of copper sulfate yielded consistent LC50 values. Work is underway to produce transcriptomics data for these samples using EcoToxChips and UPXome, with the goal to be able to derive tPODs. Coupling all of this together, these results will provide a foundation towards establishing a novel testing platform for chemical and environmental risk assessment.

1.02.T-03 Using Endpoint Response Patterns to Aid Interpretation, Support Read-Across and Reduce Testing with the Amphibian Metamorphosis Assay

Daniel Bruce Pickford[1]*, Marysia Tobor-Kaplon*[2]*, Pelagia Xirogiannopoulou*[3] *and Tara Miller*[1]*, (1)Product Safety, Syngenta Group, United Kingdom, (2)Product Safety, Syngenta Group, Netherlands, (3)Product Safety, Syngenta Group, Greece*

Read-across is regarded as a strategy to reduce animal testing for chemical safety assessment. The OECD Conceptual framework (CF) for screening and testing of endocrine disruptors (EDs) includes read-across as relevant non-test information that may be available at Level 1. The amphibian metamorphosis assay (AMA; OECD 231) is a short-term *in vivo* assay (CF Level 3) that is recommended in the ECHA-EFSA Guidance for the identification of EDs as necessary/adequate to demonstrate the absence of thyroid-mediated endocrine activity. However, in the EU context, with hazard-based cut-off criteria for EDs, the very conservative decision logic of this assay carries to significant regulatory consequences. Small changes in hind limb length at only one time point are sufficient to warrant a positive result, which may lead to unnecessary animal use through higher tier testing. We have taken a holistic approach to interpret AMA studies by looking at endpoint response patterns and applying this to an anonymised dataset comprising publicly available AMA data conducted for the US EPA EDSP, OECD validation assays, and proprietary data on plant protection active ingredients. We categorised endpoints as informing on: (i) overt toxicity, (ii) growth or (iii) development. A total of 94 independent studies were encoded for agonist-type or antagonist-type responses. Responses to the thyroid hormone agonist tetraiodothyronine and perchlorate (competitive inhibitor of the sodium-iodide symporter) were regarded as model pro-thyroidal. Anti-thyroid substances and remaining substances were sorted according to similarity of response patterns across growth and development parameters. This dataset was then interrogated for phenotypic patterns associated with indication, structural class, or known toxicological mode of action. Our findings indicate that very few plant protection actives exhibit response patterns comparable to known thyroid axis disrupters and for several classes, patterns indicative of systemic toxicity (inhibited growth and development, no compensatory changes in thyroid histopathology) are clearly apparent. This approach offers the potential for preliminary assessment of active substances through read-across to inform choices on data generation supporting evaluation of thyroid-mediated activity in non-target organisms. In turn this may support greater use of *in vitro* or other non-animal testing approaches, with consequent reductions in animal use.

1.02.T-04 An In Vitro Disposition Model for the Fish Cell Assay According to OECD Test Guideline 249

Jo Nyffeler[1] *and Beate Escher*[2]*, (1)Department of Bioanalytical Ecotoxicology, Helmholtz Centre for Environmental Research (UFZ), Germany, (2)Department of Cell Toxicology, Helmholtz Centre for Environmental Research (UFZ), Germany*

OECD TG249 describes a cytotoxicity assay with the rainbow trout gill cell line, RTgill-W1, as an *in vitro* alternative for the acute fish toxicity test. The cell assay was found to be a good predictor for *in vivo* toxicity, if the measured chemical concentration is considered instead of the nominal concentration. Binding of the chemical to the well plate, to medium and to cell components reduce the bioavailable concentration and hence the apparent sensitivity of the assay. To this day, measurement of the free chemical concentration is lower in throughput than the toxicity measurement itself. Hence, the *in vitro* disposition of chemicals is often predicted. Most *in vitro* disposition models have been developed for assays with human cells, which are typically cultured in medium containing 5-10% fetal bovine serum (FBS). The FBS acts as “buffer” and keeps the freely dissolved concentration in the medium fairly stable, when chemicals are taken up into cells and the plastic of the plates. In contrast, in TG249, the cells are exposed to the chemicals in a minimal medium without FBS, which leads to a depletion of the freely dissolved concentration. Therefore, we conceived a novel *in vitro* disposition model suitable for lean cell culture media.

To describe the *in vitro* disposition, a kinetic mass balance model was implemented as a nested model consisting of three compartments: medium, cells and plastic. Cells consist of three subcompartments (water, proteins, lipids), which are considered in instantaneous equilibrium. The initial adsorption to the plastic is fast but the internal diffusion is very slow and hence the overall loss to plastic is time-dependent and was implemented as a kinetic process. Uptake kinetics into cells was assumed to be similar as for human cell lines and was described by a first-order kinetics one-compartment model.

The model is provided as an Excel spreadsheet and as an R script. We applied it to predict the *in vitro* disposition of 199 neutral and ionized organic chemicals ($-3 < \log K_{ow} < 7$) tested in the RTgill-W1 assay. We predicted that for 72% of chemicals, the free concentration was >30% of the nominal concentration. For more hydrophobic chemicals, the free concentration was up to 1000 times lower. This indicates the importance of adjusting for *in vitro* disposition, as for those chemicals the *in vivo* effect concentration would be predicted 1000x too high, leading to a less protective effect concentration.

1.02.P Alternatives to Animal Testing for Ecotoxicity Assessments: Exploring Approaches and Avenues for the Future

1.02.P-Mo001 Single and Combined Effects of Sertraline and Polyhydroxybutyrate Nanoplastics to Amphibians: An In Vitro and In Vivo Approach

*Márcio Barreto[1], Miguel Oliveira[2] and **Isabel Lopes**[2], (1)University of Aveiro, Portugal, (2)University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Portugal*

Plastic pollution is a major factor impacting wildlife, with amphibians being a especially vulnerable group. Nanoplastics (NPs) gain relevance due to their widespread and particular characteristics, including large surface area and reactivity. Polyhydroxybutyrate (PHB) emerges as a bio-based plastic, however, the understanding of its environmental impact, particularly regarding its nanosized particles, remains limited. Sertraline, one of the most consumed antidepressants, is expected to be present in the aquatic environment due to patient excretion, inefficient wastewater treatment, and improper disposal. The objectives of this work were to assess the effects of PHB nanoplastics and sertraline, in single and combined exposure, towards two aquatic early life stages of the model organism *Xenopus laevis*. Additionally, in vitro assays were conducted to understand the suitability of two cell lines as non-animal alternatives. To attain these objectives, both embryos and tadpoles of *X. laevis* were exposed for 96-h to increasing concentrations of sertraline and PHB-NPs, as well as combined (only for tadpoles) exposures, where the endpoints assessed were mortality, occurrence of malformations, heart rate and growth (body length and body weight, the later endpoint only for tadpoles). On the other hand, 72-h cytotoxic assays were conducted with two cell lines derived from *X. laevis* (A6 and XTC-2), where the cell viability was assessed through the MTT and resazurin viability assays Our results suggested high tadpole sensitivity to sertraline (96-h LC_{50}: 0.45 mg L^{-1}), compared to embryos (96-h LC_{50}: 2.58 mg L^{-1}), while concentrations of PHB-NPs between 0.01 and 100 µg L^{-1} did not show statistically differences in the monitored endpoints. Furthermore, A6 and XTC-2 cell lines were less sensitive to sertraline with 72-h LC_{50} of 5.05 and 3.78 mg L^{-1}, respectively, while the opposite was observed for the PHB-NPs. On *in vitro* assays PHB-NPs and sertraline co-exposure showed both examples of antagonism and synergism were observed. Our results suggest cell lines, though not being more sensitive than tadpoles and embryos to sertraline, seemed to be good alternatives for animal testing, promoting fast and reliable preliminary assays, and allow a more precise selection of concentration ranges to be tested at later phases of environmental risk assessment, consequently reducing the number of organisms used in animal testing.

1.02.P-Mo002 Screening Chemicals Using High-Throughput Phenotypic Profiling (HTPP) in Two Zebrafish Cell Lines

*Felix Harris[1], Clinton Willis[2], **Bruno Campos**[3], Geoffrey Hodges[3], Sophie Cable[3], Alistair Middleton[3], Amanda Jurgelewicz[4], Richard Judson[2] and Joshua Austell Harrill[2], (1)ORISE Participant at U.S. Environmental Protection Agency, (2)U.S. Environmental Protection Agency (US EPA), (3)Unilever - Safety and Environmental Assurance Centre (SEAC), United Kingdom, (4)ORISE Participant at the U.S. Environmental Protection Agency*

High-throughput phenotypic profiling (HTPP) combines Cell Painting, where chemically treated cells are labeled with fluorescent probes to quantify changes in cell morphology, alongside a propidium iodide (PI)-based cell viability assay used to identify cell cytotoxicity. One of the goals of ongoing HTPP work is to expand the range of cell lines tested to encompass a wide array of target organs and origin species. The current study applied HTPP to two previously untested zebrafish cell lines: one from adult liver (ZFL) and one an embryonic fibroblast (ZEM2S). Two individual chemical sets were tested in 8-point half-logarithmic concentration-response format. The first, was a set of 23 reference chemicals known to cause morphological changes in a variety of cell types, and the second consisted of 42 chemicals covering a diverse range of uses such as drugs, industrial chemicals, and chemicals used in foods/consumer products. DMSO-solubilized chemicals were dispensed onto cells plated in 384-well format, and sampled after a 24-hour exposure. Treatments defined as cytotoxic by the cell viability assay were excluded from subsequent analyses. Cell Painting data were analyzed using pipelines designed to normalize data to vehicle control and dimensionally reduce data by calculating Mahalanobis distances across all features, as well as within individual categories of features. Curve fitting was performed across global, category, and individual feature level. A phenotype altering concentration (PAC) was determined as the minimum benchmark concentration between global and category-level endpoints. Active chemicals were defined as those having a PAC value below the highest tested concentration. Most of the 23 reference chemicals were active in both cell lines: 19 for ZFL, 17 for ZEM2S. Of the 42 chemicals in the larger test set, approximately half were active: 24 in ZFL, 21 in ZEM2S, with an overlap of 17 chemicals. We have previously demonstrated that HTPP is an efficient and informative approach for bioactivity screening of environmental chemicals in human-derived cell models. Here we have adapted the HTPP approach to cell types from zebrafish, a vertebrate, non-human model organism widely used in toxicology as a step to increasing the species diversity of this NAM tool. These data are foundational for future HTPP screens across cell types and model organisms. *This abstract does not reflect USEPA policy.*

1.02.P-Mo003 Ecdysone Receptor Agonism Adverse Outcome Pathway Validation for Insect-Specific In Vitro Assay Development

***Rebeka Darmati**[1], Paul Carmichael[2], Bruno Campos[3] and Nico van den Brink[4], (1)Division of Toxicology, Wageningen University & Research (WUR), Netherlands, (2)Unilever, United Kingdom, (3)Unilever - Safety and Environmental Assurance Centre (SEAC), United Kingdom, (4)Wageningen University & Research (WUR), Netherlands*

With the growing population, competitive economy and climate change, the assessment of Environmental Risks is essential for handling the pressure of a high variety of chemicals entering the environment. Historically, Environmental Risk Assessment (ERA) protocols were limited to testing a small number of endpoints on mostly *in vivo* exposures of a small number of “representative” model species as a proxy to the entire ecosystem. To address obvious shortcomings of these approaches and to address a changing regulatory and ethical landscape towards reducing or eliminating animal testing, New Approach

Methodologies (NAMs) represent a shift towards a more mechanistic ERA, including the use of Adverse Outcome Pathway (AOP). This approach is operationalised predominantly by *in silico* and *in vitro* testing assays. For such mechanistic-based ERA, the development, evaluation and qualification/ validation of *in vitro* assays is imperative, representing critical steps in advancing environmentally sound and effective risk assessment.

The aim of this project is to provide empirical evidence of an assay based on Ecdysone Receptor Agonism AOP towards establishing an *in vitro* cell-based assay. Ecdysone, an insect hormone, is released in pulses that trigger developmental transitions by initiating a cascade that begins with binding to the Ecdysone receptor. According to the proposed AOP, the ecdysone levels in the organism are reduced at a specific moment, which allows later genes in the moulting cascade to be expressed, enabling the organism to complete the moulting process. This is a highly conserved pathway across arthropod species, therefore, chemicals with the ability to interfere with Ecdysone receptor can cause incomplete moulting and subsequent mortality. Using *Drosophila melanogaster* and its embryonic (S2) cell line as a model system, we aim to characterise and quantify the molecular and cellular event cascades underlining Ecdysone receptor mediated toxicity in invertebrates and explore the applicability of the S2 cell line as an *in vitro* assay. Preliminary results show that upon exposure to ecdysone, S2 cells respond in a similar way as the initial steps of the moulting cascade that is only completed once ecdysone is removed from the system as is seen *in vivo*.
If successful this approach could be deployed for other relevant pathways and endpoints to ensure a robust environmental protection without the reliance on further generation of invertebrate data.

1.02.P-Mo004 Predicting Acute Fish Toxicity with the RTgill-W1 Assay (OECD TG 249): Putting it into Regulatory Practice
***Karen Jenner*[1]*, Georg Kreutzer*[2]*, Heike Laue*[2]*, Andreas Natsch*[2]*, Gordon Sanders*[3] *and Shojiro Yamada*[4]*, (1)Givaudan UK Ltd, United Kingdom, (2)Givaudan Suisse SA, Switzerland, (3)Givaudan International SA, Switzerland, (4)Givaudan Japan KK, Japan*
Determination of acute fish toxicity is a key regulatory endpoint for environmental hazard assessment globally. The Fish Gill Cell Line (RTgill-W1) cytotoxicity assay provides a non-animal alternative that has been validated and adopted as an OECD Test Guideline (TG 249). However, adoption of an OECD TG does not equate to regulatory acceptance. As highlighted in the recent ECHA NAM workshop report, gaining regulatory acceptance relies on demonstrating the use of, increasing confidence in, and understanding the limitations of New Approach Methodologies (NAMs). Adaptation of regulatory frameworks was also recognised as being crucial. Encouragingly, the draft REACH revision includes a proposal to replace short-term fish toxicity testing with the RTgill-W1 assay (TG 249) or the fish embryo test (TG 236).

We previously demonstrated the applicability of the RTgill-W1 assay to fragrance chemicals covering a broad range of physicochemical properties and diverse chemistries. From this study, we developed a regression equation translating the *in vitro* EC_{50} to the in vivo LC_{50}. According to TG 249, the lowest EC_{50} based on geometric mean measured concentrations among three cell viability endpoints is used as a direct estimate of the predicted LC_{50}. Here, we compare the two approaches for the fragrance chemicals of the previous study and 10 additional chemicals. Both approaches can predict LC_{50} values accurately, yet the regression approach is more conservative.

We will also present a number of case studies, demonstrating our use of the RTgill-W1 assay in regulatory applications. This includes REACH registrations; not only > 10tpa substances but also, in anticipation of the REACH revision for increased information requirements for low tonnage substances, a number of Annex VII substances. The applicability to complex mixtures is explored as is the use of the TG 249 assay as a standalone assessment or in combination with QSAR and/or to support read-across.

Only mutual acceptance of the results by regulatory bodies around the globe guarantees that no animal tests need to be conducted. Thus, we will present one case study submitted to the Japanese authorities where we used the RTgill-W1 assay supported by QSAR (ECOSAR, KATE) to demonstrate that the primary metabolite observed in the ready biodegradability study was less toxic than the parent. On this basis we proposed to waive the acute fish toxicity test of the metabolite in order to avoid unnecessary animal testing.

1.02.P-Mo005 Breaking the silos: Towards a holistic approach of animal-free human and environmental health safety assessments of cosmetics
***Amelie Ott*[1]*, Ryan Heisler*[2]*, David Allen*[3]*, Arnaud Boivin*[4]*, Maria Baltazar*[5]*, Bruno Campos*[6]*, Christopher Choi*[7]*, Carol Courage*[8]*, Iain Davies*[9]*, Nazanin Golbamaki*[4]*, Juliet Hodges*[10]*, Abdulkarim Najjar*[11]*, Véronique Poulsen*[4]*, Gladys Ouedraogo*[4]*, Andreas Schepky*[11] *and Harald Streicher*[11]*, (1)International Collaboration on Cosmetics Safety (ICCS), New York, United States, (2)International Collaboration on Cosmetics Safety (ICCS), (3)Integrated Laboratory Systems, Inc., (4)L'Oréal, France, (5)Unilever, (6)Unilever - Safety and Environmental Assurance Centre (SEAC), United Kingdom, (7)Takasago, (8)Croda, (9)PCPC (Personal Care Products Council), (10)Safety & Environmental Assurance Centre, Unilever, United Kingdom, (11)Beiersdorf, Germany*
Historically, human and environmental health safety assessments have operated as distinct entities, often in silos. The need to

move away from animal testing for chemical safety purposes stresses the importance to identify key strengths and share learnings from each domain while highlighting intricacies and opportunities towards a holistic animal-free safety assessment.

Human health safety assessments already utilize many animal-free methods within frameworks for several endpoints. This is particularly the case for the cosmetics sector with its long-standing move away from animal testing and the complete EU animal testing ban by 2013. Here, exposure led next-generation risk assessment (NGRA) frameworks are being proposed to demonstrate an absence of human health effects for cosmetics without using animals.

To eliminate animal testing for environmental safety, both animal-free methods to understand effects (e.g. aquatic toxicity) and refined exposure (including fate) methodologies are needed. However, in comparison to human health, only few animal-free approaches exist and there is simultaneously, less funding and expertise available, hindering rapid evolvements. However, the possibility of using invertebrate models to generate environmental safety data can be of benefit also for human health, as a proxy for fully functioning organisms.

While acknowledging differences, such as protection goals, a holistic animal-free approach could build on:

- Understanding biological relevance such as conserved targets, pathways and traits driving species sensitivities;
- Leveraging advancements in technologies such as microphysiological and high-throughput screening methods;
- Tackling regulatory needs such as internal exposure concentrations and endocrine disruption;
- Fostering collaborations among stakeholders including regulatory bodies, validation organizations, industry and test method developers;
- Discussing regulatory frameworks to ensure alignment between human and environmental safety assessments where appropriate;
- Demonstrating the utility of animal-free methods via case studies.

This poster will present a thought-starter from the International Collaboration on Cosmetics Safety (ICCS) to actively engage with SETAC on how to foster collaborations across human and environmental health domains, revolutionizing the way we understand potential impacts of chemicals without using animals.

1.02.P-Mo006 Lessons learnt from XETA OECD TG248 for implementation of NAMs in regulatory assessment of endocrine activity.

***David Du Pasquier**, Andrew Tindall and Gregory F. Lemkine, Watchfrog S.A., France*

In 2019, the Xenopus Eleuthero-embryo Thyroid Assay (XETA, OECD TG 248), marked a significant milestone as the first eleuthero-embryo method validated by the OECD for assessing thyroid activity.

The XETA utilises *X. laevis* eleutheroembryos to detect modulation of thyroid signalling by thyroid active chemicals. The assay is transcription-based and uses a transgenic tadpole line expressing Green Fluorescent Protein (GFP) under the control of a promoter regulated by TH. As an “alternative method”, the XETA is considered as a new approach methodology (NAM). NAMs encompass methods that predict effects by identifying molecular, cellular, and tissue changes, aiming to reduce the use of animals.

An important step for the application of the TG248 was the publication of an annex to the “Guidance for the identification of endocrine disruptors in the context of EU regulations” describing how to include the XETA in the assessment strategy of the ECHA/EFSA Guidance.

This is of great interest considering the implementation of NAMs as it followed a mechanistic approach for a comprehensive coverage of the targets of endocrine mechanism. Following this guidance, when no thyroid mediated adversity was observed in mammals and the XETA is negative then “the endocrine activity for the T-modality for non-target organisms other than mammals is considered sufficiently investigated and the Endocrine Disruptor criteria are not met.”

Since the XETA was implemented 99 active ingredients were evaluated for the T modality by the authorities. Ten were eligible for replacing the AMA by a XETA.. Considering that a typical AMA requires 452 animals, we could estimate that the implementation of the XETA as defined by ECHA and EFSA guidance saved 4520 animals. The actual number of biocides and pesticides requiring an evaluation for ED properties is estimated to 475 pesticides and 297 biocides, resulting in a total of 396 264 amphibians required to perform AMAs for the T modality. If we estimate that 10% of the AMAs will be replaced by a XETA, this will avoid the use of approximately 40 000 amphibians.

Combining eleuthero-embryos with data from in vitro single mechanism assays could provide comprehensive coverage of the targeted modes of actions along the endocrine signalling pathway. In particular, this would speed up the process of endocrine assessment of large numbers of chemicals/cosmetic ingredients which would more rapidly protect wildlife from endocrine active chemicals.

1.02.P-Mo007 Advancing Thyroid Hormone Disruption Assessment: Integration of Adverse Outcome Pathway Network and Cross-Species Relevance of In Vitro Bioassays

***Jiri Novak**, Puja Kumari, Runze Liu, Veronika Janeckova, Tereza Nesporova and Klara Hilscherova, RECETOX, Masaryk University, Czech Republic*

The applicability of data derived from alternative in vitro bioassays in risk assessment is often hindered by the inherent over-simplicity of these assays. Nevertheless, significant improvements in the applicability can be achieved through the incorporation of the Adverse Outcome Pathway (AOP) concept. This concept establishes a link between molecular initiating events (MIEs), assessed in vitro, and adverse outcomes (AO) at the individual or population level. The EU H2020 ERGO project adopts the AOP framework to develop a battery of in vitro bioassays for screening chemicals with potential endocrine-disrupting properties on the highly conserved thyroid hormone (TH) system, facilitating the acquisition of cross-species relevant data. A cross-species AOP network for TH disruption is under development, providing a basis for prioritizing MIEs within the bioassay battery.

We have established and optimized a battery of bioassays focusing on prioritized endpoints related to thyroid hormone disruption. The cross-species relevance of selected MIEs is supported by comparing the primary structure of target proteins across animals using the Sequence Alignment to Predict Across Species Susceptibility (SeqAPASS) online tool from the US EPA. Bioassays assessing the effect of thyroid-disrupting chemicals (TDCs) on iodide uptake by thyroid cells, mediated by the Na+/I− symporter (NIS), utilize a stably transfected human cell line overexpressing NIS and a rat thyroid cell model. Iodide uptake levels are detected spectrophotometrically using Sandell-Kolthoff reaction (SK). Transport of TH is evaluated by fluorometric assessment of TH displacement from its plasma transporter, transthyretin (TTR), by TDCs. TH metabolization is addressed using a cell model overexpressing deiodinase (DIO3), which is a key factor in maintaining controlled levels of TH during the developmental processes. The DIO3 inhibition by TDCs was detected using SK. These assays, tailored for screening prioritized chemicals, showcase the utility of the newly developed bioassay battery for high-throughput screening of chemicals. The results enable the characterization of their thyroid hormone-disrupting potential and identification of the most relevant MIEs. Based on SeqAPASS analysis, data from the established human cell-based bioassays are deemed relevant to most vertebrate species. The project has received funding from the EU H2020 research and innovation programme under grant agreement No. 825753

1.02.P-Mo008 Frequency of Malformations in Zebrafish Embryos Exposed to Metals

***Alma Sobrino-Figueroa**[1] and Sergio Alvarez-Hernandez[2], (1)Hydrobiology, Universidad Autonoma Metropolitana Iztapalapa, Mexico, (2)Hidrobiology, Universidad Autonoma Metropolitana Iztapalapa, Mexico*

The zebrafish *Danio rerio* has been proposed as a test organism to evaluate the effects of chemical compounds. Embryos of this species are currently used, because their response is comparable to that of adult fish. In Mexico, the use of zebrafish is not stipulated in current legislation, despite being a useful alternative to replace fish bioassays. The objective of this study was to determine the toxic effect of 10 metals, that have been detected in concentrations greater than 50 mig/L in systems in the Valley of Mexico, to determine their sensitivity and propose their use in monitoring studies. Initially, bioassays were carried out lasting 24 hours, seven metal concentrations were tested in triplicate (0.01, 0.1, 1.0, 5, 10, 20 and 40 ppm) for Cd, Cr, Cu, Hg, Pb and 6.25, 12.5, 25, 50 and 100 ppm for As, Mn, Ni, V and Zn. The LC_{50} was determined after 48 hours of exposure using the Probit method. Subsequently, another test was carried out lasting 72 hours with 2 sublethal concentrations (LC_1 and LC_{10}), where the frequency of embryos with malformations was determined. The toxicity of the metals based on the LC_{50} was (from highest to lowest toxicity): Hg > Cu > Pb > Cr > Cd > As > V > Ni > Mn > Zn. Deformed larvae were obtained in concentrations between 0.003 and 49.08 mg/L of metal. The highest frequencies of deformed embryos were recorded in the tests with Cr and Pb. Tests with embryos evaluating the frequency of malformations are a quick and economical option for carrying out biomonitoring studies.

1.02.P-Mo009 Assessing the Applicability Domain of Fish Embryo Acute Toxicity (FET) Test as Alternatives of Fish Acute Toxicity Test, Utilizing Time-to-death Data in FET Test

***Riping Huang**[1], Takahiro Yamagishi[2], Haruna Watanabe[1], Koichi Ohno[1] and Hiroshi Yamamoto[2], (1)National Institute for Environmental Studies (NIES), Japan, (2)Health and Environmental Risk Division, National Institute for Environmental Studies (NIES), Japan*

Acute fish toxicity data is globally utilized for chemical risk assessment purposes in compliance with various regulatory frameworks. However, concerns have been raised regarding the unnecessary suffering and significant fish fatalities resulting from this test, as it involves exposing fish to high concentrations of a test chemical to induce mortality. The fish embryo acute toxicity test (FET; OECD TG 236) has been emerged as a potential alternative test method to the acute fish toxicity test (OECD TG 203), as it is considered a non-protected life stage under certain animal welfare regulations. Although it has been reported that many chemicals exhibit a generally similar toxicity value between the two test methods, there are cases that discrepancies are observed in toxicity values between the two test methods. Therefore, adopting FET test as an alternative method for the fish acute toxicity testing presents challenges, primarily due to the uncertainty surrounding its applicability domain.

In this study, we aimed to define the applicability domain of the FET test as an alternative method through a novel approach that involves categorizing test chemicals based on time-to-death data obtained in the FET test. The FET test encompasses both the embryo and eleutheroembryo stages, effectively bridging the gap between cell-based assays and whole fish testing.

Therefore, we hypothesized that narcotic chemicals were expected to cause death at the early developmental stage within two days of fertilization, while chemicals acting via a specific mechanism, such as those targeting specific tissues, were anticipated to cause death at the eleutheroembryo stage, where ontogeny have concluded.

Our results indicate that pharmaceuticals and pesticides with specific targets exhibited later onset of lethality during testing except for lovastatin. Meanwhile, most general chemicals, initially predicted not to have a specific target, displayed early onset of lethality. These results indicate that time-to-death data obtained from FET testing might distinguish chemicals explained by toxicity acting on specific targets from other toxicity such as baseline (narcotic) toxicity. Furthermore, we suggest that the result based on this chemical categorization approach could be one of the crucial pieces of evidence to define applicability domain of the FET test as an alternative method.

1.02.P-Mo010 Development of an In vitro Marine Fish Bioassay for Characterizing Environmental Impact of Industry Development in the Arctic

Maria T. Hultman[1]*, Prem Chand*[2]*, You Song, PhD*[1] *and Knut Erik Tollefsen*[1]*, (1)Norwegian Institute for Water Research (NIVA), Norway, (2)Ecotoxicology and risk assessment, Norwegian Institute for Water Research (NIVA), Norway*

The ongoing changes in the Arctic, such as rising temperatures and diminishing sea ice, are likely to introduce new and/or expansion of current industrial activities, including oil, gas, and aquaculture operations. There's a pressing need to understand how these human activities affect the Arctic environment and wildlife, focusing on the transmission, bioaccumulation and effects of ecologically-relevant pollutants. To address this effectively, reproducible, cost-effective and ethically, New Approach Methodologies (NAMs), using in vitro methods were implemented to quickly assess the toxicity of compounds of concern. The main goal of the study is to develop and implement an *in vitro* testing system originating from the Arctic fish, Atlantic Halibut (*Hippoglossus hippoglossus*), examining how environmentally relevant chemicals affect the liver (hepatocyte) cells, and evaluate their use in prediction of environmental consequences. This goal will be achieved by multiple tasks: 1) Development and optimization of primary hepatocyte cell isolation, cell characterization (morphology, physiology and structure), culturing and exposure of Halibut to model compounds (e.g. Copper, β-Estradiol, 2,3,7,8-Tetrachlorodibenzodioxin (TCDD)); 2) Assessing hepatocytes sensitivity and responsiveness of key indicators of toxicity such as detoxification, hormonal disruption, and antioxidant responses; 3) Finally experimental evaluation of selected substances that are particularly relevant to the Arctic environment. The preliminary results display that the primary hepatocytes are diverse, as they consist of more than one cell population. The majority of cells (Ø12-16 µm) were complex, containing large amounts of intracellular lipid droplets, followed by a less complex, but bigger cell type (Ø ~21 µm), identified with a light microscopy. Upon exposure to the model compounds copper and TCDD, an acute toxic effect was observed in both cell membrane integrity and metabolic activity, with the latter being more susceptible. Overall, the use of *in vitro* methods such as halibut primary hepatocytes is a promising proxy for *in vivo* testing and a potential tool in future hazard and (next generation) risk assessment of Arctic contaminants. This work was supported by the EXPECT Project (#315969) funded by the Research Council of Norway.

1.02.P-Mo011 Are both the water and the solvent control required in fish early-life stage toxicity tests?

Christopher Fassbender, PhD[1]*, John W. Green*[2]*, David A. Dreier*[3]*, Daniel Faber*[4]*, Lennart Weltje, Prof. Dr.*[5] *and Gilly Stoddart*[1]*, (1)PETA Science Consortium International e.V., Germany, (2)Ecostatistical Consulting, JohnWGreen-ecostats.com, (3)Syngenta, (4)Environmental Safety, Bayer AG - Crop Science Division, Germany, (5)Agricultural Solutions - Ecotoxicology, BASF SE, Germany*

This project investigates whether it is possible to use a solvent control alone when a solvent is required in fish early-life stage (FELS) toxicity studies. Use of only one control would substantially reduce the number of fish used in studies requiring a solvent.

The project compiled a FELS toxicity test database including solvent and water controls and concentration-response data to determine whether there are systematic differences between the water and solvent controls. For each response variable, the distributions of control data (means, between- and within-replicate variances) for water, solvent and pooled controls were investigated. The authors used FELS concentration-response data to investigate the impact of control choice on the NOEC and EC_{10}. Using computer simulations, the authors determined the potential impact of using only the solvent control on the EC_x estimation and NOEC values. The simulations covered the observed ranges of variability and concentration-response shapes for each type of response across three species (Fathead Minnow, Sheepshead Minnow, and Rainbow Trout). The study explores all response variables required in FELS toxicity studies including hatching success, time to hatch, time to swim-up, larval survival, morphological and behavioural abnormalities, fish length and fish weight at study end. Furthermore, the study explores both the selection of statistical model and model averaging for EC_x estimation.

According to the simulations, for the solvent dimethylformamide (DMF) and Fathead Minnow, use of the solvent control maintains 80% power to detect 10% effects in length and weight and 20% effects in hatch/survival with lower false positive rates than other control choices. The analyses of FELS concentration-response data are also presented. Altogether, there is preliminary statistical evidence to support omitting the water control in FELS studies using a solvent.

The views, conclusions, and recommendations expressed in this presentation are those of the authors and do not necessarily represent the policies or positions of their affiliated organisations.

1.02.P-Mo012 Fins to Future: Assessing the Role of Acute Fish Toxicity Testing in Risk Assessments of Plant Protection Products in the EU and the US

***Elena Adams*[1]*, Sarah Hartmann*[1]*, Katherine K. Coady, PhD*[2]*, Audrey Bone, PhD*[2]*, Daniel Faber*[1]*, Yvonne Wolf*[1]*, Markus Ebeling*[1] *and Eric Bruns*[1]*, (1)Bayer AG - Crop Science Division, Germany, (2)Bayer AG - Crop Science Division*

Both the European Union (EU) and the United States (US) are actively pursuing initiatives to reduce the use of vertebrate animals in toxicity testing. Under Commission Regulations (EU) No 283/2013 and No 284/2013 in the EU, and the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA) in the US, the fish acute toxicity test is required for plant protection product (PPP) registration and ongoing authorization. With alternative non-vertebrate methods like the fish embryo toxicity (FET – OECD TG 236) test and the rainbow trout gill cell line assay (RT gill-W1 – OECD TG 249) available, it is important to assess the concrete value, that the fish acute toxicity test contributes to the overall environmental risk assessment.

To address this, we presented a critical review of aquatic risk assessments for EU-registered active substances (a.s.) at SETAC Dublin in 2023. To broaden the scope and enhance the relevance of this topic, an additional analysis was conducted on the approach employed in the US, complementing the EU risk assessment. The objective of this data review was to determine how frequently the acute fish toxicity endpoint, as opposed to other aquatic organism toxicity endpoints, drives the risk for a.s. in the aquatic environment across the globe.

Our evaluation covered 57 a.s. registered in the US (under Bayer ownership) and 232 a.s. registered in the EU. The findings revealed that a minimal percentage of aquatic risk assessments was driven by the acute fish endpoint for both the US and the EU risk assessment approach (less than 1% in the EU after refinement, and approximately 10% in the US; the US data set will be expanded with further registered a.s.).

This evaluation suggests significant potential for minimizing vertebrate testing while still ensuring protectivity for the aquatic environment, including fish. Moreover, alternative tools such as the FET, RT gill-W1 and in-silico tools (e.g. QSARs) can offer additional insights into fish-specific toxicity and will be addressed in future investigations. This research underscores the potential for conducting aquatic risk assessments for PPPs without relying on acute fish toxicity studies. In addition, this work aims to increase regulatory acceptance of alternative tools for the registration of PPPs in the individual regions and to support the 3Rs principle.

1.02.P-Mo013 A Network for Alternative Methods for ecological safety assessment of chemicals (ecoNAM)

***Adam Lillicrap*[1] *and Michelle Rau Embry*[2]*, (1)Norwegian Institute for Water Research (NIVA), Oslo, Norway, (2)Health and Environmental Sciences Institute (HESI)*

ecoNAM is a platform to facilitate international information exchange about animal alternatives for ecological safety assessment of chemicals. Our aim is to foster cooperation between government, academia, industry, Non Governmental Organisations, research centers and other stakeholders involved in the research, development, and application of alternative ecological hazard and risk assessment tools and methods. ecoNAM will facilitate the exchange of knowledge, data, and expertise to promote synergies and collaboration related to advances in ecological alternative methods on a global scale. We are gauging interest and resources needed for such a network and will determine the next steps and a feasible path forward. This poster describes ecoNAM and how it has development since its inception in 2023. The following critical needs, purpose and goals of ecoNAM are identified as:

CRITICAL NEED: There are existing networks for animal alternatives focused on human health endpoints, but similar groups do not exist for ecotoxicity testing. There is significant interest from different initiatives and organisations discussing NAMs but in a poorly coordinated way which needs addressing. There is a need to create a global network of multi-sector partners working to advance alternatives to ecotoxicity testing and to bridge the divide between ongoing initiatives in the human health arena.

PURPOSE: The purpose of ecoNAM is to promote global international cooperation between government, academic, industry, NGOs, research centers, and other stakeholders involved in research, development, and application of alternative ecological risk assessment methods.

GOALS: ecoNAM has the following goals:

- Facilitate exchange of knowledge, data, and expertise to promote collaboration related to advances in ecoNAMs on a global scale.
- Strategically prioritize needs and identify resources within the ecoNAM community.
- Promote the uptake and application of ecoNAMs.
- Develop training and education materials.

The Network for Alternative Methods for ecological safety assessment of chemicals can be found at the following link www.econam.org

1.02.P-Mo014 Caenorhabditis elegans Life Cycle Tests as Screening Tools to Unveil the Underlying Adverse Effects of Chemicals in Reproduction

Fábio Campos[1]*, Amadeu M.V.M. Soares*[2] *and Susana Loureiro*[3]*, (1)CESAM - Centre for Environmental and Marine Studies and Department of Biology, University of Aveiro, Portugal, (2)CESAM - Department of Biology, University of Aveiro, Portugal, (3)CESAM-Centre for Environmental and Marine Studies and Department of Biology, University of Aveiro, Portugal*

Chemical substances from various sources enter wastewater treatment plants and end up in the environment. Pesticides and pharmaceuticals are usually some of the most found chemical substance classes found in waterbodies and soil. The ubiquitous distribution of these substances raises worldwide concern regarding their potential deleterious effects on non-target organisms and humans. Adverse effects in reproduction output are some of the most concerning ones, where some effort is needed to accurately pinpoint the moment or process where the disruption occurs. In order to provide some insights, *Caenorhabditis elegans* figures out as an outstanding animal model to tackle this problem due to its well-known lifecycle and effectively suitable within a One Health approach.

For this study, four chemical substances, found worldwide in waterbodies, were selected: the insecticides cypermethrin and flupyradifurone, the herbicide MCPA, and the over-the-counter pharmaceutical diclofenac. Different life stages of *C. elegans* life cycle were assessed for each substance to unravel the effects in distinct reproductive stages/processes. The embryotoxicity/neonatal toxicity was evaluated by assessing the hatching rate of exposed *C. elegans* eggs; the developmental toxicity was evaluated by exposing individuals from L1 larvae to egg-laying adults and assessing the total reared offspring; the transgenerational effects (mother-to-progeny) were evaluated by measuring the hatching rate of unexposed eggs obtained from exposed adults. Our results show that all substances affect the reproductive output of *C. elegans* by exerting effects in one or more life stages/reproductive processes. Cypermethrin was the most toxic chemical regarding the observed developmental effects, whereas MCPA figured out as the most toxic considering the neonatal and transgenerational effects.

The present study's targeted approach provides supporting evidence on the unexpected reproductive effects of chemicals unrelated to their mode-of-action. The results obtained also highlight the potential of *C. elegans* to fill in some gaps in the development of Adverse Outcome Pathways contributing to a more realistic hazard prediction which can be extended to other organisms and, ultimately, humans and animals, within the One Health approach.

1.02.P-Mo015 Initiatives for the regulatory acceptance of New Approach Methodologies, how does it all connect?

Leonie Mueller[1]*, Robert Gregory Lee Prof*[2]*, Aleksandra Cavoski*[3]*, Laura Holden*[4] *and Francois Busquet*[1]*, (1)Altertox, Belgium, (2)Law School, University of Birmingham, United Kingdom, (3)Birmingham Law School, University of Birmingham, United Kingdom, (4)University of Birmingham, United Kingdom*

The last years were marked by a period of regulatory change, driven by important policy initiatives related to the European Green Deal, EU Chemical Strategy for sustainability and the Pharmaceutical Strategy for Europe. In response to the 2021 Parliament Resolution to 'Accelerate the transition to Innovation without the use of Animals in Research, Regulatory Testing and Education' and European Citizens' Initiative (ECI) 'Save Cruelty-Free Cosmetics', the European Commission has initiated a series of actions aimed to progress the transition to complete animal-free testing for EU chemicals legislation (e.g., REACH, Biocidal Product Regulation, Plant Protection Products Regulation and human and veterinary medicines). In parallel, academia and industry are driving the transition towards NAMs application through their research and development. Despite the considerable progress in the scientific development of NAMs, barriers to their regulatory uptake remain. These barriers have become a subject of research themselves. Major findings from an empirical study include that next to the technical barriers that have been described in the past and are a continuous subject to academic discussions, there are a range of social barriers that manifest in a resistance to the technological transition. The focus on social and people-based factors distinguishes the study from narrower scientific debate which has tended to focus on the maturity of the next generation of chemical risk assessment. The findings highlight the nuances to the subject that need to be understood in order to determine the root cause of the perceived delay in regulatory uptake of NAMs. In response to the European Citizens Initiative, the EU Commission has initiated a series of activities aimed at collating the community's expertise by designing a roadmap on the transition to NAMs and creating opportunities for engagement and generation of consensus. A detailed analysis of the ongoing and future initiatives was translated into a stakeholder map that can be used to identify major stakeholder and opinion leaders' positions. With an increasing understanding of what the crucial next steps towards the replacement of animal testing are, what challenges remain? How do our efforts need to be coordinated in this time of transition? Here we present an analysis of the most important developments in EU policy and global stakeholder driven activities that should be considered moving forward.

1.02.P-Mo016 Prediction of the In Vivo Acute Toxicity of Agrochemicals to Fish with the In Vitro RTgill-W1 Cell Line Assay

Casten Lange Dr[1]*,* ***Gunnar Schmidt***[2]*, Lea Weinisch*[1]*, Kristin Schirmer*[3]*, Stephan Fischer*[4]*, Jennifer Fitzgerald*[5] *and Maike Habekost*[1]*, (1)BASF SE, Germany, (2)BASF SE, Research Triangle Park, United States, (3)Environmental Toxicology, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (4)aQuaTox-Solutions GmbH, Switzerland, (5)Eawag - Swiss Federal Institute of Aquatic Science and Technology, Switzerland*

The RTgill-W1 cell line assay (OECD 249) provides an animal-free alternative to *in vivo* fish acute toxicity tests (e.g. OECD 203 & 236). Testing for acute fish toxicity is an integral part of the environmental risk assessment for chemicals in Europe and other parts of the world. Dozens of fish are required for a single study with mortality being the primary endpoint. The studies also require large amounts of test material and produce remarkable volumes of contaminated water. Acute fish toxicity is mainly driven by an exposure of the gill epithelium to dissolved chemicals. The gills constitute the primary uptake site for water-born substances, where unspecific effects (loss of membrane integrity or metabolic activity) might occur. On a cellular level, those adverse effects lead to death of epithelial cells and a loss of function of the gill epithelium. Affected fish suffer from respiratory failure, ultimately leading to death.

The RTgill-W1 cell line was derived from rainbow trout (*O. mykiss*) gill epithelium. Cells are treated in a 24-w plate with 6 concentrations for 24 h and EC_{50} values are generated with cell viability assays (metabolic activity, lysosomal disruption, cell membrane integrity) and are used to predict *in vivo* fish toxicity.

The RTgill-W1 cell line assay has been intensively tested on chemicals with various modes of action (MoA) and a broad range of physico-chemical properties and toxicity. However, data on plant protection products are scarce. Therefore, we conducted the RTgill-W1 assay with a selection of 11 active substances from the agrochemical sector with different indications and MoA over a broad concentration range (0.05 µg/L to 100 mg/L). A strong correlation between *in vitro* EC_{50} values and existing *in vivo* LC_{50} values (rainbow trout, 96h) with fold-change differences below 10 were observed.

With the current dataset, we provide evidence for a strong predictivity of the RTgill-W1 assay for a set of agrochemicals that have been underrepresented in published data. The data shows that the RTgill-W1 assay is applicable for agrochemicals with different indications and MoA and over a broad concentration range. The results support the potential of the *in vitro* assay to replace *in vivo* fish acute toxicity tests for agrochemicals. We also intend to raise regulatory acceptance for the use of the RTgill-W1 assay by adding another supportive piece to a convincing accumulation of data that has been published for chemicals from various sectors.

1.02.P-Mo017 Animal-free In Vitro Assessment of Receptor-Mediated Endocrine Activity Including Phase-1 Metabolism

***Inska Reichstein**, Robin Mazur, Florian Jünger, Sabrina Schiwy, Henner Hollert and Andreas Schiwy, Evolutionary ecology and environmental toxicology, Goethe University Frankfurt, Germany*

Substances interfering with the endocrine system (endocrine disruptors) are present in the environment in complex mixtures and pose a risk to organisms and entire ecosystems, even at low concentrations. Therefore, evaluation of the endocrine activity of environmental samples or individual substances is of central (eco-)toxicological importance.

One possibility for evaluation is the application of standardized, cell-based *in vitro* tests according to OECD test guidelines 455 and 458, in which estrogen and androgen receptor agonists and antagonists can be detected after the addition of the sample. Nevertheless, these *in vitro* test methods have the following disadvantages: 1) Cell-based i*n vitro* tests are conducted with the addition of animal-derived components like fetal bovine serum (FBS) to promote cell growth. However, the replacement of FBS in cell assays can be advantageous for scientific reasons in context of reproducibility (FBS having a high batch-to-batch variability, interaction with test substances, microbial contamination) and animal welfare reasons. 2) *In vitro* tests are usually performed with cell lines that do not fully reflect the metabolic capabilities of a whole organism. Thus, a lack of full metabolization capacities may lead to an over- or underestimation of the endocrine effects of a sample.

In this study, the methods, according to OECD TG 455/458, should be improved by adapting two of the OECD-relevant cell lines, ER-αCALUX® and AR-CALUX®, to animal-free culture conditions. Therefore, commercially available as well as self-developed animal-component free cell culture media were successfully used for the cultivation of both cell lines. After adaptation, the cell lines will be tested for their sensitivity to the respective reference substances to verify the suitability of the adapted cells for an OECD 455/458-compliant test procedure. In addition, both assays are to be supplemented with an external human-derived or biotechnologically produced biotransformation system (S9 homogenate) to evaluate the endocrine activity of model substances after metabolism.

Overall, the endocrine effects without and with S9 homogenates and without or with adaptation to animal-free cell culture conditions will then be compared to assess the assay adaptation and their (beneficial) impact on risk assessment. Thus, the optimized test procedure might improve assay reproducibility and strengthen *in vitro* assays as an alternative to animal experiments.

1.02.P-Mo018 Challenges in the Application of New Approach Methodologies (NAMs) to Assess the Ecological Hazard of Unknown, Variable, Complex and/or Biological substances (UVCBs)

***Maria Blanco-Rubio Ph.D**[1], Adriana C. Bejarano, PhD[2] and Sarah A. Hughes[2], (1)Shell Global Solutions International BV, Netherlands, (2)Shell Global Solutions*

New approach methodologies (NAMs) are increasingly being used for chemical hazards to support regulatory decision-making without animal testing. However, information is still scarce to demonstrate the use of NAMs in the ecological assessment of Unknown, Variable, Complex and/or Biological substances (UVCBs). This poster will provide an overview of the challenges in the application of NAMs to UVCBs and suggest recommendations to promote their implementation with this important group of substances. The complex nature of UVCBs poses technical and biological challenges in the application and regulatory acceptance of NAMs. UVCBs are considered difficult-to-test substances with technical implications in the experimental design of the in-vitro tests, including, but not limited to, the preparation of solutions, dosing, maintaining exposure concentrations, and analytical chemistry measurements. Moreover, UVCBs are usually non-intentional mixtures of chemicals, and the complete chemical structure or the specific molecular formula is unknown. Due to the lack of this information and the variable composition of multi-constituents UVCBs, the use of in-silico and QSARs models, grouping-based approaches (e.g., red-across), and the understanding of mechanisms/modes of action may be limited. Regarding biological challenges, the lack of in-vitro tools (e.g., cell lines from different tissues and species) specific for the hazard assessment of aquatic species, questions the biological coverage of the data. Moreover, the extrapolation from in-vitro to in-vivo but also from one species to the whole population needs to be considered. To validate the use of NAMs and facilitate the decision-making process, the justification for the selection of UVCB substances to build case studies needs to be clearly . Also, standard criteria and protocols for validation need to be identified to guarantee the reproducibility, robustness, and reliability of the tools and results. Mapping roadmaps to identify gaps, reviewing currently available data, improving current models and QSARs, developing specific UVCBs ecotoxicological methods and tools, integrating technologies such as omics, building case studies based on weight of evidence approaches, understanding the interpretation of the data and defining validation criteria, are key areas to promote the use of NAMs to assess the ecological hazard of UVCBs.

1.02.P-Mo019 Advancing Chronic Fish Testing: Needs and Challenges for Alternative Approaches
Julie Krzykwa[1]*, Michelle Rau Embry*[1]*, Constance Mitchell*[1] *and Adam Lillicrap*[2]*, (1)Health and Environmental Sciences Institute (HESI), (2)Norwegian Institute for Water Research (NIVA), Oslo, Norway*
Chronic fish toxicity is a key parameter for hazard classification and environmental risk assessment of chemicals. With an increased focus on the development and application of new approach methodologies (NAMs), there is a need to ensure that an effective path forward includes considerations for animal reduction, refinement, and replacement (3Rs) while also focusing on how new science can improve our ability to protect the environment from potential fish chronic effects. To address this issue, the Health and Environmental Sciences Institute (HESI) workshop on "Alternatives to Chronic Fish Toxicity Testing" was held in Paris, France on October 25-26, 2023, attended by 35 multi-sector scientists from 12 different countries, and a satellite workshop was held in Louisville, Kentucky on November 12, 2023, attended by 16 multi-sector scientists from 3 different countries. This presentation is a summary of some of the key messages representing new lines of thought regarding alternatives to chronic fish ecotoxicity testing. Based on discussions at the workshops there was a general shift away from the concept of one-for-one replacement and towards an integrated approach for chronic fish testing linking various approaches and lines of evidence. In addition, there was interest in developing a menu of approaches to prioritize traditional chronic fish *in vivo* testing such that it is only conducted when truly needed to fill data gaps. In discussions, attendees emphasized combining various approaches, both *in vivo* and NAM-based, to address different aspects of chronic fish toxicity (including bioaccumulation and endpoints associated with specific modes of action, e.g., endocrine) and to reduce uncertainty in risk assessments. Whole effluent toxicity testing in North America was identified as a potential key area where implementation of NAMs could reduce vertebrate use; however, it was decided that at this time effluent testing should be its own effort that takes learnings from the output of the workshop. A repeated need was for a concerted effort to develop a coordinated network of individuals working within the ecoNAM space to be established with an initial goal of mapping out ongoing method developments and data collection efforts. Based on the discussion from the two workshops, specific topics/projects will be considered by expert work groups for further development and investigation.

1.02.P-Mo020 Importance of the positive control in the Fish Cell Line Acute Toxicity - The RTgill-W1 cell line assay (OECD TG249)
Jennifer Fitzgerald[1]*, Melanie Fischer*[2]*, Stephan Fischer*[1] *and Kristin Schirmer*[2,3]*, (1)aQuaTox-Solutions GmbH, Switzerland, (2)Eawag - Swiss Federal Institute of Aquatic Science and Technology, Switzerland, (3)ETHZ, Institute of Biogeochemistry and Pollutant Dynamics, Switzerland*
In 2021, the OECD Test Guideline (TG) 249 was approved as the first cell line-based assay for environmental chemical risk assessment. As it no longer requires fish, it comprises a true animal alternative. It measures acute toxicity exerted to RTgill-W1 cells, using three fluorescent indicator dyes to indicate cell metabolic activity (using a resazurin dye, such as alamarBlueä), cell membrane integrity (based on the esterase substrate, CFDA-AM), and lysosomal membrane integrity (using Neutral Red). RTgill-W1 is a permanent cell line established from a rainbow trout (*Oncorhynchus mykiss*) gill. It was purposefully selected for test development as the gill epithelium is considered one of the most vulnerable tissues in acute fish toxicity testing, as performed, e.g. according to OECD TG 203. The RTgill-W1 cell line assay therefore has the potential to significantly reduce and replace application of one of the most commonly but also most severe fish toxicity tests carried out in product development and hazard assessment for chemical/product registration.

One key feature of the OECD TG 249 is that it contains, aside from negative controls, a prominent assay performance (positive) control. More specifically, with each run of the assay, a full concentration-response analysis is done with a reference chemical, 3,4-Dichloroaniline (3,4-DCA). Effective concentrations causing a 50% decline for each of the fluorescent indicator dyes (EC50 values) are derived, which must lie within a pre-defined range as specified in the TG. We have gathered a large and steadily growing set of 3,4-DCA control data. Based on this experience, it has become evident that this positive control is indeed very stringent, probably the most stringent in any of the biological OECD TG. Failures usually concern the impact on cell metabolic activity and have empirically been linked to stresses exerted on the cells, such as temperature and handling stress. On the flip side, this means that meeting these positive control criteria provide high confidence in the cell viability data measured for chemicals alongside in the same run. We will present the most comprehensive data set to date and discuss the importance of this stringent quality control.

1.02.P-Mo021 Screening Naphthenic Acid Contamination in the Athabasca Oil Sands Region in Chicken LMH 3D Spheroids

***Laura Van Raalte**[1,2], Doug Crump[2], Lukas J Mundy[2] and Jason O'Brien[3], (1)Carleton University, Canada, (2)Environment and Climate Change Canada, Canada, (3)Ecotoxicology and Wildlife Health Division, Environment and Climate Change Canada, Canada*

Oil extraction in the Athabasca Oil Sands Region (AOSR) generates large volumes of waste, called tailings, that are stored in mined out areas called tailings ponds. These tailings are toxic largely due to the presence of naphthenic acids (NAs) and there is concern about seepage into the surrounding tributaries. The objective of the present study was to determine the concentration of NAs and *in vitro* bioactivity of extracts derived from passive samplers deployed in tailings ponds and surrounding natural wetlands in the AOSR. NA concentrations were determined using liquid chromatography tandem mass spectrometry. Chicken LMH cells, cultured as 3D spheroids, were dosed with extracts and bioactivity was measured using cell viability, ethoxyresorufin-O-deethylase (EROD), and gene expression assays. Gene expression changes were determined using the chicken ToxChip qPCR array which contains 48 toxicologically relevant genes. Here, we present preliminary results for the surrounding wetland area extracts. As expected, higher levels of NAs were measured in passive sampler extracts from wetlands closer to oil sands activity compared to those further away. There were no effects on cell viability for any of the wetland extracts; however, several genes were dysregulated on the chicken ToxChip qPCR array. The dysregulated genes were associated with various pathways including xenobiotic metabolism, lipid homeostasis, and immune function. Next steps include the measurement of EROD activity to evaluate CYP1A expression in the natural wetlands, followed by determining NA concentrations and resulting bioactivity of six tailings pond extracts. Ultimately, we aim to demonstrate the use of a non-animal screening method for environmental monitoring in an ecosystem of concern in Canada.

1.02.P-Mo022 Evaluation of Positive Control Substrates for the OECD319 In Vitro Rainbow Trout Bioaccumulation Estimation Studies

***Rory Mumford**[1], Daniel T Evans[2] and Christopher Kirkman[2], (1)Environmental Fate and Metabolism, Smithers, Shawbury, Shrewsbury, United Kingdom, (2)Environmental Fate and Metabolism, Smithers, United Kingdom*

The OECD 319 guidelines for the determination of *in vitro* intrinsic clearance using cryopreserved rainbow trout hepatocytes (RT-HEP, OECD319A) and S9 sub-cellular fraction (RT-S9, OECD319B) were published in 2018. The studies are intended as a means of estimating the potential for bioaccumulation of chemicals in fish without the need for an *in vivo* fish bioconcentration factor (BCF) study (OECD305). They can be used in cases where it is not possible to run the BCF study, for example, ethical reasons such as cosmetic use, to reduce animal usage or it is not technically feasible. They may also be used to provide early screening information about bioconcentration potential or metabolism.

Since the release of the guidelines there have been discussions around the most applicable positive control substrates for the experiments. Positive controls are used to ensure the metabolic viability of the test system used (S9 or hepatocytes). A positive control usually should typically result in a minimum transformation of 20% with ideally 10% remaining unchanged by the terminal time-point of the experiment. This can present a challenge in the case of particularly high or low turnover as the positive control could be entirely transformed or remain unchanged at the end of the experiment. To validate the OECD319 study at our facility we have tested several different substrates that have the potential to be used as a convenient positive control. These can be matched to the clearance of the chemical under investigation.

This poster presentation will summarise the results from the testing of several different potential positive control substrates for both the RT-HEP and RT-S9 assays.

1.02.P-Mo023 Application of OECD TG 249 for assessment of the toxicity of metal oxide nanomaterials

***Mariia Goncharova**[1], David Hernandez-Moreno[2], Ana Valdehita[2], José M. Navas[3] and Maria Luisa Fernandez-Cruz[2], (1)National Institute for Agricultural and Food Research and Technology (INIA), Spain, (2)Institute for Agricultural and Food Research and Technology, Spanish National Research Council (INIA-CSIC), Spain, (3)Department of Environment and Agronomy, Institute for Agricultural and Food Research and Technology, Spanish National Research Council (INIA-CSIC), Spain*

The use of in vitro models to assess the toxicity of nanomaterials (NMs) is a valuable tool generating essential information that can be used in a number of approaches, for instance for designing higher tier in vivo test or in read-across procedures. OECD Test Guideline (TG) 249 allows the assessment of acute toxicity of chemicals in fish using the RTgill-W1 rainbow trout gill cell line. The test is validated for a range of organic toxicants and it demonstrated a high correlation with *in vivo* fish acute toxicity. However, its applicability to NMs has not yet been evaluated. This study aimed to apply this TG to NMs, using some metal oxide NMs and comparing the results with those obtained with other fish cell line and with fish.

The following NMs were studied: CuO, 15-20 nm, (PlasmaChem); CuO, <50 nm, (Sigma-Aldrich); ZnO NM-110, 42 nm; ZnO NM-111, 34 nm; TiO_2 NM-101, 6 nm; TiO_2 NM-104, 20 nm; and CeO_2 NM-212, 33 nm, (JRC repository). For obtaining stable dispersions the Nanogenotox protocol was applied (https://safenano.re.kr/download.do?SEQ=175). First, the usefulness of commercial L-15 (Thermo Fisher Scientific Inc.) and L-15ex, without fetal bovine serum, were compared. Cells exposed to 3,4-Dichloroanilline (3,4-DCA) served as a positive control, whereas those maintained in L-15ex with bovine serum albumin were the negative control. RTgill-W1 (35×10^4 cells/well) cells, were seeded in 24-well plates following the TG249 scheme. A triple cytotoxicity assay (Alamar Blue, CFDA-AM and neutral red) was performed according to TG249. Potential interferences of NMs with the cytotoxicity assays were assessed.

Compared to L-15, the L-15ex medium decreased cell viability by 7-15%, making it acceptable for this test. For TiO_2 and ZnO there was a characteristic interference, which should be taken into account when interpreting the results. The EC_{50} values of 3,4-DCA in RTgill-W1 cells were within the limits described in the TG and compared with those obtained with RTL-W1 cells (28×104 cells/well) that due to a decrease in sensitivity were out of limits stated in the TG. The results obtained in fish cell lines were similar to those collected from acute toxicity studies in fish. Future studies will set the best procedures to apply TG249 to NMs.

Acknowledgments: CSIC Program of Scientific Cooperation with Ukraine "Call 2022" and general protocol of action for the assessment of chemicals and nanomaterials between MITECO and CSIC.

1.02.P-Mo024 Towards next generation risk assessment for Environmental Health: how PARC Work Package 5 is contributing

Celia Garcia Arenas[1]*, Kiara Aiello Holden*[1]*, Thalia de Castelbajac*[2]*, Ondrej Adamovsky*[3]*, Katerina Kyriakopoulou*[4]*, Jana Asselman*[5]*, Gilles Riviere*[2] *and Philip Marx-Stoelting*[1]*, (1)German Federal Institute for Risk Assessment (BfR), Germany, (2)French Agency for Food, Environmental and Occupational Health & Safety (ANSES), France, (3)Recetox, Masaryk University, Czech Republic, (4)Benaki Phytopathological Institute, Greece, (5)Blue Growth Research Lab, Ghent University (UGent), Belgium*

The European Partnership for the Assessment of Risks from Chemicals (PARC) is a unique concept of partnership that brings together risk assessors, authorities and the scientific community to implement innovations in testing and chemical risk assessment into regulation. In particular, work package 5 (WP5) "Hazard Assessment" contributes to provide data to fill gaps in knowledge on poorly characterised contaminants and the consideration of new approaches and methods of hazard assessment, promoting the use of innovative methods and tools and contributing to moving towards next generation risk assessment. It also explores the improvement of mechanistic understanding of toxicity by analysing all available data and applying systems toxicology approaches and taking into account adverse outcome pathways (AOPs) and to improve modelling approaches such as PBK modelling.

WP5 focuses on hazard assessment for human and environmental health. For this purpose, two projects are dedicated to environmental toxicity assessment by filling data gaps of the substances prioritised for this first period of PARC: natural toxins and BPA alternatives. One of the projects under WP5 investigates the toxicity of naturally occurring toxins on aquatic organisms, specifically invertebrates and microalgae, so that the data generated could be a basis to set EU guidelines to achieve good environmental status for marine and freshwater environments. The other project focuses on the investigation of the potential adverse effects of certain individual substances and "real-life" mixtures of BPA alternatives on non-mammalian organisms belonging to different taxa. Moreover, the project serves as a platform for the development of new technologies, such as *in silico* and modelling tools for the grouping of substances and read-across, and advancing invertebrate and vertebrate models as new approach methodologies (NAMs) including e.g., (meta)genomic, transcriptomic, high-content analysis microscopy, high-resolution mass spectrometry, and human stem cell technology to assess (eco)toxicological endpoints such as non-genotoxic carcinogenicity, (developmental) neurotoxicity, immunotoxicity and endocrine disruption (ED), specifically thyroid hormone system disruption and metabolic endocrine disruption.

It is our aim to disseminate WP5 work in order to invite dialogue between the scientific community and regulators, promoting the integration of results into policy.

1.02.P-Mo025 What is the most sensitive cellular scale bioassay to multiple chemicals with different mode of action?

Yan Wang[1]*, Johan Lundqvist*[2] *and Nina Cedergreen*[1]*, (1)Plant and Environmental Sciences, University of Copenhagen, Denmark, (2)Biomedicine and Veterinary Public Health, Swedish University of Agricultural Sciences (SLU), Sweden*

In vivo and *in vitro* tests with unicellular organisms and cell lines show promise for evaluating diverse chemicals in cellular-scale systems. While ideal for high-throughput screening in effect-directed analysis, uncertainties persist regarding the sensitivity and selectivity of cellular-scale assays across classical *in vivo* and *in vitro* tests for identifying specific chemical classes based on their mode of action. To identify the optimal cell-based assay for sensitivity, we assessed three unicellular organisms from different kingdoms (plant, fungi, and bacterial) *in vivo*, alongside five *in vitro* cell lines, using 21 chemicals. These chemicals, ranging from antimicrobials to metals, were selected for their diverse modes of action and common occurrence in European wastewater and surface waters. *In vivo* tests included growth inhibition assays on the algae *Raphidocelis subcapitata*, the yeast *Saccharomyces cerevisiae* and bacteria *Escherichia coli*. *In vitro* tests, using MTS cell viability as an endpoint, were Zebrafish embryonic fibroblast cell line (ZF4), Hamster ovary cell line (ARecoscreen-GR-KO-M1), Mouse hepatocellular carcinoma (DR ecoscreen) and the Human breast carcinoma cell lines (VM7luc4E2 and MCF7AREc32), representing cells from different vertebrate species. Algae were the most sensitive tests across both *in vivo* and *in vitro* tests, producing concentration-response curves for 19 out of the 21 chemicals tested within the testing range. Algae was particularly responsive to antimicrobials, herbicides, fungicides and the metals Cu and Zn. Surprisingly, algae surpassed *E. coli* in sensitivity to four of five tested antimicrobials, and was more sensitive to the three fungicides tested than *S. cerevisiae*. The mammalian cell lines were the most sensitive *in vitro* tests, responding to 10-14 of the 21 chemicals within the range tested, hence, the overall hierarchy of sensitivity in terms of detection frequency was as follows: algae >human cells >rodent cells >fish cells > E. coli >yeast. Comparing the EC_{50} algae were 1- >100 fold more sensitive to 10 of the 14 common chemicals, whereas VM7luc4E2 was many folds more sensitive to the remaining four common chemicals. Therefore, the divergent yet heightened sensitivity of these two tests to a wide range of chemicals establishes them as a valuable complementary pair for screening bioactive substances in environmental samples of unknown composition.

Keywords: cellular scale bioassay, *in vivo, in vitro*; sensitivity.

1.02.P-Mo026 Identification of ToxCast bioassays associated with developmental and reproductive toxicity and their application to mechanism-based chemical screening: Case study with biocidal chemicals under K-BPR

Donghyeon Kim, *Siyeol Ahn and Jinhee Choi, School of Environmental Engineering, University of Seoul, Korea, Republic of (South)*

With the introduction of new chemical regulations, the demand for developing high-throughput screening (HTS) methods to prioritize regulatory chemicals is growing. The EPA ToxCast database, one of the largest HTS databases available, provides extensive biological coverage across diverse molecular targets, encompassing all major protein subfamily groups. To accelerate the use of ToxCast bioassays in a regulatory context, it's essential to establish links between molecular toxicity endpoints and regulatory endpoints. This study addressed this need by investigating ToxCast bioassays associated with developmental and reproductive toxicity, utilizing 499 overlapping ToxCast chemicals with animal toxicity data from ToxRefDB. Firstly, correlation analysis using Point-biserial and Pearson's methods revealed that 92 bioassays exhibited a significant correlation (p-value<0.05) with animal toxicity data. Secondly, among these assays, 31 were identified as engaged in teratogenic mechanisms, including processes related to sex hormone metabolism, oxidative stress, extracellular matrix, angiogenesis, and more. Employing the selected ToxCast bioassays, we screened 109 biocidal chemicals regulated under K-BPR that lacked available developmental and reproductive toxicity data. This screening identified 10 chemicals prioritized based on their activities in selected ToxCast bioassays, suggesting their potential to induce developmental and reproductive toxicity. These chemicals are commonly found in preservatives, disinfectants, repellents, pesticides, and rodenticides. Our approach shows promise as a mechanism-based categorization method, particularly when *in vivo* toxicity data are unavailable.

1.02.P-Mo027 Transcriptomic points of departure for solvent and positive controls in rainbow trout and human cell lines

Krittika Mittal[1], *Ke Xu*[2], *Samuel Rulli*[3] *and Niladri Basu*[2], *(1)Natural Resource Sciences, McGill University, Canada, (2)McGill University, Canada, (3)Qiagen*

Ethical concerns and high costs associated with animal testing have prompted widespread interest in developing more efficient non-animal based alternative testing strategies. There has also been increased interest in using molecular data in risk assessment for benchmark dose response analysis and the derivation of transcriptomic points of departure (tPOD). The objective here was to optimize and establish a high throughput *in vitro* transcriptomic-based toxicity test system that couples rainbow trout RTgill-W1 and human Caco-2 and HepG2 cell lines with QIAGEN’s UPXome ultraplex technology so that the combined test system can derive tPODs. Library preparation was first optimized with unexposed RTgill-W1 cells to ensure good quality libraries as verified on an Agilent Bioanalyzer. Subsequently, cells were exposed for 24 h to eight concentrations of solvent (dimethyl sulfoxide; DMSO) and positive controls (3,4-dichloroaniline; DCA – RTgilll-W1 or hydrogen peroxide; H_2O_2 – Caco-2) from which libraries were prepared and sent for sequencing. Exposures were based on the OECD test guideline 249. The advantage of this workflow is that cell lysis, conducted in microplates, allows for plate-based reverse transcription directly on the lysate without isolating RNA from each sample. During reverse transcription, a unique sample index for each sample is incorporated into the cDNA which allows for pooling of the cDNA and simplified library preparation than traditional methods. Thus, libraries can be prepared from multiple 96-well plates in one workday, and hundreds of samples can be sequenced in a single lane. The strongest concentration-dependent transcriptomic response was observed upon exposure to DMSO with over 1,000 gene BMDs across all three cell lines. Exposure to DCA resulted in the least gene BMDs and the highest tPOD (7 mg/L), whereas to H_2O_2 resulted in the most sensitive tPOD in HepG2 (0.07 mM). Many DEGs were involved in processes including stress response, cell signaling, motility and survival, and phase-II drug metabolism including heat shock proteins, selenoprotein P and angiopoietin-like 4. With increased interest in the use of transcriptomics in toxicity testing, these types of studies can help inform future test guidelines and identify appropriate candidates to be included as controls. Further exposures to evaluate the performance of this platform with diverse environmental samples and chemicals of regulatory concern are ongoing in several case studies.

1.02.P-Mo028 Microbial Assays for Risk Assessment to Evaluate Toxicity of Chemicals and Environmental Samples

Kirit Wadhia[1], *Michelle Robertson*[2] *and Carol Devine Dr*[3], *(1)Environmental, NOV Inc, United Kingdom, (2)Energy &*

Enviromental Microbiology Services, NCIMB, United Kingdom, (3)Energy & Environmental Microbiology Services Manager, NCIMB Limited, United Kingdom
Benefits of microbial bioassays

Bacteria are good candidates for ecotoxicity testing because of number of factors that include small size, rapid growth rate and ease of handling. The use of bacterial bioassays to assess toxicity is well established, and is attributed to the rapidity of results and convenience of use.
Single species bacterial tests have been in common use across a wide range of industry and environmental applications for many years.
The best known tests make use of the naturally luminescent bacteria *Aliivibrio fischeri* (previously known as *Vibrio fischeri*). The best known tests are based on the rationale that exposure to toxins disrupts the bacterial respiratory processes, which in turn results in a reduction in light output.
MARA and LumiMARA bioassays with the incorporation of a genetically diverse multiple strains combination have significantly advanced microbial assays from single species utilisation.
Bacterial testing is generally based around assessment of the acute toxicity response of a single marine species. In contrast, testing using both MARA and LumiMARA gives a measure of acute and chronic toxicity, encompassing marine, freshwater and terrestrial species of prokaryotes (bacteria) and additionally a single-celled Eukaryote (yeast).

MARA**:** The MARA test assesses toxicity by measuring the growth of ten bacterial species and one yeast, following 18 hours of incubation in the presence of a concentration gradient of the test sample. As a eukaryote inclusion of a yeast species gives a valuable additional dimension to test results.
LumiMARA: LumiMARA assesses toxicity on the basis of the reduction in luminescence of 11 species of bacteria following exposure to a concentration gradient of the test sample. The test includes nine marine and two fresh water species from a variety of habitats. Two of the strains are of A. *fischeri*, one of which is an equivalent to NRRL B-11177 referenced in ISO 11348-3.
Application in the oil and gas industry: The Oslo and Paris Commission (OSPAR) Recommendation 2012/5 requires contracting parties, of which the UK is one, to implement a risk-based approach for the management of produced water from offshore oil and gas installations. MARA and LumiMARA bioassays are recommended as part of the UK’s Department for Energy Security and Net Zero (DESNZ) preferred approach to achieving this

1.02.P-Mo029 Utility of QSARs and zebrafish embryos toxicity results in a simplified assay and in the OECD TG 236 to predict the fish acute toxicity of fragrance ingredients
*Andrea Weiner[1], Maria José Mazón[1], **Arantza Muriana**[1] and Sylvia Gimeno[2], (1)BBD BioPhenix S.L. - Biobide, Spain, (2)DSM-Firmenich, Belgium*
Fish acute toxicity data are part of the required information in the process of chemicals´ registrations around the world and are used for environmental hazard and risk assessments. Prior the regulatory process, chemicals companies screen new substances in the phase of development to understand their toxicity profiles. To that end, cost-effective and reliable tools to predict fish acute toxicity, without using animals, should be used. Fish acute toxicity results from tests (zebrafish, OECD TG 203) used for regulatory submission of fragrances ingredients were used to verify the predictivity of the outcome of QSAR models (ECOSAR and iSafeRat) and the results from the standard Fish Embryo Test (OECD TG 236) and from a simplified version. More than 30 fragrance ingredients belonging to various chemical classes (alcohol, esters, aldehydes, etc) and with a wide physico-chemical profile (water solubility from 0.01 to 1000 mg/L, vapour pressure from < 0.1 to > 100 Pa) were tested in a simplified OECD TG 236. In the case of volatile substances precautions were taken to avoid losses and cross contamination. The 96h LC50 were obtained from the simplified assays (8 concentrations, DMSO as vehicle, 15 embryos per experimental condition, 5 embryos per well in 24 well-plates, no analytical measurements). The 96h LC50 were based on the standard lethality indicators for fish embryos. The results from both embryotoxicity tests (the simplified-assay and the OECD TG 236) showed similar trends, with an average factor of 2 difference in the 96h LC50 values. In most cases, the OECD TG 236 was more conservative. There was little difference between the zebrafish juveniles LC50 values (OECD TG 203) based on measured and nominal concentrations, reflecting that the exposure concentrations had been well maintained, except for the substances with the highest vapour pressure. In the embryotoxicity simplified assays, the toxicity was also underestimated (Vp from 10 to 400 Pa). The juvenile fish toxicity predictions by ECOSAR are more conservative than the predictions by iSafeRat, while the estimations of the embryotoxicity was under-estimated in 1/3 of the cases, especially when it comes to very volatile substances. After the complete analysis of this unique dataset, we aim at finding a recommendation for a suitable approach for reliably screening new chemicals for their fish acute toxicity and potentially to use that information in a regulatory context.

1.02.P-Mo030 Optimization of Experimental Conditions in Microphysiological systems (MPS) and Evaluation of Hepatotoxicity of Triphenyl Phosphate (TPHP) in HepG2 Cells
***Ji Yun Kang**, Seongeun Park and Kitae Kim, Seoul National University of Science and Technology, Korea, Republic of (South)*
Over the recent decades, the reliance on mammalian animal testing has been customary for evaluating toxicity of chemicals. However, existing animal testing models have inherent limitations such as interspecies differences, ethical issues, and difficulty in efficiently assessing large numbers of chemicals, so there is a strong need to shift toxicity assessment paradigm away from the current dependence on animal testing. As one of notable paradigms within the framework of New Approach

Methodologies (NAMs), the implementation of Microphysiological Systems (MPS) has attracted great attention. The intricately engineered systems, designed to simulate a similar environment to the human body by integrating fluid flow and cell co-culture technologies, have evolved since the introduction of the 'Lung-on-a-chip' in 2010. Despite the technological advancements in the development of MPS, cases of its use in the toxicity assessment of chemical substances are limited and have not been sufficiently discussed. In this study, we applied human-derived cell line, HepG2 was cultured in a MPS to evaluate the hepatoxicity of an organophosphorus flame retardant, triphenyl phosphate (TPHP). In addition, we discussed how the MPS can be used in the toxicity evaluation of chemical substances in the future by comparing toxicological consequences of TPHP obtained from plate culture, an existing cell culture model.

We optimized the cell numbers and flow rates of our self-produced SperoMimic MPS and showed that LDH and ALT activities that could not be observed in traditional static culture models can be observed in MPS under optimized experimental conditions. We therefore demonstrated that MPS is a much more effective approach for identifying chemicals with the potential for hepatotoxicity. Additional research will follow to upgrade the MPS to allow for longer exposures. This allows us to better assess the incidence of hepatotoxicity or liver disease due to chemical exposure, serving as a true alternative to existing animal models

1.02.P-Mo031 Digital Patterns for the Detection and Prediction of Chemically Induced Endocrine Disruption in Fish (DiMEP = Digitale Muster Erkennung und Prädiktion)

Hannes A. Reinwald[1]*, Wibke Busch*[2]*, Paul Michaelis*[2]*, Sebastian Eilebrecht*[3]*, Elke Eilebrecht*[4] *and Tobias Pamminger, Dr.*[1]*, (1)Early Environmental Safety, Bayer AG, Germany, (2)Helmholtz Centre for Environmental Research (UFZ), Germany, (3)Ecotoxicogenomics, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (4)Ecotoxicology, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany*

Endocrine-active substances can endanger human health and the environment by impairing essential endocrine-controlled functions, such as the development and reproductive capacity of organisms. In 2018, the assessment of endocrine-disrupting properties (ED) of chemicals was included in European chemicals legislation under REACh and the Plant Protection Product regulation.

Currently, there are 434 compounds under investigation for ED, and more than 1000 are listed as potential candidates. For the aquatic environmental hazard assessment of substances with suspected ED, *in vivo* mechanistic bioassays, such as the Fish Short Term Reproduction Assay (*FSTRA*, OECD 229 & 230), are conducted with 80-120 fish per test. Therefore, more than 100,000 fish will be used for testing in the next few years for nearly 1500 chemicals. This number of sacrificed animals will further increase in the future as the ED hazard assessment applies to a wide variety of compounds (e.g., plant protection products, biocides, industrial chemicals).

To reduce the number of animal tests for ED assessment in aquatic vertebrates, in accordance with the 3R principles, the UFZ (Helmholtz-Zentrum für Umweltforschung), Fraunhofer Institute for Molecular Biology and Applied Ecology IME, and Bayer AG will launch the collaborative research Project *DiMEP* (Digitale Muster Erkennung und Prädiktion). *DiMEP* aims to enhance the regulatory assessment of the potential for ED by utilizing molecular (transcriptomic) and phenotypic fingerprints. This involves employing the zebrafish embryo (ZFE) model as an animal-free alternative to juvenile/adult fish testing. The goal is to supplement the required Fish Early Life Stage (FELS, OECD 210) test with molecular pattern-based assessment to provide additional mechanistic information regarding the potential of a substance to cause endocrine effects.

The mission of *DiMEP* is to generate sublethal transcriptomic effect patterns (ecotoxicogenomic and phenotypic) in the zebrafish embryo for a sufficiently large set of known ED reference chemicals. Based on this high-dimensional data resource, computational tools and machine learning (ML) will be deployed to identify robust toxicogenomic patterns linked to known apical ED outcomes. This approach will enable a mechanistically informed identification of substances with the potential for ED in fish, likely reducing the need for additional fish-intensive studies.

1.02.P-Mo032 Advances Towards a Harmonized Environmental Safety Analytical Toolbox for Cosmetic Ingredients (ATEST)

Adam Lillicrap[1]*, Maria Christou*[2]*, Anastasia Georgantzopoulou*[2]*, Maria T. Hultman*[2]*, You Song, PhD*[2]*, Michelle Rau Embry*[3] *and Scott E. Belanger*[4]*, (1)Norwegian Institute for Water Research (NIVA), Oslo, Norway, (2)Norwegian Institute for Water Research (NIVA), Norway, (3)Health and Environmental Sciences Institute (HESI), (4)Procter & Gamble Company (retired)*

The substantial use of laboratory animals for toxicity testing is highly cost-inefficient, and heavily against animal welfare considerations and the principles of the 3Rs (refine, reduce, replace). New Approach Methods or Non-Animal Methods (NAMs) offer a promising solution to avoid the need for *in vivo* animal tests. Although several NAMs have been proposed for environmental hazard assessments of chemicals, their maturity and stage of validation is limited or unclear. As chemicals, such as cosmetics and personal care products, can potentially produce diverse types of biological effects, there is a need to assemble a battery of NAMs with a broad coverage of endpoints for assessing the hazards of chemicals. The ATEST project is a thorough assessment of the current state of the science on available NAMs and their potential applications for cosmetic ingredients. The NAMs evaluation used an AI-based systematic review tool to identify relevant literature from public databases and the current state of the science of NAMs for environmental hazard assessments. A scoring system for assessing the weight of evidence has been developed to rank NAMs for their maturity and regulatory applicability. Information related to the NAMs (e.g. measurement of certain ecotoxicological endpoints) were used as key words for querying public databases, through an established data mining workflow. The outcome of the ATEST project is a database describing the attributes of different NAMs identified for environmental safety including a ranking scheme to assess the reliability, relevance and regulatory acceptability of different NAMs. This will provide associations such as the International Collaboration on Cosmetics Safety (ICCS) with information on where future efforts are needed to improve emerging NAMs and promote the rapid transition from conventional to non-animal chemical hazard assessment.

1.02.P-Mo033 Critical review of in vitro dosing methods for petroleum UVCB substances

Adam Lillicrap[1], *Maria T. Hultman*[2], *Anastasia Georgantzopoulou*[2], *Maria Christou*[2], *You Song, PhD*[2], *Aina Charlotte Charlotte Wennberg, MSc*[2], *Sandrine Estelle Deglin*[3], *Michelle Rau Embry*[3], *Philipp Mayer*[4], *Heidi Birch*[4], *David MV Saunders*[5], *Sandrine Sourisseau*[6], *Christopher Prosser*[7], *Kat Colvin*[8], *Sergio A Villalobos*[9], *Delina Lyon*[10] *and Leslie J Saunders*[10], *(1)Norwegian Institute for Water Research (NIVA), Oslo, Norway, (2)Norwegian Institute for Water Research (NIVA), Norway, (3)Health and Environmental Sciences Institute (HESI), (4)Department of Environmental and Resource Engineering, Technical University of Denmark (DTU), Denmark, (5)Shell Global Solutions, Netherlands, (6)TotalEnergies, France, (7)ExxonMobil, (8)BP I&E Applied Sciences, United Kingdom, (9)BP, (10)Concawe, Belgium*

Alternative approaches to traditional ecotoxicity tests, which include *in vitro* testing, are being promoted to support regulatory chemical assessments. *In vitro* test methods can be used in multiple contexts, from prioritization and screening to supporting chemical grouping and read-across. Eventually, it is anticipated that *in vitro* tests will be used in place of whole organism *in vivo* testing. An important challenge of most *in vitro* testing methods is how to establish, maintain and confirm defined test substance concentrations throughout the test. This is particularly challenging for petroleum UVCB substances (Unknown, Variable composition, Complex reaction products, or Biological origin) that typically contain a large number and variety of hydrophobic and (semi)volatile hydrocarbon constituents that are very prone to evaporative and sorptive losses.

The ability to deliver and maintain stable exposure of petroleum substances in *in vitro* test systems is challenged by several factors, including: high surface area to volume ratios of multi cell well plates, which increases the likelihood of sorption to plate walls; the inability to seal some test vessels (e.g., volatile constituents can escape open test vessels and may contaminate neighbouring cell wells); poor solubility of hydrophobic constituents in biological media and presence of lipids and proteins in biological media may differentially bind individual constituents. Here we present the first findings from a critical systematic review on the state of science of *in vitro* methods, their challenges, and their applicability in (eco)toxicological assessments of petroleum UVCBs. The outputs will be used to identify relevant *in vitro* tests and dosing methods and adaptations best suited for petroleum substances in future research and regulatory testing efforts.

1.02.P-Mo035 Comparative in vitro characterization of biotransformation enzyme kinetics in different organs of brown trout (Salmo trutta) and rainbow trout (Oncorhynchuss mykiss)

Baptiste P. M. Martin, ***Marco Enrique Franco*** *and Kristin Schirmer, Environmental Toxicology, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland*

Improving the applicability of *in vitro* methodologies to address chemical pollution in the aquatic environment requires specific knowledge about their metabolic competence, particularly for processes that drive chemical toxicokinetics, i.e. biotransformation. Currently, comparative studies regarding the presence, activity magnitudes, and inducibility of different biotransformation pathways are scarce for testing systems using fish. As a result, we here report a comparative characterization of organ-specific kinetic parameters for phase I and II biotransformation enzymes, under basal and induced conditions, using S9 sub-cellular fractions and four rainbow trout cell lines. Two of the most common biomarkers of biotransformation, CYP1A and glutathione S-transferase (GST), displayed their highest levels in liver S9 fractions and RTL-W1 liver cells. However, S9 fractions and cell lines derived from the intestine, gills, and brain also displayed these biotransformation pathways. In addition, while CYP3A4-like activity was only measured in liver and intestinal S9 fractions, all rainbow trout cell lines appeared to be equipped with this pathway. Basal CYP3A4-like activity was the highest in intestinal cells RTgutGC, but the inducibility of this pathway was higher in RTL-W1 cells. Similarly, while both RTL-W1 and RTgutGC cells appeared to be equipped with CYP2B-like activity, this was only measurable upon induction. In contrast, S9 fractions from the liver, intestine and gills displayed constitutive CYP2B-like activity. These differences among systems could be related to the complexity and potential differential functionality of biological processes at the *in vivo* level. Nonetheless, the biotransformation kinetic parameters obtained from our experimentation represent important evidence of the metabolic competence of fish *in vitro* methods. Based on our results, we suggest that both S9 fractions and cell lines are suitable testing alternatives for evaluations of organ-specific biotransformation of pollutants.

1.02.P-Mo036 Characterization of rainbow trout hepatic 3D spheroids for next generation ecotoxicity testing

Prem Chand[1], *You Song, PhD*[2], *Tania Gomes*[3], *Awadhesh Jha*[4] *and Maria T. Hultman*[2], *(1)Ecotoxicology and risk assessment, Norwegian Institute for Water Research (NIVA), Norway, (2)Norwegian Institute for Water Research (NIVA), Norway, (3)Norwegian Institute for Water Research (NIVA), Oslo, Norway, (4)Plymouth University, United Kingdom*

There is a growing need for animal alternatives using new approach methodologies (NAMs) for ecotoxicity testing of chemicals. There are currently few well-characterized *in vitro* (cell based) assays, based on both primary- and continuous cell cultures. Primary hepatocytes from rainbow trout (RT-HEP) have shown promise in acute toxicity assessments as they retain many of the native physiological functions of the liver. However, there are currently few cell-based alternative methods available for long-term toxicity assessments. A novel three-dimensional (3D) spheroid model, derived from RT-HEP, has shown promise as it preserves many of its morphological, physiological and biochemical properties for weeks after isolation and formation. However, prior to application, the RT-3D hepatic cell culture system requires comprehensive characterization and validation. We therefore employed high-resolution multiphoton fluorescence microscopy (MFM) to access the morphology, area, diameter, sphericity, physiological structure, DNA/nucleus integrity and hypoxia. We further employed OMICS and various bioassays to comprehensively characterize the RT hepatic 3D spheroids. Model chemicals, representative of different toxic modes of action such as copper, 17 β-ethinyl estradiol (EE2), pyrene, 3,4- dichloroaniline (DCA), and carbonyl cyanide m-chlorophenyl hydrazone (CCCP), were employed to assess the sensitivity and responsiveness of the RT-3D hepatic spheroids. Our assessment focused on analyzing the viability, metabolic activity, adenosine triphosphate (ATP) synthesis, vitellogenin (Vg) induction and oxidative stress response exhibited by these RT hepatic 3D spheroids when exposed to these specific model chemicals.

Initial findings suggest that the RT hepatic 3D spheroids serve as a reliable model for evaluating cytotoxicity, cell membrane integrity and oxidative stress. Additionally, the absence of hypoxia at the spheroid core was confirmed. Transcriptomics (RNA-seq) and untargeted metabolomics (mass spectrometry based) were also employed to better understand the molecular landscape of the 3D spheroids and their potential for assessing chemicals with distinct MoAs. Based on our ongoing characterization, the RT hepatic 3D spheroids model exhibits substantial potential as an ecotoxicity screening tool capable of assessing the risks associated with a diverse array of chemicals. This work was supported by the SPHERTOX Project (#324794) funded by the Research Council of Norway.

1.02.P-Mo037 A review of in silico and in vitro methods for use in a risk assessment of a substance acting via oestrogen or androgen modalities
Rebecca Jayne Brown[1], *Grace Panter*[1], *Kate Roylance*[1], *Owen Green*[1], *Olivia Lin Tran*[1], *Jorge Naciff*[2], *Kaushal Joshi*[3], *Sophie Cable*[4], *Dagmar Bury*[5], *Arianna Gusti*[6], *Dave Allen*[7], *Audrey Loisy*[8], *Christopher Choi*[9], *Daniela Lange*[10], *Mareike Böttcher*[10], *Romain Tempereau*[5], *Nina Hambruch*[11] *and Anne Riu*[5], *(1)wca environment Ltd., United Kingdom, (2)Procter & Gamble, (3)RIVM, Netherlands, (4)Unilever - Safety and Environmental Assurance Centre (SEAC), United Kingdom, (5)L'Oréal, France, (6)ICCS, (7)International Collaboration on Cosmetics Safety (ICCS), (8)Chanel, (9)Takasago, (10)Beiersdorf, Germany, (11)BASF*
The testing of cosmetics on animals is banned in many countries, but manufacturers are responsible for demonstrating the safety of constituents for users and increasingly so for the environment. Of concern are those ingredients with endocrine disrupting properties. Therefore, the cosmetics industry requires an approach for conducting risk assessments for substances with potential endocrine activity which does not require *in vivo* animal testing, instead, demonstrating their safety using *In Vitro* to *In Vivo* Extrapolation (IVIVE) approaches. These approaches rely on the use of *in vitro* bioassays supported by predictive *in silico* data. Whilst there are many *in silico* models and *in vitro* methods which are used to predict the endocrine activity of chemicals, most have been optimised with a focus on classifying substances with endocrine activity rather than consideration of their biological relevance. A review of the available *in silico* and *in vitro* methods was therefore conducted to assess which were most suitable to support a human risk assessment for a substance acting via oestrogen or androgen modalities. The review considers several aspects including the relevance of the assay for humans (tissues and receptors) and for predicting effects in the whole organism, the sensitivity and specificity of the assay, applicability domain of the methods, as well as regulatory acceptability and commercial availability. We also considered whether these assays had already been used in IVIVE approaches and if so, whether the extrapolations were realistic. While this review has focused on humans, the findings are considered useful for informing on the prioritisation of New Approach Methodologies to use for risk assessments with non-target organisms, especially given the homology of oestrogen and androgen receptors in vertebrates.

1.02.P-Mo038 Cytotoxic Disruption of Intracellular Parameters Induced by Thiacloprid in Mice Sertoli Cells In vitro
Tomas Jambor[1], *Lucia Zuscikova*[2], *Hana Greifova*[3], *Nikola Knizatova*[3], *Anton Kovacik*[1], *Denis Bazany*[2] *and Norbert Lukac*[3], *(1)Slovak University of Agriculture in Nitra, Slovakia, (2)Institute of Applied Biology, Slovak University of Agriculture in Nitra, Slovakia, (3)Institute of Applied Biology, Slovak University of Agriculture in Nitra, Faculty of Biotechnology and Food Sciences, Slovakia*
Thiacloprid (2Z)-3-[(6-chloro-3-pyridinyl)methyl]-1,3-thiazolidin-2-ylidenecyanamide belongs to the neonicotinoid family, and it is mainly exploited in agriculture. At the same time, neonicotinoid pesticides are highly effective against some destructive crop pests, and their occurrence in aquatic ecosystems could represent a relevant risk. Although previous studies described the binding affinity of thiacloprid on nicotinic acetylcholine receptors (nAChRs) or γ-aminobutyric acid (GABA) receptors in insects, some information about the sensitivity of the reproductive system still resonates. Besides that, detailed knowledge about the potential mechanisms of effect and cytotoxic potential regarding other mammalian cells stays inconsistent. The primary aim of our in vitro study was to determine the potential impact of thiacloprid on mice Sertoli cells. TM4 cells were treated with experimental doses starting from 62,5 µM to 500 µM of thiacloprid for 48 hours. Screening of cytotoxic effects was evaluated based on the changes in mitochondrial activity, changes in cell membrane integrity, as well as through inhibition of lysosomal activity. The results from the mitochondrial activity assay (MTT) revealed that the whole panel of experimental concentrations inhibited this parameter. A significant ($p<0.0001$) reduction was recorded at 250 µM, 300 µM, and 500 µM of thiacloprid. A similar tendency was observed in cell membrane integrity (CFDA-AM assay) evaluation. The higher concentrations than 125 µM significantly ($p<0.001$) affected this parameter in exposed cells. A sensitivity of TM4 cells to thiacloprid exposure was confirmed via inhibition of lysosomal activity carried out by neutral red uptake. The panel of

experimental doses significantly ($p<0.0001$; $p<0.001$) decreased this parameter after 48 hours of exposure in vitro. Gained results of our pilot study suggest, that thiacloprid could affect intracellular parameters of Sertoli cells, and concerns about the negative impact on reproductive health are justified. A considerably more detailed and systematic research in thiacloprid toxicology is definitely required for a better understanding of risks associated with reproductive health.

Keywords: Sertoli cells, thiacloprid, mitochondrial activity, membrane integrity, lysosoms

1.03.P Assessing Adverse Pollutant Effects on Host-Associated and Free-Living Microbiomes Using -Omics Approaches

1.03.P-Mo039 Chemical Metabolomics – New Chemical Biology Tools to Explore Gut Microbiome Metabolism

***Daniel Globisch**, Chemistry-BMC, Uppsala University, Sweden*

Introduction: Metabolites produced by the gut microbiome play a crucial and diverse role on host physiology, which are detectable in a wide range of biological samples including feces, plasma, urine, and cerebrospinal fluid. Microbiota dysbiosis has been associated with the development of diseases, however, the metabolic link has yet to be detected. The detailed and targeted analysis of these metabolites is important for the discovery of biomarkers, unknown bioactive molecules and toxic metabolites.

Materials and Methods: Mass spectrometric metabolomics is the method of choice for identification and quantification of these metabolites. Advanced methods at the interface of chemistry and biology coupled with metabolomics analysis are still limited. We have developed a unique and multifunctional chemoselective probe with synthetic $^{13}C/^{12}C$ isotopically labelled analogs that allows for comparative and quantitative analysis of metabolites in human samples at low concentrations. We have termed this method **Quant**itative **S**ensitive **CHE**moselective **M**et**A**bolomics (*quant*-SCHEMA). Coupled to magnetic beads, this method allows the straightforward chemoselective extraction of metabolites from human samples. This isolation procedure of specific classes of metabolites from sample matrices led to significantly increased mass spectrometric sensitivity that facilitates the detection of metabolites at attomole quantities.

Results and Discussion: Our analysis of carbonyls, thiols, amines, and short-chain fatty acids (SCFAs) revealed previously unknown metabolites. We applied this methodology in dietary intervention study with 156 samples for nutritional biomarker discovery. We have successfully found four potential food biomarkers. The success of this large-scale application of this methodology results in further validation of this method and encourages the general use in metabolomics studies. We also utilized selective enzymatic treatment of metabolites in human samples for simplified identification of converted sulfated and glucuronidated metabolites to elucidate their chemical structure using mass spectrometry. Many of these identified phase II clearance products are linked to gut microbiota-human host co-metabolism.

Conclusions: We have successfully developed unique methods for the investigation of the metabolic interaction of host and microbes that identified more than 300 previously unknown dietary and microbial metabolites in human samples with unknown bioactivity.

1.03.P-Mo040 Assessment of Taxonomic and Functional Changes in the Environmental Symbiotic and Free-living Microbiome Induced by Ag and Cu Metals

*Marina Barbudo-Lunar Ms.[1], Chiara Trombini Dr.[2], Carmen Michan[3], Jose Alhama[4] and **Julian Blasco**[5], (1)Biochemistry and Molecular Biology, ceiA3, University of Cordoba, Spain, (2)Ecology and Coastal Management, Institute of Marine Sciences of Andalusia, Spanish National Research Council (ICMAN-CSIC), Spain, (3)Dpt. Biochemistry and Molecular Biology, ceiA3, University of Cordoba, Spain, (4)Biochemistry and Molecular Biology, University of Cordoba, Spain, (5)Institute of Marine Sciences of Andalusia - Spanish National Research Council (ICMAN-CSIC), Puerto Real, Cádiz, Spain*

Despite the importance of coastal ecosystems, their ecological well-being is threatened by the increasing release of anthropogenic sources of pollution. Metals are present in the environment as a result of natural or anthropogenic inputs. Silver is well known for its toxicity to organisms. Although its levels are generally low, the associated risk in coastal ecosystems is usually high due to sewage discharges. Copper is a widespread and well-known environmental contaminant. The development of pollutant exposure experiments in controlled microcosm systems makes it possible to simulate their effects in natural ecosystems. Due to their wide distribution and close contact with pollutants, microorganisms, both symbiotic and free-living in natural environments, could be good indicators of pollution. In this work, the changes in the microbial profile, both in sediments and in the digestive gland of the bivalve mollusc Scrobicularia plana, upon exposure to silver (Ag) or copper (Cu), or a mixture of both, at 1 µg/L were characterised in an aquatic microcosm system. The phylum with the highest number of identifications in all samples was always Proteobacteria. The Desulfobactereaceae, Ectothiorhodospiraceae and Flavobacteriaceae families were highly abundant in all samples. After exposure to metals, there were a number of significant increases at the family level, highlighting Xanthomonadaceae in sediment samples after exposure to the Ag/Cu mixture with respect to individual exposure to Ag, and Chromatiaceae in digestive gland samples after individual exposure to Cu with respect to unexposed samples. These changes affected the functional potential of the microbiomes, as there was a significant increase in several functions, such as "aromatic degradation" and "hydrocarbon degradation", after exposure to the Ag/Cu mixture compared to individual exposure to Ag in the sediment samples, and after individual exposure to Cu compared to the control in the digestive gland samples. Changes at the taxonomic and functional levels of the microbiome, symbiotic and free-living, have shown great potential as an environmental monitoring tool in coastal aquatic ecosystems.

1.03.P-Mo041 Gut Microbiota of Zebra Mussels (Dreissena polymorpha) as a Holobiont Concept- Significantly Reliable Method for Aquatic Environment Monitoring?

Katerina Fialova[1]*, Pascal Poupin*[1]*, Fanny Louis*[1]*, Laetitia Minguez*[2]*, Marie Zaffino*[1] *and Laure Giamberini*[1]*, (1)Université de Lorraine, CNRS, LIEC, France, (2)French National Centre for Scientific Research (CNRS), Paris, France*

France's Water bodies are constantly exposed to emerging pollutants from urban areas. It requires constant monitoring of contamination. Zebra mussel (ZM) is an invasive species which is spread in European waters extensively. They are filter feeders that filter a large amount of water as its food source. They process and remove a high number of microorganisms (MO). ZM accumulate compounds from the water column and is an excellent indicator of the surrounding environment. The filtration process allows ZMs to absorb naturally occurring mixtures and pollutants. ZM's gut microbiota (GM) contains a high number of MO and creates a specific symbiosis with the host. It is closely connected to the outside environment and represents aquatic conditions. It shows the importance of holobiont symbiosis and its need for detailed understanding. This study investigates the GM of ZM as an indicator of emerging contaminants such as human pathogens and antibiotics resistance bacteria (ARB). The inquiry is how GM is affected by variations of diet, pathogens and contaminants appearing in aquatic environments and the overall understanding of the gut microbiota of ZMs and its essence in the accumulation of increasing quantities of pathogens and ARB.

ZMs were collected in the field and let acclimated before following steps. After the acclimation period, the field investigation selected ZMs were transferred to appointed sites and put into specially created devices for collecting faeces. The rest of the ZMs were kept in laboratory conditions to further study their gastrointestinal microbiota. Further analysis will be performed by 16S rDNA sequencing and cultivation.

The experiment combines laboratory-controlled conditions and field experiments. Obtaining data from different feeding conditions, filtration rates and the overall effect of the laboratory and field environment and possible accumulation of pathogens and ARB from the field is critical for further study. Testing of water bodies can be more reliable with ZMs accumulation of contaminants with comparison to regular grab water samples depending on many factors.

This study emphasises the importance of the microbiota of filter feeders and their ability to accumulate compounds from the water.

1.03.P-Mo042 From dysbiosis to neuropathologies: toxic effects of glyphosate in zebrafish

Benjamin Pina[1]*, Marina Bellot*[2]*, Maria Paula Losada Carrillo*[3]*,* ***Juliette Bedrossiantz***[4]*, Cristian Gómez-Canela*[2]*, Maria Vila-Costa*[5]*, Eva Prats*[6] *and Demetrio Raldua*[4]*, (1)Environmental Chemistry, Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain, (2)University Ramon Llull IQS, Spain, (3)Institute of Environmental Assessment and Water Studies, Spain, (4)Environmental Toxicology, Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain, (5)Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain, (6)CID-CSIC, Spain*

Glyphosate, the most widely used herbicide worldwide, has long been assumed to have negligible effects on animals due to its selective inhibition of the shikimate pathway in plants. However, accumulating evidence suggests physiological impacts of glyphosate exposure in both humans and animal models, ranging from neurological effects to cancer. In addition to its recognized herbicidal properties, glyphosate also possesses a selective antimicrobial activity. In this study, we investigate the effects of environmentally relevant concentrations of glyphosate on the gut microbiota, neurotransmitter levels, and anxiety in zebrafish. Our findings demonstrate that glyphosate exposure leads to dysbiosis in the zebrafish gut, alterations in central and peripheral serotonin levels, increased dopamine levels in the brain, and notable changes in anxiety and social behavior. While the dysbiosis can be attributed to glyphosate's antimicrobial properties, the observed effects on neurotransmitter levels leading to the reported induction of oxidative stress in the brain indicate a novel and significant mode of action for glyphosate, namely the impairment of the microbiome-gut-axis. While further investigations are necessary to determine the relevance of this mechanism in humans, our findings shed light on the potential explanation for the contradictory reports on the safety of glyphosate for consumers.

1.03.P-Mo043 Examining the Interlinked Dynamics of Human Activities, Microbial Communities, and Greenhouse Gas Emissions in a highly impacted river system

Milena Doreen Esser[1]*, Cameron Hoggart*[2]*, Phillip Ankley*[1]*, Helen Baulch*[2]*, John Giesy*[2]*, Markus Brinkmann*[1] *and Markus Hecker*[3]*, (1)Toxicology Centre, University of Saskatchewan, Canada, (2)University of Saskatchewan, Canada, (3)Toxicology Centre and School of the Environment and Sustainability, University of Saskatchewan, Canada*

Microbial communities play a vital role in freshwater ecosystems but are susceptible to adverse effects from human activities.

To enhance ecosystem management, it is imperative to comprehend their reactions. This study employed advanced sequencing techniques to explore the community composition and functional diversity of microbial communities in Wascana Creek, Southern Saskatchewan, Canada, a river system previously identified as highly impacted. Through targeted chemical analysis, suspect screening, and assessments of nutrients and greenhouse gases, the research aimed to pinpoint specific pollutants and characterize their presence in the creek. By combining these analytical techniques, we aimed to unravel the intricate interactions between anthropogenic activities and microbial communities, elucidating their responses and potential functional alterations. Conducted in 2022, the investigation exposed a significant human influence on Wascana Creek. Upstream of the City of Regina, agricultural practices led to increased phosphorus levels, causing shifts in microbial community composition and activity. Consequently, dissolved oxygen concentrations declined, resulting in fish mortality. Moreover, there was a noteworthy rise in methane emissions, a potent greenhouse gas. Downstream of the City of Regina wastewater treatment plant, the introduction of effluents led to substantial increases in anthropogenic pollutants and nitrogen, triggering significant changes in microbial community composition and functional diversity. These alterations aligned with heightened emissions of nitrous oxide (N_2O), another potent greenhouse gas. These findings emphasize the direct influence of anthropogenic activities on microbial communities. Understanding the intricate interactions between anthropogenic activities, microbial communities, and ecosystem functioning is crucial. By examining microbial responses to anthropogenic stressors, valuable insights were obtained into the mechanisms underlying ecosystem disruption.

1.03.P-Mo044 Metal Pollution Affects the Early-life Gut Microbiota in Small Passerine Birds

Miia Rainio*, Lyydia Irmeli Leino, Eero Vesterinen and Tapio Eeva, Department of Biology, University of Turku, Finland*

Microbes play a significant role in terrestrial and aquatic ecosystems by acting as plant, animal and human pathogens, but many microbes have protective functions as well. Metals are well-known antimicrobial elements and metal pollution is a potential but little studied modifier of microbial environment in wild birds. Pollution-induced changes in gut microbiota may have serious effects on avian health and physiology. Particularly, early-life exposure to environmental pollutants may have great impact on the gut microbiota development and microbiota-dependent physiological functions, such as immune and stress responses. We studied the effects of metal pollution on early-life microbial environment of wild passerines by exploring bacterial diversity and community in nestlings' feces by 16S rRNA sequencing. We used three common model species, great tits (*Parus major*), blue tits (*Cyanistes caeruleus*) and pied flycatchers (*Ficedula hypoleuca*), which commonly breed at metal polluted areas in Finland. The field work was conducted near a copper-nickel smelter, an area with highest rates of metal pollution in Finland. Responses of microbiota to pollution, habitat, microclimate, taxonomy and dietary differences were measured and connected to ecological (brood size, growth, survival) measures of individual performance. The most common bacterial phyla were Firmicutes, Proteobacteria and Actinobacteria. Our preliminary results showed that the fecal microbial diversity (Shannon index) and richness (Chao1) did not differ between the study areas or between the species. However, the diversity decreased with increasing brood size in great tits and blue tits, while in pied flycatchers the diversity increased with nestling mass. Also, the fecal microbial communities differed between the species and study areas and several bacterial orders were associated with metal concentrations, nestling growth and fledging success. Moreover, several bacteria at family and genus level were differently abundant between the study areas and study species. The results suggest that metals may change the early-life bacterial communities in small passerine species living close to metal polluted areas.

1.03.P-Mo045 Distribution of metals and pesticides in spoonbills from natural areas of the southwest Spain. The impact on the microbial-produced metabolites and gut microbiota

Cristina Navarro Fernández[1]*, José luis Gómez Ariza*[1]*, Claudine de Le Court*[2]*, MCarmen Collado*[3]*, Francisco Hortas*[4] *and Tamara Garcia-Barrera*[5]*, (1)Chemistry, Research Center for Natural Resources Health and The Environment (RENSMA). Department of Chemistry, Faculty of Experimental Sciences, Spain, (2)Environment and Water Agency of Andalusia, Spain, (3)Institute of Agrochemistry and Food Technology, Spanish National Research Council (IATA-CSIC), Spain, (4)Department of Biology, Institute of Marine Research (INMAR). University of Cadiz., Spain, (5)Research Centre of Natural Resources, Health and the Environment (RENSMA), Department of Chemistry, University of Huelva, Spain*

The consequences of pollution due are widely recognized on a global, regional and local scale as well as their influence on ecosystems, especially in areas with abundant water, which acts as a carrier. The common spoonbill (*Platalea leucordia*) is a wetland-dwelling wading bird highly sensitive to pollution, making it a good bioindicator for assessing the ecological health of ecosystems. To this end, 70 feathers, 146 blood samples and 60 spoonbill eggs were analyzed in four selected areas during 2006 and 2011 (Southwest Spain): Odiel Marshes Biosphere Reserve (OM), marshland nature reserve of the Marismas de Isla Cristina (MIC), Doñana Natural Park and Natural Park of Cadiz Bay (CB). The presence of metals was evaluated by inductively coupled plasma-mass spectrometry (ICP-MS) while chlorinated organic compounds (PCBs and pesticides) were assessed by gas chromatography with an electron capture detector. High Fe content was observed in blood, along with lower levels of Mn, Ni and Se compared to the feather samples. Toxic metals such as Pb, Cd and Co were absent in blood and eggs. Regarding pesticides, DDT and, into a lesser extent, β-endosulfan were the most common, with the highest pesticide levels found in MIC. Similarly, this las site point was the most contaminated area with PCBs, with the highest concentration found in the blood. A higher accumulation of metals was observed in feathers due to permanent exposure to contaminants, and the highest concentration of pesticides and PCBs was found in blood samples from MIC. Moreover, a new sampling campaing has been performed during 2023 collecting 4 samples of water, 4 samples of soils and 30 samples of faeces of spoonbills in CB. Other sampling points to increase the number of samples is ongoing. Pesticides and metals have been determined, while an untargeted metabolomic study has been performed in the faeces to determine the microbial-produced metabolites that could be potencially related with the presence of pollutants. Microbiota profiling was also determined by 16S amplicon sequencing in

Illumina platform. The metabolomic analysis was carried out by combining GC with mass spectrometry and ultra-high performance liquid chromatography coupled to quadrupole time of flight (UHPLC-QTOF). The potential gut metabolic and microbiota impairments caused by environmental pollution in the different sampling points as well as the potential associations with pollutants are under investigation.

1.03.P-Mo046 Microbial Changes in Treated Wastewater Irrigated Paddy Soils and the Impacts on Biogeochemical Cycles

*Dung Viet Pham[1], Toru Watanabe[2] and **Susan Praise**[2], (1)Department of Urban Engineering, Tokyo University, (2)Faculty of Agriculture, Yamagata University*

Global freshwater withdrawals by the agricultural sector account for approximately 72%, placing it in strong competition with global cities. As a nutrient-rich resource, treated wastewater poses a viable option for meeting the high-water demand in agriculture, especially in water-intensive farming systems. However, conventional wastewater treatment processes do not eliminate all contaminants; thus, using treated wastewater (TWW) poses potential adverse risks for plants, agricultural soils, and the environment. We examined changes in microbial communities of paddy soils following one and three years of TWW irrigation. Our aim was to assess the microbial response to TWW and the consequences for biogeochemical cycles. After one year, pH, nutrients, and heavy metals significantly increased. However, most of the initially observed spikes had significantly recovered with three years of TWW irrigation, except for total carbon, nitrogen, and toxic elements including As, Pb, and Cr. Changes in soil physical and chemical properties were accompanied by differential abundance expression, with one year of TWW use showing more differentially abundant microbes than after three years. Notably, the differentially abundant microbes of the core taxa spanned across several phyla after one year *(Acidobacteria, Chloroflexi, Proteobacteria, and Nitrospirae*), compared to only *Chloroflexi* and *Nitrospirae* after three years. Interestingly, two rare taxa (*SBR1093* and *WS3*) significantly varied after three years. Moreover, alpha diversity indices were significantly low after three years. In addition to showing a lower abundance of microbes related to methane generation, TWW-irrigated fields had an overall reduction in methanogenesis and denitrification, highlighting the potential of TWW irrigation to alter microbial composition and subsequent processes crucial for organic matter mineralization and carbon sequestration.

1.03.P-Mo047 Beyond Nutrition: Breast milk Minerals Shape Infant Microbiota

***Eduard Flores Ventura**[1], Raul Cabrera-Rubio[1], Belén Callejón-Leblic[2], Javier Estañ-Capell[3], Cecilia Martínez-Costa[3], Tamara Garcia-Barrera[2] and MCarmen Collado[1], (1)Institute of Agrochemistry and Food Technology, Spanish National Research Council (IATA-CSIC), Spain, (2)Research Centre of Natural Resources, Health and the Environment (RENSMA), Department of Chemistry, University of Huelva, Spain, (3)Department of Pediatrics, University of Valencia, INCLIVA Biomedical Research Institute, Spain*

Introduction: Breast milk (BM), a dynamic fluid influenced by the maternal exposome, raises intriguing questions about its impact on the infant's microbiota. This study explores the potential role of variations in BM minerals and heavy metal composition in shaping the infant gut microbiota.

Methods: BM samples from 98 healthy mothers from MAMI cohort at two stages, early and mature, during lactation were included. Clinical and anthropometrical data from mother-infants were available. Mineral profile was obtained by inductively coupled plasma atomic emission spectroscopy (ICP-AES) and microbial profile was obtained by high-throughput sequencing of the 16S rRNA gene in Illumina platform. Unsupervised clustering and statistical analyses, including sparse Partial Least Squares (sPLS) multi-omics integration, were applied to unravel mineral-based compositional patterns and explore mineral-microbial dynamics.

Results: Significant variations were observed in the mineral composition of early and mature BM. Cadmium, and lead increased, while molybdenum, copper, cobalt, antimony, and zinc decreased significantly. Infant fecal samples showed an increase in *Bifidobacterium* spp. and a decrease in *Klebsiella* spp. during first months. Analysis of variance revealed a significant interaction effect between k-means cluster and time on Shannon and Simpson diversity indices. Numerical differences in diversity were found to be lower in infants with early BM compared to those with mature BM in the mineral cluster 2. Mineral differences, particularly higher cadmium and lead concentrations and lower molybdenum and antimony levels in mature BM from cluster 2, were identified. sPLS analysis suggested a moderate positive influence of aluminium on *Bacteroides*, and arsenic on *Corynebacterium* in early BM samples. Negative loadings were identified on *Corynebacterium* for vanadium in early BM, and for copper and zinc in mature BM.

Conclusion: Shifts in mineral profile, including elevated molybdenum, cadmium, and lead, and reduced copper, cobalt, antimony, and zinc, were observed in mature BM compared to early milk samples. Significant interactions between clustered minerals and time on diversity suggest a potential influence of heavy metal levels on shaping the infant gut microbiota. Further investigation is required to understand the biological or clinical significance of mineral-microbiota relationships in the context of initial infant gut seeding.

1.03.P-Mo048 Potential associations of chiral thyroid hormones and microbiota in human milk

***Rafael de Fátima Vélez-Pérez**[1], Raúl Cabrera Rubio[2], Ana Arias Borrego[3], Inés Velasco-López[4], Berta Soldevila[4], MCarmen Collado[5] and Tamara Garcia-Barrera[6], (1)Universidad de Huelva. Research Center for Natural Resources, Health and The*

Environment (RENSMA), Spain, (2)Institute of Agrochemistry and Food Technology, Spain, (3)Chemistry, University of Sevilla, Spain, (4)Hospital Universitari Germans Trias i Pujol, Spain, (5)Institute of Agrochemistry and Food Technology, Spanish National Research Council (IATA-CSIC), Spain, (6)Research Centre of Natural Resources, Health and the Environment (RENSMA), Department of Chemistry, University of Huelva, Spain
Iodine can only be obtained from the diet, and its requirements increase during pregnancy to fulfil altered maternal thyroid physiology and foetal development. There are previous studies related to the impact of iodine deficiency on the metabolome of human milk (HM). Thyroid hormones (TH) are the only compounds that contain iodine with biological activity and they are important for the infant's health. TH have chiral centers and their enantiomers present different biological and metabolic efficiency. Likewise, the levels of D-thyroxine (D-T4) do not influence the metabolic rate, but on the contrary, the levels of L-T4 do clearly influence it. However, D-T4 influences the levels of lipogenic enzymes in the liver, reduces cholesterol present in the plasmatic serum and decreases the secretion of thyrotropin (TSH). However, it is known that the efficiency of the L-T4 is much higher than that of its D form, but under our knowledge, chiral forms have not been previously reported in HM.

Herein, a novel analytical method was developed to separate 8 TH in HM using a column switching system mounted into an ultra-high performance liquid chromatography (UHPLC) that combines chiral and reversed stationary phases. TH were determined combining quadrupole time of flight (QTOF) tandem mass spectrometry, inductively coupled plasma triple quadrupole mass spectrometry (ICP-QQQ-MS) and ion mobility mass spectrometry (IMMS). Sample treatment involved hollow-fiber liquid-phase microextraction (HF-LPME) in three-phase mode. HF-LPME is a reliable method, simple and low cost that due to fiber disposability, avoids sample cross-contamination. The method allows determining 8 TH in HM at natural levels. The methodology has been applied to 134 HM samples. The concentration (ng/g) of TH followed the order D-T4 (96.78 ± 164.00) > L-T4 (71.23 ± 112.65) > 3,3',5'-triiodothyronine (65.22 ± 112.54 = rT3) > 3,3',5-triiodothyronine (43.85 ± 68.43 = T3) > 3,5-diiodothyronine (43.42 ± 56.35 = T2) > thyronine (19.94 ± 34.41 = T0) > 3,5-diiodotyrosine (9.86 ± 21.86 = DIT) > 3-iodotyrosine (9.53 ± 26.27 = MIT). Moreover, the microbiota profiling was obtained by 16S amplicon sequencing in Illumina platform and our results demonstrated a separation between mothers with iodine deficiency from control samples. The potential associations between clinical variables and the concentration of thyroid hormones with HM microbiota are under investigation.

1.03.PC Assessing Adverse Pollutant Effects on Host-Associated and Free-Living Microbiomes Using -Omics Approaches

1.04.A Behavioural Toxicology: Methodologies and Research Needs

1.04.A.T-01 Perceptions about the quality and utility of Behavioural (Eco)Toxicology to protect human and ecosystem health

***Alex Ford**[1], Marlene Ågerstrand[2], Tomas Brodin[3], Bryan W. Brooks[4], Gerd Maack[5], James M. Lazorchak[6], Minna Saaristo[7] and Bob Wong[8], (1)University of Portsmouth, United Kingdom, (2)Stockholm University, Sweden, (3)Wildlife, Fish and Environmental Studies, Swedish University of Agricultural Sciences (SLU), Sweden, (4)Environmental Science, Environmental Science & Public Health, Baylor University, (5)German Environment Agency (UBA), Germany, (6)Office of Research and Develoment, U.S. Environmental Protection Agency (US EPA), (7)Environment Protection Authority Victoria, Australia, (8)School of Biological Sciences, Monash University, Australia*
A survey was conducted on the perceptions and role of behavioural ecotoxicology in the protection of the environment and human health. Those surveyed included environmental scientists working in the field of environmental toxicology and behavioural ecology and represented industry, government, NGOs and academia/research centres. Of the 166 respondents, 57% worked already with behavioural endpoints in ecotoxicology and/or ecology. The respondents agreed that contaminants can (97%) and are impacting wildlife (77%), and can (84%) and are impacting humans (62%). Those responding to questions about the impacts on humans resulted in more answers that were neutral or don't know. Overall respondents believed behavioural experiments to be repeatable (60%), reliable (61%) and relevant (84%), although those not studying behaviour were more cautious in their answers. Respondents were more likely to be neutral when asked whether behavioural endpoints are more sensitive (43%) but agreed (80%) that they provide important alternative information to standard endpoints. The largest overall response was to disagree with the statement that behavioural endpoints are currently used in risk assessment (42%) but the greatest proportion agreed they were essential (55%). The majority of respondents disagreed (63%) with the statement that we understood the risks of contaminants to wildlife and human health. However, 68% agreed that regulatory authorities should consider behavioural endpoints when making decisions over risk, with 78% of respondents agreeing this would likely come with increased costs for regulators and/or industry. Interestingly, 54% agreed and 28% were neutral that understanding the effects of contaminants on wildlife behaviour is critical to protecting human health. The largest proportion of respondents disagreed (35%) or were neutral (30%) with the statement that behavioural are easily linked to standardised apical endpoints and population-level effects. We discuss how this data could be used to further support our understanding and confidence in the effects of contaminants on human and wildlife behaviour and the mechanisms by which they can be incorporated into risk assessment and regulation.

1.04.A.T-02 Impact Of Environmentally Relevant Concentrations Of Fluoxetine On Zebrafish Larvae: From Gene To Behavior

***Daniela Veloso Correia**[1], Marina Bellot[2], Eva Prats[3], Cristian Gómez-Canela[2], Hugo Moro[4], Demetrio Raldua[5], Ines*

Domingues[6], Miguel Oliveira[7] and Melissa Diogo Faria[5], (1)University of Aveiro, Portugal, (2)University Ramon Llull IQS, Spain, (3)CID-CSIC, Spain, (4)Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain, (5)Environmental Toxicology, Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain, (6)CESAM - Department of Biology, University of Aveiro, Portugal, (7)University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Portugal
The selective serotonin reuptake inhibitor class of antidepressants (SSRIs) are usually prescribed for treatment of depressive states, acting at the level of the central nervous system, consequently affecting non-target organisms. Our work aimed to investigate the influence of environmentally relevant fluoxetine concentrations (1 to 1000 ng/L) on *Danio rerio* development, assessing both embryotoxicity and behavior, gene expression and neurotransmitter levels at larval stage. Exposure to fluoxetine during early development accelerated embryo hatching, reduced larval size and increased heart rate. Behavioral impairments (decreased startle response and increased larvae locomotor activity) were associated with effects on monoaminergic systems, detected through the downregulation of key genes (*vmat2*, *mao*, *tph1a* and *th2*) and with altered levels of neurochemicals belonging to the serotonergic and dopaminergic systems (increased levels of tryptophan and norepinephrine and decrease in 3,4 dihydroxyphenylacetic acid levels). Overall, the results highlight the sensitivity of early life stages of *Danio rerio* to low concentrations of fluoxetine, inducing effects that may compromise larval survival. The obtained data support the need to test low concentrations of SSRI in environmental risk assessment and the use of biomarkers at different levels of biological organization for a better understanding of modes of action.

1.04.A.T-03 Impacts of pharmaceuticals on animal behaviour: a systematic map of evidence and open access database
***Jake Mitchell Martin**[1], Michael Grant Bertram[2], Paul J. Blanchfield[3], Jack Brand[4], Tomas Brodin[2], Bryan W. Brooks[5], Daniel Cerveny[1], Kate Fergusson[4], Malgorzata Lagisz[6], Isaac Ligocki[7], Lea Marie Lovin[8], Marcus Michelangeli[9], Shinichi Nakagawa[6], Shiho Ozeki[10], Natalia Ivone Sandoval Herrera[11], Kendall Rose Scarlett[8], Josefin Sundin[1], Hung Tan[4], Eli S.J. Thoré[1], Bob Wong[4] and Erin McCallum[1], (1)Swedish University of Agricultural Sciences (SLU), Sweden, (2)Wildlife, Fish and Environmental Studies, Swedish University of Agricultural Sciences (SLU), Sweden, (3)Fisheries and Oceans Canada, Canada, (4)School of Biological Sciences, Monash University, Australia, (5)Environmental Science, Environmental Science & Public Health, Baylor University, (6)University of New South Wales (UNSW), Australia, (7)Millersville University, United States, (8)Environmental Science, Baylor University, (9)University of California San Francisco (UC San Francisco), (10)School of Biological Sciences, Monash University, Melbourne, Australia, (11)Department of Wildlife, Fish, and Environmental Studies, Swedish University of Agricultural Sciences (SLU), Sweden*
Over the last decade, there has been a rapid resurgence of behaviour as a tool for assessing the impacts of emerging pollutants. Behaviour is proposed as a particularly sensitive indicator for contaminant-induced impacts on non-target species—especially compared to standard ecotoxicological endpoints; it can also act as a bridge, linking the immediate effects at the sub-organismal level to broader, ecologically relevant outcomes at the population level. Despite this, behaviour is rarely used in a regulatory context. Recently, there has been a concerted effort to integrate behavioural assessments into environmental regulation and risk assessment. To make the most well-informed decisions during this critical integration process, there is an urgent need for a systematic synthesis of currently available data. In essence, without knowing what we have done, how can we best guide practice moving forward? Accordingly, our team employed a large-scale systematic evidence map approach to identify, categorise, and visualise research detailing the effects of pharmaceuticals on the behaviour of aquatic animals. The primary objective was to create a large open-access database on the impacts of pollution on animal behaviour for regulators and researchers. In brief, we searched two electronic databases (Web of Science and Scopus) with an exhaustive search string structure using a PECO framework. The resulting articles were screened in two stages, title and abstract, followed by full-text screening. After removing duplicates, 5503 articles underwent title and abstract screening. In total, 1103 articles proceeded to full-text screening and metadata extraction. The metadata taken from the articles centred around four themes: (1) species information, (2) compound information, (3) behavioural measurements, and (4) quality criteria (based on the criteria for reporting and evaluating ecotoxicity data). In total, 774 individual articles were included in our final database, representing 1472 individual compound–species assessments. There were 405 compounds and 170 species identified in our database, representing over 1800 behavioural assays. During my presentation, I will use this new database to highlight current knowledge gaps, overrepresented study systems, and areas currently well-suited for meta-analysis approaches.

1.04.A.T-04 EthoCRED: A Framework to Guide Reporting and Evaluation of the Relevance and Reliability of Behavioural Ecotoxicity Studies
***Michael Grant Bertram**[1], Marlene Ågerstrand[2] and Tomas Brodin[1], (1)Wildlife, Fish and Environmental Studies, Swedish University of Agricultural Sciences (SLU), Sweden, (2)Stockholm University, Sweden*
Behavioural analysis has been garnering significant attention as a broad indicator of sub-lethal toxicity, and has secured a place as an important sub-discipline in ecotoxicology. One of the most notable characteristics of behavioural research, compared to other established approaches in sub-lethal ecotoxicology (e.g. reproductive and developmental bioassays), is the wide range of study designs being used and the diversity of endpoints considered. At the same time, environmental hazard and risk assessment, which underpins regulatory decisions to protect the environment from potentially harmful chemicals, often recommends that ecotoxicological data be produced following accepted and validated test guidelines. These guidelines typically do not address behavioural changes, meaning that these, often sensitive, effects are not represented in hazard and risk assessments. In this presentation, we propose a new tool, the EthoCRED evaluation method, for assessing the relevance and reliability of behavioural ecotoxicity data, which considers the unique requirements and challenges encountered in this field. This method, and accompanying reporting recommendations, are designed to serve as an extension of the 'Criteria for

Reporting and Evaluating Ecotoxicity Data (CRED)' project. As such, EthoCRED can both accommodate the wide array of experimental design approaches seen in behavioural ecotoxicology, and is able to be readily implemented into regulatory frameworks in different jurisdictions to allow better integration of knowledge gained from behavioural testing into environmental protection. Furthermore, through our reporting recommendations, we aim to improve the reporting of behavioural studies in the peer-reviewed literature, and thereby increase their usefulness in chemicals regulation.

1.04.P-Tu001 Behavioral consequences through telomere shortening in wildlife birds living in a chronic exposure of urban pollution

Matteo Schiavinato[1]*, Shivani Ronanki*[2]*, Ignacio Miro Estruch*[3]*, David Spurgeon*[4] *and Nico van den Brink*[1]*, (1)Wageningen University & Research (WUR), Netherlands, (2)Department of Toxicology, Wageningen University & Research (WUR), Netherlands, (3)Toxicology, Wageningen University & Research (WUR), Netherlands, (4)UK Centre for Ecology & Hydrology (UKCEH), United Kingdom*

Urban pollution lead to oxidative stress. Telomeres (non-coding DNA at the end of the chromosomes) are particularly sensitive to oxidative damage, since ROS (Reactive Oxygen Species) can accelerate their normal shortening in length due to aging. Individual differences in telomere length are also associated with differences in behaviour: the shorter the telomeres, the more nervous the animals are. A possible explanation for this link could reside in the "telomere position effect" (TPE), or rather the silencing of the genes at the end of the chromosome by the spread of the telomeric heterochromatin. Therefore, the shorter a telomere becomes, the more the closer genes are expressed. TPE could alter the phenotype according to senescence, regulating the expression of specific genes involved in behaviour as the dopamine receptors. To test this hypothesis, we used a free living bird, the blue tit (*Cyanistes caeruleus*), as model. We collected a blood sample at days 8 and 15 after hatching from nestlings in artificial nest boxes along a gradient of air pollution, in order to assess their telomeric shortening during the juvenile phase. The oxidative status of some subjects was experimentally manipulated through Polyinosinic:polycytidylic acid (Poly I:C), a synthetic RNA that binds the Toll-like receptor 3 (TLR3) producing ROS. We have then studied the nestlings' behaviour in the bold-shy continuum in relation to their telomere shortening, through an open-field test we designed. Chicks raised from nests in the most polluted area expressed higher telomere loss compared to those in the less polluted zone. The treated individuals with Poly I:C showed accelerate telomere shortening compared to those who received a saline solution, potentially indicating a causal role of ROS in telomeric loss. Finally, the rate of individual's telomere shortening correlated with its agitation and bold personality. Our study provides support for an association between air pollution and telomeric loss, and for a relation between telomere shortening and personality traits. Our finding calls into question the role of telomere length in behavioural modulation, and we hypothesize that the mechanism of action may reside in the TPE. We hypothesize the adverse outcome pathways (AOP) for which chronic exposure to urban pollution may alter animal personality, through a different expression of genes that regulate behaviour by the telomere position effect, triggered by ROS-induced telomere shortening.

1.04.P-Tu002 Exploring the Effects of Two Surface Coatings on Titanium Dioxide Nanoparticles in "Danio rerio" Embryos

Mário Araújo[1]*, Elza Fonseca*[1]*, Elizabeth Bigorra-Ferré*[1]*, Carla Ferreira Melo*[2]*, Sergio Fernández-Boo*[1]*, Laura Rodriguez-Lorenzo*[3]*, Miguel Oliveira*[4]*, Vitor Vasconcelos*[1,5]*, Begoña Espina*[6] *and Alexandre Campos*[1]*, (1)University of Porto, Interdisciplinary Centre of Marine and Environmental Research (CIIMAR), Portugal, (2)University of Aveiro, Portugal, (3)Water Quality Group, International Iberian Nanotechnology Laboratory (INL), Portugal, (4)University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Portugal, (5)Department of Biology, Faculty of Sciences, University of Porto, Portugal, (6)International Iberian Nanotechnology Laboratory, Portugal*

The environmental safety of titanium dioxide nanoparticles (TiO_2 NPs) is under increasing debate. Previous works showed that TiO_2 NPs with a primary size of 5 and 25 nm induce hepatocyte ultrastructural alterations, along with metabolic alterations, inflammation, and oxidative stress in fish. However, these effects depend on several variables, such as average particle size, route of exposure, and sensitivity/resistance of the model organism. Since the type of surface coating is also reported to affect the biological response of NPs, in the present work, we studied alterations induced by 45 nm TiO_2 NPs exposure with two different coatings [sodium citrate and N-(trimethoxysilylpropyl)ethylenediamine, triacetic acid (EDTA-silane)] using *Danio rerio* embryos. Three trials were performed to study (i) developmental effects (inc. hatching, length, and malformations), (ii) behaviour (inc. swimming distance and responses to light/dark transitions), and (iii) gene expression (alterations of genes involved in the regulation of oxidative stress - CAT and SOD, immune responses and inflammation - NFKB1 and PPARab, and lipid metabolism - ACOX1, CPT1ab, PPARab, HADH, and ELOVL5). The concentrations tested ranged between 5 and 200 mg TiO_2 NPs/L.

Overall, the exposure to 45 nm TiO_2 NPs with the two tested coatings induced relatively low harmful effects on *D. rerio* embryos regarding early life development. However, gene expression alterations were observed to depend on the type of surface coatings. Genes related to lipid metabolism (HADH and ELOVL5), oxidative stress (SOD), and immune response (NFKB1) are differentially modulated by the type of coating, with EDTA-silane inducing more alterations (mostly down-regulation of genes) than sodium citrate. Besides, behavioural alterations (swimming distance and inactivity) were detected, suggesting more stress on organisms exposed to the EDTA-silane-coated than the citrate-coated TiO_2 NPs.

While waterborne exposure to 45 nm TiO_2 NPs may seem relatively less toxic to aquatic organisms when compared to other lower-sized NPs, some surface coatings may increase their reactivity and interaction with (bio)molecules, and the overall toxicity to aquatic organisms. Given the immense range of parameters reported to affect the biological response to engineered nanomaterials exposure, general assumptions on nanoparticle safety/toxicity should be taken carefully.

1.04.P-Tu012 Effects of Acute 6PPD-Quinone Exposure on Swimming Performance and Aerobic Metabolism in Juvenile Lake Trout (Salvelinus namaycush)

Summer Selinger[1]*, Markus Hecker*[2]*, Steve Wiseman*[3]*, Lynn Weber*[1]*, David M. Janz*[4] *and Markus Brinkmann*[5]*, (1)University of Saskatchewan, Canada, (2)Toxicology Centre and School of the Environment and Sustainability, University of Saskatchewan, Canada, (3)University of Lethbridge, Canada, (4)Western College of Veterinary Medicine and Toxicology Centre, University of Saskatchewan, Canada, (5)Toxicology Centre, University of Saskatchewan, Canada*

N-(1,3-Dimethylbutyl)-N′-phenyl-p-phenylenediamine-quinone (6PPD-quinone) is a transformation product of the most widely used rubber tire antioxidant, 6PPD. Commonly found in road-way runoff, a variety of studies have reported this compound to cause acute lethality in several salmonid species at roughly ≤ 1 µg/L, including lake trout (*Salvelinus namaycush;* 24 h LC_{50} = 0.51 µg/L). However, there is currently a lack of research targeted at understanding sublethal toxicities of 6PPD-quinone exposure, particularly on swimming performance. Sensitive species show characteristic symptoms including gasping, spiraling, increased ventilation, loss of equilibrium and impaired swimming ability, suggesting a possible impact on cardiometabolic physiology. To evaluate potential effects of 6PPD-quinone on swimming performance and aerobic metabolism, juvenile lake trout were exposed to nominal aqueous concentrations of 0 or 0.5 µg/L in a swim tunnel respirometer for 20 hours to assess temporal changes in standard metabolic rate (SMR) compared to unexposed controls. Following exposure, fish underwent a swim trial to determine critical swim speed (U_{crit}), oxygen consumption (MO_2), active metabolic rate (AMR), aerobic scope (AS) and energetic cost of transport (COT). After conducting the swim trial, fish were euthanized, and concentrations of muscle triglycerides and glycogen were determined. Preliminary data show that 6PPD-quinone exposure does not significantly impact oxygen consumption rates or energetic cost of transport during a critical swim test. In contrast, exposure appeared to cause a significant decrease in critical swim speed and active metabolic rate, providing evidence of altered metabolism. These results suggest that aqueous 6PPD-quinone exposure at environmentally relevant concentrations produces adverse effects that can diminish endurance and maximum swim speeds, which may affect survival of fish populations. This is the first study to analyze the toxicity of 6PPD-quinone on the swimming performance of fishes of commercial, cultural, and ecological importance and provides urgently needed information for environmental risk assessments of this emerging contaminant of concern.

1.04.B Behavioural Toxicology: Methodologies and Research Needs

1.04.B.T-01 Environmental Concentrations of Tire Rubber-Derived 6PPD-Quinone Alter CNS Function in Zebrafish Larvae

Demetrio Raldua[1]*, Marina Ricarte*[2]*, Eva Prats*[3]*, Nicola Montemurro*[4]*, Juliette Bedrossiantz*[1]*, Marina Bellot*[5] *and Cristian Gómez-Canela*[6]*, (1)Environmental Toxicology, Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain, (2)Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain, (3)CID-CSIC, Spain, (4)Department of Environmental Chemistry, Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain, (5)University Ramon Llull IQS, Spain, (6)School of Engineering, Institut Químic de Sarrià-Universitat Ramon Llull, Spain*

N-(1,3-Dimethylbutyl)-*N*′-phenyl-*p*-phenylenediamine quinone (6PPD-quinone) is a degradation product of 6PPD, an antioxidant widely used in rubber tires. 6PPD-quinone enters aquatic ecosystems through urban stormwater runoff and has been identified as the chemical behind the urban runoff mortality syndrome in coho salmon. However, the available data suggest that the acute effects of 6PPD-quinone are restricted to a few salmonid species and that the environmental levels of this chemical should be safe for most fish. In this study, larvae of a "tolerant" fish species, *Danio rerio,* were exposed to three environmental concentrations of 6PPD-quinone for only 24 h, and the effects on exploratory behavior, escape response, nonassociative learning (habituation), neurotransmitter profile, wake/sleep cycle and circadian rhythm were analyzed. Exposure to the two lowest concentrations of 6PPD-quinone resulted in altered exploratory behavior and habituation, an effect consistent with some of the observed changes in the neurotransmitter profile, including increased levels of acetylcholine, norepinephrine, epinephrine and serotonin. Moreover, exposure to the highest concentration tested altered the wake/sleep cycle and the expression of *per1a*, *per3* and *cry3a*, circadian clock genes involved in the negative feedback loop. The results of this study emphasize the need for further studies analyzing the effects of 6PPD-quinone in "tolerant" fish species.

1.04.B.T-02 Comparative Assessment of the Behavioral Responses in Local Amphipod Species to Anthropogenic Stressors

Laura Johanna Soose[1]*, Jörg Oehlmann*[1]*, Andreas Schiwy*[2]*, Henner Hollert*[2] *and Jonas Jourdan*[1]*, (1)Aquatic Ecotoxicology, Goethe University Frankfurt, Germany, (2)Evolutionary ecology and environmental toxicology, Goethe University Frankfurt, Germany*

Chemical pollution is increasing and one of the main drivers of biodiversity loss. Current methods for chemical risk assessment could be insufficient to detect subtle threats to biodiversity. Behavioral ecotoxicology offers the potential to detect adverse effects at environmentally relevant and sublethal concentration ranges. The lack of standardization is a major drawback for the use of behavioral endpoints in chemical regulation. To achieve standardization and incorporate environmental realism, it is important to establish stronger connections between ecological and ecotoxicological research. This can be accomplished, for example, by examining the interactions of local keystone species with realistic stressors. Anthropogenic environmental

stressors arise from various sources, such as diffuse inputs from agriculture that occur as event-related pulsed inputs following heavy rain events. Also point sources like wastewater treatment plants are relevant, causing continuous release of pollutants like pharmaceuticals and personal care products into aquatic systems. For both input pathways we developed behavioral assays using several local amphipod species with an optical behavior monitoring tool.

Our first test scenario represents pulsed pollutant exposure by tracking the behavioral response of the test organisms immediately after exposing them to stressors for 2 hours. First, we worked with *G. pulex*, a commonly used amphipod in ecotoxicology. We found that pesticides induced a more pronounced response than pharmaceutical compounds. We assumed that *G. pulex* might have some kind of familiarization effect due to its sampling location. Consequently, we expanded our species portfolio to the four most common local species. We found that species that are naïve to pollutant exposure reacted most strongly to pulsed exposure. In our second test scenario we focused on the effect of pre-exposure and the resulting behavioral response to light stimuli: We used a light-dark transition tests and were again able to identify differences between the local amphipods. With both behavioral assays, we can demonstrate the benefits of behavioral ecotoxicology and contribute to the debate on standardization.

1.04.B.T-03 Sensitive Behavioural Endpoints and Generational Effects in Daphnia magna Upon Acute and Chronic Toxicity Testing

Vanessa Saalmann*, Kirsten Germing and Lena Kosak, Ecotoxicology, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany*

The crustacean *Daphnia magna* is a widely used model organism in ecotoxicological testing. So far, according to the OECD guidelines 202 and 211, immobility and reproduction are the main endpoints used for the determination of toxicity. Recent studies show, that sublethal concentrations of chemicals can result in behavioral changes in daphnids, which are not assessed in current guideline testing. Since these behavioral changes can have an effect on population-relevant traits of daphnids and therefore may affect the aquatic food chain, their implementation is of major importance.

Behavioural endpoints addressing the locomotor activity, phototaxis and chemotaxis of *D. magna* were tested in a 48-hour acute test as well as a 21-day chronic reproduction test (F_0 and F_1 generation) with the neurologically active insecticides imidacloprid, thiacloprid and fipronil. All have shown to cause alterations in swimming behaviour in sublethal concentration ranges and the behavioral parameters appear to be more sensitive than the classical endpoints immobilization and reproduction.

The data was evaluated under the aspect of the respective mode of action of the insecticides and according to the applicability of the behavioural endpoints allowing a predictability of substance effects. NOEC values for the behavioural parameters for all insecticides could be determined and an overview over the behavioural endpoints could be obtained regarding the sensitivity and reproducibility.

During the acute tests, the phototactic behaviour appeared to be the most sensitive parameter for imidacloprid and thiacloprid and the activity time for fipronil. During the chronic exposure tests, insights in behavioural changes of *D. magna* during development could be gained as well as the most sensitive parameters could be suggested. The phototactic behaviour seems to be the most sensitive parameter for imidacloprid at 48 hours and 7 days, the locomotor activity for thiacloprid and fipronil. The data of the F_1 generation born under exposure was compared to the data of the F_0 generation and the data from the acute behavioural tests. The F_1 generation has shown to be more sensitive under neonicotinoid exposure and did not show recovery during 48 hours without exposure. For the F_1 generation born under neonicotinoid exposure, the phototactic behaviour and locomotor activity were the most sensitive parameters, while no significant sensitivity could be shown for F_1 daphnids born under fipronil exposure.

1.04.B.T-04 A method for assessing thermal preference and locomotion of a soil arthropod, Folsomia candida and its application in ecotoxicology

***Jian Ge**[1], Jesper Givskov Sørensen[2], Stine Slotsbo[1] and Martin Holmstrup[1], (1)Department of Ecoscience, Aarhus University, Denmark, (2)Department of Biology, Aarhus University, Denmark*

Conventional physiological endpoints like survival and reproduction are useful for environmental risk assessment (ERA) because they link directly to population dynamics, however, chemicals may also affect more subtle traits at low environmental concentrations, for example the behaviour of organisms. The behaviour of springtails is important for their persistence, ecological roles in decomposition and critical to survive extreme thermal conditions. However, standardised methods for assessing behavioural response of springtails to temperature or/and chemical exposure is lacking. This study aimed to investigate the thermal preference and locomotive response to temperature of springtails *Folsomia candida* under Cu contamination. We hypothesized that springtails would be behaviourally responsive to temperature and that Cu contamination can alter thermal preference and compromise mobility of springtails. Soils contaminated with three Cu levels (ca. 40, 400 and 1500 mg/kg dry soil) were collected from a former timber preservation industry at Hygum, Denmark. Age-synchronized springtails were exposed to the three exposure levels in Hygum soil for 3 weeks. In the thermal preference study, springtails were placed in the centre of rectangular arenas with a temperature gradient from 0 to 50 °C and the distribution were recorded after 5, 15, 30 and 60 mins. In the locomotion test, springtail was placed on a petri dish (diameter: 30 mm) at temperatures of 10, 15, 20, 25, 30, 33, 36, 40, 43 and 45 °C for 40 mins and the maximum velocity (V_{max}), jumping intensity (J_{int}), jumping counts (J_{fre}) and other locomotion parameters were calculated. Our results showed that the majority of springtails were able to adjust body temperature by moving along the temperature gradient to a preferred benign temperature, while few of them were trapped at thermal extremes. Cu exposure shifted the thermal preference of springtails and increased the risk of being trapped in the warm region of the arenas. V_{max} and J_{fre} also demonstrated unimodal relationship with temperature and was reduced by Cu exposure at high temperature. High V_{max} and J_{fre} matching with low occurrence at high temperature was possibly an escaping strategy for springtails. Increased J_{int} induced by extremely high temperature or Cu exposure suggested alterations in movement pattern. We conclude that assessment of toxic effects on thermal preference and locomotion is feasible and may be a valuable early-warning system for ERA.

1.04.P-Tu003 Is Disrupted Reproductive Behaviour Population-Relevant?

Charles Hazlerigg[1], *Alice Tagliati*[1], *Laurent L.-M. Lagadic*[2], *Edward Salinas*[2] *and Thomas G Preuss*[2], *(1)Enviresearch Ltd., United Kingdom, (2)Bayer AG - Crop Science Division, Germany*

Plant Protection Products and Biocides that are classified as EDCs will no longer be approved for use in the EU. Recently, there has been a growing interest in behavioural endpoints as EDCs have been shown to alter fish reproductive behaviours. Furthermore, environmental assessments are focussed on protection of wild populations, not individual organisms. Population models provide the potential to explore the population relevance of chemically-induced changes in individual behaviour. Here we present a study using a stickleback IBM to explore the population response to EDC-induced changes in reproductive behaviour; nesting and courtship behaviour.

After a 3-year spin-up period to stabilise the modelled stickleback population, hypothetical chemical effects were imposed disrupting the nesting and courtship behaviour of male stickleback. The behaviours were disrupted at four magnitudes: 10, 20, 50 and 90%. The effects were imposed continuously for 10 years. For each scenario, 70 simulations were performed. The population (abundance and biomass) response was evaluated across the entire 10 year effect period. The evaluation criteria used to determine an adverse population effect were taken from the recent EFSA Birds & Mammals guidance.

10 and 20% disruption in courtship behaviour did not lead to any adverse effects on the stickleback population. 50% disruption in courtship behaviour did lead to an observable reduction in abundance and biomass, whist 90% disruption in courtship behaviour almost led to population extinction within the 10 years. Meanwhile, no population effects were observed following disruption of nesting behaviour at any of the four testing magnitudes of effect (data not shown). When comparing with effects on fecundity and sex ratio (male skew), the stickleback population was shown to be less sensitive to disruption of nesting and courtship behaviour.

Here we demonstrate how models can be used to assess the population relevance of disrupted behaviour observed in laboratory studies. Disruption of different behaviours have different population relevance. Results also show that other endpoints may be more relevant for population level assessment, making behavioural endpoints an indicator of endocrine activity rather than adversity in terms of the regulatory criteria.

1.04.P-Tu004 A Multifactorial Environmental Stressors Approach: Chironomus riparius Exposed to Sulfoxaflor with Presence of Predator Cues and Increased Temperature

Sofie Bruun Rasmussen[1], *Thijs Bosker*[1], *S. Henrik Barmentlo*[2], *Olof Berglund*[3] *and Martina G. Vijver*[2], *(1)Leiden University, Netherlands, (2)Institute of Environmental Sciences (CML), Leiden University, Netherlands, (3)Lund University, Sweden*

Growing evidence suggests that standard toxicity testing might underestimate the environmental risk of neurotoxic insecticides by not accounting for potential sublethal effects. Behavioural endpoints such as locomotion and mobility have been suggested as both sensitive and ecologically relevant alternatives to the standard tested endpoints to predict sublethal effects more accurately. Additionally, low levels of environmental realism in conventional toxicity testing raise concerns, as possible synergistic effects of a chemical and additional stressors are typically overlooked in standard risk assessment. Therefore, we aimed to investigate how concurrent exposure to environmental stressors and a nicotinic acetylcholine receptor (nAChR)-modulating insecticide ('sulfoxaflor') impact *Chironomus riparius* across a wide range of conventional and non-conventional responses.

To this end, a multifactorial experimental design encompassing three stressors, sulfoxaflor (at six different concentrations), predation risk (presence/absence of predatory cues), and temperature stress (20°C and 23°C), was used, yielding a total of 24 distinct treatment conditions. To assess potential additive effects, we applied the Independent Action (IA) model to predict the impact on eight endpoints, including standard endpoints (e.g., growth, survival, and emergence) and less conventional endpoints (e.g., swimming abilities and exploration behaviour). For the standard endpoints, observed effects were either lower than expected or well-predicted by the IA model. In contrast, we found synergistic effects of predation cues and temperature in combination with sulfoxaflor on adult size and larval exploration behaviour. Furthermore, the results indicated synergistic effects on larval swimming velocity between sulfoxaflor and increased temperature but not when combined with predation cues.

In conclusion, the results show that the total emergence of *C. riparius* is sensitive to the effects of sulfoxaflor, confirming their importance for standard ecotoxicity testing. However, we also found that conventional endpoints such as emergence, mortality, and growth do not pick up on possible synergistic effects between the neurotoxic insecticide and important environmental stressors: predation cues and increased temperature. Awareness of this disparity will be critical for future studies and to improve risk assessment.

1.04.P-Tu005 Effects of Chemical Stresses on the Freshwater Mussel Dreissena polymorpha's Crawling Behaviour

Nicolas Berthelot[1]*, Melissa Palos Ladeiro Dr.*[1]*, Mathilde Orquevaux*[2] *and Alain Geffard Pr*[1]*, (1)UMR-I 02 Sebio, University of Reims Champagne-Ardenne (URCA), France, (2)Direction de l'Eau et de l'Assainissement, Communauté urbaine du Grand Reims, France*

Bivalves are relevant organisms in which it can be measured biological responses (biomarkers) for water toxicity assessment. In this context the freshwater zebra mussel, *Dreissena polymorpha*, is a widespread sentinel species. Behaviors are known as biomarkers offering early responses to stresses. In bivalves there are many methods based on valvometry measurement (valves closures). But in *D. polymorpha* the other behaviors, as crawling, are largely under-researched. So, the present work aims to answer the question: can the locomotion be modulated by chemical stress in zebra mussels? Experiments was conducted in laboratory on young (10-15 mm) mussels. It consists of seven separately exposures (7 days) to copper, lead, triclosan, metformin, fluoxetin, and ofloxacin at 0; 1; 10; 100 and 1.000 µg/L, and to chlorpyrifos at 0; 0,1; 1; 10 and 100 µg/L. After the exposure step the crawling of mussels for each chemical condition is recording by video tracking. Significantly lower distances were registered in organisms exposed to 100 and 1.000 µg/L of copper with a mean individual distance of 19.22 mm for 0 µg/L but only35 mm and 0.88 mm for 100 and 1.000 µg/L respectively. The mobility rate (number of mussels which have moved) is also significantly linked to the concentration, with 13 unmoving mussels for 0 µg/L and 25 unmoving mussels for 1000 µg/L. These results could be explain by the fact that copper is a biocide and it is attested as decreasing mobility in other bivalves. For fluoxetine exposure, mean individual distance is 12.63 mm for 0 µg/L exposed mussels while it is significantly higher (26.38 mm and 33.60 mm respectively) for 100 and 1.000 µg/L. The mobility rate did not depend on fluoxetine concentration. The increased crawling distances could be result from a stimulant effect of the fluoxetine regarding the mode of action of this pharmaceutical which is a selective inhibitor of the serotonin reuptake. To complete the discussion about present results with copper and fluoxetine other parameters as speed or delay before crawling can be used for describe the mobility. This work is in our knowledge the first evidences of chemical exposures effects on the locomotion in *D. polymorpha*. These present results show that *D. polymorpha* locomotion can be modulate under a chemical stress by increasing as well as decreasing traveled distances, showing a promitting potential for crawling as futur tool in biomonitoring.

1.04.P Behavioural Toxicology: Methodologies and Research Needs

1.04.P-Tu001 Behavioral consequences through telomere shortening in wildlife birds living in a chronic exposure of urban pollution

Matteo Schiavinato[1]*, Shivani Ronanki*[2]*, Ignacio Miro Estruch*[3]*, David Spurgeon*[4] *and Nico van den Brink*[1]*, (1)Wageningen University & Research (WUR), Netherlands, (2)Department of Toxicology, Wageningen University & Research (WUR), Netherlands, (3)Toxicology, Wageningen University & Research (WUR), Netherlands, (4)UK Centre for Ecology & Hydrology (UKCEH), United Kingdom*

Urban pollution lead to oxidative stress. Telomeres (non-coding DNA at the end of the chromosomes) are particularly sensitive to oxidative damage, since ROS (Reactive Oxygen Species) can accelerate their normal shortening in length due to aging. Individual differences in telomere length are also associated with differences in behaviour: the shorter the telomeres, the more nervous the animals are. A possible explanation for this link could reside in the "telomere position effect" (TPE), or rather the silencing of the genes at the end of the chromosome by the spread of the telomeric heterochromatin. Therefore, the shorter a telomere becomes, the more the closer genes are expressed. TPE could alter the phenotype according to senescence, regulating the expression of specific genes involved in behaviour as the dopamine receptors. To test this hypothesis, we used a free living bird, the blue tit (*Cyanistes caeruleus*), as model. We collected a blood sample at days 8 and 15 after hatching from nestlings in artificial nest boxes along a gradient of air pollution, in order to assess their telomeric shortening during the juvenile phase. The oxidative status of some subjects was experimentally manipulated through Polyinosinic:polycytidylic acid (Poly I:C), a synthetic RNA that binds the Toll-like receptor 3 (TLR3) producing ROS. We have then studied the nestlings' behaviour in the bold-shy continuum in relation to their telomere shortening, through an open-field test we designed. Chicks raised from nests in the most polluted area expressed higher telomere loss compared to those in the less polluted zone. The treated individuals with Poly I:C showed accelerate telomere shortening compared to those who received a saline solution, potentially indicating a causal role of ROS in telomeric loss. Finally, the rate of individual's telomere shortening correlated with its agitation and bold personality. Our study provides support for an association between air pollution and telomeric loss, and for a relation between telomere shortening and personality traits. Our finding calls into question the role of telomere length in behavioural modulation, and we hypothesize that the mechanism of action may reside in the TPE. We hypothesize the adverse outcome pathways (AOP) for which chronic exposure to urban pollution may alter animal personality, through a different expression of genes that regulate behaviour by the telomere position effect, triggered by ROS-induced telomere shortening.

1.04.P-Tu002 Exploring the Effects of Two Surface Coatings on Titanium Dioxide Nanoparticles in "Danio rerio" Embryos

Mário Araújo[1]*, Elza Fonseca*[1]*, Elizabeth Bigorra-Ferré*[1]*, Carla Ferreira Melo*[2]*, Sergio Fernández-Boo*[1]*, Laura Rodriguez-Lorenzo*[3]*, Miguel Oliveira*[4]*, Vitor Vasconcelos*[1,5]*, Begoña Espina*[6] *and Alexandre Campos*[1]*, (1)University of Porto, Interdisciplinary Centre of Marine and Environmental Research (CIIMAR), Portugal, (2)University of Aveiro, Portugal,*

(3)Water Quality Group, International Iberian Nanotechnology Laboratory (INL), Portugal, (4)University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Portugal, (5)Department of Biology, Faculty of Sciences, University of Porto, Portugal, (6)International Iberian Nanotechnology Laboratory, Portugal
The environmental safety of titanium dioxide nanoparticles (TiO_2 NPs) is under increasing debate. Previous works showed that TiO_2 NPs with a primary size of 5 and 25 nm induce hepatocyte ultrastructural alterations, along with metabolic alterations, inflammation, and oxidative stress in fish. However, these effects depend on several variables, such as average particle size, route of exposure, and sensitivity/resistance of the model organism. Since the type of surface coating is also reported to affect the biological response of NPs, in the present work, we studied alterations induced by 45 nm TiO_2 NPs exposure with two different coatings [sodium citrate and N-(trimethoxysilylpropyl)ethylenediamine, triacetic acid (EDTA-silane)] using *Danio rerio* embryos. Three trials were performed to study (i) developmental effects (inc. hatching, length, and malformations), (ii) behaviour (inc. swimming distance and responses to light/dark transitions), and (iii) gene expression (alterations of genes involved in the regulation of oxidative stress - CAT and SOD, immune responses and inflammation - NFKB1 and PPARab, and lipid metabolism - ACOX1, CPT1ab, PPARab, HADH, and ELOVL5). The concentrations tested ranged between 5 and 200 mg TiO_2 NPs/L.

Overall, the exposure to 45 nm TiO_2 NPs with the two tested coatings induced relatively low harmful effects on *D. rerio* embryos regarding early life development. However, gene expression alterations were observed to depend on the type of surface coatings. Genes related to lipid metabolism (HADH and ELOVL5), oxidative stress (SOD), and immune response (NFKB1) are differentially modulated by the type of coating, with EDTA-silane inducing more alterations (mostly down-regulation of genes) than sodium citrate. Besides, behavioural alterations (swimming distance and inactivity) were detected, suggesting more stress on organisms exposed to the EDTA-silane-coated than the citrate-coated TiO_2 NPs.

While waterborne exposure to 45 nm TiO_2 NPs may seem relatively less toxic to aquatic organisms when compared to other lower-sized NPs, some surface coatings may increase their reactivity and interaction with (bio)molecules, and the overall toxicity to aquatic organisms. Given the immense range of parameters reported to affect the biological response to engineered nanomaterials exposure, general assumptions on nanoparticle safety/toxicity should be taken carefully.

1.04.P-Tu003 Is Disrupted Reproductive Behaviour Population-Relevant?
***Charles Hazlerigg**[1], Alice Tagliati[1], Laurent L.-M. Lagadic[2], Edward Salinas[2] and Thomas G Preuss[2], (1)Enviresearch Ltd., United Kingdom, (2)Bayer AG - Crop Science Division, Germany*
Plant Protection Products and Biocides that are classified as EDCs will no longer be approved for use in the EU. Recently, there has been a growing interest in behavioural endpoints as EDCs have been shown to alter fish reproductive behaviours. Furthermore, environmental assessments are focussed on protection of wild populations, not individual organisms. Population models provide the potential to explore the population relevance of chemically-induced changes in individual behaviour. Here we present a study using a stickleback IBM to explore the population response to EDC-induced changes in reproductive behaviour; nesting and courtship behaviour.

After a 3-year spin-up period to stabilise the modelled stickleback population, hypothetical chemical effects were imposed disrupting the nesting and courtship behaviour of male stickleback. The behaviours were disrupted at four magnitudes: 10, 20, 50 and 90%. The effects were imposed continuously for 10 years. For each scenario, 70 simulations were performed. The population (abundance and biomass) response was evaluated across the entire 10 year effect period. The evaluation criteria used to determine an adverse population effect were taken from the recent EFSA Birds & Mammals guidance.

10 and 20% disruption in courtship behaviour did not lead to any adverse effects on the stickleback population. 50% disruption in courtship behaviour did lead to an observable reduction in abundance and biomass, whist 90% disruption in courtship behaviour almost led to population extinction within the 10 years. Meanwhile, no population effects were observed following disruption of nesting behaviour at any of the four testing magnitudes of effect (data not shown). When comparing with effects on fecundity and sex ratio (male skew), the stickleback population was shown to be less sensitive to disruption of nesting and courtship behaviour.

Here we demonstrate how models can be used to assess the population relevance of disrupted behaviour observed in laboratory studies. Disruption of different behaviours have different population relevance. Results also show that other endpoints may be more relevant for population level assessment, making behavioural endpoints an indicator of endocrine activity rather than adversity in terms of the regulatory criteria.

1.04.P-Tu004 A Multifactorial Environmental Stressors Approach: Chironomus riparius Exposed to Sulfoxaflor with Presence of Predator Cues and Increased Temperature
***Sofie Bruun Rasmussen**[1], Thijs Bosker[1], S. Henrik Barmentlo[2], Olof Berglund[3] and Martina G. Vijver[2], (1)Leiden University, Netherlands, (2)Institute of Environmental Sciences (CML), Leiden University, Netherlands, (3)Lund University, Sweden*
Growing evidence suggests that standard toxicity testing might underestimate the environmental risk of neurotoxic insecticides by not accounting for potential sublethal effects. Behavioural endpoints such as locomotion and mobility have been suggested as both sensitive and ecologically relevant alternatives to the standard tested endpoints to predict sublethal effects more

accurately. Additionally, low levels of environmental realism in conventional toxicity testing raise concerns, as possible synergistic effects of a chemical and additional stressors are typically overlooked in standard risk assessment. Therefore, we aimed to investigate how concurrent exposure to environmental stressors and a nicotinic acetylcholine receptor (nAChR)-modulating insecticide ('sulfoxaflor') impact *Chironomus riparius* across a wide range of conventional and non-conventional responses.

To this end, a multifactorial experimental design encompassing three stressors, sulfoxaflor (at six different concentrations), predation risk (presence/absence of predatory cues), and temperature stress (20°C and 23°C), was used, yielding a total of 24 distinct treatment conditions. To assess potential additive effects, we applied the Independent Action (IA) model to predict the impact on eight endpoints, including standard endpoints (e.g., growth, survival, and emergence) and less conventional endpoints (e.g., swimming abilities and exploration behaviour). For the standard endpoints, observed effects were either lower than expected or well-predicted by the IA model. In contrast, we found synergistic effects of predation cues and temperature in combination with sulfoxaflor on adult size and larval exploration behaviour. Furthermore, the results indicated synergistic effects on larval swimming velocity between sulfoxaflor and increased temperature but not when combined with predation cues.

In conclusion, the results show that the total emergence of *C. riparius* is sensitive to the effects of sulfoxaflor, confirming their importance for standard ecotoxicity testing. However, we also found that conventional endpoints such as emergence, mortality, and growth do not pick up on possible synergistic effects between the neurotoxic insecticide and important environmental stressors: predation cues and increased temperature. Awareness of this disparity will be critical for future studies and to improve risk assessment.

1.04.P-Tu005 Effects of Chemical Stresses on the Freshwater Mussel Dreissena polymorpha's Crawling Behaviour
Nicolas Berthelot[1]*, Melissa Palos Ladeiro Dr.*[1]*, Mathilde Orquevaux*[2] *and Alain Geffard Pr*[1]*, (1)UMR-I 02 Sebio, University of Reims Champagne-Ardenne (URCA), France, (2)Direction de l'Eau et de l'Assainissement, Communauté urbaine du Grand Reims, France*
Bivalves are relevant organisms in which it can be measured biological responses (biomarkers) for water toxicity assessment. In this context the freshwater zebra mussel, *Dreissena polymorpha*, is a widespread sentinel species. Behaviors are known as biomarkers offering early responses to stresses. In bivalves there are many methods based on valvometry measurement (valves closures). But in *D. polymorpha* the other behaviors, as crawling, are largely under-researched. So, the present work aims to answer the question: can the locomotion be modulated by chemical stress in zebra mussels? Experiments was conducted in laboratory on young (10-15 mm) mussels. It consists of seven separately exposures (7 days) to copper, lead, triclosan, metformin, fluoxetin, and ofloxacin at 0; 1; 10; 100 and 1.000 µg/L, and to chlorpyrifos at 0; 0,1; 1; 10 and 100 µg/L. After the exposure step the crawling of mussels for each chemical condition is recording by video tracking. Significantly lower distances were registered in organisms exposed to 100 and 1.000 µg/L of copper with a mean individual distance of 19.22 mm for 0 µg/L but only35 mm and 0.88 mm for 100 and 1.000 µg/L respectively. The mobility rate (number of mussels which have moved) is also significantly linked to the concentration, with 13 unmoving mussels for 0 µg/L and 25 unmoving mussels for 1000 µg/L. These results could be explain by the fact that copper is a biocide and it is attested as decreasing mobility in other bivalves. For fluoxetine exposure, mean individual distance is 12.63 mm for 0 µg/L exposed mussels while it is significantly higher (26.38 mm and 33.60 mm respectively) for 100 and 1.000 µg/L. The mobility rate did not depend on fluoxetine concentration. The increased crawling distances could be result from a stimulant effect of the fluoxetine regarding the mode of action of this pharmaceutical which is a selective inhibitor of the serotonin reuptake. To complete the discussion about present results with copper and fluoxetine other parameters as speed or delay before crawling can be used for describe the mobility. This work is in our knowledge the first evidences of chemical exposures effects on the locomotion in *D. polymorpha*. These present results show that *D. polymorpha* locomotion can be modulate under a chemical stress by increasing as well as decreasing traveled distances, showing a promitting potential for crawling as futur tool in biomonitoring.

1.04.P-Tu006 Chronic Exposure of Environmentally Relevant Concentration of Tire Derived Chemical Causes Anxiety-like Behavior and Memory Deficits in Adult Zebrafish
Hohyun Jin *and Kitae Kim, Seoul National University of Science and Technology, Korea, Republic of (South)*
The presence of 2-((4-Methylpentan-2-yl)amino)-5-(phenylamino)cyclohexa-2,5-diene-1,4-dione(6PPDQ), an oxidation product of the tire antioxidant N-(1,3-Dimethylbutyl)-N'-phenyl-p-phenylenediamine (6PPD), has been known as the causative substance for a syndrome of mass mortality in Coho salmon before spawning in the northwestern United States[1]. Furthermore, tire-derived chemical have been found to exert a wide range of toxic effects on various species of fish. And these studies reported abnormal behavior such as ventilation failure, gasping, spiraling, and loss of equilibrium [2]. We hypothesized that these fish's behaviors were induced due to neurotoxicity, and we assess changes in neurobehaviors in adult zebrafish after chronic exposure to them at environmentally relevant concentrations. And neurosteroid analysis was conducted to unravel the underlying neurotoxicity mechanism.

Overall, we demonstrated the commonality in potential neurotoxicity of 6PPD and 6PPDQ as confirmed by neurobehavior assessment and neurosetorid analysis. Even taking into account the difference exposure methods and durations, both 6PPD and 6PPDQ casued anxiety-like behaviors in NTT assay and did not memory and learning deficits in T-maze test. Also, it is highlighted that profiles of neurosteroids affected by both 6PPD and 6PPDQ were similar, showing that Allopregnanolone and its precursor Progesterone, Estradiol, Testosterone associated with $GABA_A$ and NMDA receptor dysfunction were reduced. The alteration of these neurosterodis well explain the anxiety-like neurobehavior inducement and also suggests the potential for neurotoxicity associated with memory, excitatory, etc. although memory deficits were not observed in neurobehavior phenotypic observations. Our findings provide the insight to more deeply explore the similarity of neurotoxicity mechanism of 6PPD and 6PPDQ, and further related studies should be conducted to better understand the toxicity of both substances.

1.04.P-Tu007 From behaviour to gene transcription. Unraveling the molecular mechanisms that regulate diel vertical migration in th zooplanktonic Daphnia magna
María Paula Carrillo Losada[1], Benjamin Pina[1], Maria Vila-Costa[2] and ***Carlos Barata Dr**[2]*, *(1)Environmental Chemistry, Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain, (2)Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain*
Animal behaviour is closely related with individual fitness allowing animals to choose suitable mates or avoid predation. The central nervous system (CNS) regulates many aspects if not all of animal behaviour responses, therefore behavioural responses can be special sensitive to compounds with a neurodevelopmental or neuro-functional mode of action. Phototactic behavioural changes against fish in the freshwater crustacean *Daphnia magna* have been the subject of many ecological and more recently genomic investigations. The aim of this study was to identify the molecular pathways that modulate the phototactic behaviour to fish kairomones. We used two clones showing two contrasting responses. A positive phototactic clone ($P_1$32,85) that shows a marked negative phototactism after exposure to fish kairomones, to the muscarinic acetylcholine receptor scopolamine, and additive effects when exposed to both treatments; and a negative phototactic clone F that shows the opposite behaviour was . Fish conditioned water was obtained with juveiles of *Leuciscus idus*. Adults of both clones were exposed to three treatments plus their respective unexposed control: fish kairomnes and scopoplamine alone and its mixture. Whole transcriptomic illumina analyses indicated a greater number of de-regulated genes of the fish kairomone sensitive clone $P_1$32,85 (1650) than the F one (1138), which were grouped in four clusters (two per clone). Two of the clusters (A) grouped genes down-regulated by the tested treatments, whereas in clusters (B) genes were up-regulated. In both clones gene transcription there was also additivity in animals exposed to both scopolamine and fish kairomone treatments. From the 35 enriched functional KEGG pathways 11 were shared by all clusters, whereas 14 and 5 were unique for clones $P_1$32,85 and F, respectively. Over 50% of the shared and clonal specific metabolic routes were related with neurological pathways and regulation of cell proliferation/differentiation, whereas specific routes of the most responsible clone $P_1$32,85 included the Wnt signaling pathway. Our results indicated that fish kairomone de-regulate not only neurological signalling routs but also cell differentiation/proliferation ones that a linked with the observed behavioural responses and the reported morphogenetic effects.

1.04.P-Tu008 Impacts of a Psychoactive Pollutant on Interactions Between Native and Invasive Freshwater Fish
***Raiko Rafeeq**[1]*, *Minna Saaristo[2] and Bob Wong[3], (1)School of Biological Sciences, Monash University, Melbourne, Australia, (2)Environment Protection Authority Victoria, Australia, (3)School of Biological Sciences, Monash University, Australia*
As the need for medications continues to rise worldwide, pharmaceuticals are being increasingly detected in the environment. In particular, the antidepressant venlafaxine has become one of the most pervasive pharmaceutical pollutants in aquatic systems. The receptors targeted by venlafaxine are conserved across most animal groups, and venlafaxine can therefore affect ecologically important traits in non-target organisms. Disruptions to behavioural traits, such as boldness and aggression, can lead to changes in both intra- and interspecific interactions, causing further disturbances to vital ecological processes, including competition and predation. These interactions also play a key role in mediating invasion success, but research on the impacts of chemical pollution on native-invasive species interactions remains scarce. As such, our study aimed to investigate whether exposure to environmentally realistic concentrations of venlafaxine affected interspecific behavioural interactions between the southern pygmy perch (*Nannoperca australis*), a small freshwater fish native to Australia, and the invasive eastern mosquitofish (*Gambusia holbrooki*). Fish were exposed to either an unexposed freshwater control (i.e., no venlafaxine), low-venlafaxine exposure (0.5 µg/L), or high-venlafaxine exposure (1 µg/L) for 28 days. Following the exposure period, individuals were matched with a heterospecific from the same exposure treatment and both fish completed a behavioural trial to test aggression and foraging behaviours in the presence of a competitor. Preliminary results show that whilst there were no significant effects of venlafaxine treatment on aggressive behaviours in either species, mosquitofish in the high treatment were faster to first consume a prey item in comparison to the control treatment. This effect was not observed in southern pygmy perch, demonstrating a species-dependent effect of venlafaxine. A possible consequence of this effect could be that non-natives may outcompete native species, potentially leading to cascading effects on community structure and function. These findings highlight the need to better understand the complex interactions between different forms of human-induced environmental change.

1.04.P-Tu009 Cardiac and Neurobehavioral Impairments in Three Phylogenetically Distant Aquatic Model Organisms Exposed to Environmentally Relevant Concentrations of Boscalid

Juliette Bedrossiantz[1]*, Júlia Goyenechea*[2]*, Eva Prats*[3]*, Cristian Gómez-Canela*[4]*, Carlos Barata Dr*[5]*, Jérôme Cachot*[6] *and Demetrio Raldua*[1]*, (1)Environmental Toxicology, Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain, (2)IQS School of Engineering, Ramon Llull University, (3)CID-CSIC, Spain, (4)School of Engineering, Institut Químic de Sarrià-Universitat Ramon Llull, Spain, (5)Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain, (6)EPOC CNRS, University of Bordeaux, France*
Boscalid (2-Chloro-N-(4'-chlorobiphenyl-2-yl) nicotinamide), a pyridine carboxamide fungicide, is an inhibitor of the complex II of the respiration chain in fungal mitochondria. As boscalid is only moderately toxic for aquatic organisms (LC_{50} > 1 -10 mg/L), current environmental levels of this compound in aquatic ecosystems, in the range of ng/L-µg/L, are considered safe for aquatic organisms. In this study, we have exposed zebrafish, Japanese medaka and *Daphnia magna* to a range of concentrations of boscalid (1-1000 µg/L) for 24-h, and the effects on heart rate (HR), basal locomotor activity (BLA), visual motor response (VMR), startle response (SR), and habituation (HB) to a series of vibrational or light stimuli have been evaluated. Moreover, changes in the profile of the main neurotransmitters have been determined. Boscalid altered HR in a concentration-dependent manner, leading to a positive or negative chronotropic effect in fish and *D. magna*, respectively. While boscalid decreased BLA and increased VMR in Daphnia, these behaviors were not altered in fish. For SR and HB, the response was more species- and concentration-specific, with Daphnia exhibiting the highest effects. At the neurotransmission level, boscalid exposure decreased the levels of L-aspartic acid in fish larvae and increased the levels of dopaminergic metabolites in *Daphnia magna*. Our study demonstrates that exposure to environmental levels of boscalid alters cardiac rate, impairs ecologically relevant behaviors, and leads to changes in different neurotransmitter systems in phylogenetically distinct vertebrate and invertebrate models. Thus, the results presented emphasize the need to review the current regulation of this fungicide.

1.04.P-Tu010 The C.elegans as a Reliable Tool in Neuro-Behavioural Toxicology: Case study of Diesel Exhaust Particles
Nivedita Chatterjee[1] *and Ernesto Alfaro-Moreno*[2]*, (1)International Iberian Nanotechnology Laboratory, Portugal, (2)NanoSafety Group, International Iberian Nanotechnology Laboratory, Nanosafety, Portugal*
Exposure to particulate matter is increasingly associated with a heightened risk of neurodegenerative diseases, particularly Alzheimer's disease. This study investigates the behavioural and neurotoxic effects of diesel exhaust particles (DEP) on glutamatergic and dopaminergic neurons in the model organism *Caenorhabditis elegans* (*C. elegans*). Locomotion behaviours were assessed in two modes: swimming in a liquid medium using the Wmicrotracker system and crawling path and velocity analysis using the Image J system with captured video on NGM agar plates. A significant reduction in average speed ($p < 0.001$), altered crawling paths, and decreased swimming activities ($p < 0.01$) were observed under mid (0.167 µg/cm²) to higher (1.67 µg/cm²) concentrations. Evaluation of neurodegeneration markers in glutamatergic (DA1240) transgenic worms revealed notable degeneration in glutamatergic neurons at both concentrations. At 0.167 µg/cm², approximately 30% exhibited moderate degeneration, with 20% showing advanced degeneration. At 1.67 µg/cm², around 28% displayed moderate degeneration, and 24% demonstrated advanced degeneration ($p < 0.0001$). Dopaminergic neurons (BZ555 transgenic strain) exhibited structural deformities without significant degeneration. In summary, DEP exposure induces distinctive neurodegenerative effects in *C. elegans*, with glutamatergic neurons being more vulnerable, suggesting a potential link between locomotion defects and glutamatergic neurodegeneration.

Keywords: Diesel exhaust particles (DEP), *C. elegans*, behaviour, Glutamatergic neurons, and Dopaminergic neurons, Neurodegenration

1.04.P-Tu011 Neurotoxicity evaluation of β-citronellol, a major component of air freshener, in adult zebrafish
Soyeon Park*, han-Seul Lee and Kitae Kim, Seoul National University of Science and Technology, Korea, Republic of (South)*
β-citronellol is a substance incorporated into perfumes and various household chemical products for fragrance enhancement. β-citronellol has been known to have positive effects at low concentrations, such as suppressing the activity of nerve cells related to pain signals, but its effects at high concentrations are not studied. Therefore, in this study, changes in neurobehaviors were evaluated in adult zebrafish after exposure to β-citronellol in adult zebrafish, and the alteration in endogeneous concentration of a total of neurochemicals and neurosteroids were measured in the brain using LC-MS/MS to explore the neurotoxicity mechanism. Male zebrafish were exposed to β-citronellol for 14 days at concentrations of 0, 0.04, 0.2, and 1.0 mg/L. Considering the stability of β-citronellol and the fragrance exposure scenarios, we conducted exposure for 4 hours daily. The test solution was changed every day to maintain the concentration of β-citronellol. The exposure conditions were determined based on instrumental analysis reulst that measured changes in the concentration of β-citronellol in the exposure tank. After exposure, three behavioral assays(i.e., novel tank test(NTT), photomotor response test (PMR) and T-maze test) were performed immediately to investigate neurobehavioral changes in response to β-citronellol. Neurotransmitters and neurosteroids were measured in dissected brain samples using LC-MS/MS. Behavioral assessment revealed that β-citronellol induced anxiety and memory impairment in zebrafish at all exposure concentration groups, and photosensitivity damage was observed at 1.0 mg/L exposure group. The result of neurosteroids, cortisol, which regulates stress and anxiety, increased in a concentration-dependent manner. Additionally, a significant decrease in progesterone and its metabolite allopregnanolone, was observed. Significant changes were also observed in neurochemicals related to the GABAergic system, dopaminergic system, and cholinergic system. Overall, in this study, we demonstrated that above a certain concentration of β-citronellol disrupts the balance between neurochemical systems and neurosteroids in zebrafish, leading to alterations in neurobehavior such as memory and anxiety. These results suggested that the high concentration of β-citronellol, which is mainly used in air freshener

products, must be well managed, and that an actual survey is needed to determine how much β-citronellol is contained in air freshener products.

1.04.P-Tu012 Effects of Acute 6PPD-Quinone Exposure on Swimming Performance and Aerobic Metabolism in Juvenile Lake Trout (Salvelinus namaycush)

Summer Selinger[1]*, Markus Hecker*[2]*, Steve Wiseman*[3]*, Lynn Weber*[1]*, David M. Janz*[4] *and Markus Brinkmann*[5]*, (1)University of Saskatchewan, Canada, (2)Toxicology Centre and School of the Environment and Sustainability, University of Saskatchewan, Canada, (3)University of Lethbridge, Canada, (4)Western College of Veterinary Medicine and Toxicology Centre, University of Saskatchewan, Canada, (5)Toxicology Centre, University of Saskatchewan, Canada*

N-(1,3-Dimethylbutyl)-N′-phenyl-p-phenylenediamine-quinone (6PPD-quinone) is a transformation product of the most widely used rubber tire antioxidant, 6PPD. Commonly found in road-way runoff, a variety of studies have reported this compound to cause acute lethality in several salmonid species at roughly ≤ 1 μg/L, including lake trout (*Salvelinus namaycush;* 24 h LC_{50} = 0.51 μg/L). However, there is currently a lack of research targeted at understanding sublethal toxicities of 6PPD-quinone exposure, particularly on swimming performance. Sensitive species show characteristic symptoms including gasping, spiraling, increased ventilation, loss of equilibrium and impaired swimming ability, suggesting a possible impact on cardiometabolic physiology. To evaluate potential effects of 6PPD-quinone on swimming performance and aerobic metabolism, juvenile lake trout were exposed to nominal aqueous concentrations of 0 or 0.5 μg/L in a swim tunnel respirometer for 20 hours to assess temporal changes in standard metabolic rate (SMR) compared to unexposed controls. Following exposure, fish underwent a swim trial to determine critical swim speed (U_{crit}), oxygen consumption (MO_2), active metabolic rate (AMR), aerobic scope (AS) and energetic cost of transport (COT). After conducting the swim trial, fish were euthanized, and concentrations of muscle triglycerides and glycogen were determined. Preliminary data show that 6PPD-quinone exposure does not significantly impact oxygen consumption rates or energetic cost of transport during a critical swim test. In contrast, exposure appeared to cause a significant decrease in critical swim speed and active metabolic rate, providing evidence of altered metabolism. These results suggest that aqueous 6PPD-quinone exposure at environmentally relevant concentrations produces adverse effects that can diminish endurance and maximum swim speeds, which may affect survival of fish populations. This is the first study to analyze the toxicity of 6PPD-quinone on the swimming performance of fishes of commercial, cultural, and ecological importance and provides urgently needed information for environmental risk assessments of this emerging contaminant of concern.

1.04.P-Tu013 Frontiers in Quantifying Wildlife Behavioural Responses to Chemical Pollution

Michael Grant Bertram[1]*, Jake Mitchell Martin*[2] *and Tomas Brodin*[1]*, (1)Wildlife, Fish and Environmental Studies, Swedish University of Agricultural Sciences (SLU), Sweden, (2)Swedish University of Agricultural Sciences (SLU), Sweden*

Animal behaviour is remarkably sensitive to disruption by chemical pollution, with widespread implications for ecological and evolutionary processes in contaminated wildlife populations. However, conventional approaches applied to study the impacts of chemical pollutants on wildlife behaviour seldom address the complexity of natural environments in which contamination occurs. This presentation aims to guide the rapidly developing field of behavioural ecotoxicology towards increased environmental realism, ecological complexity, and mechanistic understanding. We identify research areas in ecology that to date have been largely overlooked within behavioural ecotoxicology but which promise to yield valuable insights, including within- and among-individual variation, social networks and collective behaviour, and multi-stressor interactions. Further, the review features methodological and technological innovations that enable the collection of data on pollutant-induced behavioural changes at an unprecedented resolution and scale in the laboratory and the field. In an era of rapid environmental change, there is an urgent need to advance our understanding of the real-world impacts of chemical pollution on wildlife behaviour. This review therefore provides a roadmap of the major outstanding questions in behavioural ecotoxicology and highlights the need for increased cross-talk with other disciplines in order to find the answers.

1.04.P-Tu014 Evaluation of ecological toxicity for remediated soils contaminated with heavy metal using earthworm: Study on mechanism of toxicity manifestatio

Woo-chun Lee[1]*, Soon-oh Kim*[2] *and Sang-Woo Lee*[1]*, (1)HS Environmental Technology Research Center, Hosung Inc., Korea, Republic of (South), (2)Department of Geology and Research Institute of Natural Science, Gyeongsang National University, Korea, Republic of (South)*

The firing range soil contaminated with heavy metals was remediated through a washing process. Heavy metal concentrations can be lowered below soil contamination standards, soil health deteriorated during the remediation process. Hence, there is a need for suitable techniques and methods to validate them for recovering the low-health remediated soil. The objective of this study was to explore techniques for recovering low-health contaminated soil and to verify the recovery levels using chemical and biological methods. The agents used in the recovery technology were vermicompost (biological agent), biochar (organic agent), and lime soil (inorganic agent). The soil mixed with the agents and remediated soil was aged while providing constant moisture for two weeks. The verification of soil health using earthworms utilized both OECD methods and the VISSET (Vibration Sensor for monitoring of Soil Ecological Toxicity) developed by the researchers. Earthworm survival rate, body weight change rate, and bioaccumulation concentration (BAF) methods were commonly applied, but earthworm behavior was additionally evaluated using the VISSET test method. The earthworm survival rate and weight variation in the remediated soil decreased significantly compared to the uncontaminated soil. This indicates a greater deterioration in soil health during the remediation process than during the contamination process. The results of earthworm activity also showed a significant increase in the remediated soil, indicating stress imposed on the earthworms. In soils treated with vermicompost and

vermicompost + lime soil, earthworm activity levels similar to uncontaminated soil, and it was confirmed that the level of chemical recovery was high. Conversely, in experiments utilizing biochar, lower chemical recovery levels were observed, and reduced earthworm activity was attributed to skin irritation. Since deterioration of soil health can occur not only during the contamination process but also during the remediation process, it is considered necessary to apply appropriate techniques to recovery the health of remediated soil for its reuse and recycling.

1.04.P-Tu015 Toxicokinetic and behavioral effects of environmentally realistic microplastics
Andrew Barrick *and Tham C. Hoang, Auburn University*
Plastics are ubiquitous substances with approximately 42,000 tons entering the environment annually. Upon entering the environment, plastics can be broken into micro(nano)plastics, particles with three dimensions <5mm, which increases their potential for bioaccumulation and trophic transfer. Plastics also contain hydrophobic contaminants. Micro(nano)plastics can potentially be novel vectors for biological uptake of these chemicals. Some plastics have neurotoxic additives such as phthalates, which can influence the behavior of exposed organisms. Alteration to behavior can influence predator-prey relationships and eventually cascade into ecological impacts. The relationship between plastics, neurotoxic additives, and environmental impact is poorly understood. Plastics are hydrophobic and are rarely neutrally buoyant, causing them to either float on the top of test chambers or sink to the bottom. This makes it difficult to establish dose-response profiles as the number of plastics introduced into a testing chamber is not equivalent to the number of plastics an organism will interact with. Therefore, it is necessary to understand the behavior surrounding consumption, excretion and retention of micro(nano)plastics to comprehend ecotoxicity. This presentation explores the toxicokinetics of micro(nano)plastic uptake and excretion, how it affects behavior, and how bioaccumulation relates to acute toxicity. Environmentally realistic micro(nano)plastics were prepared at <120µm by cyromilling commercially available plastic cups and forks. *Daphnia magna*, an aquatic crustacean, was exposed to plastic cup and fork particles following a dose-response format to determine acute toxicity and bioaccumulation. Both plastic fork and cup plastics were identified to be polyethylene and of similar sizes after cryogrinding, indicating that physical properties were comparable. Plastics were not acutely toxic towards *D. magna*. Marked differences in bioaccumulation and depuration between fork and cup particles were observed. Behavioral analysis demonstrated no change in localization of organisms within test chambers but demonstrated there may be slight alterations in how fast they moved. The study shows that minor changes in plastic composition, in particular color, can influence the uptake kinetics of micro(nano)plastics.

Keywords: behavioral effects, environmentally realistic plastics, *Daphnia magna,* dose-response relationships

1.04.P-Tu016 Interactions between chronic pollution and behavioural variability within and among individuals of aquatic invertebrates.
Harmony Lautrette-Quinveros[1]*, Olof Berglund*[1]*, Viktor Nilsson*[2] *and Anders Nilsson*[1]*, (1)Lund University, Sweden, (2)Aquatic Ecology, Lund University, Sweden*
Environmental pollution is often characterized by low-dose, chronic exposure regimes. Dose-response relationships of these types of exposure often fail to generate major effects on mean response, especially when utilizing conventional endpoints. We hypothesize that non-conventional endpoints like behaviour may capture more subtle effects of pollution and also, that variability in behaviour may be used to predict effects at population and community level. Variability may influence effects of pollution and vice versa, pollution may affect variability. These changes in variability may have profound effects on species interactions, and population dynamics, e.g. predator-prey interactions.

The aim of this project is to assess impact of low-dose chronic exposure of an antidepressant Fluoxetine and a metal Copper on behaviour and metabolism in populations of the freshwater isopod, *Asellus aquaticus*. First, we quantify within and among individual behaviour of wild populations of *A. aquaticus* and test the behavioural syndrome and pace-of-life hypothesis. Second, we test the effect of Fluoxetine and Copper on within and among variability of individual behaviour and metabolic rate. Third, we will test predictions generated on pollutant effects on the predator-prey dynamics in a mesocosm set-up with realized predation.

Here, we present results from the first step where behaviour and metabolic rate of wild-caught *A. aquaticus* was quantified without exposure to chemicals. We tested associations among behaviours i.e., behavioural syndrome, repeatability, and if behaviours were correlated with metabolic rate i.e. the pace-of-life hypothesis. We selected behaviours that strongly influence predator-prey interactions like activity, boldness/exploration and escaping behaviour. Activity and boldness/exploration showed a high repeatability and were positively correlated. *A. aquaticus* metabolism was a repeatable endpoint but was not correlated with any other endpoints measured.

This project is part of the CHRONIC project funded by EU under the Marie Sklodowska-Curie Actions, and the aim is to incorporate findings into Environmental Risk Assessments using low-dose chronic chemical exposure and non-conventional endpoints to identify sensitive ecosystems at risk.

1.04.P-Tu017 Assessing the Behavioural Sensitivity of Gammaridae to Pesticides and Pharmaceuticals
Elien Versteegen[1]*, Edwin Peeters*[1]*, Ivo Roessink*[2] *and* ***Paul van den Brink***[2]*, (1)Aquatic Ecology and Water Quality*

Management, Wageningen University & Research (WUR), Netherlands, (2)Wageningen University & Research (WUR), Netherlands
Freshwater systems are continually exposed to various was streams, including municipal wastewater and agricultural runoff. Pollutants in the aquatic environments might change the behaviour of animals. Gammaridae are essential in marine and freshwater ecosystems as both decomposers, prey, and predators. Changes in their behaviour as a result of environmental pollution, may impact their ecological roles in the food chain.

In this study we aim to provide more insight in whether behavioural responses are potentially reliable forebodes for toxic effects in our aquatic environments. Therefore, we evaluate the sensitivity of swimming activity as an endpoint compared to mortality and immobility and compare how this sensitivity of swimming related endpoints differs between toxins with different modes of action.

In four laboratory experiments, we exposed the gammarid *Gammarus. pulex* to different compounds (two pesticides: imidacloprid (IMI) and chlorpyrifos (CPF), and two pharmaceuticals: carbamazepine (CBZ) and citalopram (CIT)) with different modes of action. After 48-h of exposure the dead and immobile organisms are counted, after which the swimming activity of all mobile organisms was individually assessed.

The immobility count was a more sensitive endpoint then mortality (EC50 < LC50) for IMI, CPF and CIT, while no mortality and immobility was observed in organisms exposed to CBZ concentrations up to 2000 µg/L. Exposure to IMI, CIT or CBZ resulted in a decreased swimming speed and acceleration of *G. pulex* individuals, additionally, IMI exposure also resulted in a decreased thigmotaxis. No behavioural effects are observed after exposure to CPF, even though mortality and immobility occur at higher exposure concentrations. On the contrary, CBZ exposure that does not result in immobility or mortality, does influence the organisms swimming behaviour.

The four compounds all have a different ratio between traditional endpoints (mortality and immobility) and swimming behaviour endpoints. The sensitivity of swimming activity and its relation to mortality and immobility differs much between the four tested pollutants. The behavioural endpoints are therefore not a reliable forbode of lethal effects, but these differences in sensitivity can give more insight in the mode of action of these pollutants in *G. pulex*.

1.04.P-Tu018 Review: Opportunities and Limitations of Invertebrate Behaviour as Relevant Endpoint in Ecotoxicological Testing

***Vanessa Saalmann**, Kirsten Germing and Lena Kosak, Ecotoxicology, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany*
Invertebrates are important model organisms in ecotoxicological testing as they occupy key positions in food webs of terrestrial and aquatic ecosystems. Next to the classical endpoints of OECD testing guidelines, environmental relevant chemicals can affect invertebrate behaviour. Behavioural alterations may lead to effects on population level traits, e.g. a reduction in foraging, reproduction, migration or predator avoidance. Therefore, the resulting impacts may affect populations and ecosystems in general function.

Examples for terrestrial invertebrates used as ecotoxicological model organisms are *Apis mellifera*, *Folsomia candida* and *Eisenia andrei* as well as *Daphnia magna* and *Lymnaea stagnalis* as aquatic model organisms. Invertebrates include a wide range of species of terrestrial and aquatic organisms. Much data is available on the ecology of most invertebrates, but often, little is known of the effects of chemicals (pesticides, pharmaceuticals, …) on the behaviour of invertebrates. The OECD guidelines for the testing of chemicals (Section 2: Effects on Biotic Systems) mostly address lethality/immobility, size, hatching, emergence or reproduction and do not consider relevant behavioural endpoints. Behavioural endpoints, whose affection might lead to population-relevant impacts, are phototaxis, locomotion, rheotaxis, activity time and predator avoidance behaviour, among others.

As mentioned above, alterations in behaviour can occur for many parameters and have effects on diverse population-relevant traits. If the vertical migration of daphnids was affected due to chemical exposure, they would not be able to respond to predator presence and be an easy prey. If the swarming behaviour of *Chironomus riparius* was time-shifted by behavioural alterations from chemical exposure, the mating might occur for fewer pairs, leading to a shrinking population. If the defensive behaviour of *Lymnaea stagnalis* was affected, they might not or slower withdraw into their shell and therefore have a raised risk of predation.

The common ecotoxicological model organisms and also non-standard invertebrates shall be examined with regard to their ecology and their suitability for behavioral observations. Literature was reviewed and evaluated based on the suitability, opportunities and limitations for behavioural endpoints in different invertebrates. Existing guidelines are discussed with regard to the possibilities of integrating behavioral endpoints in a regulatory environment.

1.04.P-Tu019 Chronic exposure of environmentally relevant concentrations of the SSRI sertraline impact feeding and behaviour in the freshwater worm Tubifex tubifex

Wing Sze Chan[1], *Martina Santobuono*[1], *Elettra D'Amico*[2], *Henriette Selck*[1] *and Olof Berglund*[3], *(1)Roskilde University (RUC), Denmark, (2)INM, Roskilde University (RUC), Denmark, (3)Lund University, Sweden*
Pharmaceuticals, like antidepressants, have been identified as potential threats to aquatic ecosystems due to their widespread and increasing use, and incomplete removal during wastewater treatment. This study focuses on the potential behavioural effects of the SSRI sertraline, on aquatic invertebrates. These effects, observed at environmentally relevant concentrations, encompass physiological and behavioural endpoints, highlighting the need for non-conventional measures that align with the intended mode of action. Antidepressants, designed to modulate neural and behavioural processes, may induce subtle changes that conventional endpoints might overlook. Incorporating behavioural bioassays, assessing indicators like movement patterns and feeding habits, offers a more comprehensive understanding of the ecological impacts of pharmaceuticals. This inclusion is crucial for identifying and quantifying sublethal effects, safeguarding ecosystem health.

Addressing the limited information on sertraline's impact on behavioural change in sediment-based ecosystems, our study evaluated the chronic toxicity of sertraline on *T. tubifex*. Assessing feeding rate, oxygen consumption, and behavioural changes, we found that sertraline concentrations correlated with reduced feeding rates, increased locomotion, and delayed light avoidance in *T. tubifex*. This research enhances our understanding of sertraline's ecotoxicity in sediment environments, emphasizing the importance of considering behavioural endpoints in environmental risk assessments.

1.04.P-Tu020 Effects Of Copper And Cadmium, Isolated And In Mixture, On The Behavior Of The Copepod Eurytemora Affinis

Giseli Swerts Rocha[1,2,3], *Caroline Arcanjo*[3], *Laís Lopes*[1], *Romain Coulaud*[3], *Aurélie Duflot*[3], *Nathalie Giusti-Petrucciani*[3] *and Céline Boulange-Lecomte*[3], *(1)Escola de Engenharia de São Carlos - USP, Brazil, (2)Chemical Engineering, Universitat Rovira i Virgili, Spain, (3)Sebio, Le Havre Normandy University (ULHN), France*
Metals are ubiquitous in the environment and anthropogenic and natural activities can increase their amounts. Most likely they end up in the aquatic systems, where they can interact among themselves and with other contaminants (e.g., microplastics, bisphenols, pharmaceuticals) resulting in complex mixtures that can affect biota. Copper (Cu) is an essential metal for organisms, while cadmium (Cd) is considered a non-essential metal, which contribute to the challenge of studies dealing with Cu-Cd mixtures. Copepods are an important link between primary producers and higher trophic levels, being sensitive organisms in ecotoxicology studies. *Eurytemora affinis* (Copepoda, Calanoida), which is very representative from estuaries was collected in the Seine estuary (Tancarville, Normandie, France), and were exposed to Cu (20 µg L^{-1}), Cd (30 µg L^{-1}) and their mixtures (CuCd) during 24 h, in addition to control. Velocity of the organisms was evaluated using DanioVision/Ethovision. After 6 min of acclimation in dark conditions in the chamber, 48 organisms per condition were assessed during one cycle of 2 min dark followed by one cycle of 2 min light. Data were evaluated using LMEM (Linear Mixed Effect Model), GLMM (General Linear Mixed Model) and GAMLSS (Generalized Additive Model for Location, Scale and Shape) models in time bins of 10 sec and 2 min. The best adjustment for our data was obtained using the GAMLSS model with ZAGA (zero adjusted gamma) distribution and the time bin of 10 sec. In the time bin of 10 sec, the results indicate a higher activity of the organisms according to the time, with a great inter-individual variance, independent of the treatment. The organisms were more active in light, with a slightly higher velocity in Cu and CuCd treatments, but without significant differences compared to control. For the time bin of 2 min, the organisms were more active in light and with higher velocity in Cu and CuCd treatments. These data indicate how sensitive it is to deal with behavioral analysis since the variance obtained with the organisms can be significant and the use of different time bins can result in different outputs. In addition, we recommend the use of different statistical models to evaluate the responses and to obtain a better data adjustment.

1.04.P-Tu021 Drugs in a Noisy World: A Dangerous Combination

Michael J Barry, *Asma Mohammed Al Shuraiqi, Bayan Al Harrasi, Marwa Al Shammakhi and Reem Al Mukhaini, Biology, Sultan Qaboos University, Oman*
The close proximity of freshwater habitats to urban centres poses direct threats to fish through discharge of chemicals, pharmaceuticals and other wastes. While the effects of a small number of high profile pharmaceuticals are well documented, aquatic habitats can be contaminated with dozens of different chemicals. Simultaneously, human activities generate noise which can penetrate freshwater ecosystems and disturb natural behaviors. While there has been a gradual increase in awareness of the harmful effects of noise on wildlife almost no study has investigated the interactions of sound and chemicals on fish behavior. In this study we exposed zebrafish to either the antibiotic amoxicillin at either 0.2 or 20 µg/L or the anti-inflammatory diclofenac at 0.004 or 4 µg/L, or a combination of both, for 28 days. The behavior of the fish was then measured using a series of standardized behavioural and shoaling tests in the presence and absence of an anthropogenic noise (motor boat). Prior exposure to both drugs affected the fish’s response to noise, including time to emerge in a boldness test, time to reach food and habitat use. Importantly, for future research we noted the order of noise exposure in each test was important. In some cases we observed different outcomes dependent on whether the fish were exposed to control conditions or noise in the first test. Increasingly fish live in a multi-stressor world that includes both chemicals and physical stressors. As the effects of human activities penetrate even the deepest oceans we need a better understanding of the harmful effects of noise

1.04.P-Tu022 Heat Stress Makes Antibiotics More Dangerous to Zebrafish

Asma Mohammed Al Shuraiqi[1], *Michael J Barry*[1], *Raeid M.M. Abed*[2] *and Aziz Al Habsi*[2], *(1)Biology, Sultan Qaboos University, Oman, (2)Sultan Qaboos University, Oman*
The widespread use of antibiotics for humans and livestock has led to widespread contamination of surface waters. Beta-

lactam (amoxicillin) is one of most frequently used antibiotics. After administration more than 80% is eliminated from the body, ultimately ending up in the environment with low biodegradability and high toxicity.

Due to climate change aquatic species are increasingly facing temperature challenges. Temperature is critical for maintaining organism homeostasis including metabolic rate and body function. Thermally stressed fish use heat shock proteins (HSP) as chaperones to mitigate the influence of heat stress through binding to proteins. Increased expression of HSPs is an indicator of temperature stress. Several studies found that HSP70 and HSP90 genes are key biomarkers of thermal stress.

When we combine stressors of different natures simple rules of additive and synergistic effects may not apply. In the present study we measured the effects of environmentally realistic concentrations of amoxicillin at two different temperatures on zebrafish. We analysed the effects of these stressors on fish shoaling behavior and the fish's response to a predator alarm cue.   We also measured levels of heat shock proteins and the composition of the gut microbiome. We hypothesize that: 1) The impact of amoxicillin will be greater at high temperature, 2) Both amoxicillin and high temperature will alter the composition of the gut microbiome, and 3) Both temperature and amoxicillin will inhibit zebrafishes response to predation cues

The results show a strong effect of heat stress the gut microbiome ($p \leq 0.0001$), with no effect of treatment ($p=0.495$) or sex (0.862). All the three exposure factors: amoxicillin, conspecific alarm and heat affected shoaling behavior. In nature fish must respond and adapt to multiple natural and anthropogenic stressors. We found that temperature had a strong effect on the gut micribiome but there was surprising little effect of amoxcillin. On the other hand both temperature and amoxcillin affected fish behavior, as well as the way that the fish responded to an alarm chemical. We live in a complex world. Ecotoxicological studies should reflect this complextity in their design.

1.04.P-Tu023 Neurotoxicity Assessment in Adult Danio rerio using a Battery of Behavioral Tests in a Single Tank
Juliette Bedrossiantz[1]*, Eva Prats*[2] *and Demetrio Raldua*[1]*, (1)Environmental Toxicology, Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain, (2)CID-CSIC, Spain*
The presence of neuropathological effects proved to be, for many years, the main endpoint for assessing the neurotoxicity of a chemical substance. However, in the last 50 years, the effects of chemicals on the behavior of model species have been actively investigated. Progressively, behavioral endpoints were incorporated into neurotoxicological screening protocols, and these functional outcomes are now routinely used to identify and determine the potential neurotoxicity of chemicals. Behavioral assays in adult zebrafish provide a standardized and reliable means to study a wide range of behaviors, including anxiety, social interaction, learning, memory, and addiction. Behavioral assays in adult zebrafish typically involve placing the fish in an experimental arena and recording and analyzing their behavior using video tracking software. Fish can be exposed to various stimuli, and their behavior can be quantified using a variety of metrics. The novel tank test is one of the most accepted and widely used tests to study anxiety-like behavior in fish. The shoaling and social preference tests are useful in studying the social behavior of zebrafish. This assay is particularly interesting since the behavior of the entire shoal is studied. These assays have proven to be highly reproducible and sensitive to pharmacological and genetic manipulations, making them valuable tools for studying the neural circuits and molecular mechanisms underlying behavior. Additionally, these assays can be used in drug screening to identify compounds that may be potential modulators of behavior. We will show in this work how to apply behavioral tools in fish neurotoxicology, analyzing the effect of methamphetamine, a recreational drug, and glyphosate, an environmental pollutant. The results demonstrate the significant contribution of behavioral assays in adult zebrafish to the understanding of the neurotoxicological effects of environmental pollutants and drugs, in addition to providing insights into the molecular mechanisms that may alter neuronal function.

1.04.P-Tu024 Analysis of sleep/wake cycles in zebrafish larvae
Juliette Bedrossiantz[1]*, Marina Ricarte*[2]*, Eva Prats*[3] *and Demetrio Raldua*[1]*, (1)Environmental Toxicology, Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain, (2)Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain, (3)CID-CSIC, Spain*
Zebrafish larvae are a model organism increasingly used in the study of the effect of neuroactive chemicals on vertebrate sleep/wake cycles. Sleep disturbances have a negative impact on mood, cognition and overall health. Here we present a protocol to assess over 24 h sleep/wake cycles in zebrafish larvae subjected to 12 hr light/dark periods in 48-well plates, using video-tracking technologies. The protocol can be used to determine if the exposure to environmental pollutants or drugs can lead to sleep disturbances. The results on the effect of the tire rubber-derived 6PPD-quinone on zebrafish sleep/wake cycles presented here demonstrate the suitability of using this protocol in fish neurotoxicity studies. This protocol provides a new relevant tool to be used in the pharmacology and toxicology fields.
Simultaneous determination of sleep/wake cycles in 48 zebrafish larvae
The determination of sleep/wake state is based on mobility and immobility bouts

1.04.P-Tu025 Chronic Exposure of Bis(2-ethylhexyl) Phthalate Accelerates the Development of Depression Caused by Chronic Stress
Jae Soon Kang*, Ji Hyeong Baek and Hyun Joon Kim, Department of Anatomy and Convergence Medical Sciences, Gyeongsang National University, Korea, Republic of (South)*
Depression is a psychiatric disorder that leads to suicide at a high rate, and a positive correlation between depression and

exposure to environmental pollutants is suspected. In previous studies, we reported that long-term exposure of bis(2-ethylexxyl) phthalate (DEHP) causes depression in a mouse model. DEHP-induced depression occurs by inhibiting glutamatergic neurotransmission through disruption of glutamate (Glu)-glutamine (Gln) homeostasis in the medial prefrontal cortex (mPFC), which is like to the mechanism of chronic stress-induced depression. To investigate the correlation between DEHP exposure and chronic stress in the development of depression, we exposed mice to low levels of DEPH, subjected them to a level of stress that did not cause depression, and observed changes in depressive behaviors and biomarkers of depression. As a result, changes in depressive behaviors and biomarkers were observed in DEHP-exposed and stressed mice, but these changes were not shown in mice DEHP-exposed or stressed mice alone. In DEHP-exposed and stressed mice, the behaviors indicating anxiety, despair and anhedonia were observed, and levels of corticosterone and ROS/RNS were increased. In addition, the disruption of Glu-Gln cycle such as suppressed glutamine synthetase activity and decreased Glu and Gln levels was revealed in mPFC. These results prove that the development of depression can be accelerated by the synergy of exposure to environmental pollutants and chronic stress and notice the need for a new approach in studying the human toxicities of environmental pollutants in the future.

1.04.P-Tu026 Studying behavior and physiological stress in fish: a case study on the effect of artificial light at night on cortisol excretion and accumulation of thinlip mullet (Chelon ramada)

Caroline Roux[1]*, Alex Bois*[1]*, Fabrice Vétillard*[1]*, Patrick Chèvre*[1]*, Marie-Laure Begout*[2]*, Soizic Morin*[3] *and Laure Carassou*[1]*, (1)INRAE EABX, France, (2)MARBEC, Univ. Montpellier, CNRS, Ifremer, IRD, INRAE, France, (3)INRAE UR EABX, France*

Urban ecosystems are submitted to multiple anthropogenic stresses, which impact aquatic communities. Among those urban stressors, artificial light at night (ALAN) affects the aquatic biota. The wavelengths penetrating below the surface and the residual light intensity after diffraction and reflection on it vary according to the physical and biological characteristics of the water (salinity, density, suspended matter, including biological particles, e.g., plankton). All the characteristics of light play a role in the biology and physiology of all the species studied, including fish. The scientific literature highlights species-specific differences in the effects of ALAN on fishes. Furthermore, while the literature on the impact of nighttime illumination on urban biodiversity is growing, studies on fish behavior remain rare. In this work, we used thinlip mullet (*Chelon ramada,* Mugilidae), a common species widely distributed in European urbanized aquatic environments, as a biological model. Thinlip mullet is a rare representative of the herbivore/detritivore trophic guild in the ichthyological fauna, and as such, plays an essential role as a vector of energy between the benthic and pelagic compartments of aquatic food webs. An experiment was set up to understand the effects of ALAN on the behavior and physiological stress of thinlip mullet under controlled conditions. A total of 15 fish were exposed to different light modalities to mimic natural or altered photoperiods in an urban context during four successive trials of 72 hours each. The "control" aquaria received daytime light exposure, followed by no exposure during the night hours, and with gradual day/night transitions to mimic a "natural" photoperiod. The "exposed" aquaria received a continuous light during both day and night and with either direct or indirect modalities, to mimic an “altered” urban photoperiod. Fish behavior was analyzed with video imaging (Ethovision; variables including distance between subjects, movement velocity, distance traveled). In parallel, physiological impacts were assessed by measuring cortisol concentrations in the water and in fish blood at successive time steps. Results are currently being analyzed, but preliminary findings suggest significant differences in swimming and schooling behaviors of fish between the control and exposed conditions, while cortisol response (in the water and in fish blood) appears similar in all conditions.

1.04.P-Tu027 Larval White Sturgeon Behavior Affected by Copper

Holly J Puglis*, Robin Calfee and Edward E Little, U.S. Geological Survey (USGS)*

Early life stage white sturgeon are sensitive to copper with adverse behavioral responses observed during previous studies. The objectives of the present study were to quantify the effects of copper exposure on white sturgeon swimming behaviors and determine their time to response. Larval sturgeon (1 day post hatch) were exposed to copper (0.5-8 µg/L) for 14 days. Abnormal behavioral changes were observed within the first few days of exposure including loss of equilibrium and immobilization. Digital video tracking software revealed decreased swimming activity with increasing copper concentration. Significant changes in behavior and mortality occurred at concentrations of copper between 1-8 µg/L. Effect concentrations were calculated for all responses on Day 14. The 20% lethal concentration (LC20) was 4.36 µg/L Cu and the 20% effect concentration (EC20) for loss of equilibrium/immobility (LOE/IM) was 2.13 µg/L Cu. Swimming activity EC20s ranged from 1.30–1.50 µg/L Cu. Water quality criteria normalized for the test water chemistry using the biotic ligand model was less than the LC20 but greater than the EC20 for LOE/IM and swimming activity endpoints. Our results indicate that behavioral endpoints were more sensitive than some standard toxicity test endpoints and can be effectively expand the sensitivity of standard toxicity tests for white sturgeon. Swimming behavior was impaired to the extent that survival in the field would likely be jeopardized. Such data would provide managers a useful metric for characterizing the risks of copper contamination to white sturgeon.

1.04.P-Tu028 Low Doses of Antidepressants Impair the Visual Motor Response Behavior of Zebrafish (Danio rerio) Embryos − a Red Flag for Developmental Neurotoxicity

Maria Fischer[1]*, Katharina Brotzmann*[1] *and Thomas Braunbeck*[2]*, (1)University of Heidelberg, Germany, (2)Centre for Organismal Studies, University of Heidelberg, Germany*

Venlafaxine, paroxetine, and sertraline, widely used and increasingly prescribed antidepressants, are gaining increasing attention as pollutants in the aquatic environment. Their presence in water bodies is due to excretion by humans and incomplete removal during wastewater treatment. These pharmaceuticals, which have been developed to interfere with neurotransmitter homeostasis in humans at low doses, have the potential to affect aquatic organisms such as fish, as the nervous system of vertebrates is fundamentally similar.

When characterizing the acute effects of these compounds on the developing zebrafish embryo using the Fish Embryo Acute Toxicity (FET; OECD TG 236) test, pericardial edemata, jaw deformation, fin seam degradation and balance disturbances during swimming were observed. At EC_{10} concentrations, behavior was examined in more detail using the visual motor response (VMR) assay, which allows a direct investigation of swimming behavior and the reaction to light-dark transition stimuli. The data showed reduced activity in both, swimming behavior and response to the stimulus.

In summary, the results of the experiments indicate a disruption of key behavior patterns in early life-stages, which in turn may be an indicator of developmental neurotoxicity. Considering the environmental concentrations already present in European waters and the increasing trends in annual prescription rates, these pollutants can pose a realistic threat to the aquatic environment.

1.04.P-Tu029 Testing if and how municipal wastewater effluent affects fish habitat choice in the wild

Erin McCallum[1]*, Petter Lundberg*[1]*, Daniel Cerveny*[1]*, Gustav Hellström*[1]*, Jake Mitchell Martin*[1]*, Natalia Ivone Sandoval Herrera*[1]*, Sarah Rossi*[1] *and Tomas Brodin*[2]*, (1)Swedish University of Agricultural Sciences (SLU), Sweden, (2)Wildlife, Fish and Environmental Studies, Swedish University of Agricultural Sciences (SLU), Sweden*

Wastewater treatments plants (WWTPs) are one of the largest point-sources of nutrient and chemical pollution to freshwater habitats around the world. Mounting evidence shows that WWTP effluents can have detrimental effects on aquatic organisms. And yet, research has shown that fish are still abundant near WWTPs in the wild. This raises an important question: are WWTPs an ecological trap for aquatic wildlife? Ecological traps attract animals, but expose them to sub-optimal conditions facilitating local population declines. To begin to test the hypothesis that WWTPs act as ecological traps, we evaluated whether fish are behaviourally attracted to wastewater effluents in the wild. We measured fish habitat choice and residence time at a WWTP outfall site in Sweden using acoustic telemetry. We deployed an array of acoustic receivers spanning 2 km up- and downstream from the wastewater outfall to track fish movement and habitat choice. We collected and tagged 80 fish of 4 different species representing two prey species (Bream, Rudd) and two predator species (Zander, Northern pike; we tagged 20 fish of each of the four species). We measured their movements after release over 6 months, from May – Oct 2023. We predicted that if fish can detect and are attracted to the effluent (indicating that WWTPs may be an ecological trap), then they will spend longer near the outfall, than in the up- or downstream habitats. Contrarily, if fish are unable to detect the effluent, then we expect fish to distribute themselves along the acoustic receiver gradient with no detectable attraction to the outfall site. We will relate our findings to water quality data and contaminant loadings measured along the river. Although there is mounting concern about the effects of WWTPs on aquatic animals, we still lack data on how long animals reside in effluent impacted habitats. This study will help us understand the extent to which fish are exposed to effluents and the contaminants within them.

1.04.P-Tu030 Zebrafish embryos as model for behavioral toxicology assessment of pharmaceuticals

Claudia Miguel-Sanz, Sofía Barreiro, Christian Cortes-Campos, Valentina Schiavone, Vincenzo Di Donato and ***Anna Navarro-Cuenca****, ZECLINICS, S.L., Spain*

The use of pharmaceuticals has increased in recent years. Since wastewater treatment plants are not efficient in removing these compounds, a fraction are released into aquatic ecosystems, posing concern for both environmental and human health concern. Indeed, the 4th WatchList (Under the Water framework directive) identified some pharmaceuticals like cytostatic drugs as substances of concern.

In Our study, we used zebrafish embryos to evaluate the acute effect of 8 pharmaceuticals, 5 cytostatics (5-fluorouracil, cisplatin, cyclophosphamide, imatinib and dasatinib) and 3 anticonvulsants (topiramate, valproic acid and carbamazepine) on larvae behavior. The use of zebrafish embryos in toxicology represents an alternative strategy aligned with the 3Rs principles, seeking to reduce the impact of experimental procedures on animal welfare. Furthermore, given the substantial costs and prolonged assessments associated with developmental toxicology, zebrafish has emerged as a preferred model organism for conducting high-throughput developmental toxicity studies. Zebrafish embryos were exposed from 6 hpf to 120 hpf and at the end of the exposure, mortalities and effect on behavior were assessed. Behavior was evaluated by using the Light/Dark Transitional test with an acclimatization period followed by a range of light and dark intervals. Substances such as topiramate and 5-fluorouracil did not show mortality or effect on behavior. On the other hand, changes in behavior were observed in other substances such as valproic acid and cyclophosphamide, in the case of valproic acid (LC50 18.40 µM) showed hypoactivity at 27 µM.

The outcome of our study provides valuable information on the effect of pharmaceuticals in aquatic organisms. Moreover, our results support the use of zebrafish embryos as an alternative to the animal models for the screening and assessing toxicity of candidate compounds for regulatory acceptance. It also lays the foundations for a faster and reliable environmental and human risk assessment based on New approach methodologies (NAMs).

1.04.P-Tu031 The antidepressant paroxetine reduces intraspecific behavioural variance in zebrafish

Carla Ferreira Melo[1], Leandro Cunha[2], Peter Kille[3] and ***Miguel Oliveira****[2], (1)University of Aveiro, Portugal, (2)University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Portugal, (3)Cardiff University, United Kingdom*

The presence of distinct personality traits (e.g., bold and shy) among individuals and within a population is a vital component of a survival strategy to optimise an adaptive response to environmental stressors including drug pollution. Paroxetine (PAR) is a selective serotonin reuptake inhibitor (SSRI) antidepressant widely detected in surface waters (up to 270 ng/L) and in fish tissues. Several studies demonstrated the ability of SSRIs to interfere with fish behaviour however, effects on personality/coping styles, which is strictly associated with behaviour, remain largely unknown.

In this study, zebrafish embryos (3hpf) were submitted to acute and chronic exposures to PAR to assess potential effects on personality-associated behavioural responses. In the acute exposure, organisms were exposed up to 48 hpf to 0 µg/L, 0.4 µg/L and 40 µg/L and allowed to recover in clean media up to 45 dpf, whereas, in the chronic exposure, embryos were exposed up to 45 dpf to the same concentrations of PAR (0 µg/L, 0.4 µg/L and 40 µg/L). At 45dpf fish from all experimental groups were submitted to group and individual-based behavioural tests to separate and rank fish according to their personality pattern (bold and shy). The basal swimming activity of bold and shy fish under light and dark conditions was analysed using the Zebrabox automated tracking system (Viewpoint, Lyon, France), considering the total swimming distance (TD, mm) and the total time of inactivity (%).

The obtained results revealed that under control conditions, bold fish are more active than shy fish (higher swimming distance and lower inactivity time) in dark and light conditions. However, exposure to PAR disrupted this personality-associated behavioural pattern, with bold fish adopting a similar behaviour to shy individuals (decreased swimming distance and increased time of inactivity in comparison with controls) in both light conditions (light and dark). The acute exposure in a key susceptibility window (from 3hpf to 48hpf) to a low concentration of PAR (0.4 µg/L) induced similar effects to those elicited by chronic exposure to a higher concentration (40 µg/L). These results, particularly those observed for the acute exposure in the first 48hpf, require further studies to explore the underlying mechanisms and the potential intergenerational and transgenerational implications of PAR on behavioural phenotypic variation in fish.

1.04.P-Tu032 Understanding Anxiety Behavior in Developing Zebrafish (Danio rerio) Exposed to Environmental Toxicants

Bianca Dechent*[1], Helene Juul Belling[2], Sebastian Eilebrecht[3], Markus Hecker[4], Richard Ottermanns[5], Stefan Scholz[6], Henner Hollert[7,8], Amparo Acker Palmer[2], Bettina C. Kirchmaier[9] and Sarah Johann[8], (1)Goethe University Frankfurt, Germany, (2)Molecular and Cellular Neurosciences, Goethe University Frankfurt, Germany, (3)Ecotoxicogenomics, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (4)Toxicology Centre and School of the Environment and Sustainability, University of Saskatchewan, Canada, (5)Environmental Biology and Chemodynamics, RWTH Aachen University, Germany, (6)Bioanalytical Ecotoxicology, Helmholtz Centre for Environmental Research (UFZ), Germany, (7)Environmental Media Related Ecotoxicology, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (8)Evolutionary ecology and environmental toxicology, Goethe University Frankfurt, Germany, (9)Molecular and Cellular Neuroscience, Goethe University Frankfurt, Germany*

The environment is facing an ever-growing input of substances that interact with the nervous system. Neurotoxicity has been found to be the most prevalent toxic mode of action in European surface waters and it is estimated that up to 30% of commercially used substances may act neuroactive. To assess the impact of these chemicals to non-target ecological receptors of concern (i.e. fish), a fundamental understanding of the mechanistic processes leading to altered behavioral phenotypes is required. One neurotoxic outcome that has received limited consideration to date is anxiety, despite its obvious impacts on the fitness of affected organisms and populations, such as feeding, mating and predator avoidance.

The AnxioTox project aims to address this knowledge gap by studying anxiety in fish, improving our understanding of the specific mechanisms leading to anxiety-like behavior and establishing a robust line of evidence across different levels of biological organization. Using a set of environmentally relevant substances known to modulate anxiety-like behavior in fish through different neurotoxic modes of action, we will characterize anxiety-like behavioral alterations of zebrafish as a representative model species across different developmental stages up to 8 days post fertilization (dpf). Preliminary experiments investigating the effects of the anxiolytic buspirone and the anxiogenic caffeine on zebrafish locomotion have identified the light/dark transition test, in combination with other endpoints including thigmotaxis, as a promising tool for discriminating anxiety-like behavior in early developmental stages (5 dpf). We will repeat these experiments with other anxiety modulators and verify the method with suspect substances not previously associated with anxiety. Optimized data analysis and quantification will facilitate detailed description of movement patterns, creation of holistic locomotor profiles and thus enable sensitive detection of alterations. Furthermore, we will assess social avoidance behavior by evaluating the response of an exposed organism to conspecifics.

By studying the anxiety-like behavior in zebrafish, this project will contribute to a better understanding of how exposure to chemicals of environmental concern affects normal behavioral patterns. This is essential to efficiently design experimental setups, to increase confidence in such experiments, and to promote future standardization of behavioral assays with zebrafish larvae.

1.04.P-Tu033 Short-Term Exposure to Median Avoidance Concentration of Chloropyrifos Induces Behavioral and Physiological Consequences in Poecilia gillii fish

*Freylan Mena[1], Galit Akerman[2], Andrés Molina[2], **Diwö Huc-Bouge**[2], Karla Solano[1], Cristiano Araújo[3] and Adarli Romero Vasquez[4], (1)Universidad Nacional, Costa Rica, (2)Universidad de Costa Rica, (3)Institute of Marine Sciences of Andalusia, Spanish National Research Council (ICMAN-CSIC), Spain, (4)Universidad de Costa Rica UCR, Costa Rica*

Chemical contamination has the potential to influence the habitat selection of organisms. Chemicals can either repel, attract, or confuse an organism, thereby influencing their decision to remain in or flee from a particular habitat. In scenarios where animals are exposed to discharges of contaminants and must decide whether to tolerate or avoid them, can they experience physiological consequences during this habitat selection process? To explore this, we assessed the avoidance response of the tropical fish, *Poecilia gillii*, to the organophosphate insecticide chlorpyrifos (CPF) using a non-forced open gradient exposure system. Once the AC50 (median avoidance concentration) was calculated and, then, fish were forcedly exposed to that concentration (AC50) for a duration of 3 hours, matching the avoidance test period. We then assessed signs of physiological and behavioral effects, including changes in brain and muscle cholinesterase activity (ChE), respiratory frequency, and swimming patterns. During the avoidance test, the fish exhibited a random distribution throughout the open gradient system during the initial period of the test, displaying a clear avoidance response only after 3 hours of exposure, with an AC50 of 18.6 (14.8 – 25.6) µg/L. The forced 3-hour exposure of *P. gillii* to their CPF AC50 resulted in significant ChE inhibition in their brains and alterations in their swimming patterns. The exposure eliminated their side preferences in the aquarium and increased their presence in the upper part of the water column. Our findings contribute to the understanding of the immediate effects that fish may experience during the rapid process of recognizing and avoiding of neurotoxic contaminant in the event of a discharge of contamination. These physiological and behavioral effects can potentially impact the fitness and stability of the population.

1.04.P-Tu034 Development of a High Throughput Thigmotaxis Assay to evaluate Neurotoxicity in Zebrafish Embryos

***Monica Torres-Ruiz**[1], Maria Muñoz Palencia[1], Antonio De la Vieja[2], Patricia Iglesias-Hernandez[3] and Ana Isabel Cañas Portilla[1], (1)National Centre for Environmental Health, Instituto de Salud Carlos III, Spain, (2)Endocrine Tumors Unit, Unidad Funcional de Investigación en Enfermedades Crónicas (UFIEC), Instituto de Salud Carlos III, Spain, (3)National Centre for Environmental Health and Endocrine Tumors Unit , Instituto de Salud Carlos III, Spain*

Neurotoxicity (NT) of commercialized chemical substances is mainly studied directly following guidelines 424 and 426 of the OECD that include behavioral endpoints in rodents such as activity, learning, and memory but do not include endpoints related to anxiety. Moreover, rodent studies are time-consuming, costly, and present ethical issues regarding animal welfare. There is therefore a need for the development of new approach methodologies (NAMs) to evaluate the potential neurotoxicity of thousands of chemicals on the market in a high throughput human relevant manner. The present work will be done within the European Partnership for the Assessment of Risks from Chemicals (PARC), subtask 5.2.1e, that has the objective of developing and evaluating NAMs to address NT. In this context the zebrafish embryo (ZFE) up to 120 hours post fertilization (hpf) is an *in vivo* model with high human homology but not included in animal welfare regulations and considered a NAM. Our objective is to develop a high throughput thigmotaxis assay to evaluate possible effects on anxiety-like behavior of neurotoxic chemicals in 120 hpf ZFE. The assay will include anxiety-like responses to visual and acoustic stimuli. Results of assay development, including responses to known anxiogenic, anxiolytic, and putative negative substances, and comparisons between 24 round and 96 square well plate formats will be presented. When completed and evaluated for performance with a suite of neuroactive chemicals, this assay could be included in a second-generation developmental NT and a first-generation adult NT alternative test batteries.

1.04.PC Behavioural Toxicology: Methodologies and Research Needs

1.05 Better Alignment of New Approach Methodologies and Adverse Outcome Pathways to Support Next Generation Risk Assessment

1.05.T-01 The Cross-Species Applicability of the Thyroid Hormone System Disruption (THSD) AOP Network and it's Utilisation in Cross-species Extrapolations

***Ann-Cathrin Haigis**, Lucia Vergauwen and Dries Knapen, University of Antwerp, Belgium*

Thyroid hormone system disruption (THSD) is considered a human and environmental health issue. Consequently, multiple efforts are underway to develop fast and reliable test methods to detect compounds causing THSD. These efforts aim to reduce rodent-based testing strategies by introducing new approach methodologies (NAMs) like zebrafish embryos. Under the current EU legislation, zebrafish embryos are not protected up to five days post fertilization. Further, the hypothalamic-pituitary-thyroid axis of vertebrates is highly conserved and thus zebrafish embryos could be employed as *in vivo* NAMs to support the extrapolation of THSD effects to mammals. These extrapolations can be supported by the adverse outcome pathway (AOP) framework as it provides information about the linkages between a molecular initiating event (MIE) and an adverse outcome (AO) via causally linked key events (KEs).

By combining single THSD AOPs, developed in different species, an AOP network is formed for which we previously assessed the cross-species applicability. This cross-species AOP network is the basis of our case study in which we explore the use of zebrafish embryo test as NAMs for extrapolations of THSD-effects to mammals. First, the response of the (zebra)fish and mammalian thyroid hormone (TH) system to THSD model compounds (methimazole, 6-propyl-2-thiouracil, perchlorate, iopanoic acid) was investigated qualitatively and focusing on MIEs, KEs and AOs. Comparing these results to the outcome of

the tDOA evaluation supports the relevance of KEs and AOs linked e.g., to impaired neural development or eye development for cross-species extrapolations. Secondly, we compare TH levels of exposed/unexposed mammals and (zebra)fish to determine whether TH level alterations in both taxa are comparable in direction and magnitude. Baseline TH levels were established and the impact of THSD model compounds is currently evaluated. Based on preliminary results it appears that e.g., methimazole-induced decreases of T4 levels are similar in rats and fish.

Our work highlights the potential of the THSD AOP network to support the extrapolation of THSD effects across vertebrate taxa, thereby promoting the use of alternative test methods. Specifically, our ongoing comparison of TH level alterations will facilitate this effort and help bridging THSD effects between mammals and (zebra)fish.

1.05.T-02 Bridging the gap between human toxicology and ecotoxicology via the development of Cross Species Adverse Outcome Pathway: a case study on silver nanoparticles

Elizabeth Dufourcq Sekatcheff, PhD *and Jinhee Choi, School of Environmental Engineering, University of Seoul, Korea, Republic of (South)*

Historically, toxicological and ecotoxicological risk assessment of stressors were conducted separately. But recent efforts have been made in both disciplines to reduce animal testing and develop predictive approaches instead, e.g., via conserved molecular markers, and in vitro and in silico approaches. Among them, Adverse Outcome Pathways (AOPs) have been largely adopted to facilitate the prediction of molecular toxic effects to larger biological scales. Thus, more and more, toxicological data are used to inform on ecotoxicological risks and vice versa. An AOP has been previously developed that summarized all the available data on Caenorhabditis elegans (AOP 207) and predicted reproductive toxicity of silver nanoparticles (AgNPs) via oxidative stress. In the current study, we aim to extend the taxonomic domain of applicability (tDOA) of this AOP. Various types of data including in vitro human cells, in vivo, molecular to individual, etc. from our previous studies have been collected and structured into a new cross species AOP network that can be used for both human toxicology and ecotoxicology risk assessment. The first step of our approach was the assessment of endpoints from selected studies to fit the AOP criteria. For each study, the endpoints were listed and translated into AOP wiki Key Events (KE) terms. The second step aimed to extend tDOA using the SeqAPASS web-based tool on each KE and for the overall AOP. Cross species extrapolation enabled to predict the reproductive toxicity of AgNPs for over 1000 species. This approach shows that various types of data can be integrated into an AOP framework and thus facilitates access to knowledge and prediction of toxic mechanisms without the need for further animal testing. Next steps will focus on expanding this approach to literature data, for example by combining it with systematic review approaches, and the extrapolation of tDOA for KE with no specific target receptor, using other approaches than SeqAPASS, e.g., phylogenetic approaches. To go further, quantitative data can also be assessed to build a quantitative AOP.

1.05.T-03 Explainable Artificial Intelligence Models for Developmental and Reproductive Toxicity Prediction using ToxCast Data in Adverse Outcome Pathway Framework

Donghyeon Kim *and Jinhee Choi, School of Environmental Engineering, University of Seoul, Korea, Republic of (South)*

Artificial intelligence (AI) models offer a new opportunity to assess the potential toxicity of a vast amount of environmental chemicals. However, many toxicity prediction models are inherently 'black boxes', making interpretation challenging for toxicologists and hindering the regulatory acceptance of these models. Inherently, the mechanisms leading to the onset of apical toxicity are complex, and in the absence of process evidence, it is difficult to trust the results, which may be, in the worst case, a mere coincidence. The adverse outcome pathway (AOP) framework holds promise in addressing this issue. AOPs can link molecular toxicity endpoint to human and ecotoxicity endpoint. In response, this study aims to develop explainable artificial intelligence models for predicting developmental and reproductive toxicity using ToxCast data within an AOP framework. Initially, in vitro bioactivity data from ToxCast and in vivo toxicity data from eChemPortalDB and ECOTOX DB were gathered. ToxCast database offer extensive and publicly accessible molecular toxicity information for thousands of chemicals. These data were then integrated into AOPs associated with developmental and reproductive toxicity, and each assay-AOP pair underwent further assessment to determine relevance to taxa within ecosystems. Finally, machine learning models were developed to predict each mechanistic and regulatory endpoint-based toxicity. As a result, models for each key event and apical endpoint achieved high performance, with AUC-ROC values ranging from 0.56 to 0.88. To broaden the applicability of models to both human and ecotoxicology contexts, further analysis of the taxonomical domain of applicability (tDOA) of AOP-based prediction models is underway. This study can serve as a guide for developing explainable machine learning models based on AOPs, addressing the current primary bottleneck in using AI models for chemical risk assessment.

1.05.T-04 A quantitative adverse outcome pathway (qAOP) linking mitochondrial uncoupling to growth inhibition in Lemna minor

Li Xie[1]*, Yang Cao*[2]*, Jannicke Moe*[1]*, Jan Thomas Rundberget*[1]*, Maria T. Hultman*[1]*, Knut Asbjørn Solhaug*[3] *and You Song, PhD*[1]*, (1)Norwegian Institute for Water Research (NIVA), Norway, (2)Clinical Epidemiology and Biostatistics, Orebro University, Sweden, (3)Norwegian University of Life Sciences (NMBU), Norway*

Uncouplers are a group of chemicals that can cause uncoupling of oxidative phosphorylation (OXPHOS) in mitochondria, leading to mitochondrial dysfunction and various adverse effects in organisms. The study aims to construct a quantitative adverse outcome pathway (qAOP) based on the OECD-endorsed AOP (AOPwiki# 263) for ecological risk assessment. Using the OECD TG 221 protocol (Lemna sp. Growth Inhibition Test), tailored laboratory studies were conducted to generate a matrix of data capturing temporal and concentration-dependent changes of four key events (KE1446, KE1771, KE1821, and KE1521) in *Lemna minor* exposed to the model uncoupler CCCP (carbonyl cyanide m-chlorophenyl hydrazone). The KEs were quantified at 48h, 96h, and 7d using the TMRM assay, ATP luminescent assay, EdU assay, and length/size measurement, respectively. Multiomics analysis (transcriptomics + metabolomics) provided mechanistic insights into possible feedback/feedforward loops influencing the quantitative understanding. The results indicated that after 7-day exposure, CCCP induced concentration-dependent reductions in OXPHOS, ATP, cell proliferation, and growth *in L. minor*, with increasing EC_{50} values of 0.49, 1.98, 2.18, and 2.75 µM, respectively. Such increased EC_{50} values not only demonstrated sensitivity of these endpoints to CCCP, but also supported dose-response concordance and possible causal relationships between these KEs. Analysis of results from 48h and 96h is ongoing. Subsequently, the qAOP models were built using two approaches, piecewise structural equation modeling (PSEM) and Bayesian network (BN). Besides quantification of response-response relationships, both approaches were capable of identifying the most influencing KE(s) in the pathway and evaluating the predictive ability of the qAOP. Results demonstrated the initial qAOP model presented good predictability of the AO from MIE. The approaches used herein can be easily adopted by other studies for de novo development of qAOP models.

1.05.T-05 Navigating Complex Biological Systems with PBPK, Text Mining and AI: in silico NAMs for the Development of Reliable and Robust Quantitative Adverse Outcome Pathways

Achilleas Karakoltzidis*, Elisavet Renieri, Nafsika Papaioannou, Ilias Frydas, Thanasis Papageorgiou, Dayna Schultz, Catherine Gabriel, Nancy Georgiou, Spyros Karakitsios and Dennis Sarigiannis, Aristotle University of Thessaloniki, Greece*

In the context of this study, a computational methodology is presented. It starts with environmental exposure and concludes with the a disease by constructing qAOPs. Numerous tools and methodologies are developed encompassing NLP, AI, exposure, PBTK, and systems biology models. Commencing with exposure scenarios, the exposure is quantified across the three routes. Pharmacokinetic models are employed to convert external exposure into internal exposure. To delve into the molecular level, in vitro experiments to generate untargeted metabolomics and transcriptomics data were conducted. The data were integrated to generate multi-omics, aiding in the identification of metabolic pathways perturbed following internal exposure. This data was input into MINER, a text mining toolbox developed to convert representations of KEGG pathways into systems biology models. The incorporation of as many biological pathways as possible resulted in the construction of a big systems biology model, consisting of 1348 differential equations. The kinetics of the model were parameterized with data originating from the BRENDA and SABIORK databases as well as with the use of Deep Learning models to estimate the enzyme properties of interest. Data derived from the HMDB database were utilized to initialize the model. In addition, a methodology was developed using ML and GANs to initialize the model. An ML model was generated for each endogenous metabolite, irrespective of whether its concentration was known. This was conducted for validation purposes. Subsequently, the model was executed twice. The second run also incorporated the fold change results obtained from the omics. The simulation output unveiled metabolites whose concentrations changed by an order of magnitude. Owing to this circumstance, publicly available were gathered to scrutinize the variations in concentrations when an individual is impacted by a disease. The mathematical equation describing the endogenous metabolite provides a comprehensive network of interactions involving metabolites, genes, and proteins. For the AOP development, a bottom-up approach is employed, leveraging our knowledge of the AO and the available information about the MIE. By utilizing transcriptomics, conducting network analysis, and performing a literature review, the precise MIE was determined. Utilizing the developed NLP tools, the AOP was established. Additionally, experimental studies were identified for the quantitative description of KERs.

1.05.P Better Alignment of New Approach Methodologies and Adverse Outcome Pathways to Support Next Generation Risk Assessment

1.05.P-Th001 AOP-Network: Investigation of a Crosstalk Between Retinoic Acid Signaling and Thyroid Hormone Signaling During Zebrafish Early Development.

***Audrey Phan**[1], Adela Marterova[2], Aleksandra Sokolova[2], Lisa Annie Baumann[3] and Klara Hilscherova[4], (1)Masaryk University, Czech Republic, (2)RECETOX, Faculty of Science, Masaryk University, Czech Republic, (3)Environmental Health and Toxicology, Vrije University Amsterdam, Netherlands, (4)RECETOX, Masaryk University, Czech Republic*

As realistic scenarios involve exposure to environmental mixtures of chemicals, characterizing regulatory mechanisms during embryonic development is crucial for a more realistic hazard assessment. This study contributes to a novel Retinoic Acid signaling (RA) AOP network (AOPN) and to a better mechanistic understanding of existing Thyroid Hormone (TH) signaling AOPN. It investigates the crosstalk between RA and TH signaling during zebrafish early development.

Both RA and TH signaling pathways play a major role in various early developmental processes. RA, known as a morphogen, influences anteroposterior patterning, organogenesis, craniofacial, spine, and tail development. And TH signalling plays a significant role in the development of structures such as the anterior and posterior swim bladder, and eye development (AOPs #155-159 and #363 respectively). Our data indicate that RA signaling disruption may also affect posterior swim bladder inflation and eye development in zebrafish embryos, suggesting a potential crosstalk between RA and TH signaling. The potential crosstalk could be either direct, meaning that RA will affect TH signaling, or indirect meaning that both signaling pathways regulate similar developmental processes and need to be balanced to lead to normal development.

To explore this hypothesis, zebrafish embryos were exposed and co-exposed to All-Trans Retinoic Acid (ATRA) and TH Receptor antagonist (Diclazuril) during critical developmental windows (4-48hpf, 4-72hpf, and 4-120hpf). An assessment of malformations associated with each signaling pathway was performed. Craniofacial and tail malformation at 120hpf were indicative of RA signaling disruption, and eye malformation (changes in retinal pigment epithelium morphology) at 120hpf and posterior swim bladder inflation at 170 hpf were associated with TH signaling disruption. To further investigate TH disruption, we used a zebrafish transgenic line (thyroglobulin – mCherry) expressing a fluorescent signal in thyroid follicles. Finally, gene expression analysis at 15hpf focusing on key genes related to TH and RA signaling disruption, and the wnt and Sonic Hedgehog (shh) pathways, was performed. Both wnt and shh pathways are known for their role in cell migration during development and were identified as key players in developmental processes leading to observed malformations.

This study is part of PRORISK-ITN, EU Horizon 2020, Marie Skłodowska-Curie grant (agreement No. 859891).

1.05.P-Th002 Quantitative Systems Modeling of Adverse Outcome Pathways as Translational Tools in Human Health Risk Assessment

***Huan Yang**, Mark Davies and Stephan Schaller, esqLABS GmbH, Germany*

Adverse outcome pathway (AOP) is a mechanistic representation of a causal chain of critical toxicological effects at diverse biological organizations ranging from the initial (chemical) stressor-target interaction to an apical or population adverse outcome. Along with developing different AOPs for predicting human health risk, *in vitro* effect assays can provide mechanistic evidence about novel key events (KE) and possibly fill data gaps. In practice, individual *in vitro* effect assays often use human cell lines to provide information about subsets of molecular or cellular KEs. To enhance biological coverage, we propose cross-systems modeling to integrate *in vitro* and *in vivo* data to offer mechanism-based toxicity prediction.

First, we develop quantitative systems modelling to advance quantitative understanding of key event relationship (KER) as outlined by OECD guidelines about AOPs, namely about response-response relationship, time scale, modulating factor, as well as feedback loops. We demonstrate detailed systems modelling of chemical-induced activation of cellular stress pathways using public data. Second, we apply systems modelling on apical hepatotoxicity endpoint by integrating *in vivo* biomarkers. For both cases, we also exemplify an integration of systems modelling of AOP with biokinetics, which inform chemical fate and distribution *in vitro* or *in vivo* setups. Besides, we create platforms to interactively visualize model perdictions for the two examples, which aims to facilitate the modelling update for potential users without modelling experience.

To conclude, systems modelling of AOPs can integrate various types of data to increase coverage of biological mechanisms to better assess chemical-induced human health risk. A broader perspective of systems modelling of AOP for non-chemical stressors will also be discussed.

1.05.P-Th003 Unveiling an Adverse Outcome Pathway for Caridina africana Following Exposure to Nanodiamonds.

***Nichole Sasha-lee Donough**[1], Tarryn Lee Botha[1,2] and Victor Wepener[1,3], (1)Water Research Group, North-West University, South Africa, (2)Department of Zoology, University of Johannesburg, South Africa, (3)Water Research Group, Unit for Environmental Sciences and Management, North-West University, South Africa*

Nanomaterials, characterized by having at least one dimension within the range of 1 nm to 100 nm, hold promise as emerging technologies for various applications. Nanodiamonds (NDs) have unique properties that make them appealing for use in the medical field. However, once introduced into aquatic environments, nanomaterials can have adverse effects on the resident organisms. To elucidate the underlying mechanism, these effects can be unravelled through the adverse outcome pathways (AOPs) construct. Adverse outcome pathways outline the sequence of events by which contaminants affect organisms, from molecular-level changes, progressing to physiological, individual, and population-level consequences. While AOPs have been established for many toxicants, they are relatively scarce for nanomaterials. This study aimed to fill this gap by constructing an AOP on the effects of NDs on the freshwater shrimp, *Caridina africana. Caridina africana* was exposed to NDs at sublethal concentrations, and the metabolomic, respiration rate, heart rate as well as behavioural responses were determined. Exposure of *C. africana* to NDs resulted in an increased level of Proline metabolites, an elevated oxygen consumption rate and reduced behavioural activity. These responses of *C. africana* was a result of increased physiological stress, which in turn led to an increased mortality rate. Although NDs are considered inert, its toxicity is attributed to its particle size, agglomeration potential, and the adsorption to the shrimp's external surface. These toxicity attributions generated reactive oxygen species which affected the shrimp's physiological responses. These hierarchical biological responses were successfully integrated into the AOP construct, which provides valuable insight into the mechanism by which nanomaterials can impact aquatic organisms.

1.05.P-Th004 Development of Quantitative Adverse Outcome Pathway for Respiratory Diseases Induced by CMIT/MIT using Transcriptomic Profiling

***Yongmin Jung** and Jinhee Choi, School of Environmental Engineering, University of Seoul, Korea, Republic of (South)*

Respiratory diseases linked to humidifier disinfectant (HD) exposure, particularly involving the biocide mixture 5-chloro-2-methyl-4-isothiazoline-3-one and 2-methyl-4-isothiazolin-3-one (CMIT/MIT), have raised significant health concerns in Korea. Despite established epidemiological connections between HD exposure and respiratory diseases, the precise toxicity mechanisms remain elusive. This study aimed to construct a quantitative adverse outcome pathway (AOP) for CMIT/MIT-induced respiratory diseases, employing transcriptomic profiling. First, differentially expressed genes (DEGs) analysis revealed a dose-response relationship for the three time points (4, 24, 72h) using BMDExpress2 ($|Log2FC| > 0.6$, $P\text{-value} < 0.05$). Subsequently, toxicity pathways were identified using Ingenuity Pathway Analysis (IPA) ($P\text{-value} < 0.05$) and the Benchmark Dose (BMD) medium value were calculated for each pathway. We selected toxicity pathways with a time- and dose-response relationship and linked them to four respiratory diseases based on epidemiological findings. This study supported the early toxicity pathways by analyzing transcriptome data from established AOP based on epidemiological studies conducted at CMIT/MIT. Also, our study proposes a quantitative AOP for CMIT/MIT through the time- and dose-response relationship of transcriptome data, highlighting the understanding of toxicity mechanisms by quantifying early key events in respiratory diseases following CMIT/MIT exposure.

1.05.P-Th005 Development of Quantitative Adverse Outcome Pathway Leading to Hepatocellular Carcinoma using Transcriptomics Data with Benchmark Dose Analysis

Jaeseong Jeong[1], *Fatima Baldo*[2] *and Jinhee Choi*[1], *(1)School of Environmental Engineering, University of Seoul, Korea, Republic of (South), (2)University of Seoul, Korea, Republic of (South)*

Hepatocellular carcinoma (HCC) is the fourth most common cancer globally and is the second leading cause of cancer death in East Asia. Allyl alcohol is an allylic alcohol used as a precursor in the manufacture of plasticisers, pharmaceuticals, resins, acrolein, and herbicides. Allyl alcohol undergoes alcohol dehydrogenase oxidation to form acrolein leading to hepatotoxicity and eventually HCC. An adverse outcome pathway (AOP) is a framework that integrates existing knowledge to describe the effect of a substance from its initial interaction with a biological system (molecular initiating event) cascading through the different levels of cellular, linked together by key event relationships required to produce a toxic effect (adverse outcome). In this study, we present an AOP for HCC using transcriptomic data and benchmark dose (BMD) analysis to identify the pivotal point at which key events in the AOP occur. We extracted human gene expression data of allyl alcohol exposure from Open TG GATEs database, and calculated the BMD and mapped the values onto genes and biological processes to identify the important processes initiated at these values. Disease and biological process data were collected from the Comparative Toxicogenmic Database to build the AOP. We found that the pathways leading to HCC were time and dose sensitive. We suggest an AOP leading to HCC via "upregulation of FGFR3", "upregulation of IGF1R", "activation of P13K cascade", upregulation of mitotic G2-G2/M phases", and "cell proliferation and survival". This study provides a framework to suggest the adverse outcomes of environmental toxins through integrating publicly available multi-omics data. Furthermore, benchmark dose analysis can be used to predict the pivotal point at which key events in the AOP occur.

Acknowledgements: This work was supported by Korea Environmental Industry & Technology Institute (KEITI) through 'Core Technology Development Project for Environmental Diseases Prevention and Management', funded by Korea Ministry of Environment (MOE) (2021003310005).

Keywords: transcriptomics, quantitative adverse outcome pathway, benchmark dose, allyl alcohol, hepatocellular carcinoma

1.05.P-Th006 Development of adverse outcome pathways and testing strategies for endocrine disrupting chemicals and mixtures promoting metabolic dysfunction-associated steatotic liver disease

You Song, PhD[1], *Jorke Kamstra*[2], *Maria T. Hultman*[1], *Emma Kasteel*[3], *Jannicke Moe*[1], *Tuulia Hyötyläinen*[4] *and Matej Orešič*[5], *(1)Norwegian Institute for Water Research (NIVA), Norway, (2)Utrecht University, Netherlands, (3)Institute for Risk Assessment Sciences (IRAS), Utrecht University, Netherlands, (4)School of Science and Technology, Orebro University, Sweden, (5)School of Medical Sciences, Orebro University, Sweden*

Metabolic dysfunction-associated steatotic liver disease (MASLD) is the most common liver disorder found in a quarter of the world's population. Growing evidence suggests that exposure to endocrine disrupting chemicals (EDCs) can promote the initiation and/or progression of MASLD, either directly or by exacerbating the effects of a high-fat diet, genetics and/or lifestyle factors. The newly launched ***Horizon Europe project EDC-MASLD (2024-2029)*** aims to elucidate the impact of EDCs on the initiation and progression of MASLD, utilizing cutting-edge systems biological/toxicological approaches. One of the missions of EDC-MASLD is to develop adverse outcome pathways (AOP) and integrated testing strategies for rapid identification and assessment of EDCs promoting MASLD. New AOPs will be assembled based on a collection of existing knowledge through systematic review, relevant key events and relationships in the AOPWiki, in-house data, and systems biological understanding (e.g., genome-scale metabolic model) of the progression of MASLD. The strength of evidence support for the AOPs will be assessed based on the Evolved Bradford Hill weight of evidence considerations, according to OECD's guidance document on AOP development. The chemical applicability domain will be defined by identifying EDCs affecting the same MIE or KEs in the MASLD AOPs, based on existing information from screening programs such as the Tox21. Bioinformatics approaches will be used to identify similarities of major genes and proteins across biological systems and define the biological applicability of the AOPs. In addition, quantitative AOPs will be constructed for selected chemicals. The AOPs will suggest critical knowledge needs, relevant chemical domain, test doses/concentrations, key events for measurement and exposure duration for the EDC tests with different experimental models. As an alternative to the mammalian models, zebrafish (*in vitro* hepatic 3D spheroids and *in vivo* transgenic embryos) will be used as a pre-screening tool to select candidate EDCs and mixtures (as suggested by human cohort studies) for in-depth assessment. Combined effect modeling will be performed with the screening data to identify possible interactive effects of EDC mixtures on the progression of MASLD. The project will generate comprehensive knowledge on the chemical-mediated progression of MASLD and supply useful tools for future regulation of EDCs.

1.05.P-Th007 Alterations of ubiquitin-dependent catabolic pathway and growth in the brackish water clam Corbicula japonica caused by environmental stress in estuaries revealed by transcriptome analysis

Ihn-Sil Kwak[1] *and Kiyun Park*[2]*, (1)Department of Ocean Integrated Science, Chonnam National University, Korea, Republic of (South), (2)Fisheries Science Institute, Chonnam National University, Korea, Republic of (South)*

Estuaries are dynamic ecosystems that experience environmental impacts, such as saltwater intrusion and the influx of anthropogenic and natural resources, including heavy metal pollution and hazardous substances. The brackish water clam (*Corbicula japonica*) is constantly exposed to stressful salinity gradients and high levels of heavy metals in the freshwater-saltwater interface of estuary environments. To identify the key molecular pathways involved in the response to salinity changes and heavy metal bioaccumulation, we obtained the transcriptomes of *C. japonica* inhabiting different salinities and heavy metal distributions in Gwangyang Bay (Korea) using RNA sequencing. Among a total of 404,486 assembled unigenes, 5534 differentially expressed genes were identified in *C. japonica* inhabiting different conditions, 1549 of which were significantly upregulated and 1355 were significantly downregulated. Correlation analyses revealed distinct gene expression patterns between the low and high conditions of salinity and heavy metal bioaccumulation. Functional annotation revealed significant downregulation of genes involved in "ubiquitin-dependent protein catabolic process," "tricarboxylic acid cycle," and "intracellular protein transport" in *C. japonica* from the high condition compared to the low condition. Transcription and translation pathways were significantly enriched in the high condition. Additionally, upon comparison of the low and high conditions by qRT-PCR and proteasome enzyme activity analyses, our findings demonstrated that environmental stress could suppress the ubiquitin-proteasome complex (UPC). Additionally, transcriptomic changes under high salinity stress conditions may be related to an increase in cellular protection by defense enzymes, which leads to more energy being required and a disruption of energy homeostasis. Ultimately, this could cause growth retardation in the clam *C. japonica*. In summary, this study provides the first evidence of UPC suppression induced by a combination of high salinity and heavy metal bioaccumulation stress in *C. japonica*, which could compromise the survival and growth of estuarine bivalves.

1.05.P-Th008 Ecotoxicogenomic Hazard Assessment of Artificial Sweeteners in Aquatic Model Organisms

Alexandra Loll[1]*, Christoph Schaefers*[2]*, Henner Hollert*[3] *and Sebastian Eilebrecht*[1]*, (1)Ecotoxicogenomics, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (2)Ecotoxicology, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (3)Evolutionary ecology and environmental toxicology, Goethe University Frankfurt, Germany*

Since their approval as food additives, artificial sweeteners are commonly used in food, beverages as well as in personal care products all around the world. The widespread and intensive consumption of artificial sweeteners in combination with their high stability and water solubility has led to their release into the aquatic environment, where they prove to be persistent. Given that no detailed environmental risk assessment was carried out as part of the food additive approval process, it is still unclear whether and to what extent ecotoxic effects are to be expected. Although this has already been pointed out in literature multiple times, studies regarding the ecotoxicity of artificial sweeteners are still lacking. The few studies that have been carried out, could already reveal some ecotoxic effects, such as neurotoxicity in zebrafish embryos caused by Acesulfame K or increased immobility of daphnids caused by Sucralose.

With this in mind, the aim of this project is to enable an assessment of the ecotoxic potential of artificial sweeteners, using OMIC-methods. To fill the existing data gaps, investigations regarding their effects on ecotoxicologically relevant model organisms from different eukaryotic kingdoms will be performed. More precisely, the aquatic plant *Lemna minor*, the Crustacean *Daphnia magna* and the teleost fish *Danio rerio (embryo)* will be examined. In addition to the performance of the corresponding guideline of the Organisation for Economic Cooperation and Development (OECD), effects will be recorded at the gene expression level using RNA sequencing and thus enable insights into the modes of action that correspond to the hazardous effects. This promising combination of methods will be performed on artificial sweeteners for the first time, which finally may show that the assessment of ecotoxicity should no longer be neglected in the approval procedures for food additives.

1.05.P-Th009 Omics-based fingerprinting of neurotoxic and microtubule-disrupting pesticides in zebrafish embryos

Steve Uwa Ayobahan Dr.[1]*, Hannes A. Reinwald*[2]*, Christoph Schaefers*[3] *and Sebastian Eilebrecht*[1]*, (1)Ecotoxicogenomics, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (2)Early Environmental Safety, Bayer AG, Germany, (3)Ecotoxicology, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany*

Plant protection products play a pivotal role in agriculture, yet their impact on non-target organisms and the environment raises growing concerns due to some of their non-selective harmful effects and bioaccumulation potential. Conventional environmental risk assessments of pesticides primarily focus on lethal concentrations, neglecting the intricate influence of sublethal effects and exposure timing during critical developmental phases, potentially leading to developmental abnormalities. This study employs transcriptomic analysis to uncover the molecular fingerprints of two pesticides – the neurotoxic insecticide endosulfan and the microtubule assembly inhibitor herbicide benfluralin - in zebrafish embryos. In the present study, zebrafish embryos were exposed to different sublethal concentrations of endosulfan and benfluralin in a modified 96 hours zebrafish embryo toxicity test (zFET). Notably, no significant effects on survival or hatching rates were observed compared to the control group. However, transcriptomic analysis revealed distinct molecular responses in embryos exposed to each pesticide, delineating their specific impacts on biological processes. Benfluralin exposure led to differential expression of genes associated with muscle cell differentiation, heart contraction, and skeletal muscle development. Conversely, endosulfan exposure targeted genes crucial for hormone response, neuron apoptotic processes, and neuron death, pivotal for nervous system development. These findings highlight the intricacy of sublethal effects induced by these compounds on non-target organisms, emphasizing the need for a more comprehensive assessment beyond survival-focused evaluations. Integrating these molecular insights into risk assessment frameworks is imperative, especially in establishing transcriptomic points of departure (tPODs) protective against chronic effects. This integration recognises complexities beyond traditional endpoint measurements and provides additional weight-of-evidence for a more holistic assessment of pesticide toxicity.

1.05.P-Th010 In vitro assessment of the synergistic potentials of the ingredients in surface applied preservatives for dermal cytotoxicity and skin sensitization

Haena Kim*, Kyounghee Kang, Sangmoon Han and Sunmi Kim, Chemical Analysis Center, Korea Research Institute of Chemical Technology (KRICT), Korea, Republic of (South)*

Wood preservatives are biocidal products used to protect wood used in building materials, furniture or consumer products. Consumers may be exposed to low concentrations of biocidal components on the skin through direct daily use of the products. Taking into account the dermal route of exposure, we attempted to determine the cytotoxicity and skin sensitization of single components and their mixtures contained in commercial wood preservatives. Three preservatives were selected because their ingredient information was available in a previously established biocidal product database in South Korea. As a first step, nine compounds were tested for their cytotoxicity using the HaCaT, skin keratinocytes. The compounds with EC50 values less than 1,000 μM were included in binary or tertiary equitoxic mixtures, depending on whether these compounds were simultaneously present in the same preservative product. The ECx value derived from the mixture toxicity test was compared with the ECx value predicted by the concentration addition (CA) model to calculate the model deviation ratio (MDR) to determine the interaction between mixture components. We found that certain combinations showed synergism in the cytotoxicity assay, so as a further step we tried to confirm the mode of action and synergistic effects by the ARE-Nrf2 assay using KeratinoSens^{TM} cell line based on OECD TG 442D. In the cytotoxicity test, five compounds showed EC_{50} values of less than 1,000 μM, and a synergistic effect was observed with an MDR of 7.28 to 25.03 in a mixture containing a carbamate family compound. In the KeratinoSens assay, a synergistic effect was also observed in a carbamate compound containing mixtures. We confirmed that the synergistic interaction of a carbamate group biocidal compound was mediated by the second key event (KE) of the AOP (Adverse Outcome Pathway) for skin sensitization. Given the relatively high synergistic effect, further research and consideration of the hazards and interactions of the mixtures in commercial products is needed for the safety management of wood preservatives and related biocidal products.

1.05.P-Th011 In vitro Toxicity screening of real-life mixture using HepG2 cells

Kang Kyoung Hee*, Haena Kim, Sangmoon Han and Sunmi Kim, Chemical Analysis Center, Korea Research Institute of Chemical Technology (KRICT), Korea, Republic of (South)*

To develop the risk prediction technology for mixture toxicity, a reliable and extensive dataset of experimental results is required. In everyday life, people are exposed to complex mixtures comprising more than ten compounds unintentionally, yet most published literature has only data in combinations with two or three substances. Therefore, there is a very limited dataset for predicting the toxicity of complex mixtures. On the other hand, complex mixtures may have different mode of actions (MoA) due to their variety of composition, posing difficulty in the prediction using conventional toxicity prediction models, i.e., concentration addition (CA) and independent action (IA) models. In this study, we aimed to generate an experimental dataset comprising complex mixtures. These mixtures were representative of our real-life exposure to be served as reliable dataset for developing the prediction model for mixtures with different MoA. To identify the target complex mixtures, we referred the findings of the HBM4EU project. We identified three groups of 7~10 substances that were commonly detected together in human bodies, namely environmental phenols, perfluorinated compounds, and heavy metal compounds, assuming them to have different MoA. Additionally, we added a separate mixture consisting of 9 organophosphate flame retardants (OPFRs) which may have a similar MoA. All target substances were tested for cytotoxicity using HepG2 cell lines and the EC10 values were derived after 48-hrs exposure. Then, 50 different complex mixtures were generated with equitoxic mixtures of EC10 levels, randomly selected. To determine the interaction effect, the model deviation ratio (MDR) was calculated by comparing the observed EC10 with the predicted EC10 from the CA model. These values were then categorized to the three types of interactions. Dose-response curves and EC50 values were calculated for all complex mixtures. Out of 50 mixtures, none demonstrated synergism, while 6 mixtures exhibited antagonistic effect (MDRs 0.31~0.48). The remaining mixtures showed additivity (MDRs 0.50~1.34). Our experimental data has been formatted and constructed to the database. It will be used to conduct further research that aims to develop a novel two-stage mixture prediction model for application in the mixture risk assessment.

1.05.P-Th012 Apical and molecular endpoints in zebrafish embryos exposed to cadmium

Bruna Veira[1], Janan Gawra[2], Énia Correia[3], Joana Luisa Pereira[3], ***Ines Domingues[1]*** *and Laia Navarro-Martin[2], (1)CESAM - Department of Biology, University of Aveiro, Portugal, (2)Environmental Chemistry, Institute for Environmental Assessment* *and Water Research, Spanish Research Council (IDAEA-CSIC), Spain, (3)Department of Biology, University of Aveiro, Portugal*

The EPIBOOST project aims at validating the epigenetic modifications caused by chemicals as biomarkers of relevance which can support more accurate environmental risk assessment. For this, a multiparametric approach is pursued by looking at effects of chemicals from the individual and biochemical levels to the transcriptomic and epigenetic levels, with the aim of establishing a link between phenotypic and molecular endpoints. In this work, taking cadmium (Cd) as case study, 96 hours zebrafish larvae were exposed to sublethal concentrations of Cd for 24 hours. Apical endpoints analysed included mortality, development, and swimming behaviour (swimming distance and path angles). At the same time, we analysed biochemical endpoints including biotransformation enzymes (glutathione-s-transferase (GST)), antioxidant enzymes (catalase (CAT), glutathione peroxidase (GPx) and glutathione reductase (GR)), oxidative damage markers (lipid peroxidation (LPO)), and neurotoxicity markers (acetylcholinesterase (AChE)). At concentrations tested no effects on survival or development (delays or anomalies were observed) and the antioxidant system did not seem to have been activated (no changes in GST, CAT, GPx or GR activities were detected). AChE was however inhibited suggesting neurotoxicity elicited by the tested Cd concentrations. This was further supported by changes in behavioural parameters at the last concentration tested namely changes in the proportion of rapid/slow movements and changes in the proportions of zigzag movements/straight movements. At present, we are performing transcriptomic and DNA methylation analysis to evaluate the effects of Cd exposure at the genomic level. In the near future we will integrate molecular and apical endpoints to identify biomarkers of exposure to cadmium. This data will contribute to understand the Cd adverse outcome pathway and validate epigenomic effects as a valuable tool to understand effects of contaminants at larger ecological scales.

EPIBOOST is funded by the European Union (UE) through the Grant 101078991 - views and opinions expressed are however those of the authors only and do not necessarily reflect those of the EU or the European Research Executive Agency; neither the EU or the granting authority can be held for them.

Keywords: *Danio rerio*, embryo development, locomotor behaviour, biomarkers, transcriptomics, DNA methylation

1.05.P-Th013 Molting inhibition in non-model species Calanus finmarchicus exposed to aquatic veterinary agents
*Celine Våga[1], Knut Erik Tollefsen[2], Dag Altin[3] and **Bjørn Henrik Hansen**[4], (1)Faculty of Environmental Sciences and Natural Resource Management, Norwegian University of Life Sciences (NMBU), Norway, (2)Norwegian Institute for Water Research (NIVA), Norway, (3)Research Infrastructure SeaLab, Norwegian University of Science & Technology (NTNU), Norway, (4)SINTEF, Norway*
The Norwegian aquaculture industry is one of the most important industries in coastal areas and farmed Atlantic salmon (*Salmo salar*) represents the second largest export in Norway. Control of threats to this economically important industry is important at both local and national levels. One of the largest threats to this industry is parasite infections of salmon from salmon louse (*Lepeophtheirus salmonis).* Chemotherapeutics and other strategies have been used to protect farmed fish in open-net pens from this parasite, one of them being the use of chitin synthesis inhibitors (CSI) such as teflubenzuron (TEF) and emamectin benzoate (EMB). TEF and EMB are among the most used feed-administered CSI. Although the adverse endpoints are similar, the compounds have different molecular modes of action. TEF inhibits the expression of the enzyme chitin synthase causing reduced chitin production and disrupted molting in immature stages of salmon louse. EMB on the other hand, has a neural inhibitory effect on the regulation of ecdysis causing the same endpoint as TEF, Thus, both these CSI have adverse effects on the molting process in salmon louse and are especially effective against the more molting frequent larval and pre-adult life stages. As chitin synthesis is an arthropod-specific process, CSI has low toxicity to vertebrates and algae. However, they are likely to have adverse effects on nontarget arthropod species such as the copepod *Calanus finmarchicus* a key species in the Northern Atlantic ecosystem. The aim of this project is to assess the sensitivity of *C. finmarchicus* to CSI exposure and uncover the causal relationships between CSI exposure and adverse effects. The objectives are to study CSI-mediated changes in chitin content, expression of genes related to molting (ecdysis), and imaging of structural deterioration of the copepod cuticle. Based on this information, a conceptual overview linking events together in relationships in an adverse outcome pathway (AOP) framework will be outlined. Preliminary results indicate that nauplii of *C. finmarchicus* display increased mortality at concentrations >200 times lower for teflubenzuron than emamectin benzoate, thus C. finmarchicus are much more sensitive to the teflubenzuron.

1.05.P-Th014 A Gamechanger In The Mutagenicity Characterization of Azo Dyes
***Gabriely Fernanda Groto Militão**[1], Anjaina Fernandes de Albuquerque[1], Nelson V. Benitez[2] and Gisela de Aragão Umbuzeiro[1], (1)Faculdade de Tecnologia, Universidade Estadual de Campinas (UNICAMP), Brazil, (2)Wilson College of Textiles, NCSU*
Azo dyes, characterized by the functional group (-N=N-), are the most widely used dye class in several applications such as textiles, cosmetics, pharmaceuticals and food. That is why studies on their mutagenicity have been carried out over the years. However, the uncertainty about their purities, solubility issues, and lack of molecular confirmation may have compromised

some of the published results. Well-chemically characterized samples are mandatory in the development of high quality *in silico* prediction models. The Salmonella/microsome assay is the most common and easy way to evaluate chemicals mutagenicity, using different genetically modified strains of *Salmonella* bacteria to detect gene mutations. In the literature, the use of TA98 and TA100 strains has been considered enough to detect the mutagenicity of the majority of chemicals. The strain YG1041 has shown higher sensitivity to azo dyes. In a recent publication, from six azo dyes evaluated, two would not be considered mutagenic if not tested with this strain. But YG1041 has not been included in any regulatory testing battery so far. This study aimed to verify the effect of the inclusion of YG1041 in the mutagenicity evaluation of five highly purified azo dyes (purity > 97%) selected from the North Carolina State University's Maax Weaver Library (MWDL). Chemical structures and purity were confirmed using a High-performance liquid chromatography quadrupole-time-of-flight mass spectrometry (HPLC-Q-TOF MS) equipped with an electrospray ionization (ESI). Dyes were tested with YG1041, TA98 and TA100 with and without metabolic activation (rat liver S9 5%, Aroclor induced) in a miniaturized version of the Salmonella/microsome assay, the microplate agar (MPA). Dyes were dissolved in dimethyl sulfoxide at their solubility limit and tested in concentration-response experiments. The five dyes showed mutagenicity to YG1041 with S9, but only one was also mutagenic with TA98. None was mutagenic to TA100. The inclusion of YG1041 was crucial to detect the mutagenicity of 4 of the five dyes tested. Along with the literature data, and the results obtained in this work we believe that the YG1041 should be considered by regulatory agencies for azo dyes mutagenicity evaluation.

1.05.P-Th015 Insights into the Microbial Degradation Potential of Hydrocarbon Contaminants across the Baltic Sea Environment

Joeselle Serrana[1], *Francisco J. A. Nascimento*[2], *Benoît Dessirier*[3], *Malte Posselt*[4] *and Elias Broman*[2], *(1)Stockholm University Center for Circular and Sustainable Systems, Sweden, (2)Department of Ecology, Environment, and Plant Sciences, Stockholm University, Sweden, (3)Baltic Sea Centre, Stockholm University, Sweden, (4)Department of Environmental Science, Stockholm University, Sweden*

The Baltic Sea is loaded with petroleum-based substances, e.g., hydrocarbons and plastic waste, from various sources. Microbial communities drive organic matter degradation, and are naturally capable of degrading environmental pollutants. The information on the degradation potential of contaminant-exposed microbial communities can be used to estimate persistence or to predict the fate or accumulation of petroleum-based pollutants in the environment. This would be useful in managing and mitigating the crisis in crude oil and plastic pollution in the Baltic region. However, there is still limited information on the degradation potential of microbial communities in the Baltic Sea, alongside the lack of environmental monitoring information on these contaminants. This prompts the need for a comprehensive profile of the microbial degradation capacity of the region. In this study, we utilize metagenomics and profile the microbial degradation potential of the Baltic Sea, specifically focusing on hydrocarbon aerobic degradation in its benthic ecosystem. We report the genes and enzymes involved in alkane, alkene, aromatic, and plastic aerobic degradation, and biosurfactant production across Baltic Sea regions, and identify key environmental factors influencing gene diversity. Our report aims to deepen our understanding of microbial degradation of contaminants that would be useful for improving mitigation strategies for crude oil spills and plastic pollution in the Baltic Sea while addressing critical environmental concerns.

1.05.P-Th016 Differential expression of different clusters of non-coding RNAs (ncRNAs) and altered gene regulation in response to exposure of ten environmental stressors to EndoC-BH1 pancreatic b - cells

Ilias Frydas[1], ***Dayna Schultz***[1], *Spyros Karakitsios*[1], *Paloma Magdalena Alonso Dr.*[2] *and Dennis Sarigiannis*[1], *(1)Aristotle University of Thessaloniki, Greece, (2)Universidad Miguel Hernández, Spain*

Non-coding RNAs (ncRNAs) play a crucial role in epigenetic alterations after exposure to environmental chemical factors. NcRNAs include the microRNAs (miRNAs), the long non-coding RNAs (lncRNAs), small nucleolar RNAs (snoRNAs), and among others include also the pseudogene transcripts which are RNA molecules that have been transcribed from a DNA segment that resembles a protein-coding gene but, this DNA is never expressed as a protein. In the context of the OBERON Horizon2020 European project ten different environmental stressors including BPA, BPF, BPS, BP, DBP, $CdCl_2$, PFOS, PFOA, DEHP, and DDE in various concentrations ranging from 0.1 to 100 nM, and to timepoints ranging from 24 to 72 hours. Afterwards, cells were subjected to RNA extraction and whole genome microarray analysis was performed using the Agilent SureScan platform. Bioinformatic analysis was conducted applying two different methods, the Agilent GeneSpring software and the limma R package. Subsequent analysis was focused to identified differentially expressed genes (DEGs) that encode for lncRNAs and pseudogenes that have been found to all treated concentrations for each different chemical. Microarray probes are updated and originate from the eArray database and include identified or predicted lncRNAs, snoRNAs and pseudogenes. Results have shown that in all the treated cells with environmental stressors differential expressed lncRNAs regulate genes associated to DNA repair, modulation of chromatin function, interference with signalling pathways, and nucleotide excision repair. In addition, snoRNAs which affect cell and tissue pathophysiology were found to be significantly altered in all concentrations in DDE, DEHP, DBP and BPA treated cells. All the aforementioned ncRNAs ultimately affect gene expression in diverse biological and physiopathological contexts. Thu, since EndoC-βH1 cell line is a model for human beta cells, the next step is on the hand to validate the differentially expressed ncRNAs as novel biomarkers of exposure linked to insulin secretion, proliferation, apoptosis, and endoplasmic reticulum (ER) stress, and on the other hand to develop Adverse Outcome Pathways

(AOPs) with the final endpoint being different conditions of the metabolic syndrome, such as insulin resistance, type 2 diabetes, obesity and non-alcoholic fatty liver disease (NAFLD).

1.05.P-Th017 An overview of the effects of Polycyclic Aromatic Hydrocarbons (PAHs) mixtures in both in vivo and in vitro models.

***Beatriz Matos**[1], Isabella Bramatti[2], Neusa Figueiredo[1], Mário Diniz[3], Vasco Branco[2,4] and Marta Martins[1], (1)MARE - Marine and Environmental Sciences Centre, NOVA School of Science and Technology, Portugal, (2)Research Institute for Medicines (iMed.Ulisboa), Faculty of Pharmacy, Universidade de Lisboa, (3)UCIBIO, REQUIMTE, Portugal, (4)Egas Moniz Center for Interdisciplinary Research (CiiEM); Egas Moniz School of Health &Science, Campus Universitário, Portugal*

Polycyclic aromatic hydrocarbons (PAHs) are complex carbon and hydrogen compounds formed by the fusion of aromatic rings and are commonly found in the environment. Due to their low water solubility, PAHs persist, bioaccumulate, and induce toxic effects (oxidative stress, inflammation, and cell death). Some PAHs, pose challenges as they exist in complex mixtures in the environment. The main objective of this work is to understand the mode of action (MoA) of environmentally relevant PAH mixtures using several biological models, like fish primary hepatocytes, zebrafish immortalized hepatocytes (ZFL cell line), immortalized human hepatocytes (HepG2 cell line) and adult fish.

In the *in vitro* experiments cells were exposed to three PAHs (Benzo[a]pyrene - B[a]P, Phenanthrene - Phe and Benzo[b]fluoranthene - B[b]F) individually and in mixtures (1:1, 1:2, 2:1). Toxicological responses, including viability, CYP1A1 expression and activity, and DNA damage, were assessed after 24h and 48h in a concentration range from 5 to 100 µM. For the *in vivo* bioassay, *Sparus aurata* specimens were exposed for 42 days to Phe and B[a]P individually and in mixtures (1:2, 2:1). Biochemical analyses related to oxidative stress and PAH detoxification pathways were conducted.

Results from the *in vitro* assays showed that B[a]P upregulated CYP1A1, enhancing activity and inducing genotoxic DNA damage. Mixtures of Phe and B[a]P exhibited heightened CYP1A1 mRNA levels and DNA damage. In the *in vivo* bioassay, was found that in adult *S. aurata*, PAH mixtures showed different effects on antioxidant enzymes and CYP1A1 expression compared to individual compounds. However, no significant increase in DNA damage or lipid peroxidation was observed.

Overall, this study demonstrates the unpredictable behavior of mixtures. These findings highlight the underestimated risk posed by PAH mixtures. Therefore, efforts should be made to improve environmental guidelines, as the possible synergistic or antagonistic effects of mixtures of different types of PAH may be underestimated.

1.05.P-Th018 Deriving Predicted No-effect Concentration of Tributyltin for Marine Environment Using Taxon-specific Adverse Outcome Pathways

***Zhaochuan Li**, Ying Wang and Juying Wang, National Marine Environmental Monitoring Center, China*

Tributyltin (TBT), an acknowledged endocrine disrupting chemical (EDC), can trigger endocrine disruption in marine organisms, resulting in adverse outcomes of growth and reproductive effects. The marine ecological risks posed by TBT compounds remain a concern following the global ban. However, conventional procedures for the derivation of predicted no-effect concentration (PNEC) typically fail to account for non-apical endpoints for endocrine disrupting effects and diverse taxonomic groups, which may provide insufficient protection for marine species. In this study, a method for PNEC derivation of EDCs was constructed applying taxon-specific adverse outcome pathways (AOPs) and species sensitivity distribution. Chronic toxicity dataset for indigenous marine species containing apical endpoints as well as non-apical endpoints associated with taxon-specific AOPs were employed to derive TBT's PNEC for Chinese marine environment. Sensitive non-apical endpoints included craniofacial malformations (fish; growth), morphology alteration of appendages (crustaceans; growth), ecdysteroid levels (crustaceans; growth), vas deferens sequence index (mollusca; reproduction), levels of sex hormones (fish; reproduction), and developmental stage of testicular cells (fish; reproduction). According to the sensitivity discrepancy analyses, the sensitivity of fish, crustaceans, mollusca, and microalgae to TBT decreased sequentially. The reproduction had a lower hazardous concentration for 5% of species (0.693 ng/L) in comparison to the growth effect (1.53 ng/L). The PNEC based on combined apical and non-apical endpoints was 1.3 ng/L (95% confidence intervals: 0.23~7.1 ng/L), which was 2.4 times lower than that estimated on the basis of apical endpoints. Imposex data from field studies on gastropods highlighted the significance for supplementation of non-apical endpoints to improve the conservativeness of PNEC. The current results will provide a valuable reference for deriving PNEC of EDCs with ecological relevance and low uncertainty, protecting marine organisms from endocrine disruption.

1.05.P-Th019 Modes of Action of Thyroid Disruption: Insights from Zebrafish Transcriptomics

***Fabian Essfeld**[1], Antonia Bruder[2], Julia Alvincz[3], Steve Uwa Ayobahan Dr.[3], Christoph Schaefers[2] and Sebastian Eilebrecht[3], (1)Ecotoxicogenomics, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Schmallenberg, Germany, (2)Ecotoxicology, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (3)Ecotoxicogenomics, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany*

Chemicals released into the environment pose a significant threat to wildlife species. Traditional approval processes, especially for detecting endocrine-disrupting compounds, involve costly and ethically challenging animal experiments. This study explores an alternative approach, utilizing transcriptome analysis in zebrafish embryos to identify gene biomarkers for thyroid-related modes of action (MoA) with the aim to potentially serve as screening tool for compound prioritization. Four reference substances, iopanic acid (IOP), methimazole (MMI), propylthiouracil (6-PTU), and triiodothyronine (T3), all targeting thyroid pathways, were examined. Zebrafish embryos were exposed to different concentrations of all test substances following OECD guideline 236. Physiological endpoints and low sub-lethal concentrations for the main study were determined. The main test involved RNA sequencing and differential gene expression analysis at 96 hours post fertilization. Survival and swim bladder length reduction were observed in embryos exposed to IOP and MMI, with delayed hatching observed only for MMI. Transcriptome analysis identified 973 differentially expressed genes (DEGs) for IOP and 1211 DEGs for MMI, with distinct expression patterns. These patterns correlated with underlying mechanisms of action, such as deiodinase inhibition by IOP or thyroperoxidase inhibition by 6-PTU and MMI. Physiological effects, especially delayed hatching and decreased swim bladder size, are in accordance with the adverse outcome pathway concept, since impaired underlying muscle fibre development could already be observed at the gene level. The results for IOP and MMI are also supported by results for T3 and 6-PTU and demonstrate the applicability of the approach for screening purposes. Overall, our methodology demonstrated sensitivity comparable to currently utilized guideline tests that involve extensive animal use. Therefore, our experimental design, in alignment with OECD guideline 236, has potential for replacing existing guidelines in a 3R compliant manner, enhancing early hazard assessment of chemicals.

1.06.P Exploring Long-Term Ecological Impacts: From Epigenetic Biomarkers to Multigenerational Genomic Effects of Environmental Contaminants

1.06.P-We023 Amelioration of Transgenerational Liver Disease by an Epigenetic Modifier Treatment

Ramji Bhandari, *Biological Sciences, University of Missouri*

Epigenetic inheritance of environmentally and lifestyle-induced phenotypes has been demonstrated in many model organisms in a laboratory setting, suggesting that current generations could be harboring ancestral exposure-induced molecular memories, or future generations will be carrying such memories due to exposure at the current generation. Ancestral exposure-related transgenerational traits may be detrimental at the population level if occurring in a natural population. It is essential to develop strategies to correct transgenerational abnormalities before they are transferred to offspring via germline transmission or to block the heritable pathways leading to the abnormal health phenotype before they induce the disease. As a proof of concept, we investigated using medaka fish as test subject, whether the environmentally induced transgenerational non-alcoholic fatty liver disease (NAFLD) can be reversed by epigenetic modifiers and NAFLD development. Ancestral bisphenol A (BPA) exposure from the day of fertilization through 15 days after fertilization at F0 generation led to transgenerational NAFLD leading to nonalcoholic steatohepatitis (NASH) at F2 generation, which persisted for five generations. The intergenerational transmission of the disease trait was mediated by both male and female germlines. The severity of the disease was sexually dimorphic- with females affected more than males. Past F2 generation, the BPA-exposure-initiated transgenerational NAFLD started after puberty, developed in adulthood, and progressed toward NASH as the fish aged. We performed transcriptomic, metabolomic, and methylome analyses to understand the mechanisms involved. An integrated -omics analysis revealed impairments in metabolic pathways involved in proline, tryptophan, and bile acids. A larger percentage of transgenerational differentially methylated regions (DMRs) present in the NAFLD liver at the F2 generation were removed in the F4 generation during germline transfer, but the phenotype persisted with comparatively reduced severity. Treatment of the fish with a known epigenetic modifier resulted in a) correction of the majority of BPA-induced DMRs, irrespective of their methylation status, b) correction of the stressor-induced DNA methylation alterations, and c) blockade of development and progression of NAFLD in adulthood. The present results suggest that low-concentration epigenetic erasures may be useful for correcting BPA-induced transgenerational liver injury.

1.06.P-We024 Copper Exposure During Early Life Results in Long Term Alterations in Copper Responses Within the Life Span of Individuals and Across Generations

***Eduarda Santos**[1]*, *Lauren Laing[1], Hannah Littler[1], Jemima Onime[1], Rob McFarling[1], Nicolas Bury[2], Ronny van Aerle[3] and Tamsyn Uren Webster[4], (1)University of Exeter, United Kingdom, (2)Ocean and Earth Science, University of Southampton, United Kingdom, (3)Centre for Environment Fisheries and Aquaculture Sciences (Cefas), United Kingdom, (4)Swansea University, United Kingdom*

Metals are important contaminants in freshwater systems with concentrations reaching toxic levels to fish in some regions affected by mining activities, industrial or agricultural effluents. In regions affected by mining, genetically distinct populations of fish have been identified, capable of living in metal contaminated waters above the lethal thresholds for their naïve counterparts. In addition to the well described genetic adaptation to toxic metals, we hypothesised that other mechanisms could be at play and mediate rapid alterations in susceptibility to toxic metals within the life span of individuals and subsequent generations following exposure to toxic metals. To test this, we exposed stickleback embryos to a sublethal concentration of copper during embryogenesis and assessed their responsiveness to copper in the adult life stage using a series of measures including transcriptomics, DNA-methylome and microbiome analysis. We also tested the sensitivity to copper of the exposed group in comparison with naïve fish over three subsequent generations. We observed a greater tolerance to copper in the F1 and F2 generations but this effect was no longer visible in the F3 generation. At the mechanistic level, transcriptome, microbiome and DNA-methylome analysis revealed that F0 fish which had been pre-exposed to copper had a greater ability to respond to copper via adaptive mechanisms avoiding the adverse responses observed in naïve fish exposed to copper in parallel. Together these datasets provide evidence of the ability of animals to rapidly acclimate to stressors in their environment and the transient nature of those effects.

1.06.P-We025 Identification of Repressive Histone Methylation-mediated Reproductive Toxicity of Chemical Additives in C. elegans Using the Adverse Outcome Pathway (AOP) Concept and Benchmark Concentration Analysis

Jiwan Kim *and Jinhee Choi, School of Environmental Engineering, University of Seoul, Korea, Republic of (South)*

Although histone methylation has been proposed as the toxic mechanism of various environmental chemicals due to its role in transcriptional regulation, relatively little is known about the hazard information and adverse outcome pathways (AOPs) for chemicals inducing these epigenetic changes. This study reports the role of repressive histone marks in toxicity to environmental chemicals and a strategy for applying epigenetic marks to an AOP framework. We measured reproduction, germline de-silencing, histone methyltransferase (HMT) activity, histone methylated protein expression, and gene expression in *Caenorhabditis elegans* exposed to environmentally pervasive chemical additives [di (2-ethylhexyl) phthalate (DEHP); hexabromocyclododecane (HBCD); tetrabromobisphenol A (TBBPA); bisphenol A (BPA); triclosan (TCS)]. In addition, benchmark concentrations (BMCs) for the experimental values with multiple concentrations were calculated to quantify the POD of each endpoint. TCS and TBBPA showed higher reproductive toxicity, increasing H3K9me3, H3K27me3, and HMTs activities in a concentration-dependent manner. These reproductive defects were alleviated following H3K27-specific HMT inhibitor (GSK343) exposure, suggesting that repressive histone methylation plays a key role in the adverse outcomes of TCS and TBBPA. The GSK343 co-treatment with the two chemicals also altered the expression of vitellogenin (*vit-1*, *vit-3*), xenobiotic metabolism (*cyp-35a2, gst-4, fmo-2*), and oxidative stress response (*ctl-2*) genes. Collectively, "HMT activation" can be proposed as an MIE that causes subsequent KEs such as H3K27 methylation and histone methylation-regulated transcriptional responses in epigenetic AOP for TCS and TBBPA. Furthermore, the utilization of BMC analysis and selective inhibitor assay can be useful to enhance the essentiality and empirical support, which are crucial considerations for AOP.

1.06.P-We026 Multigenerational Exposure to Antidepressants Induces Endocrine Disruption in the Estuarine Polychaete Capitella teleta: From Molecular- to Population-Level Effects

Martina Santobuono[1]*, Mette Albreksen[2], Wing Sze Chan[1], Elettra D'Amico[3] and Henriette Selck[1], (1)Roskilde University (RUC), Denmark, (2)Science and Environment, Roskilde University (RUC), Denmark, (3)INM, Roskilde University (RUC), Denmark*

Due to the continuous release of low doses of chemicals into the environment, environmental risk assessment of chemicals (ERA) is evolving in order to meet the new regulatory requirements to protect wildlife and nature. Long-term exposures and exposures across multiple generations are some of the new frontiers to assess the adverse effects of chemicals on non-target species. Current knowledge on the sublethal effects of lipophilic chemicals on sediment-dwelling invertebrates is scarce, and thus, the impacts on key ecological benthic species are still quite unexplored. This study is the first to expose three generations of the estuarine deposit-feeding polychaete *Capitella teleta* to environmentally realistic concentrations of the lipophilic antidepressant sertraline.

Selective serotonin reuptake inhibitors (SSRIs), like sertraline, have been proven to exert neurotoxic and endocrine-disruptive effects in non-target species even at low concentrations. We developed a conceptual adverse outcome (AOP) highlighting sertraline´s potential mechanisms of action (MoA) underlying phenotypical changes. Therefore, herein we examined life-history traits and reproductive-related endpoints proven valuable when forecasting population impact of chemical exposure, to assess sertraline repercussions on *Capitella teleta*. Further, we analyzed the alteration of serotonin levels, energy allocation, and the population-level consequences of sediment-associated sertraline exposure. The results reveal that sediment-associated sertraline has detrimental effects on egg production, the hatching success of the progeny, and sex distribution over time and across generations. This study emphasizes the importance of conducting multigenerational studies (e.g., as part of the current ERA) to assess the adverse effects of low concentrations of chemicals in conditions simulating environmentally relevant scenarios to preserve natural ecosystems.

1.06.P-We027 Trans-/multi-generational Reproductive Toxicities Induced by Zearalenone Associated with Epigenetic Changes in Caenorhabditis elegans

Yong-Shan Li[1] *and Chia-Cheng Wei[2], (1)National Taiwan University, Taipei, Taiwan (China), (2)Institute of Food Safety and Health, College of Public Health, National Taiwan University, Taiwan*

Zearalenone, a mycotoxin widely found in crops, poses an increased risk of contamination globally due to the effects of climate change. Based on this concern, there is a clear necessity to study the trans-/multi-generational toxicology of zearalenone, as environmental exposures often have long-term effects across subsequent generations. To achieve these research goals, relatively sensitive reproductive endpoints were investigated for five generations in the *Caenorhabditis elegans* model. Worms were exposed to zearalenone for 72 hours to simulate long-term exposure and produce filial generations.

The results showed that 50 µM zearalenone exposure at parental generation can only induce transmitted reproductive defects in the first and second filial generations. As for relatively lower 0.1 and 1 µM continuous exposure, the amplification of toxicity was observed with each successive generation, even if the initial exposure in the parent generation showed no apparent effects. The inheritance of toxicities is regulated by epigenetic changes at the molecular level to alter gene expressions without affecting sequences through chromatin modifications, such as histone methylation. Our results showed that the parental zearalenone exposure decreased expressions of genes encoding histone methyltransferases, including *set-2*, *met-2*, *mes-2*, and *mes-4*, indicating a disruption in epigenetic processes. Besides, the downregulation of gene expression exhibited a trend towards recovery in subsequent non-exposed generations. Interestingly, the trans-generational reproductive toxicities caused by zearalenone in the second filial generation might mainly be attributed to the decline in *mes-4* expression observed across three generations.

In conclusion, these findings emphasize the significance of zearalenone-induced trans-generational toxicological effects on reproduction and linked epigenetic alterations. We hypothesize that zearalenone disrupted epigenetic regulation in the parental generation, resulting in abnormal epigenetic inheritance across generations, ultimately leading to declined transcription levels of *mes-4* until the second filial generation. Moreover, the lack of *mes-4* led to reproductive defects, contributing to trans-generational effects.

1.06.P-We028 Aquatic neurotoxins – Multi-parametric Analysis of Saxitoxins Effects on Daphnia magna

Albano Pinto[1,2]*, Inês PE Macário*[1,3]*, Sérgio Marques*[1,3]*, Jana Asselman*[4]*, Patrícia Pereira*[1,3] *and Joana Luisa Pereira*[1,3]*, (1)Department of Biology, University of Aveiro, Portugal, (2)University of Aveiro, Portugal, (3)CESAM - Centre for Environmental and Marine Studies and Department of Biology, University of Aveiro, Portugal, (4)Blue Growth Research Lab, Ghent University (UGent), Belgium*

Saxitoxin and its derivatives are potent natural aquatic neurotoxins produced by certain cyanobacteria and marine algae species during harmful cyanobacterial and algal blooms. These harmful bloom events and the toxins produced during these events are a human and environmental health concern worldwide. Indeed, their occurrence, frequency and severity is predicted to keep increasing due to ongoing climate change scenarios. Saxitoxins constitute an interesting case study since they are produced by both freshwater and marine phytoplankton species, meaning that exposure to these toxins may occur in both aquatic compartments. Despite saxitoxins human health impacts being the focus of extensive research over the past years, adverse effects on other biota and particularly in the aquatic biota are still largely unexplored. This work aims at evaluating the effects of exposures of the model cladoceran *Daphnia magna* to an environmentally relevant concentration of saxitoxin (30 µg/L), that also corresponds to the safety guideline established by the World Health Organization (WHO) for these toxins in recreational freshwaters. Saxitoxin toxic effects were assessed through a comprehensive array of physiological (heart rate), neurotoxicity (total cholinesterases activity), biochemical (antioxidant enzymes activity and lipid peroxidation) and epigenetic biomarkers (5-mC global DNA methylation). Saxitoxin exposure resulted in decreased heart rate, total cholinesterases activity and catalase activity. Contrarily, other antioxidant enzymes, namely glutathione-S-transferases and selenium-dependent glutathione-peroxidase had their activity increased, together with lipid peroxidation levels. Global DNA 5-mC level was significantly decreased in exposed organisms. Results showed that even an ecologically relevant concentration of saxitoxin may cause changes on the antioxidants defenses, leading to oxidative stress, as well as significant physiological impairments and epigenetic alterations in *D. magna* individuals. This study highlights effects on critical molecular and cellular pathways caused by saxitoxin in *Daphnia,* suggesting that these toxins may represent a marked challenge to their thriving even at a concentration deemed safe for humans by the WHO.

1.06.P-We029 EPIBOOST: A Project Aiming to Link Epigenetic Changes to Phenotypic Outcomes in Microalgae, Microcrustaceans and Fish

Joana Luisa Pereira[1]*, Jana Asselman*[2] *and Laia Navarro-Martin*[3]*, (1)Department of Biology, University of Aveiro, Portugal, (2)Blue Growth Research Lab, Ghent University (UGent), Belgium, (3)Environmental Chemistry, Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain*

Epigenetics has been providing robust and reliable biomarkers for human health diagnosis and therapy, but this step is still largely unexplored in Ecological Risk Assessment (ERA). Many shortcomings contribute to this scenario, including the scarcity of comprehensive functional genomics information on ecotoxicological models, the still short standardization of assessment protocols, the budget required to run epigenomic studies, or, importantly, the need to establish consistent links between epigenetic modifications and downstream effects, primarily gene expression and then phenotypic impairment, allowing reliable extrapolations at larger ecological scales. This link is the focus of the EPIBOOST project, a Twinning Horizon Europe Action. The research component of the project aims to advance knowledge on global and gene-specific DNA methylation changes induced by legacy and emergent aquatic contaminants, using a metal, an antibiotic and a neurotoxin as model chemicals. Furthermore, it extends towards assessing the consequent gene expression changes and phenotypic effects, ranging from the sub-cellular to the population level, concerning specific (e.g. photosynthetic efficiency, neurotoxicity) and more general (e.g. growth rates, behavior) responses to stress. This integrated assessment framework is applied to freshwater and marine microalgae, microcrustaceans and fish, allowing comparative approaches between environmental compartments and different organisms within compartment for a given stressor. Such comprehensive framework will ultimately allow a meaningful insight on the adverse outcome pathways for the selected contaminants, and particularly support the validation of epigenetic modifications as biomarkers of relevance in supporting ERA. As a Twinning Action, EPIBOOST is also strongly dedicated to training. A large group of researchers are being trained hands-on through the research course, but many opportunities have ben also created for external researchers and students through the development of Advanced Courses, Sumer Schools and Workshops dedicated to transferring scientific and technical/technological knowledge in the field of environmental epigenetics.

EPIBOOST is funded by the European Union (UE) through the Grant 101078991 - views and opinions expressed are however those of the authors only and do not necessarily reflect those of the EU or the European Research Executive Agency; neither the EU or the granting authority can be held for them.

1.06.P-We030 Multigenerational epigenetic effects of long-term exposure of Daphnia magna to diazinon.

Floriane Tisserand[1]*, Micaela Faria*[2]*, Aurélien Thomas*[3]*, Federica Gilardi*[3] *and Nathalie Chèvre*[2]*, (1)IDYST, Ecotoxicology, Faculty of Geoscience and Environment, University of Lausanne, Switzerland, (2)Faculty of Geoscience and Environment, University of Lausanne, Switzerland, (3)Unit of Toxicology, CURML, University of Lausanne, Switzerland*

The widespread use of insecticides is leading to growing concerns about their impact on aquatic macrocrustacean. In ecotoxicology, *Daphnia magna* is used as a model for evaluating the effects of chemicals on this class of organisms. Our study focuses on the multigenerational effect of diazinon on *Daphnia magna*. Literature and our previous results highlight various effects of diazinon on *Daphnia magna* during parental exposure. These effects can be physiological modifications and behavioural alterations. In particular, we observed alterations in reproduction, growth and survival, suggesting the transmission of deleterious effects from one generation to the next. Underlying mechanisms, such as epigenetic alterations, were explored to explain the persistence of diazinon effects over several generations. In this study, we aim in identifying epigenetic markers, in particular DNA methylation, across generations of *Daphnia magna*. We set up a rigorous experimental protocol, exposing exclusively parents for a period of 7, 10 and 15 days to diazinon. The main objective was to detect the effects of parental exposure on subsequent generations, that were not directly exposed to diazinon. By focusing on DNA methylation as an epigenetic marker, we aim in understanding potential alterations in gene regulation that could be transmitted epigenetically from one generation to the next. To obtain DNA methylation, a reduced representing bisulfite sequencing (RRBS) mode was applied. We observed differences in methylation patterns between 7-day-old exposed parents (F0) to concentrations of 30 ng/L in contrast to 7-day-old control parents (F0). Notably, discernible differences were identified within the individuals of the first generation (F1). Moreover, within the F1 generation, an increase in the count of methylated CpG sites was observed. This phenomenon was particularly notable in individuals whose parental exposure extended from 7 days to 15 days with a number of methylated CpGs sites from 81 to 231 methylated CpG sites respectively. Initial results showed an increase in DNA methylation as a function of parental exposure time. Identification of the genes involved according to the localization of methylation on CpG sites and regions is currently in progress. Our results will shed light on the mechanisms underlying the multigenerational effects of diazinon.

1.06.P-We031 The Hidden Dangers of Water-Soluble Polymers: Unraveling Epigenetic Changes across multiple generations of Daphnia magna

Lara Nigro[1]*, Andrea Binelli*[1] *and Jana Asselman*[2]*, (1)Biosciences, University of Milan, Italy, (2)Blue Growth Research Lab, Ghent University (UGent), Belgium*

Water-soluble polymers (WSPs) are widely used in many industrial, medical and consumer products due to their physical-chemical characteristics that allow their ability to dissolve in water. Despite their widespread applications, these polymers remain unregulated as either plastics or chemical contaminants leading to their continuous release into the environment. Consequently, their presence in the ecosystem can be considered ubiquitous, raising concerns about potential threats to the health of freshwater organisms, including keystone species as *Daphnia magna*. Considering the significant role of epigenetic mechanisms in environmental stress response and regulation and their potential transmission across generations, their assessment is crucial for understanding and mitigating the ecological impact of these WSPs. Thus, in this context, this project aims to assess the transgenerational inheritance of epigenetic changes (global cytosine methylation) across multiple generations in *D. magna* following exposure to two WSPs commonly used in medical applications: the Polyethylene glycol (PEG) and the Polyvinylalchol (PVA), at the environmental concentration of 1 $\mu g\ L^{-1}$. Specifically, this study focuses on the inheritance of epigenetic changes transferred to subsequent generations of *D. magna* even if the triggering contaminant is removed. This transgenerational experiment involved a 17-day exposure of the first generation (F0) to both the WSPs, followed by subsequent generations (F1, F2, and F3) exposed to the same contaminants or subjected to a recovery phase, representing the progeny returned to the fresh culture medium. Each generation underwent a 17-day exposure period after which, DNA was extracted for the analysis of the global cytosine methylation.

Our study aims to provide deeper insights into the impact of WSPs on epigenetic processes, their heritability across generations, and their correlation with organism-level effects. These findings hold broader implications for comprehending the ecological impacts of WSPs, since their transgenerational effects on a keystone species like *D. magna* can potentially disrupt population dynamics and community structures in aquatic ecosystems. Therefore, our results can contribute to better-informed environmental policies aimed at regulating the use of WSPs and minimizing their impact on aquatic environments

1.06.P-We032 Assessing Multigenerational Effects of Exposure to Crude Oil on the Arctic Keystone Species Boreogadus saida and Gadus morhua, and the Model Danio rerio

Abby L. Chapman[1]*, Claudia Erhart*[1]*, Marianne Frantzen*[2]*, Derrick Kwame Odei*[1]*, Fride Tonning*[1]*, Helge Tveiten*[1] *and Jasmine Nahrgang*[1]*, (1)Arctic University of Norway (UiT), Norway, (2)Akvaplan-niva, Norway*

Understanding the impacts of petroleum exposure on reproducing fish and subsequent generations is crucial, as petroleum and its compounds may disrupt the endocrine system, leading to altered gamete quality and reproductive success. Parental exposure to petroleum can induce changes in epigenetic marks in both parents and offspring and may cause morphological deformities in unexposed offspring. Here, we explore three mechanisms of toxicity resulting from parental petroleum exposure: endocrine disruption, maternal transfer of toxic compounds, and epigenetic inheritance. Employing a comprehensive approach, we showcase preliminary experimental data and outline upcoming experimental designs that will shed light on these mechanisms.

Endocrine and epigenetic alterations along the reproductive axis are assessed on keystone arctic fish polar cod *Boreogadus saida* exposed to crude oil during late vitellogenesis. Preliminary data on the impact of exposure on gonad maturation, sperm motility analyses, plasma sex-steroid analysis and expression of key genes will be presented. Furthermore, oil-induced changes in DNA methylation transferred to first generation offspring will be analyzed through an analysis of gametes and embryos from a parentally exposed Atlantic cod *Gadus morhua*, an important commercial fish species.

Epigenetic effects in subsequent generations will be analyzed using zebrafish as a model, where reproducing adults will be exposed to a crude oil water accommodated fraction (WAF). DNA methylation, miRNA, and gene expression will be analyzed in liver and gonad tissues of F1 and F2 generations to identify changes in epigenetic control and evaluate fitness indicators.

Finally, the toxicity of maternally transferred compounds will be quantitatively and qualitatively analyzed in zebrafish embryos. Lethality and sublethal effects of a synthetic mixture mimicking the bioaccumulated fraction will be compared to those from maternal transfer and waterborne exposure. Through evaluating epigenetic and phenotypic indices transferred within and across generations, this project aims to provide insight into the impacts of petroleum exposure on reproductive success and hereditary traits of fish populations.

1.06.P-We033 Reproductive Toxicity of the Cadmium Exposome: A Transgenerational Study With C.elegans
Norah Almutairi[1]*, Volker Arlt*[2] *and Stephen Stürzenbaum*[2]*, (1)King Abdullah University of Science and Technology, Saudi Arabia, (2)King's College London, United Kingdom*
The exposure and subsequent accumulation of cadmium within biological systems triggers destructive outcomes as it displaces essential metals such as zinc (Zn). Cadmium induces the synthesis of metallothioneins (MTs) and antioxidant proteins that are involved in neutralizing the toxicity. Despite the activation of these detoxification mechanisms, cadmium has the potential to exert long-lasting direct/indirect consequences of exposure that might also affect the (unexposed) next generation(s). *Caenorhabditis elegans*, a well-established nematode organism model, was chosen to study the changes in the accumulation and the distribution of cadmium in parents and the resultant (unexposed) progeny by means of laser ablation inductively coupled plasma mass spectrometry (LA-ICP-MS). In addition, the transcriptomic fingerprints of the cadmium exposome was defined by RNAseq and linked with key life-cycle endpoints (reproduction and growth). In summary, whilst metals were not shown to be transferred from the exposed parents to the unexposed progeny, and no transgenerational differences were observed in terms of growth, a significantly reduced reproductive capability was apparent. In addition, the transcriptome analysis of the unexposed F1 generation identified the upregulation of numerous genes (e.g., *mtl-1*, *T22F3.11*, and *C17F4.3*) which were upon further examination by qPCR confirmed their upregulation also at the F2 generation. This suggests their possible involvement in the transmission of transgenerational effects within the context of metal stress. To conclude, cadmium toxicity has long-lasting effects that are not limited to the direct exposure of individuals, but unexposed offspring can exhibit distinct consequences, namely reproductive toxicity and the alteration of gene expression, that can last for at least two generations.

1.06.P-We034 Assessing the Effects of Imazalil on Hepatic DNA Methylation and Gene Expression Profiles in Xenopus tropicalis Frogs
Mauricio Roza[1]*, Sofie Svanholm*[2]*, Cecilia Berg*[3] *and Oskar Karlsson*[4]*, (1)Stockholm University, Sweden, (2)Department of Environmental Toxicology, Uppsala University, Sweden, (3)Department of Environmental Science, Uppsala University, Sweden, (4)Environmental Science, Stockholm University, Sweden*
Amphibians are the most vulnerable group of vertebrates, with almost half of the species facing threat of extinction. The drivers are mainly anthropogenic, and include environmental pollution. Pesticide contamination in waters and soil is common in areas with intensive agricultural activity, and often occurs in tropical areas where amphibians species richness and abundance is high. Imazalil, for example, is an azole fungicide used in post-harvest treatment of fruits with reported water concentrations near plantation areas in central America reaching concentrations around 100 µg/L. *In vivo* studies evaluating effects of imazalil in vertebrates focus on rodent and fish models, and studies evaluating effects on amphibians are lacking. Reported effects include reproductive alterations, associated with its anti-androgenic mechanisms, and hepatotoxic effects, such as alterations in lipid and glucose metabolism that could lead to metabolic diseases. Therefore, the present study aims to evaluate the effects of imazalil on epigenetic and gene expression hepatic profiles in *Xenopus tropicalis* frogs. To this end, 45 days post-metamorphosis juveniles were exposed to 17 µg/L of imazalil during 15 days and DNA and RNA was extracted from liver samples. Genome-wide DNA methylation levels were analyzed by using Reduced Representation Bisulfite Sequencing (RRBS), and RNA expression levels by using RNA sequencing. Epigenetic marks such as DNA methylation can be important early predictors of organismic response to pollutants, often leading to changes in gene expression that can ultimately cause physiological long-term effects. Developmental effects of xenobiotics are often studied during early stages, however, understanding the effects during pubertal development is also important, as hepatic functions are developed during later stages. The exposure to an environmentally relevant concentration of imazalil caused alterations in the liver methylome and affected the transcriptome in pathways related to metabolism. We expect that the present study will contribute to understanding the link between epigenetic mechanisms and gene expression patterns in animals exposed to pollutants. This could help to better comprehend the connection of environmental pollution with the global amphibian decline, but also suggest possible implications to human health, due to the substantial degree of synteny between *X. tropicalis* and mammalian genomes.

1.06.P-We035 Exploring the Molecular Response of Anthropogenic Impacts on Feral Brown Trout Using a Translocation Experiment

Fabian Weichert[1]*, Barbara Feldmeyer*[2]*, Jörg Ahlheim*[3]*, Werner Brack*[3]*, Mario Brauns*[4]*, Markus Brinkmann*[5]*, Patrick Fink*[4]*, Markus Hecker*[6]*, Sarah Johann*[7]*, Martin Krauss*[3]*, Markus Pfenninger*[2]*, Joachim Sturve*[8] *and Henner Hollert*[7]*, (1)Evolutionary Ecology & Environmental Toxicology, Goethe University Frankfurt, Germany, (2)Department of Molecular Ecology, Senckenberg Biodiversity and Climate Research Centre, Germany, (3)Department of Effect-Directed Analysis, Helmholtz Centre for Environmental Research (UFZ), Germany, (4)Department of River Ecology, Helmholtz Centre for Environmental Research (UFZ), Germany, (5)Toxicology Centre, University of Saskatchewan, Canada, (6)Toxicology Centre and School of the Environment and Sustainability, University of Saskatchewan, Canada, (7)Evolutionary ecology and environmental toxicology, Goethe University Frankfurt, Germany, (8)Biological and Environmental Sciences, University of Gothenburg, Sweden*

Freshwater bodies are characterised by a growing number of pollutants, resulting in the exposure of resident organisms to complex mixtures of chemicals. The effects of these exposures are difficult to assess, and impact-oriented *in situ* studies are scarce. This study aimed to explore molecular response patterns using RNAseq analyses to characterise the impacts of complex environmental exposure scenarios on feral brown trout (*Salmo trutta*) collected along a pollution gradient of a well-studied small river (Holtemme) in Central Germany. To explore the adaptability of these fish populations, we also conducted translocation experiments by relocating fish from the reference site to sites upstream and downstream of the wastewater treatment plant (WWTP) Silstedt. In comparison to fish caught and caged at the reference site (group RR), fish caught and caged at the WWTP-influenced site (group BB) exhibited three times greater number of differentially expressed genes than fish translocated to this site from the reference site (group RB). Gene ontology enrichment revealed that biological processes connected to signalling as well as catabolic and metabolic processes were commonly enriched in fish exposed downstream of the WWTP. Furthermore, differentially expressed genes in group BB were related to a variety of biological processes semantically connected to response to toxic substances, while those in group RB were primarily linked to response to oxidative stress. Finally, overrepresentation of processes connected to leukocyte regulation were only found in group RB and translational processes were enriched in group BB. Differential gene expression as well as connected biological processes differed considerably between translocated and locally adapted individuals. This is a strong indication that adaptational processes play an important role when interpreting transcriptomic response patterns.

1.06.PC Exploring Long-Term Ecological Impacts: From Epigenetic Biomarkers to Multigenerational Genomic Effects of Environmental Contaminants

1.07.A Fish Model Species in Human and Environmental Toxicology

1.07.A.T-01 A Biotechnological Metabolization System has the Potential to Improve the Predictive Ability of the Fish Embryo Acute Toxicity (FET) Test with the zebrafish (Danio rerio)

Inska Reichstein[1]*, Alischa Helena Becker*[1]*, Sarah Johann*[1]*, Thomas Braunbeck*[2]*, Sabrina Schiwy*[1]*, Henner Hollert*[1] *and Andreas Schiwy*[1]*, (1)Evolutionary ecology and environmental toxicology, Goethe University Frankfurt, Germany, (2)Centre for Organismal Studies, University of Heidelberg, Germany*

The Fish Embryo Acute Toxicity (FET) Test with zebrafish embryos (*Danio rerio*) was developed to assess the acute fish toxicity of chemicals or environmental samples as a replacement for the Acute Fish Test (AFT) with juvenile fish. However, the FET is not yet established in the regulatory context. One reason is the (postulated) difference between the biotransformation capacities of embryos and juvenile fish, which might lead to an under- or overestimation of toxicity.

The present study was designed to develop a procedure for external metabolization of test substances prior to testing in the FET. The workflow allows simultaneous exposure of the embryos to the maternal substances and their potential metabolites throughout the entire exposure period. After a 2 h incubation of the samples at 37 °C with a rat liver S9 homogenate or a biotechnological, animal-free (ewoS9R) metabolization system, zebrafish embryos are added shortly after fertilization and incubated up to 120 hours post-fertilization at 26 °C. Five biotransformable model substances (allyl alcohol, benzo[a]pyrene (B[a]P), chlorpyrifos (CP), tris(1,3-dichloro-2-propyl) phosphate (TDCPP) and bisphenol A (BPA)) were evaluated for embryotoxicity with and without external metabolization. Non-embryotoxic concentrations of rat S9 and ewoS9R, as well as NADPH necessary for CYP activity, were determined individually and in combination. The metabolic capacities of both S9 homogenates were assessed as exemplary for the enzymes cytochrome P450 1A1, 1A2 and 1B1 *via* a fluorescence-based EROD assay.

Only for allyl alcohol, external metabolization with both rat S9 and ewoS9R resulted in significantly higher embryotoxicity than under non-premetabolized conditions and, thus, in a better correlation of FET and AFT data. For B[a]P, CP, TDCPP and BPA, there was no relevant difference between data derived from the FET (with and without pre-metabolization) and literature AFT data, even though the FET results with and without pre-metabolization differed significantly for BPA (with rat S9 and ewoS9R) and TDCPP (rat S9 only).

External pre-metabolization appears to be a promising add-on to the FET protocol to improve the correlation with AFT data of certain biotransformable substances and might help to strengthen the FET as an alternative to the AFT and finally to reduce or replace sentient animals used for acute fish toxicity data in the regulatory context.

1.07.A.T-02 Assessment of the impact of realistic mixtures of plant protection products on Dario rerio

***Ana-Belen Muniz-Gonzalez*[1]**, *Erica Leertouwer[2], Ines Domingues[3], Isabel Campos[4], Ana Ré[5], Joana Luisa Pereira[6], Fernando J. M. Gonçalves[4] and Nelson Abrantes[7], (1)Physics, Mathematics and Fluids, UNED, Spain, (2)Faculty of medicine, Radboud University, Netherlands, (3)CESAM - Department of Biology, University of Aveiro, Portugal, (4)University of Aveiro, Portugal, (5)Department of Environment and Planning, Department of Environment and Planning & Centre for Environmental and Marine Studies (CESAM), University of Aveiro, Portugal, (6)Department of Biology, University of Aveiro, Portugal, (7)Department of Biology, University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Portugal*

Plant Protection Products (PPPs) are a current environmental problem due to their intensive use in farming systems to secure crop yields. In fact, in the European Union, 466 pesticide-active ingredients are currently approved. Due to the excessive and indiscriminate use of these substances, substantial quantities enter water systems, posing a significant risk to non-target organisms living there. To date, the risk assessment associated with the PPPs is mainly focused on single exposure ignoring the real case scenarios where multiple PPPs are applied for the crop's protection leading to the presence of mixtures in the environment. In this context, this study conducted under the framework of the EU-H2020 SPRINT project, aimed to assess the impacts of realistic mixtures of PPPs on the model fish organism *Danio rerio*. With this purpose, 11 case study sites (CSSs) were selected, comprising 10 in Europe and 1 in Argentina. The minimal environmental concentration (MEC) of PPPs was quantified for each CSS. From that, the 5 PPPs that compose each CSS mixture were then ranked based on the Risk Quotient and frequency of presence. Following the OECD test guideline 236, embryos of the zebrafish *Dario rerio* were exposed to each of the 11 mixtures at four concentrations: MEC, predicted environmental concentration (PEC), 3*PEC and 5*PEC, plus a control. The % of mortality, % of hatching, behavioural and Cholinesterase activity (ChE) were measured after 96h of exposure. Our findings indicate minimal effects on *D. rerio* mortality, demonstrating lower susceptibility in comparison to invertebrate and producer species that were exposed to the same mixtures in the SPRINT Project. This reduced sensitivity aligns with expectations for a higher biological organism, characterized by more intricate response systems and enhanced protection mechanisms. However, the tested PPP mixtures can modulate the zebrafish behaviour, particularly evident in terms of speed, distance and turning angle. This behavioral modulation was corroborated by the inhibition observed in the ChE, suggesting a neurotoxic effect of the tested mixtures. These results are extremely relevant as they unveil effects at concentrations presently detected in aquatic systems (MEC) as well as predicted ones (PEC). It is important to emphasize the fact that these exposures are acute (96 hours), so understand the long-term impact of these mixtures that are already present in aquatic systems becomes imperative.

1.07.A.T-03 Use of in vitro Oocyte Maturation Assays to Predict Reproductive Capacity of Fishes

***Steve Wiseman*[1]**, *Chloe Devoy[1], Yamin Raza[1], Paul Jones[2], Jonathon Doering[1] and Makenna Kleiner[1], (1)University of Lethbridge, Canada, (2)University of Saskatchewan, Canada*

Oogenesis is a dynamic process by which fertilizable oocytes develop from germ cells [1]. Oogenesis can be divided into a growth phase and a maturation phase. Many endocrine disrupting chemicals impair reproduction by disrupting vitellogenesis that occurs during the growth phase. From this research, several AOPs have been developed for decreased fecundity due to disruption of vitellogenesis, including AOP 30 (direct oestrogen receptor antagonism), and AOP 25 (depression of E2 synthesis through inhibition of aromatase). During the final stage of oogenesis, oocyte maturation, maturation inducing hormone (MIH) binds to membrane progestin receptors (mPRs) on the oocyte and signals the formation of maturation promoting factor (MPF), which promotes germinal vesicle breakdown (GVBD) and oocyte maturation, resulting in a fertilizable oocyte. Our lab has been investigating inhibition of oocyte maturation as a mechanism of decreased fecundity in three model species – zebrafish (Danio rerio), Japanese medaka (*Oryzias latipes*), and fathead minnow (*Pimephales promelas*). This presentation will summarize a series of studies with each model species in which we develop and use *in vitro* assays of oocyte maturation to understand the molecular mechanisms by which chemical exposures at different stages of development impact oocyte maturation, as well as the potential to use this assay as a novel tool to predict reproductive performance of fish exposed to chemical stressors. Much of the presentation will focus on our work with Japanese medaka. Using an assay previously described for zebrafish we developed an assay to assess chemical inhibition of oocyte maturation in Japanese medaka. Using this assay, we show that chemical exposure at different life stages can result in impairment of oocyte maturation leading to decreased fecundity of female fish. Potential mechanisms of chemical inhibition of oocyte maturation will also be presented.

1.07.A.T-04 Sperm Quality Characterization of Male Mummichog (Fundulus heteroclitus) in Response to Legacy Urban Contaminants

***Sabine Malik*[1]**, *Tyler Edward Frankel[2], Carys Louise Mitchelmore[3], Candice Duncan[1] and Lance T Yonkos[4], (1)University of Maryland, (2)Earth and Environmental Sciences, University of Mary Washington, (3)Chesapeake Biological Laboratory, University of Maryland Center for Environmental Science, (4)Environmental Science & Technology, University of Maryland*

Historically contaminated urban rivers harbor significant loads of legacy persistent organic pollutants within sediments that remain a significant hazard to both human and ecosystem health. Endocrine disrupting compounds are of particular concern, as they influence reproductive success and threaten the viability of native fish populations over time. Impacts to female reproductive competence, including delayed oogenesis, impaired hormone signaling, and reduced fecundity have been found across fish taxa, but descriptions of sperm-related effects are limited. Using the mummichog (*Fundulus heteroclitus)* as an ecologically relevant model, we developed and validated a field-adaptable method for measuring aquatic sperm quality using three metrics: 1) *sperm motility,* measured by computer-assisted sperm analysis (CASA); 2) *sperm energetic capacity,* measured by a firefly-luminescence adenosine triphosphate (ATP) assay; and 3) *sperm DNA damage,* measured by Comet assay. These methods were used on sperm from field-collected *F. heteroclitus* sourced from two historically contaminated US rivers (Christina River, DE, USA; Anacostia River, MD, USA) and from a clean reference location (Wye River, MD, USA). Ten male mummichog were collected from several sites within each river and sperm cryopreserved for laboratory Comet and ATP analysis following in-field CASA video capture of sperm motility characteristics. Samples across all assays displayed consistency among replicates, sites, and time, demonstrating effective sperm extraction and cryopreservation. Motility appeared reduced in contaminated sites, though high variability among fish limited the ability to detect statistical significance. Significant differences were seen in DNA damage (via Comet assay) and in energetic capacity (via ATP assay). Samples from the PAH-laden Christina River had the most severe DNA damage, but comparatively little reduction in ATP, indicating the potential for genetically damaged sperm to swim and fertilize an egg. In contrast, samples from the Anacostia River had marked decreases in ATP along with moderate to severe DNA damage. These results emphasize the importance of multi-faceted reproductive health testing, as many adverse outcomes are likely being overlooked with current standard approaches.

1.07.A.T-05 Comparison of different fish model species for the assessment of thyroid hormone system disruption
Lisa Annie Baumann[1]*, Lisa Goelz*[2]*, Marian Stoll*[3]*, Thomas Braunbeck*[4]*, Pauline Pannetier*[5]*, David Du Pasquier*[6]*, Elise Pesce*[7]*, Daniel L. Villeneuve*[8]*, Dries Knapen*[9]*, Lucia Vergauwen*[9] *and Henrik Holbech*[10]*, (1)Environmental Health and Toxicology, Vrije University Amsterdam, Netherlands, (2)Institute for Pharmacology, University of Heidelberg, Germany, (3)COS, Aquatic Ecology and Toxicology, University of Heidelberg, Germany, (4)Centre for Organismal Studies, University of Heidelberg, Germany, (5)ANSES, French Agency for Food, Environmental and Occupational Health & Safety, France, (6)Watchfrog S.A., France, (7)LABORATOIRE WATCHFROG, France, (8)U.S. Environmental Protection Agency (US EPA), (9)University of Antwerp, Belgium, (10)University of Southern Denmark, Denmark*
The current OECD testing framework for assessment of potential environmental endocrine disrupting chemicals (EDCs) covers various test guidelines that primarily use the most popular fish model species, zebrafish, fathead minnow or Japanese medaka. The choice for a species mainly depends on regulatory requirements, regional preferences and experience of laboratories. For the assessment of EDC-induced effects on sexual development and reproduction, all species are equally represented in the OECD test guidelines. However, for other endocrine modalities, this is not (yet) the case. Several EU-funded and OECD-endorsed projects are currently working on the implementation of thyroid hormone system-related endpoints into fish test guidelines for EDC assessment. This is because testing of EDCs potentially targeting the thyroid hormone system is usually performed in amphibians, even though many developmental processes and molecular markers in fish could equally be used as thyroid hormone system-related endpoints for risk assessment of chemicals. A broad data basis resulting from zebrafish experiments confirms this assumption, and, consequently, a validation of test methods at OECD level has recently been initiated. Apart from this, data from other fish species are still scarce and hinder the development of internationally applicable test guidelines. This presentation will summarize and compare the available data on thyroid hormone system disruption in different model fish species (zebrafish, Japanese medaka, fathead minnow), including less frequently used species such as rainbow trout. This will help identifying knowledge gaps might help to set impulses for new research initiatives supporting the optimization of the current testing strategy for EDCs in fish. In the fish model species session, we hope to reach a broad audience of researchers working with different fish species to initiate collaborations.

1.07.B Fish Model Species in Human and Environmental Toxicology

1.07.B.T-01 Adverse Effects on Eye Development of Zebrafish Embryos after Exposure to Tricyclic Antidepressants
Marwin Jafari[1]*, Daniela Maria Pampanin*[2]*, Fabian Essfeld*[3]*, Sebastian Eilebrecht*[4]*, Katharina Brotzmann*[5] *and Jason Tyler Magnuson*[6]*, (1)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (2)Chemistry, Bioscience and Environmental Engineering, University of Stavanger, Norway, (3)Ecotoxicogenomics, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Schmallenberg, Germany, (4)Ecotoxicogenomics, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (5)University of Heidelberg, Germany, (6)University of Stavanger, Norway*
Due to their presence in aquatic ecosystems and their high efficacy towards very specific molecular targets, active pharmaceutical ingredients are considered contaminants of emerging concern. Tricyclic antidepressants (TCAs) are a group of APIs that target the reuptake of neurotransmitters in the presynaptic nerve endings. Previous ecotoxicological studies with zebrafish (*Danio rerio*) revealed their potential to cause behavioural effects. However, it is unknown if effects to vision play a role in these effects.

This study aims to assess, if exposure to TCAs has effects on the development of the vertebrate eye using the zebrafish as a model organism. Effects at different levels of biological organization were measured: transcriptomics, which was assessed via mRNA sequencing at 48, 72 and 96 hours post fertilization (hpf), eye structure, which was assessed via histopathology at 120 hpf, and eye function, which was assessed via the optokinetic response (OKR) assay at 120 hpf,.
Embryos were exposed to amitriptyline (AMI) and nortriptyline (NOR) in a concentration range from 30 ng/L to 300 µg/L (nominal concentrations).
OKR assay showed a significant decrease in the frequency of eye movements for AMI in concentrations of 3 and 300 µg/L, and for NOR in concentrations of 300 µg/L. Histopathology revealed the retinal pigment epithelium thickness to be

significantly increased in the 300 µg/L treatment group of AMI by 15.8% and in NOR by 15.3%.
mRNA sequencing results showed effects on expression of multiple genes related to eye development. Next to eye development, gene expression effects were also found in genes related to synaptic signalling, confirming the mechanism of action to be conserved in zebrafish embryos, muscle development, neuronal development, lipid metabolism, and thyroid signalling.
As thyroid disruption can cause adverse effects on eye development, and the transcriptomics data also implies thyroid disruption to be affected, current experiments investigate the involvement of thyroid disruption in the adverse outcome pathway through which TCAs affected the eye.
The present findings provide evidence of adverse eye development as a previously unknown effect of antidepressant exposure to vertebrates on multiple levels of biological organization and contribute towards establishing an understanding for the mechanism through which this effect occurs.

1.07.B.T-02 How to Assess Thyroid Hormone System Disruption in Zebrafish: A Case Study with Methimazole
***Sina Volz*[1]*, Karin Lund Kinnberg*[1]*, Katrine Kirkegaard*[2]*, Pernille Raun Klausen*[1]*, Bente Frost Holbech*[1] *and Henrik Holbech*[1]*, (1)University of Southern Denmark, Denmark, (2)Biology, University of Southern Denmark (SDU), Odense, Denmark*
The thyroid hormone system (THS), a crucial regulator of vertebrate development, is a major target for a variety of endocrine-disrupting chemicals. Currently, the assessment of THS disruption in non-mammalian toxicology primarily relies on amphibian assays, whereas effects on other endocrine modalities are tested in fish studies. Given the high degree of conservation of the THS across vertebrate classes, it is likely that incorporating newly identified THS-sensitive endpoints into established OECD fish test guidelines would allow for the assessment of THS disruption in fish. The present case study thus aimed at determining suitable endpoints and developmental stages to assess THS disruption in developing zebrafish. Methimazole, a medication used to treat hyperthyroidism, was selected as a test substance due to its well-described effects on thyroid hormone synthesis.

Zebrafish were exposed to 3.2-100 mg/L methimazole, from 2 hours to 33 days post fertilization (dpf). At 5, 21, and 33 dpf, samples were taken to assess various THS-sensitive endpoints. At 5 dpf, THS disruption could be detected by gene expression analysis (altered expression of *thyroperoxidase*) and immunohistochemical assessment of intrafollicular thyroid hormone levels. Histopathological analyses of the eyes are still ongoing and will be finished by the end of the year. Following 21 days of exposure, inflation of the anterior chamber of the swim bladder was impaired; this is a known effect of THS-disrupting chemicals. At 33 dpf, THS disruption was evident on the gene expression level (altered expression of *thyroperoxidase*) and morphological level (increased height of thyroid follicular epithelium). Furthermore, effects on eye development, which is dependent on the THS, were detected via gene expression analysis and histopathology. Targeted thyroid hormone determination at 5, 21, and 33 dpf are still pending but expected to be ready for presentation in May.

Taken together, THS disruption caused by methimazole could be detected at both 5 dpf and 33 dpf. These findings indicate that THS disruption could be assessed in the fish embryo acute toxicity test (OECD TG 236) as well as the fish early life stage test (OECD TG 210). While the results of this case study are promising, it is essential to compare both specificity and sensitivity between amphibians and fish test systems to conclude whether fish studies could replace amphibian assays in the risk and hazard assessment of THS disruptors.

1.07.B.T-03 Early life stage toxicity of radium (226Ra) to three fish species of ecological, cultural, and commercial importance in Canada
Edgar Ramiro R Perez[1]*, Charlotte Lacroix-Durand*[1]*, Karsten Liber*[2] *and* ***David M. Janz***[3]*, (1)Toxicology, University of Saskatchewan, Canada, (2)School of Environment and Sustainability, University of Saskatchewan, Canada, (3)Western College of Veterinary Medicine and Toxicology Centre, University of Saskatchewan, Canada*
In Canada, the mining, petroleum, and metal processing industries generate waste that contain metals and radionuclides of concern, like Radium (^{226}Ra). Despite strict discharge regulations for ^{226}Ra in effluents, a Canadian federal water quality guideline that protects aquatic organisms from ^{226}Ra exposure is not in place, casting doubt on the condition and well-being of current fish stocks. To assess the most sensitive stages of fish development (i.e., fertilization to swimup), we exposed rainbow trout (*Oncorhynchus mykiss*), white sucker (*Catostomus commersonii*), and fathead minnow (*Pimephales promelas*) to a series of environmentally relevant ^{226}Ra activities (0, 0.1, 0.5, 2.5, 12.5, or 62.5 Bq/L) using a modified version of EPS 1/RM/28 for *O. mykiss* and *C. commersonii*, and OECD method 210 for *P. promelas*. Under static renewal conditions, *P. promelas* embryos were exposed to ^{226}Ra in reconstituted hard water (160 – 180 mg/L $CaCO_3$), while *O. mykiss* and *C. commersonii* embryos in very soft water (10 – 13 mg/L as $CaCO_3$), with the aim of identifying sensitive toxicity endpoints. Early life stage toxicity data for *O. mykiss* and *C. commersonii* are presented, while the *P. promelas* experiment is in progress. The results indicate that ^{226}Ra was not toxic to *O. mykiss* or *C. commersonii* survival or time to stage for eyed, hatch, or swim-up. However, for *O. mykiss* only, significant increases ($p<0.05$) in length, mass, and the scaled mass index (SMI) were observed at lower activities of 0.1 and 0.5 Bq/L ^{226}Ra as the exposure time increased, generating a significant interaction between activities and time to stage in degree days. A deformity analysis on *O. mykiss* revealed a biologically significant increase in total frequency of deformities at 62.5 Bq/L ($p=0.07$). In summary, the no observed effect concentration (NOEC) for time to stage and survival endpoints was 62.5 Bq/L for both *O. mykiss* and *C. commersonii*, whereas for *O. mykiss*, the lowest observed effect concentration (LOEC) for length was 0.1 Bq/L, mass and SMI 0.5 Bq/L, and total deformity frequency 62.5 Bq/L. Other pending analyses for *O. mykiss* include targeted transcriptomics and bioaccumulation in embryos and fry, while data for *C.*

commersonii and *P. promelas* are pending completion. As of now, the monthly mean discharge limit of 0.37 Bq/L total ^{226}Ra in effluents may pose a potential risk to fishes in Canadian aquatic ecosystems.

1.07.B.T-04 2,2′,4,4′-Tetrabromodiphenyl Ether Causes Depression-like Effects in Zebrafish Larvae via a Non-image-forming Visual Mechanism

***Miao Cao**, Ting Xu and Daqiang Yin, Tongji University, China*

Background: Depression is a high-incidence mood disorder that is frequently accompanied by sleep disturbances. Circadian disruption triggered from disordered non-image-forming (NIF) visual pathway is accordingly proposed as a new pathogenic factor of depression. Polybrominated diphenyl ethers (PBDEs), with visual impairment being the emerging toxicological feature, have been extensively used as flame retardants and new cohort studies reported the relationships between PBDEs and depressive symptoms.

Research Purpose: This study aimed to delineate the performances of NIF system under 2,2′,4,4′-Tetrabromodiphenyl Ether (BDE-47) exposure, especially with day-night differences, and to verify the action mode of melanopsin, which is the major photopigment of NIF system, in facilitating depression-like effects in zebrafish larvae.

Methods: We employed diurnal zebrafish model for this study. The nominal BDE-47 concentrations herein were designed as 0, 2.5 μg/L, and 25 μg/L with 0.01% DMSO based on the reported environmental levels. Considering the possible involvement of the circadian system, samples were collected at various circadian time points in subsequent experiments of quantitative Real-Time PCR, immunofluorescent staining, enzyme-linked immunosorbent assay, *in situ* hybridization (ISH), etc.

Results: BDE-47 caused a distinct day-night difference in the melanopsin and associated NIF functions at 5 and 6 dpf zebrafish larvae. The differences were transmitted to clock genes and neuropeptides in SCN and impacted the adjacent 5-HT and melatonin receptors. However, the changes in the vital factors of depression and sleep were unidirectional, which led to the depression-like (including thigmotactic and sleepy) effects in BDE-47-exposed larvae. The melanopsin antagonism suggested it was possibly primarily due to the direct photoentrainment function of melanopsin.

Conclusion**:** BDE-47 exposure disrupted NIF visual pathway and resulted in depression-like effects, which may further exert profound health effects like mood disorders.

Implication: Our study provided mechanistic cues for the epidemiological correlation between human depression and PBDE exposure. Such mechanism successfully explained the circadian differences in some depression indicators. Of note, the neurotoxic sensitivity of melanopsin at environmental-relevant BDE-47 concentrations might indicate its implication potential as a novel target in ecological risk assessment of aquatic PBDE exposure.

1.07.P-Th020 Towards Standardization of the Dark/Light Transition Test with Zebrafish (Danio rerio) embryos. Reporting of Results from an Inter-laboratory Ring Test

*Riccardo Massei, Dr[1], **Maria Christou**[2] and Adam Lillicrap[3], (1)Helmholtz Centre for Environmental Research (UFZ), Germany, (2)Norwegian Institute for Water Research (NIVA), Norway, (3)Norwegian Institute for Water Research (NIVA), Oslo, Norway*

Over the last few decades, there has been a rapid increase in the analysis of behavioral responses in zebrafish embryos following exposure to chemicals, primarily due to their potential for providing more informative data compared to traditional endpoints described in the Fish Embryo Acute Toxicity Test (OECD TG 236). One of the most commonly utilized behavioral assays is the dark/light transition test (DLTT), which involves recording and quantifying the swimming activities of hatched zebrafish eleutheroembryos under different light conditions. Commercially available behavioral systems are used to conduct this test. However, the DLTT lacks standardization, and guidelines have yet to be established. As a result, zebrafish laboratories employ in-house protocols to record the activity of zebrafish eleutheroembryos. Additionally, different statistical tests are employed to explain the results and analyze the output. Consequently, comparing the results across different studies becomes a challenging task and poses a potential obstacle to bring these tests to regulators. Prior to developing an internationally accepted standard test guideline, it is necessary to characterize and understand the general variation in the DLTT. Currently, it remains unclear whether the variation could be attributed to the use of different standard operating procedures (SOP) or other variables such as exposure conditions, data analyses or even the strain of the fish. Previous attempts by labs to conduct different ring trials were hindered by non-standardized exposure scenarios and a low number of participants, making interpretation of results difficult. To address these limitations, a ring test involving 24 institutions from both the European Union (EU) and non-EU countries was organized in 2023 and an SOP was distributed to all the participants. Participants exposed zebrafish embryos to either caffeine, a known neurotoxicant, or 3,4-dichloroaniline from 3 to 120 hours post fertilisation (hpf) and performed a DLTT at 96 and 120 hpf. The primary goals of this ring test are to: 1) determine the reproducibility of the DLTT with zebrafish embryos across different laboratories; 2) understand the potential experimental factors and test procedure key steps that contribute to observed variation in the general DLTT; 3) produce a comprehensive dataset that can be utilized to test different statistical approaches and 4) develop user-friendly data analysis pipeline for statistical analysis.

1.07.P-Th021 Bisphenols A alternatives alters Thyroid Hormone System (THS) sensitive endpoints in zebrafish - are they safer alternatives?

Pernille Ambus Hansen[1], *Jane Ebsen Morthorst*[2] *and Henrik Holbech*[2], *(1)Biology, University of Southern Denmark, Denmark, (2)University of Southern Denmark, Denmark*

Since REACH included Bisphenol A (BPA) under Category 1B due to toxicity for reproduction and endocrine disruption properties various BPA-alternatives like BPE, BPAP and BPS-MAE, have been marketed. We investigate if these BPA-alternatives affects the thyroid hormone system (THS), as have been shown for BPA, or if they are safer alternatives in relation to THS disruption. We do that by proposing an Adverse Outcome Pathway (AOP) in zebrafish embryos <120 hours post fertilization (hpf), to investigate THS sensitive endpoints. The experimental design is based on the OECD Test Guideline 236: Fish Embryo Toxicity Test (FET) with addition of the THS sensitive endpoint posterior swimbladder inflation and analysis of swimming performance at the end of the test.

We tested BPE, BPAP and BPS-MAE. As an example, for the Bisphenol E (BPE), we exposed zebrafish larvae from 2 hpf – 120 hpf in a semi-static renewal system to 5 concentrations (5 µg/L, 25 µg/L, 125 µg/L, 625 µg/L and 3125 µg/L). BPS-MAE and BPAP were tested with a similar approach at different concentrations.

In the test for BPE we found a decreased swimbladder inflation rate and a change in the swimming performance which can be regarded as an adverse effect with population relevance. This indicates that BPE adversely affects zebrafish embryos via disruption of the thyroid hormone system. We will present the full datasets from these tests including internal T3- and T4 measurements, statistical analysis of the swimbladder inflation rates and a potential correlation between decrease in swimbladder inflation rate and swimming performance.
We will also present if the same tendency applies for other BPA-alternatives like BPAP and BPS-MAE.

1.07.P-Th022 Identification of ingredients in Air Freshener Commercial Products Causing Neurotoxicity to zebrafish

han-Seul Lee *and Kitae Kim, Seoul National University of Science and Technology, Korea, Republic of (South)*

(Introduction)Household products contain a variety of chemicals for their function. Given that we use a variety of household products on a daily basis, it is reasonable to expect that chemical exposures from the use of household chemicals contribute significantly to our overall chemical exposure. Recently, a variety of toxicities such as skin, respiratory, neurological, and systemic disorders from chemicals in these household chemicals have been reported. However, despite the presence of multiple active ingredients in a single household chemical, toxicity is often reported by listing only the toxicity caused by individual substances. It is not known which substances cause toxicity based on the active ingredients in household chemicals, or how to find them.

(Materials and Methods)Zebrafish embryos were used to evaluate the toxicity of air freshener products from a neurotoxicity perspective based on whole extract. After evaluating the toxicity of air freshener products, we sought to identify the causative agents responsible for the toxicity. To identify the neurotoxicants, we searched the literature for keywords related to neurotoxicity and investigated lipid affinities to narrow the three individual substances. Among the three identified causative agents, the one with the highest initial toxicity in zebrafish embryos was validated by analyzing neurobehavioral changes after long-term exposure to adult zebrafish. Neurochemicals were analyzed in the brains of adult zebrafish to determine the mechanism of neurotoxicity.

(Conclusions)Toxicity tests and behavioral assays using zebrafish embryos indicated that whole and extracted mixtures of the air freshener product could be neurotoxic. To identify the neurotoxicants, we searched the literature for keywords related to neurotoxicity and investigated lipid affinities to narrow the list, and citronellol, geraniol, and linalool were identified as suspected toxicants. The neurobehavioral changes we observed after long-term exposure of adult zebrafish to citronellol, geraniol, and a mixture of both substances demonstrated that the individual substances we identified were neurotoxic. Our research represents the pioneering effort in formulating a methodology for identifying toxic culprits in household products. Moreover, we have substantiated the toxicity of these identified agents utilizing the zebrafish animal model. Moving forward, we plan to extend this work to a broader range of product groups in a follow-up study.

1.07.P Fish Model Species in Human and Environmental Toxicology

1.07.P-Th020 Towards Standardization of the Dark/Light Transition Test with Zebrafish (Danio rerio) embryos. Reporting of Results from an Inter-laboratory Ring Test

Riccardo Massei, Dr[1], ***Maria Christou***[2] *and Adam Lillicrap*[3], *(1)Helmholtz Centre for Environmental Research (UFZ), Germany, (2)Norwegian Institute for Water Research (NIVA), Norway, (3)Norwegian Institute for Water Research (NIVA), Oslo, Norway*

Over the last few decades, there has been a rapid increase in the analysis of behavioral responses in zebrafish embryos following exposure to chemicals, primarily due to their potential for providing more informative data compared to traditional endpoints described in the Fish Embryo Acute Toxicity Test (OECD TG 236). 1.07.P-Th023 A Comparative Study of toxic pathway according to the Large Microplastic Shape Characteristics (Polyethylene Terephthalate) on juvenile Rockfish Sebastes schlegeli

Kwang-Min Choi[1]*, Seong Hee Mun*[2]*, Dongju Shin*[1] *and Jee hyun Jung*[1]*, (1)Korea Institute of Ocean Science and Technology (KIOST), Korea, Republic of (South), (2)Korea Institute of Ocean Science and Technology (KIOST), Yeongdo-gu, Korea, Republic of*

Microplastics are heterogeneous materials which diverse not only in particle size and shape, but also in polymers types depends on the chemical composition including the additives products. It still remains unknown what the plastic characterization itself are the major factor and impacts for microplastic toxicity. In the study, two different shape types (fragment and fiber type) microplastics that dominate the coastal environmental types were administered orally in juvenile. In this study, LMP was made of polyethylene terephthalate (PET) in the form of fragments and fibers with a size of 3 mm and administered orally using a gelatin capsule. After exposure, fiber-type PET-LMP (FiPET-LMP) induced stronger cytotoxicity than fragment-type PET-LMP (FrPET-LMP), decreased antioxidant enzyme activity in hepatocytes, and increased reactive oxygen species (ROS) production in a concentration-dependent manner. Transcriptomic analysis confirmed that exposure to FrPET-LMP and FiPET-LMP affected biological processes such as energy metabolism and cell homeostasis, respectively. Based on metabolomics analysis, we found the impact of nicotinate and nicotinamide metabolism pathway involved in energy metabolism under stress caused by FrPET-LMP feeding. After FiPET-LMP ingestion, more liver metabolic pathways were affected, confirming problems with the tryptophan metabolism pathway related to inflammation. Our results can be used as reference data to evaluate the effects of PET exposure and can be useful for identifying correlations between toxic effects and physiological functional properties of marine fish after exposure to MPs.

1.07.P-Th024 A Method for the Detection of Steroid Hormones in Fish Holding Tank Water

Emily Kennedy[1]*, David M. Janz*[2] *and Markus Hecker*[3]*, (1)Toxicology, University of Saskatchewan, Canada, (2)Western College of Veterinary Medicine and Toxicology Centre, University of Saskatchewan, Canada, (3)Toxicology Centre and School of the Environment and Sustainability, University of Saskatchewan, Canada*

Endocrine disruption, caused by the presence of chemical compounds in the environment, poses a significant threat to aquatic ecosystems and the health of fish populations. These impacts are often directed towards steroidogenic pathways, making the assessment of circulating steroid hormone concentrations a valuable method for understanding such effects. While blood sampling is the conventional approach for steroid hormone quantification, it presents challenges, particularly in the case of small fish species like the fathead minnow commonly used in studying endocrine disrupting compounds (EDCs). Often, these fish are too small to provide sufficient blood volume for sample analyses necessitating the pooling of multiple samples and reducing statistical power. Additionally, ethical concerns arise regarding the sacrifice of a large number of animals in both laboratory and field-based biomonitoring programs for the purpose of blood collection. As such, the objective of this project was to develop a liquid chromatography tandem mass spectrometry (LC-MS/MS) method for the quantification of steroid hormones excreted into holding tank water to be used in the screening of EDCs. Using 500 ml of water collected from a tank containing 4 L of water and a single fathead minnow detection limits for 7 steroid hormones including 11-ketotestosterone and 17-β-estradiol ranged from 0.02-0.15 ng/L. Moving forward, this method will now be calibrated by comparing concentrations of hormones in water to those in blood as well as tested for its ability to detect endocrine disruption following exposure to known EDCs. Once fully validated this method will be invaluable to the non-lethal screening of EDCs, and thus, the assessment of fish health and improving fish welfare.

1.07.P-Th025 Assessing the Impact of Combined Anticancer Drugs On the Early Life Stages of Danio Rerio

Daniel Alexandre Bruno[1]*, Diana Isabel Oliveira Carneiro*[2]*, Susana Loureiro*[3] *and Maria D Pavlaki*[2]*, (1)University of Aveiro, Portugal, (2)University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Portugal, (3)CESAM - Centre for Environmental and Marine Studies & Department of Biology, University of Aveiro, Portugal*

Across the world, millions of patients are undergoing chemotherapy, resulting in an increased consumption of anticancer agents (AAs). After AAs are administered to patients, they can end up in the environment due to wastewater treatment plants' lack of efficacy. Furthermore, in real-world scenarios, AAs do not exist isolated in the environment but rather in mixtures with other AAs and/or contaminants. Therefore, is urgent to evaluate the effects of such a potential mixture on aquatic species. In this study, we assessed the single and joint eco- and genotoxicity of three AAs, trabectedin (TRAB), doxorubicin (DOX), and oxaliplatin (OXA), commonly used in cancer treatment patients jointly or in sequence, thus increasing their possibility to be found as part of mixtures. Embryos of *Danio rerio* were exposed to the three AAs individually and in combination following the OECD 236 Fish Embryo Acute Toxicity Test to assess acute toxicity, developmental alterations and DNA damage of zebrafish embryonic stages. A full factorial design was used to assess the joint toxicity effects of the three AAs and deviations from the reference models (Concentration Addition and Independent Action) whenever possible, along with calculating synergistic ratios. Using no-effect concentrations, the comet assay evaluated DNA damage after 96 hours of exposure to single and binary mixtures. The single acute toxicity tests revealed that TRAB and DOX caused mortality and malformations in zebrafish embryos. On the other hand, OXA did not cause any effects at concentrations up to 100 mg/L. Trabectedin was shown to be the most toxic, followed by DOX and then OXA, in terms of mortality, embryo/larvae malformations and DNA damage. Results from the mixtures suggest a Dose Ratio Deviation between TRAB and DOX, when evaluating mortality, showing synergism when TRAB concentrations are high, and antagonism when DOX concentrations are high, while in DOX – OXA and TRAB – OXA mixtures was observed an increasing pattern of effects on zebrafish larvae with increasing oxaliplatin concentrations. Effects of the binary combinations of the three AAs show potentiation of effects in two of the mixtures, while a possible antagonism appears to occur in the TRAB-OXA mixture when larvae are exposed to lower TRAB and higher OXA concentrations. The results of this study highlight the importance of assessing the effects of AAs mixtures in the environment rather than solely focusing on their individual effects.

1.07.P-Th026 Cardio- and Neurotoxicological Characterization of Sediment Flood Samples Taken After the 2021 Extreme Flood Event in Western Germany using Zebrafish Embryos

*Jennifer P. Bayer[1], **Jakob Pfefferle**[1], Henner Hollert[2,3] and Sabrina Schiwy[2], (1)Evolutionary Ecology & Environmental Toxicology, Goethe University Frankfurt, Germany, (2)Evolutionary ecology and environmental toxicology, Goethe University Frankfurt, Germany, (3)Environmental Media Related Ecotoxicology, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany*

In July 2021, severe thunderstorms caused extreme flood events in several European countries. In Western Germany, which was one of the most affected areas, the floods resulted not only in many fatalities and infrastructural damage but also seriously affected the environment. On this background, sediment samples were taken within 5 days after the flood event around the city of Stolberg, North Rhine-Westphalia (Germany), which has a long history of metalworking and chemical industries. As part of a comprehensive ecotoxicological profiling, the sediments were tested for their cardio- and neurotoxic potential in *Danio rerio* embryos up to 120 hours post fertilization (hpf). After freeze-drying, the sediments were extracted using pressurized liquid extraction, completely dried and reconstituted with dimethyl sulfoxide for further testing. The Fish Embryo Acute Toxicity test was performed (OECD 236 and ISO 15088), with minor adjustments) to evaluate lethal and sublethal morphological endpoints of the different samples. From the concentration-response relationship, EC_5 and EC_{10} were obtained for further testing. A battery of behavioural assays (spontaneous tail coiling (24 hpf), touch-evoked response (72 hpf) and light/dark transition (120 hpf)), as well as Acetylcholine esterase (AChE) activity measurement in zebrafish larvae homogenates, was conducted to assess the neurotoxicity of the samples. For evaluation of the cardiotoxic potential, sublethal morphological effects and heartbeat were analyzed, and 7-ethoxyresorufin-O-deethylase activity (EROD) was measured in zebrafish larvae homogenates. In contrast to our expectations, the neurotoxicological profiling did not reveal significant deviations from the controls, only AChE activity was slightly elevated for a few samples. For cardiotoxic profiling, however, significant effects could be observed. Increased heartbeat was detected in several samples and all samples showed significant induction of EROD activity. These results indicate a heavy pollution of the sediments with polycyclic aromatic hydrocarbons, polychlorinated biphenyls and dioxin-like compounds, which may originate from leaked fuels and heating oils as well as the remobilization and redistribution of contaminated sediments. Combined with the pending chemical analysis, the results will help to identify the actual sources of contaminants and thus contribute to a more detailed assessment of the environmental threats caused by extreme events like this.

1.07.P-Th027 Characterisation of Zebrafish Embryos Developmental Stages using Automated Computer Device

***Sizenando Nogueira Abreu**[1,2], Ines Domingues[3], Bruna Veira[3], Fatima Jesus[3], Amadeu M.V.M. Soares[3], Rui Martins[2,4] and Miguel Oliveira e Silva[2,4], (1)CESAM & Department of Biology, University of Aveiro, Portugal, (2)TekenBio, Portugal, (3)CESAM - Department of Biology, University of Aveiro, Portugal, (4)Ieeta - Deti, University of Aveiro, Portugal*

Zebrafish (*Danio rerio*) embryos are a popular model increasingly used in ecotoxicology assays not only due to their characteristics (e.g., transparency and quick development) but also because they comply with the 3 R's policy promoted by the European Union Directive 2010/63/EU on the protection of animals used for scientific purposes, being considered an alternative model for animal experimentation. Setting up a zebrafish embryo assay involve the laborious and time-consuming task of counting and selecting large number of newly fertilised embryos. The equipment for automated detection of small organisms that has been, in previous works, tested and validated for counting zebrafish eggs/embryos. In this work, the equipment was used to obtain an optic characterisation of the different developmental stages of zebrafish embryos from 2 to 7 hours post fertilisation as well of the non-viable and dead (coagulated) embryos that can always be observed together in variable degrees in the eggs' batches. Optic characterisation and direct embryo observation were performed for calibration of the computer device. Embryos showed different levels of light absorbance, having non-viable embryos lower absorbances and coagulated eggs having the higher values. Although, non-viable and viable embryos absorbances distribution show some overlap areas in the first 3 hours, data indicate that at 4-5h post fertilisation, a differentiation is observed, being the most accurate time point post fertilisation where well-developed eggs can be better differentiated from non-viable or dead embryos.

Overall data can be used to evaluate the non-viable, viable and dead embryos distribution in the eggs' batches, and it could be used as a tool to infer the levels of fertilisation success in zebrafish facilities.

1.07.P-Th028 Characterising the Functional Homology of Central Nervous System Drug Targets in Fish.

***Siobhân Alexandra Monaghan**[1], Matthew Winter[1], Charles Tyler[1] and Stewart Owen[2], (1)University of Exeter, United Kingdom, (2)AstraZeneca UK Ltd, United Kingdom*

Many pharmaceuticals designed to target receptors in the human central nervous system (CNS) are increasingly detected in the aquatic environment. Critically, the genes encoding the molecular targets of many of these drugs are highly conserved between humans (the intended target species) and fish. Consequently, it has been proposed that many are likely to be biologically active in fish when they enter aquatic environments. However, there is limited information on whether many of these targets exhibit functional homology between humans and fish. Here we sought to address this knowledge gap for a range of CNS targets applying a suite of techniques to assess whether their gene sequence homology confers conservation of biological (pharmacological) function. Firstly, we employed bioinformatics to identify the CNS drug targets with the highest degree of similarity between humans and zebrafish (*Danio rerio*, our chosen study fish species). We then used this information to prioritise CNS drugs that also are detected widely in surface waters. We then assessed the impact of exposure to pharmacologically (from human therapeutic data) and environmentally relevant levels of these drugs on zebrafish embryo - larval development that included assessing for CNS-specific impacts (via behaviours). Bioavailability of the drugs in the embryo-larvae was also assessed using liquid chromatography with tandem mass spectrometry. Collectively, these data guided studies for more specific CNS-focussed tests designed to better establish the neurobehavioral effects of these compounds. For this, larval zebrafish with a pan neuronal genetically-encoded Ca^{2+} sensor in combination with light sheet microscopy was used to measure brain activity after exposure to each test drug for 4 days. This approach allowed us to assess the impact of drug exposure across multiple brain regions, which we then correlated with the distribution of the drug molecular targets in the brain, indicating whether orthologous targets are being modulated within the fish. Mapping brain regions affected can furthermore provide insights into likely behavioural impacts, such as those mediated by olfactory, visual or locomotory activity. A key overall aim of this work is to assess the degree of functional homology of drug targets between mammals and fish, thereby identifying more sensitive endpoints for risk assessment as well as gaining a better understanding of likely effects of these neuroactive drugs on fish in the wild.

1.07.P-Th029 Combined effects of benzisothiazolinone and propyl paraben using embryonic and adult zebrafish
***Chaeun Park** and Kyunghee Ji, Yong In University, Korea, Republic of (South)*
Benzisothiazolinone (BIT) and propyl paraben (PP) are often mixed and used as preservatives in cleaning products. In the present study, the toxicity of the binary mixture to BIT and PP through *in vivo* zebrafish experiments, considering the content ratio and chemical combination of the cleaning products. Zebrafish embryos were exposed to BIT (2.29 and 229 μg/L), PP (0.64 and 64.5 μg/L), and mixtures for 96 h, and the effects on the growth hormone (GH), insulin-like growth factor-1 (IGF-1), and the transcription of genes related to GH/IGFs axis were investigated. Zebrafish pairs were also exposed to BIT, PP, and mixtures for 21 d, and the effects on sex hormones and transcription of genes related to hypothalamus-pituitary-gonad axis and vitellogenin were assessed. The mixtures had greater effects on development, reproduction, hormones, and gene expressions than individual exposure. Larvae exposed to 229 μg/L BIT or mixtures showed significant reductions in growth. Reduced contents of GH and IGF-1 are well supported by regulation of genes associated to GH/IGFs axis. In larvae exposed to BIT, PP, or mixtures, reactive oxygen species and the levels of superoxide dismutase, catalase and glutathione peroxidase were significantly increased. Although no significant changes were observed in *vitellogenin* gene transcription, a decrease in gonadosomatic index in male fish and number of eggs were observed in mixed exposure. The results of a significant decrease in testosterone in males and a significant decrease in 17β-estradiol in females exposed to binary mixture suggest the anti-estrogenic and anti-androgenic potential. The results of this study indicate that the toxicity of mixtures of preservatives in consumer products may be greater than the toxicity of individual substances, which may be helpful in managing the risks of mixtures in products.

Acknowledgment: This study was supported by Korea Environment Industry & Technology Institute (KEITI) through "the Technology Development Project for Safety Management of Household Chemical Products" (grand number 288 2020002960006; 485017189), funded by Korea Ministry of Environment.

1.07.P-Th030 Development of toxicity test protocols for Atlantic cod (Gadus morhua) – a relevant test species for the Northern Atlantic Ocean
***Bjørn Henrik Hansen**[1], Stefania Piarulli[2], Lisbet Sorensen[2], Bjarne Kvæstad[1] and Julia Farkas[2], (1)SINTEF, Norway, (2)SINTEF Ocean, Norway*
Atlantic cod (*Gadus morhua*) is a keystone species in the North Atlantic ecosystem, playing a crucial role in maintaining the balance of marine food webs. Additionally, it has been a vital resource for centuries, supporting fisheries that have shaped the cultural and economic basis for coastal communities. Climatic- or pollution-related impacts on cod recruitment would have devastating biological, societal, and economic consequences. We have developed a standardized protocol for ecotoxicological testing using this species based on the OECD Test No. 236: Fish Embryo Acute Toxicity (FET) which is based on the use of zebrafish (*Danio rerio*) embryos. Atlantic cod eggs are comparable to zebrafish eggs in size, but in contrast, cod eggs have a lower density (pelagic eggs), develop at lower temperature and over a longer period from fertilization to hatch (approx. 100 degree days, d°). Compared to the OECD guideline, we used larger exposure volumes (>100 mL), an increased number of individuals (approximately 100 eggs per 100 mL beaker) and a lower temperature (8.5 ± 1 °C). In addition, we standardized sublethal toxicity endpoints relating to cardiotoxicity and morphological deformations using automated analyses of videos and images. A positive control experiment using 3,4-dichloroaniline (DCA) revealed that cod embryos were significantly more sensitive to acute DCA exposure compared to other species tested and reported in the literature. Reduced survival, as well as cardiac, developmental, and morphometric alterations were observed at concentrations as low as 8 µg/L. Large interspecies variation in sensitivity to chemicals needs to be considered when performing environmental risk and impact assessment, and toxicity data on relevant species should be selected.

1.07.P-Th031 Ecotoxicity of Perovskites as Multi-component Advanced Materials (AdMs) in Aquatic Environments: from Cellular Effects to Acute Toxicity and Bioaccumulation Potential in Fish

Mona Connolly[1]*, Gerardo Pulido-Reyes*[1]*, Lars Skjolding*[2]*, Anders Baun*[2] *and José M. Navas*[1]*, (1)Department of Environment and Agronomy, Institute for Agricultural and Food Research and Technology, Spanish National Research Council (INIA-CSIC), Spain, (2)DTU Sustain, Technical University of Denmark (DTU), Denmark*

Perovskites can exist with specific crystal structures and unique chemical compositions, leading to their tunability for applications in various industries. Intelligent testing strategies are required to meet regulatory demands for the safe use of such advanced, multi-component nanomaterials. Since fish represent model organisms for aquatic ecotoxicity testing and there are standardised test guidelines (TGs) based on these organisms, one of the objectives of this work was to assess the applicability of such TGs in a testing strategy for evaluating the toxicity of these advanced materials. With this in mind, the rainbow trout (*Oncorhynchus mykiss*) RTgill-W1 cell line acute toxicity test (OECD TG 249), the fish 96h acute toxicity test (OECD TG 203) and the fish bioaccumulation test (OECD TG 305) were used. The use of the RTgill- W1 cell line provided a high throughput approach to material testing. It acted as a predictive screen and a tool for deeper mechanistic adverse outcome pathway (AOP) focused investigations. Adaptations to the standardised OECD TG 203 were incorporated (e.g. use of turbines and humic acid) to facilitate material exposure concentration maintenance during testing with juvenile rainbow trout. While material stability was overcome by applying the dietary exposure route to test material bioaccumulation using TG 305.

Lanthanum-nickel-cobalt perovskites were tested, as well materials doped with Pt and the rare earth metal Pd, using the mentioned strategy. As well as providing much needed ecotoxicological information, collectively the information generated fed into a safe and sustainable by design (SSbD) approach ranking material hazard potential. Links were made between the materials physico-chemical properties and effects. Single particle inductively coupled plasma mass spectrometry (SP-ICP-MS) was used to analyse fish tissues for different accumulation patterns. By measuring the uptake and depuration of specific perovskite metal components, differences in potentials for accumulation were identified. Also fish were analysed for sublethal biomarkers of toxicity associated with potential underlying mechanisms of chronic toxicity (e.g. oxidatve stress). This developed strategic AOP directed integrative approach on testing and assessment (IATA) using fish as a model organism for aquatic toxicity testing will be used in the decision support tool being developed within the EU Horizon 2020 project HARMLESS grant agreement No. 953183.

1.07.P-Th032 Effect of Psychoactive Compounds on Neurotransmission in Fish

Gayani Rajakaruna Kapukotuwa[1]*, Serhii R Boryshpolets*[2]*, Alina Sadchenko*[3]*, Anatolii R Sotnikov*[2]*, Kateřina Grabicová*[3]*, Vitaliy R Kholodnyy*[2] *and Ganna Fedorova*[3]*, (1)University of South Bohemia Ceske Budejovice, České Budějovice, Czech Republic, (2)University of South Bohemia Ceske Budejovice, Faculty of Fisheries and Protection of Waters, Czech Republic, (3)University of South Bohemia in České Budějovice, Faculty of Fisheries and Protection of Waters, Czech Republic*

Psychoactive compounds, including psychiatric pharmaceuticals and illicit drugs, are emerging contaminants in the aquatic environment. They are introduced to the aquatic ecosystem either as parent compounds or their metabolites through improper disposal, human urine and feces. Furthermore, these compounds have been found in aquatic organisms, noticeably in fish. The neurotoxicity of psychoactive substances is revealed in fish behavioral alteration, hyperactivity and hypoactivity. Moreover, psychoactive substances cause reproductive toxicity, including altered sperm morphology and decreased courtship and reproductive output in fish. This study aims to observe the changes in neurotransmitters concentrations in fish as a response to exposure to psychoactive compounds. Bioaccumulation of psychoactive drugs, as well as histological changes and sperm motility, were also investigated. The experiment was conducted in the laboratory under controlled conditions in 200 L aquaria with adult males of European Perch (*Perca fluviatilis*). A mixture of seven psychoactive compounds (citalopram, donepezil, gabapentin, methamphetamine, sertraline, tramadol, venlafaxine) was used for the study at the final concentration of 1 µg/L and introduced to each aquarium, excluding control aquaria, which were maintained in drug-free water. Water samples (n = 180) were taken during the test in 24-hour intervals before and after water change in the aquaria. The samples were analyzed using the in-line-SPE-LC/MSMS method. The actual concentration corresponded to the nominal with the average difference of 18% for all compounds except of sertraline, for which a significant concentration decrease after 24 hours was observed. Fish were exposed to the target psychoactive compounds for 23 days, and sampling was conducted in 0-, 7- and 23-day. Specifically, fish brains, eyes, gonads and sperm samples were analyzed for the selected neurotransmitters and for psychoactive drugs using LC/HRMS/MS. Information about contaminant-induced changes in neurotransmitters can be crucial because it may link behavior and physiology in the exposed fish.

1.07.P-Th033 Effects of Tributyltin Exposures in Zebrafish Embryos by Multi-omics

Albert Menéndez-Pedriza, ***Janan Gawra****, Liliya Sokalchuk Sokalchuk, Joaquim Jaumot and Laia Navarro-Martin, Environmental Chemistry, Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain*

The Zebrafish (Danio rerio) has emerged as a powerful model organism across a broad range of scientific fields, including ecotoxicology. The Zebrafish model presents various advantages over other common model organisms such as its effortless manipulation or large offspring. Strikingly, toxicological data from zebrafish can be extrapolated not only to aquatic species but also to other vertebrates, including humans. Furthermore, zebrafish embryos are considered an excellent alternative animal model with fewer ethical restrictions, ensuring compliance with 3R's principle (Replacement, Reduction, and Refinement) in animal research. As a result, their use in ecotoxicological studies particularly in endocrine-disrupting chemical (EDCs) assessment has gained recent importance.

While single-omic technologies have been widely used in ecotoxicology to identify molecular disruptions induced by environmental pollutants in target samples, they are specific to a single biological layer, leading to overly simplistic approaches that provide a limited understanding of complex molecular pathways and biological processes. In recent years, multi-omic approaches have gained significant attention due to their potential to provide a more comprehensive understanding of underlying mechanisms and pathways in biological systems. Therefore, the integration of multi-omic analysis is a powerful tool to efficiently capture not only the toxic mechanisms but also multifaceted networks from gene to phenotype.

In the present work, we investigated the endocrine-disrupting behavior of Tributyltin (TBT), an organotin compound known to cause significant environmental consequences. To accomplish this, we conducted a multi-omic analysis combining untargeted LC-HRMS lipidomics and RNA-Seq transcriptomics data after exposing zebrafish eleutheroembryos to environmentally relevant concentrations (from 0.3 to 100 nM) from four to five days post fertilization. The results obtained from the multi-omic pathway enrichment were in concordance with the main single omics results. Interestingly, the multi-omic analysis also revealed the disruption induced in pathways that were not found significantly affected in the single-omic studies. To confirm the accuracy of the multi-omic, we conducted complementary behavioral testing and neurotransmitter analysis. Collectively, this study demonstrates the usefulness of multi-omic data analysis in better understanding the modes of action of EDCs.

1.07.P-Th034 Effects of a Reduced Graphene Oxide-Silver Nanoparticle Hybrid Material on Zebrafish Embryos
*Maddi Aramburu[1], Radmila Tomovska PhD[2], Miren P. Cajaraville PhD, PhD[1] and **Amaia Orbea PhD**[1], (1)CBET+ Research Group, Department Zoology and Animal Cell Biology, Faculty of Science and Technology and Research Centre for Experimental Marine Biology and Biotechnology PiE, University of the Basque Country UPV/EHU, Spain, (2)POLYMAT and Department of Applied Chemistry, Faculty of Chemical Sciences, UPV/EHU, Joxe Mari Korta Zentroa & Basque Foundation for Science, Spain*
The hybrid material consisting of reduced graphene oxide and silver nanoparticles (rGO-Ag) is one of the most promising compounds for optoelectronic, catalytic and electrochemical applications. Taking into account the nanosize of this material and its large surface area, possible ecotoxicological and environmental safety aspects are raised. The aim of this study was to analyze the hazard of rGO-Ag in zebrafish embryos and to compare them with the effects caused by other silver and graphene family compounds. Newly fertilized embryos were exposed for 120 h up to 2.5 mg/L of rGO(PVP)-Ag and to the equivalent concentrations of ionic silver and Ag nanoparticles (size range: 5-50 nm; mean size: 17 nm), as well as to the rGO-Ag filtrate in order to study the effect of potentially dissolved silver. Developmental parameters (survival, hatching and malformations) were monitored along exposure and effects on cell death and on catalase and acetylcholinesterase (AChE) activities were measured at the end of the exposure. Acute toxicity tests showed that the LC50 value for the rGO-Ag (0.306 mg/L) was 12 and 7,5 times higher than the LC50 value for ionic silver (0.025 mg/L) and for Ag nanoparticles (0.041 mg/L), respectively. The LC50 value of filtrated rGO-Ag could not be calculated as it was higher than tested concentrations, indicating a low contribution of dissolved silver ions to the observed toxicity. Moreover, at equivalent concentrations, higher fluorescence intensity revealing cell death was observed in embryos exposed to ionic silver and Ag nanoparticles than in those exposed to rGO-Ag. Increased malformation prevalence was only recorded at the highest concentration of rGO-Ag filtatre, but at concentrations ≥0.156 mg/L of rGO-Ag. Both silver forms provoked malformations, especially yolk sac edema, at lower concentrations. No significant changes were recorded in catalase activity. Exposure to 3.8 and 7.7 µg/L of Ag nanoparticles, but not of ionic silver, and to 0.156 mg/L of rGO-Ag significantly inhibited AChE activity. These results demonstrated that the hybrid compound rGO-Ag is less toxic than ionic silver and than Ag nanoparticles, but still can pose a risk for aquatic organisms. *Work funded by Basque Government (consolidated research group IT1302-19 and IT1743-22) and Spanish MINECO project NACE (CTM2016-81130-R).

1.07.P-Th035 Effects of exposure to Piriproxifen on the survival of adult Danio rerio (Zebrafish)
*Beatriz Gomes Gameiro[1], **Rafaella da Silva Brito**[1], Fabio Kummrow[1], Gisele Giannocco[1], Dimitrius Leonardo Pitol[1] and Bruno Fiorelini Pereira[2], (1)Federal University of São Paulo, Brazil, (2)Biology, Federal University of São Paulo, Brazil*
Considering the great concern about controlling the proliferation of vectors that reproduce in aquatic environments, the adoption of larvicides in water reservoirs for various purposes has become increasingly frequent. Among the active ingredients recommended by the WHO for use in drinking water is Pyriproxyfen (PPF). The most common risk assessment procedures use occurrence and toxicity data on pesticide active ingredients. Therefore, it is necessary to evaluate the real harmful effects of these substances that are increasingly present in aquatic environments. The model based on *Danio rerio* - zebrafish has become popular for toxicity assessment, mainly because it is an organism with anatomy, physiology and development similar to higher vertebrates and because it is representative and recognized as a model for aquatic environments. Thus, our objective was to identify the possible toxic effects resulting from acute exposure of *Danio rerio* adults to PPF, aiming to obtain the LC50 for this molecule. For this study, fish of the AB lineage were used, from the fish facility of the Federal University of São Paulo, with 3 months of age, and for each exposure, replicates were carried out with 10 individuals each. PPF was solubilized with the help of DMSO. The first concentrations tested were: 0.0001, 0.001, 0.01, 1, 5 and 10 mg/L. Only concentrations of 5mg/L and 10 mg/L induced mortality of 60% and 86.6%, respectively. In a second experiment, concentrations of 2, 3 and 4 mg/L were selected, and all of these concentrations presented similar mortality percentages (63.3%, 60% and 56.7%, respectively). In a

third stage of experimentation, concentrations of 2, 4 and 6 mg/L were tested, which were capable of inducing mortality rates of 62.5%, 60% and 87.5%, respectively. As a final step, we carried out the tests using concentrations of 1; 1.5; two; 2.5; 3; 3.5 and 4 mg/L. In this final experiment we obtained mortality percentages from 0 to 1 mg/L; 10% to 1.5; 60% for 2 and 2.5 mg/L; 62.5% for 3 mg/L; 60% for 3.5 and 4 mg/L. Our results do not allow us to obtain a reliable LC50 value, however it is possible to infer that the LC50 of PPF is between concentrations of 1.5 and 2 mg/L. The impossibility of precisely estimating the LC50 of PPF is probably due to solubility problems of the compound.

1.07.P-Th036 Effects of the thyroid hormone system disrupting compound metformin on the development of early life stages of zebrafish (Danio rerio)

Simone Fibiger Sørensen, *Biology, University of Southern Denmark, Denmark*

Metformin is the most widespread antidiabetic drug treatment in the world, and with the increasing number of diabetic patients, an increasing production and consumption of metformin follows. Due to the incomplete uptake and metabolization of metformin when ingested, as well as insufficient wastewater treatment, metformin is released into the environment. In Germany, metformin has been detected in surface waters at an average concentration of 467 ng/L. Worldwide, metformin is amongst the top three most frequently detected pharmaceuticals in aquatic environments and has been shown to cause endocrine disruption in fish. Although, knowledge about the long-term effects of metformin on aquatic organisms is limited. To investigate effects of metformin on aquatic organisms, zebrafish (*Danio rerio*) will be used as a model organism, focusing on thyroid hormone system (THS) sensitive endpoints, such as swim bladder inflation and eye histopathology. It is known that THS is involved in numerous developmental processes, and that exposure to thyroid hormone system disrupting chemicals (THSDC), can have detrimental long-term effects on several organisms. Assessment of the effects of metformin on THS will be done with experiments based on the OECD TG 236: Fish embryo Acute Toxicity Test, testing concentrations of metformin that are environmentally relevant and focusing on sublethal and behavioral endpoints. Results from this study will contribute to a better understanding of the potential thyroid disrupting mechanisms of metformin on aquatic organisms, and how this might affect aquatic ecosystems.

1.07.P-Th037 Effects of three alkyl-organophosphate flame retardants on neurobehavioral development and oxidative stress in zebrafish larvae

Kijeong Yun[1] *and Kyunghee Ji*[2]*, (1)Yong In University, Gyeonggi-do, Korea, Republic of, (2)Yong In University, Korea, Republic of (South)*

While concerns are growing on the presence of alkyl-organophosphate flame retardants (alkyl-OPFRs) in the environment, there is significant lack of knowledge on their potential toxicity. In the present study, we evaluated the neurobehavioral development and oxidative stress induction of trimethyl phosphate (TMP), triethyl phosphate (TEP), and tris(2-butoxyethyl) phosphate (TBEP) using zebrafish embryo/larvae. Zebrafish embryos were exposed to TMP, TEP, and TBEP (0, 0.02, 0.2, 2, 20, and 200 mg/L) for 96 h, and changes in developmental parameters, locomotor behavior, reactive oxygen species (ROS), and antioxidant enzymes were measured. TBEP exposure reduced body length and weight of larvae, whereas TMP and TEP did not significantly affect developmental parameters. Hypoactivity, decreased levels of acetylcholinesterase and dopamine, and down-regulation of genes involved in central nervous system (e.g., *ache*, *gap43* and *mbpa*) were observed in fish exposed to TEP and TBEP. The levels of ROS, superoxide dismutase, catalase, and glutathione peroxidase were significantly increased in fish exposed to TEP and TBEP. Pretreatment with N-acetylcysteine, the classic antioxidant, alleviated TEP and TBEP-induced neurobehavior toxicity and oxidative stress. The results of this study revealed that zebrafish locomotor behavior impairments and developmental delay induced by TEP and TBEP exposure are attributed to oxidative stress.

Acknowledgment: This study was supported by the National Research Foundation of Korea (NRF; Project no. RS-2023-00251751) and Korea Environment Industry & Technology Institute (KEITI) through Technology Development Project for Safety Management of Household Chemical Products Program, funded by Korea Ministry of Environment (MOE) (1485019252, RS-2022-KE002023).

1.07.P-Th038 Embryotoxicity assessment of Diflubenzuron commercial formulations using the zebrafish model system

Rafaella da Silva Brito[1]*, Fabio Kummrow*[1]*, Gisele Giannocco*[1]*, Ana Carolina Luchiari*[2]*, Aline Garvene Favero*[1]*, Maria Célia SANCHES OLIVEIRA Luz*[1] *and Bruno Fiorelini Pereira*[3]*, (1)Federal University of São Paulo, Brazil, (2)Federal University os Rio Grande do Norte, Brazil, (3)Biology, Federal University of São Paulo, Brazil*

Diflubenzuron (DFB), a synthetic benzoylurea larvicide, is a chitin inhibitor used to control arthropods, including insect vectors of human and veterinary diseases. It is currently used to control insect infestations in agriculture and livestock and for ectoparasite control. Although this active ingredient is expected to have low toxicity to non-target species, unknown components in its commercial formulations, such as excipients, adjuvants, and surfactants, may contribute to or interfere with its toxicity. To understand the environmental impact of DFB applications, the most relevant approach is to test the commercial formulations due to the lack of information on their ingredients. In this study, we evaluated the toxicity of two formulations of DFB: (*i*) an oral formulation for bovine use and (*ii*) a water-soluble formulation for agricultural use, the latter tested by direct water dilution or using DMSO as co-solvent. Embryotoxicity was evaluated according to OECD Test Guideline No. 236. Zebrafish embryos up to 4 hpf were exposed to different concentrations of the formulations and the active ingredient (0.025, 0.125, 0.25, 1.25, 2.5, and 10 mg L^{-1}) for 120 h (extended FET) to assess biomarkers related to development, morphological changes and cardiotoxicity, and for 168 h to assess their effects on larval respiration rate (prolonged exposure until larvae are large enough for measurement). For the statistical analysis, the assumptions of normality and homoscedasticity were tested. Parametric data was compared using one way ANOVA/ Tukey and non-parametric data was compared using Kruskall-Wallis/DSCF. Our results showed that both formulations caused an increase in larval heart rate ($p < 0.001$) and changes in respiratory rate ($p < 0.05$), indicating the possible influence of these formulations on larval metabolism. In addition, larvae embryos to the water-dispersible formulation (containing DMSO) at 10 mg L^{-1} showed an increase in notochord malformations compared to the control group ($p = 0.042$). To date, we have performed an exploratory assessment of the potential teratogenic effects induced by commercial formulations of DFB on zebrafish embryos, and the effects were associated with sublethal changes observed under acute exposure. Thus, our results provided insights into the potential environmental impact of DFB formulations. In the next steps of this work, we will investigate effects at the cellular level, as well as tests on adult individuals.

1.07.P-Th039 Exploiting Zebrafish Tools for a Safe and Sustainable Development of Nano-Enabled Antimicrobials to Reduce the Presence of Antimicrobial-Resistant Bacteria in the Aquatic Environments
***Beatrice Negrini**[1,2,3], Christian D'Abramo[1], Patrizia Bonfanti[1], Anita Colombo[1], Mattia Costamagna[3], Ahmad Seyed Aldaghi[3], Massimo Perucca[3] and Paride Mantecca[1], (1)Department of Earth and Environmental Sciences, POLARIS Research Center, University of Milano-Bicocca, Italy, (2)Department of Biotechnology and Biosciences, University of Milano-Bicocca, Italy, (3)Project Hub-360, Sustainability & Innovation Consultancy Company, Italy*
Nanoparticles (NPs) and nano-enabled products (NEPs) emerged as novel antimicrobial agents with proven efficacy against antimicrobial-resistant bacteria polluting aquacultures. Nevertheless, their safety and sustainability must be evaluated at an early design phase.
This work aims at evaluating the safety and sustainability of a platform of nano-antimicrobials in exploitation scenarios by using zebrafish (*D. rerio*) as model organism for high-throughput developmental and behavioural screening, in parallel with the Life Cycle Assessment (LCA) methodology.
The study focused on CuO NPs-nano-engineered antimicrobial/biofilm fish cage nets and water filtration membranes, as well as on marine-derived nano-formulated antimicrobial agents, proposed as an alternative to antibiotics for fish. Specifically, the study investigated water-based copper oxide (wCuO) NPs and wCuO-based NEPs, including coated, co-extruded polymers and coated filtration membranes, along with nano-formulations of microalgae-derived lipid NPs and quorum quenching enzymes. A definition of new protocols for the leaching of nanomaterials was attempted and is here proposed. The NPs suspensions and leachates from the NEPs were characterized by TEM, DLS and ICP-OES, while their aquatic toxicity potential was assessed using the Fish Embryo acute Toxicity test (OECD n.236). The Lethal Concentration 50 (LC50) and the Effective Concentration 50 (EC50) were calculated. Morphometric and behavioural analyses were performed on exposed embryos to assess additional indicators of sub-lethality.
LCA studies were carried out to assess the environmental sustainability of the materials' production. The associated impacts were assessed with the CML 2001 impact method and the OpenLCA software. Within the inventory phase, primary data and information on the synthesis/production processes of the NPs and the NEPs were collected and modelled.
Toxicology analyses did not highlight any significant lethal effect for all the NEPs and the hatching was the most affected endpoint at sub-lethal level. The LCA analyses identified the most impactful steps within the materials' production.
The integration of nano-ecotoxicology assessment and standard LCA studies is suggested as an effective methodology to provide a comprehensive and harmonised framework for decision-making during the design stage of safe and sustainable nano-enabled antimicrobials, for example, within the field of fish farming.

1.07.P-Th040 Filling The Fish Toxicity Data Gap of Pesticides Using in silico Tools:
***Selen Gökçe Selçuki**, Institute of Environmental Sciences, Bogazici University, Turkey*

Pesticides are a common group of chemicals used to facilitate human life in many areas. In 2018, the total amount of pesticide use in Turkey increased by 10.9% compared to 2017 and had reached 60,020 tons. Aquatic toxicity is one of the major concerns since the life cycle of chemicals mostly ends up in the water compartment. Considering all types of pesticides and the damage they cause to the environment, the need for toxicological and ecotoxicological data is very high. It is almost impossible to allocate enough time, budget and chemical use for the experimental testing required to fill this data gap. For this reason, substitution methods are used for the replacement of laboratory tests (i.e., *in vitro,* and *in vivo* methods) with alternative methods (i.e., non-experimental *in silico* methods) like quantitative structure-toxicity relationships (QSTRs). QSTR models for *Oncorhynchus mykiss* toxicity predictions of pesticides are notably depends on a small dataset, without using 3D descriptors or do not fulfill the OECD validation requirements. In the presented study, robust and reliable quantitative structure-toxicity relationships (QSTRs) for the toxicity of pesticides to fish with a defined applicability domain were generated and fish toxicity of pesticides with no experimental data was predicted by using the novel QSTR models.

For model development, experimental aquatic freshwater toxicity data of pesticides (from reliable sources which showed compliance with OECD principles for testing of chemicals) for fish were gathered from several databases and literature. Both for external validation and to fill the gap in the literature, the missing data for fish were estimated using these models. The chemicals within the AD of each model were listed. Validated QSTR models based on the Ordinary Least Square method were developed for acute toxicity prediction towards *Oncorhynchus mykiss*. Robust and predictive QSTR models were using 313 pesticides' toxicity data. The importance of 3D descriptors for pesticides in QSTR models for fish was underlined. The presented QSTR models were used to fill data gap for more than 300 pesticides without fish toxicity, by providing wider applicability domain than the existing studies in the field. The generated fish toxicity QSTR models for pesticides has a potential to be used in screening and prioritizaiton of pesticides.

1.07.P-Th041 Harmful Effects of Caffeine on the Fish Poeciliopsis gracilis Heckel, 1848 (Poeciliidae)

Alma Sobrino-Figueroa[1] *and Alberto Perez-Rojas*[2]*, (1)Hidrobiology, Metropolitan Autonomous University (UAM) Iztapalapa, Mexico, (2)Autonomous Metropolitan University-Iztapalapa, Mexico*

Poeciliopsis gracilis is a species native to Mexico, it lives in lentic areas of rivers and streams in the tropical portion of the coasts of the Gulf of Mexico and the Mexican Pacific. Because there are no studies on the response of *P. gracilis* to pollutants, in this study an evaluation of the effects on survival and physiological rates (respiration rate, excretion rate, feeding rate and growth rate) was carried out: in juvenile fishes exposed to caffeine. Initially, an acute bioassay was carried out where six concentrations of caffeine (0.0, 0.5, 1.0, 5.0, 10.0, 15.0, 20.5 1 mg/L) were tested (n = 10 in triplicate), to determine the lethal concentration (LC_{50}) (Probit) to 96 hours. Subsequently, a test lasting 20 days was carried out. Fish were exposed to 2 sublethal concentrations (LC_{50}/100 and LC_{50}/10). Samples were taken at 5, 15 and 20 days to measure physiological rates and at the end of the exposure period the growth rate was evaluated. TheLC_{50} obtained in the acute bioassays was 14.1 mg/L. In the sublethal bioassays, an increase in the respiration rate was observed in the first days of exposure and subsequently a decrease. On the contrary, the excretion rate increased throughout the exposure time. The feeding rate decreased after 15 days of exposure, consequently the rate of weight gain was lower compared to the control group. The O:N ratio obtained showed that the organisms presented high stress after 15 days of exposure to caffeine. The data obtained demonstrate that caffeine causes harmful effects to juveniles of *P. gracilis*.

1.07.P-Th042 INTOB: Advancing Digital Infrastructure for Enhanced and findable, accessible, interoperable, and reproducible (FAIR) Management and Analysis of Toxicological Data Obtained with Zebrafish Embryo

Nils Kluver, Paul Michaelis, Kristina Haase, Janet Krüger, ***Bente Nissen*** *and Wibke Busch, Helmholtz Centre for Environmental Research (UFZ), Germany*

Toxicological testing plays a pivotal role in diverse contexts, ranging from regulatory approvals for chemical substances to environmental assessments and scientific investigations into toxicity's cause-and-effect relationships. Here we introduce INTOB (Integrated effect data base for toxicological observations on organism scale), a software designed for the structured management of toxicological data and metadata according to the FAIR principles ("findable, accessible, interoperable, and reproducible"). INTOB facilitates the FAIR management of observation data generated through the widely employed zebrafish embryo toxicity test, a recognized OECD standard (OECD TG 236). The application extends to areas such as the quality assessment of wastewater in accordance with DIN EN ISO 15088.

INTOB serves as a comprehensive solution, its central in-house database not only ensures data sovereignty for users, but also provides a robust system for quality control and standardisation, and flexibility in data usage. In a landscape where the digitization of toxicological observations is still in its infancy, INTOB emerges as a state-of-the-art solution, addressing the urgent need for efficient data management in response to political, regulatory, and industrial demands. Furthermore, INTOB sets the stage for the integration of artificial intelligence-based analytical methods in the realm of toxicology, presenting a forward-looking perspective on the evolution of toxicological data management and analysis. Here we explore the functionalities, benefits, and potential applications of INTOB, offering valuable insights into the future trajectory of digitization in toxicology.

1.07.P-Th043 Identification of Differences in Mechanisms of Developmental Neurotoxicity of Methyl-, Ethyl-, and Propyl-Parabens in Zebrafish Embryos Through Transcriptome Analysis

Tran Cong, ***Ji Yun Kang****, Seongeun Park and Kitae Kim, Seoul National University of Science and Technology, Korea, Republic of (South)*

Para-hydroxybenzoates, including methyl, ethyl, and propyl parabens, are widely used industrial preservatives known for their antiseptic properties. However, their chemical nature allows easy release into indoor environments during product use, posing concerns for infants and young children who spend extended periods indoors. This study employed a zebrafish embryo model to assess the neurotoxicity of commonly encountered methyl, ethyl, and propyl parabens.

In response to the limited comparative developmental (neuro)toxicity studies on parabens, the investigation aimed to align phenotypic observations with transcriptomic analyses. Zebrafish embryos (2–4 hours post-fertilization) were exposed to varying concentrations (0, 5, 10, 20, 40, 80, 150, and 300 μM) of the parabens. Acute toxic effects were assessed through embryonic mortality-based POD (M-POD) values at 120 hpf, utilizing a 5% benchmark dose. Behavioral assessments were conducted on 120 hpf zebrafish at M-POD concentrations of 0, M-POD/50, M-POD/10, and M-POD, with behavior analyzed using Zebrabox. Transcriptome analysis at 120 hpf after exposure to sublethal paraben concentrations (0, M-POD/50, M-POD/10, and M-POD) provided tentative transcriptome-based POD (T-POD) values for each paraben, compared with M-POD values.

In conclusion, long-chain propyl paraben exhibited greater acute toxicity than short-chain methyl and ethyl parabens. Behavioral assays at BMD 5 concentrations, determined based on morphological incidence, revealed changes in larval behavior only in the ethyl paraben-exposed group. Subsequent transcriptome analysis confirmed that the observed hyperactivity was associated with derangement. T-POD values for the three parabens were similar, despite differences in embryotoxicity and malformation based on chain length. This suggests that adverse effects of the three parabens can manifest at similarly low concentrations. However, distinct molecular perturbations determine varying degrees and consequences of toxicity. The study demonstrates that POD-based transcriptome alterations are effective for comparing molecular mechanisms regulating phenotypic traits between two or more toxic chemicals.

This study was supported by Korea Environment Industry & Technology Institute (KEITI) through "the Technology Development Project for Safety Management of Household Chemical Products", funded by Korea Ministry of Environment (MOE) (grant number 2020002960006).

1.07.P-Th044 Identification of Molecular Markers on Zebrafish Embryo for Thyroid Disruption by Transcriptomic Analysis

Noémie de Crozé[1]*, Celia Marti Marti*[2]*, Laurent Sachs*[3] *and Nicolas Buisine*[3]*, (1)L'Oréal, France, (2)MNHN, France, (3)UMR 7221 CNRS/MNHN Muséum National d'Histoire Naturelle, France*

Environmental pollution is a rising concern for both human and environmental health. Among others, the evaluation of endocrine disruptor chemicals is a challenge for both regulators and industry. Only a few methods exist to identify Thyroid Disruptor Chemicals (TDC). Those methods are low throughput and expensive or do not often comply with the animal testing ban of cosmetic regulation. Therefore, it is becoming urgent to develop novel strategies and screening methods to identify TDCs. As thyroid signaling is highly conserved between teleost and mammals, zebrafish embryo is an alternative model for studying both physiological regulations and disruption. We design a transcriptomic analysis where embryos are exposed to reference compounds alone or in combination with thyroid hormones (T_3 and T_4) according to the FET test protocol (Fish Embryo Test - OECD guideline, n°236). We selected four reference compounds: Iopanoic acid (IOP), Sodium Perchlorate (PCL), Tetrabromobisphenol A (TBBPA) and Propylthiouracil (PTU) based on their different modes of action on the thyroid signaling pathway. We choose to expose the embryos at dose corresponding to FET EC10 and analyzed their transcriptomes by RNA sequencing.

After quality control, reads were mapped to Danio rerio genome. Lists of differentially regulated genes (DEGs) are classified in several clusters, each corresponding to a type of biological response. Despite a great diversity of biological responses, DEGs are classified into three families: chemical dependent (Only compound), Thyroid Hormone dependent (TH only) and crosstalk responses (Potential TD). These correspond to specific effects due to the action of selected compounds alone or in co-treatment with thyroid hormones (crosstalk responses).

We found major effects with our reference compound alone, but virtually no effect with THs alone. Co treatment TH + compound revealed not independent responses thereby identifying potential thyroid signaling disruption. The biological processes affected are related to apoptosis, metabolism, and immune system. We provide a list of around 80 potential biomarkers of thyroid signaling disruption.

1.07.P-Th045 Impact of Trifloxystrobin Exposure on the Early-Stage Zebrafish (Danio rerio) Metabolome

Chaeeun Kim*, Donghyeon Kim and Sung-Eun Lee, Department of Applied Biosciences, Kyungpook National University, Korea, Republic of (South)*

Trifloxystrobin (TFS) belongs to the strobilurin group of fungicides widely used in agriculture. TFS is known for its broad-spectrum activity against a wide range of fungal pathogens. This fungicide inhibits the mitochondrial respiratory chain complex III in fungi, disrupting their ability to generate energy. TFS was found to cause severe developmental toxicity in zebrafish (*Danio rerio*) embryos, resulting in developmental delays as well as heart and vascular defects. As the alterations in metabolic pathways induced by TFS are still unknown, we carried out metabolomics to identify developmental toxicity. After being treated with TFS 0.2 mg/L to zebrafish embryos up to 96 h post-fertilization (hpf). Phenotypes were photographed at the endpoint and samples were collected for analysis of metabolites. Embryos exposed to TFS showed various phenotypes like curved spine, yolk sac edema, and heart edema at 96 hpf. Relative amounts of compounds that were included in metabolic pathways were confirmed with GC-TOF-MS. Based on the results of multivariate statistical analysis, the control group and TFS-treated group were well distinguished. 42 metabolites were selected and identified by the OPLS-DA model, and the amounts of glutaric acid were relatively increased in the TFS-treated group. Compared to the control group, the TFS-treated group showed relatively lower fatty acid and its derivatives. Taken together, TFS exposure can lead to the disruption of various pathways in developing zebrafish embryos with potential implications for carbohydrates and fatty acids in organisms. These findings indicate that the application of TFS in the agricultural field could potentially have adverse effects on the early-stage development of organisms in aquatic ecosystems.

1.07.P-Th046 Investigating The Mechanisms of Endocrine Disrupting Chemical-Induced Masculinization in Medaka (Oryzias latipes)

Ching-Hsin Yang Mr[1] *and Pei-Jen Chen*[2]*, (1)Department of Agricultural Chemistry, National Taiwan University, Taiwan, (2)National Taiwan University, Taiwan*

Endocrine disrupting chemical (EDC)-induced sex disruption in fish is blamed to severely reduce fish populations and cause critical effects to aquatic ecosystem [1]. However, the molecular mechanisms of chemical induced sex disruption in fish are not well-understood yet. Recent studies indicate that late-embryonic to early larval stages are the critical period for gonad differentiation in medaka (*Oryzias latipes*). The sex of medaka is basically determined by genotypes (XX/XY) and the critical sex determination gene, *DMY/ dmrt1bY*, is located on Y chromosome [2]. Meanwhile, some key genes expressed in the critical period for gonad differentiation are also identified in medaka. The aim of this research is to investigate the mechanisms of chemical induced sex disruption in gonad differentiation during late-embryonic to early larval stages of medaka after exposure to synthetic sex hormones. Candidate genes at early stages are firstly selected by comparing the expression levels in XX and XY medaka larvae. Next, known EDCs, such as 17α-methyltestosterone (MT), are applied for investigation of the molecular mechanisms of chemical induced sex disruption in medaka. In addition, we will further discover novel genes by RNA-seq to depict the molecular mechanisms of chemical induced sex disruption in medaka.

1.07.P-Th047 Is the Japanese Medaka a Reliable Species for Testing Endocrine Disrupting Compounds?

*Sylviane Gony[1], Ines Conrad[2] and **Giuliana de Araujo**[2], (1)Eurofins Agroscience Services Regulatory, France, (2)Eurofins Agroscience Services Regulatory, Spain*

The Japanese medaka *Oryzias latipes* is one of the recommended species in various internationally validated guidelines for the testing of chemicals to assess fish toxicity, including those developed for identifying the potential of substances for endocrine disruption (ED). Several of these tests are exclusively conducted with this species (OECD TG 240: Medaka extended one generation reproduction test - MEOGRT; OECD TG 251: Rapid Androgen Disruption Activity Reporter Assay – RADAR; OECD Series on Testing and Assessment GD 379: Juvenile medaka anti-androgen screening assay - JMASA). In the following, the pros and cons for using the Medaka in ED testing are discussed.

There are various reasons for the popularity of medaka. First of all, it is an easy-to-breed species in laboratory conditions, and it has been used for so long in testing that all its requirements are well-known and well handled. Moreover, it is small enough to allow testing on a sufficient number of fish for statistical robustness while being large enough to allow a detailed analysis of several parameters. The duration of its life cycle with an early sexual maturity at 2-3 months, is compatible with laboratory experimentation, and results can be expected in a reasonable time. Finally, the species is characterized by easily identifiable secondary sex characteristics in the male individuals, explaining the interest in this species for ED testing.

Based on such elements, this species could be the perfect choice for conducting testing for the identification of ED compounds, and that is probably why it is recommended in so many guidelines. Then why could the use of medaka in ED testing be questioned? The fact is that under some breeding conditions, medaka may undergo sex reversal from female to male without any exposure to any xenobiotic compound, during early development. The effect of temperature on the potential for sex reversal has been indeed known for more than a decade and is briefly mentioned in the JMASA guideline introduction. But more recent papers indicate that other stress factors could also induce sex reversal.

Therefore, since sex reversal can be induced without direct interaction of the tested chemical with an EAS modality, positive results in tests involving developmental phases such as MEOGRT and JMASA, but also FELS test (OECD 201: Fish early-life stage toxicity test), and fish full life-cycle test (EPA OPPTS 850.1500) should be considered with care.

1.07.P-Th048 Metabolomics approach to detecting toxicity in Oreochromis niloticus exposed to natural and synthetic organophosphates

***Larissa Souza Passos**[1], Paloma Nathane Nunes de Freitas[2], Alexander Ossanes de Souza[2], Mariana de Almeida Torres[3], Éryka Costa de Almeida[3] and Ernani Pinto[2], (1)Center for Nuclear Energy in Agriculture (CENA), University of São Paulo (USP), Butantã, Brazil, (2)Center for Nuclear Energy in Agriculture (CENA), University of São Paulo (USP), Brazil, (3)School of Pharmaceutical Sciences (FCF), University of São Paulo (USP), Brazil*

The proliferation of toxic cyanobacteria, caused by the intensification of the eutrophication process, generally coincides with pesticide pollution, mainly by surface runoff and leaching. Therefore, this study aimed to evaluate the toxicity of the cyanobacterium *Sphaerospermopsis torques-reginae* (ITEP-024 strain), which produces a natural organophosphate (guanitoxin) associated with synthetic organophosphate pesticides in specimens of *Oreochromis niloticus*. For this, we verified the exposure of *O. niloticus* for 96 h to six treatments, being: control group (C), aqueous extract of ITEP-024 250 mg/L (T1), insecticide malathion 1 mg/L (T2), insecticide trichlorfon 0.5 mg/L (T3), ITEP-024 + malathion (T4), ITEP-024 + trichlorfon (T5), and ITEP-024 + malathion + trichlorfon (T6). To detect the deleterious effects on fish, we used a global metabolomics approach with the quantification of primary metabolites by UHPLC-MS/MS. Besides that, an Integrated Biomarker Response - version 2 (IBRv2) was employed to correlate the response of the metabolites in the treatments to the control group. Thirty-nine primary metabolites were quantified, including amino acids, nitrogenous bases of DNA, nucleosides, and organic osmolytes. Among them, 11 showed a down or up-regulation. Proline, glycine, alanine, histidine, serine, aspartate, and guanosine presented a downregulation, while carnitine, cystine, thymine, and trimethylamine N-oxide (TMAO) showed an up-regulation. The higher IBRv2 values were in the T4 and T2, indicating the most deregulation for both treatments. Amino acid deregulation may impair vital organism activities, even as changes in thymine levels can affect DNA integrity and gene expression, which can have several negative consequences for organisms. Furthermore, guanosine has several biological functions, and the decrease in the content suggests inhibiting the organism's cellular growth activity. In conclusion, this study represents the first attempt to assess the synergistic interactions between guanitoxin-producing cyanobacteria and insecticides. We indicated that the combination of malathion and guanitoxin-containing extracts was particularly concerning. Despite the importance of observing these metabolites in ecotoxicological assessments, there is a need for studies examining their concentrations in fish following chemical exposure, indicating the urgency of understanding how these metabolites can be deregulated and how aquatic animals cope with this damage.

1.07.P-Th049 Nanoplastic-induced toxicity mechanism in intact zebrafish larvae revealed by novel magnetic resonance method

Bashirova Narmin*, Institute of Medical Physics and Biophysics, Leipzig University, Leipzig, Germany Institute of Analytical Chemistry, Leipzig University, Leipzig, Germany*

Considering the ubiquitous presence and enduring nature of plastics globally, exposure to these materials, especially nanoplastics (NPs), is unavoidable for both humans and animals. Polyethylene terephthalate (PET) is one of the most widely used plastics. Despite the widespread use of PET in packaging, currently, limited research exists on the bioaccumulation and toxicity of nanoparticle originating from PET (PET NPs). Moreover, due to lack of appropriate methods, the system-level understanding of toxicity mechanism of PET NPs is not known. The present study aimed to systematically investigate the physiological and metabolic effects of PET NPs exposure and to explore the underlying toxicity mechanism. To elucidate systematic understanding of the toxicity mechanism of PET NPs we utilized state-of-the-art high-resolution magic angle spinning nuclear magnetic resonance (HRMAS NMR), applied to intact zebrafish (*Danio rerio*) embryo. Accumulation of PET NPs in larvae was observed in the liver, brain as well as intestine which coincides with the localization of reactive oxygen species in this area. HRMAS NMR based metabolic profile of zebrafish coupled with multivariate analysis revealed liver impairment caused by PET NPs. Targeting of liver by PET NPs was also indicated by an increase in various potential biomarker of the hepatoxicity. HRMAS NMR spectra also clearly show elevated levels of fatty acids as well as polar head groups of phospholipids, signifying PET NPs induce disruption of membrane integrity. Furthermore, metabolites associated with cellular bioenergetics (e.g., glucose, lactate, acetate, ATP and NADH) were significantly affected by PET NPs exposure. Taken together, our work provides a comprehensive system level insight into the mechanism of PET NPs induced toxicity.

1.07.P-Th050 Neurodevelopmental Effects of Petroleum Exposure on Developing Zebrafish (Danio rerio): Insights into Sensory-, Motor- and Anxiety- Responses

Alischa Helena Becker[1]*, Bianca Dechent*[2]*, Philippe Eschmann*[3]*, Constanze Heinzen*[4]*, Bettina C. Kirchmaier*[5]*, Virginie Lecaudey*[4]*, Jakob Pfefferle*[6]*, Henner Hollert*[1] *and Sarah Johann*[1]*, (1)Evolutionary ecology and environmental toxicology, Goethe University Frankfurt, Germany, (2)Goethe University Frankfurt, Germany, (3)Department of Molecular and Cellular Neuroscience, Goethe University Frankfurt, Germany, (4)Department Developmental Biology of Vertebrates, Goethe University Frankfurt, Germany, (5)Molecular and Cellular Neuroscience, Goethe University Frankfurt, Germany, (6)Evolutionary Ecology & Environmental Toxicology, Goethe University Frankfurt, Germany*

Oil spills cause serious threats to aquatic ecosystems and are very challenging to assess due to the highly complex and unique composition of oils. Studies demonstrated that developing fish exposed to crude oils were particularly susceptible to adverse effects at low concentrations, which can have severe consequences for entire populations. In this context, our previous work showed a structural impairment of the visual system and first indication of developmental neurotoxicity (reduced spontaneous tail coiling) in oil-exposed zebrafish. However, the impact on other sensory organs such as the lateral line system (LLS) and a detailed understanding of different neurotoxic pathways remains largely unknown. Hence, the present study aimed to investigate whether water-accommodated fractions (WAF) of native and chemically dispersed crude oil and chemical dispersant alone impact 1) the development of the LLS, 2) the motor neuron development, and 3) anxiety-like behavior in zebrafish embryos. Embryos were exposed to sublethal effect concentrations of WAFs ($\leq EC_5$) below the threshold for visible morphological malformations. For posterior LLS assessment, potential apoptotic hair cells and hair cell damage were quantified using *in vivo* double-staining with DAPI (nuclei) and DASPEI (mitochondria) at 96 hours post fertilization (hpf). Using confocal laser scanning microscopy, examination of *in vivo* embryonic motor development was performed by focusing on primary motor neurons in a double-transgenic zebrafish line (24-48 hpf), highlighting caudal primary motor neurons expressing the GFP-bound receptor neuropilin 1a (*nrp1a:eGFP*), in a pan-neuronal reporter background (*xla.tubb:DsRed*). As an indicator for anxiety-behavior we studied thigmotaxis in 120 hpf zebrafish assessed by stimulating thigmotactic (wall-hugging) behavior using an external stressor (sudden darkness). Preliminary results indicated increased thigmotaxis after petroleum exposure and a trend towards increased relative axonal motor neuron length at 24 hpf after chemically dispersed crude oil exposure. We expected a higher responsiveness of the hair cells after WAF exposure due to the direct interface with the surrounding medium. Overall, the present results will help to provide a more holistic profile of neurodevelopmental toxic effects and potential modes of action after petroleum exposure.

1.07.P-Th051 Neurotoxic effects of antidepressants on zebrafish embryos.

Ines Lacchetti[1]*, Giulia Gatti*[2]*, Kevin di Domenico*[3]*, Walter Cristiano*[4]*, Melissa Barra*[5]*, Aurora Mancini*[2] *and Mario Carere*[5]*, (1)Environmental and Health, Italian Institute of Health (ISS), Italy, (2)Damsa, Italian Institute of Health (ISS), Italy, (3)Environment and Health, Italian National Institute of Health, Italy, (4)Environment and Health, Italian Institute of Health (ISS), Italy, (5)Italian Institute of Health (ISS), Italy*

Increasing use of Benzodiazepines has been linked to an increase in anxiety and depression cases in the post-pandemic period. As they are able to avoid the most common purification treatments, it is reasonable to expect an increase of their concentrations in surface waters. The aim of the study has been to evaluate the ecotoxicological effects of benzodiazepine on zebrafish model, in particular the research focused on the neurotoxic effects on zebrafish embryos.

The active substance that has been chosen is alprazolam, a widely used benzodiazepine even among the younger population. Ecotoxicological data is currently unavailable and the Predicted No Effect Concentrations (PNEC) for fish was estimated by ECOSAR to be 18 µg/L.

Therefore, in order to obtain more informations, two ecotoxicological tests were applied and compared: the "Fish Embryo toxicity (FET) test" (OECD 236, 2013) and the neurotoxicity test "Coiling Activity of Tail (CAT) test". Thus, the tests were conducted at three concentration levels: 25 µg/L, 250 µg/L, and 2500 µg/L. The comparison of the results obtained with the ecotoxicological test showed that there were no significant acute effects with the FET since the maximum measured value (25%) was detected for concentrations of 250 µg/L and 2500 µg/L. The increasing trend of concentrations is described by the effects of sublethality. In particular, the CAT test showed a direct relationship with the concentrations analyzed. In addition, the effect percentage of the endpoint number of tail beats per minute (one of the three parameters measured with CAT), showed significantly higher values than the control already at the lowest concentration of alprazolam 25 µg/L .

In conclusion, the present study has shown the neurotoxic effect of alprazolam on zebrafish embryos, in particular the drug has determined hyperactivity for all the tested concentrations. Finally, it should be noted that the lowest concentration 25 µg/L is similar to the PNEC value 18 µg/L extrapolated and has determined important effects of neurotoxicity on embryos.

Therefore, more attention should be paid to the monitoring and effect of benzodiazepines in surface waters. Early warning systems such as CAT are also key and useful tools for detecting the effects of climate change The upcoming harmonisation and standardization of this method would be necessary due to its potential value in implementing EU guidelines and regulatory strategies to identify neurotoxic risks in ecosystem.

1.07.P-Th052 Osmotic diuretic exposure blocks aryl phosphate ester-induced pericardial edema in zebrafish embryos
John X Hoang[1]*, Jenna Wiegand*[1]*, Zoe Mersman*[1]*, David C. Volz*[1,2]*, Kevin Michalicek*[1] *and Nicholas Jimenez*[1]*, (1)University of California Riverside (UC Riverside), (2)Department of Environmental Sciences, University of California Riverside (UC Riverside)*
Pericardial edema (PE) – fluid accumulation within the pericardium – is a frequently observed malformation in zebrafish embryo-based chemical toxicity screens. We recently found that triphenyl phosphate (TPHP)-induced PE was mitigated by an increase in the osmolarity of exposure media, suggesting that PE may be driven by a disruption in osmoregulation across the embryonic epidermis. Therefore, the objective of this study was to investigate whether, similar to TPHP, PE induced by other structurally related aryl phosphate esters (APEs) is dependent on the osmolarity of exposure media. To accomplish this objective, we first mined the peer-reviewed literature to identify other APEs that 1) induced PE in zebrafish embryos within a minimum of 3 peer-reviewed publications and 2) demonstrated a statistically significant induction of PE in ≥60% of the studies. Based on this meta-analysis, we identified 5 other APEs that caused PE in zebrafish embryos: triisophrophylated phenyl phosphate (IPP-3), cresyl diphenyl phosphate (CDP), tricresyl phosphate (TMPP), 2-ethylhexyl diphenyl phosphate (EDHP), and tert-butylphenyl diphenyl phosphate (BPDP). Using TPHP as a positive control and PE as a readout, we developed concentration-response curves for all 5 APEs based on a static exposure from 24-72 h post-fertilization (hpf). Using the EC50 concentration (based on PE) for each APE, we then conducted co-exposures with D-Mannitol (an osmotic diuretic) from 24-72 hpf to determine whether, similar to TPHP, an increase in the osmolarity of exposure media mitigated APE-induced PE at 72 hpf. Using PE as an endpoint, the approximate EC50s for TPHP, IPP-3, CDP, TMPP, and EDHP were 6.25, 3.125, 3.125, 25, and 100 µM, respectively. Interestingly, similar to our findings with TPHP, co-exposure with D-Mannitol from 24-72 hpf completely blocked IPP-3- CDP-, TMPP-, and EDHP-induced PE in zebrafish embryos. For BPDP, we are currently finalizing BPDP-alone and BPDP+D-Mannitol exposures, albeit we expect that D-Mannitol will also block BPDP-induced PE. Overall, our findings to date suggest that chemically-induced PE may be 1) dependent on the osmolarity of exposure media and 2) driven by a disruption in osmoregulation across the embryonic epidermis. Therefore, our findings underscore the need to standardize the osmolarity of exposure media in order to minimize the potential for false positive/negative hits in zebrafish embryo-based chemical toxicity screens conducted around the world.

1.07.P-Th053 Paired Computer-Assisted Sperm Analysis (CASA) and ATP Quantification Methods to Assess Reproductive Capacity of Male Mummichog (Fundulus heteroclitus)
Sabine Malik[1]*, Tyler Edward Frankel*[2]*, Carys Louise Mitchelmore*[3]*, Candice Duncan*[1] *and Lance T Yonkos*[4]*, (1)University of Maryland, (2)Earth and Environmental Sciences, University of Mary Washington, (3)Chesapeake Biological Laboratory, University of Maryland Center for Environmental Science, (4)Environmental Science & Technology, University of Maryland*
While many methodologies exist to assess female reproductive competence in aquatic species, there are little to no standard methods developed for male reproductive health. Though male contribution to offspring success has historically been considered relatively small, increasing bodies of evidence support that sperm quality can have a lasting influence on the health of offspring. Current sperm quality characterization methods rely on expensive, specialized equipment that prevent widespread use of sperm quality assays when conducting reproductive health assessments of a particular system. To counter this, we developed a field-adaptable sperm motility characterization method able to be conducted with only standard laboratory equipment, validated using the male mummichog, *Fundulus heteroclitus.* Most notably, computer-assisted sperm analysis (CASA) was conducted on sperm from field-collected mummichogs and analyzed using an open-source ImageJ plugin. Because sperm movement is powered by ATP release, ATP was also quantified in inactivated sperm from the same fish using a firefly-luciferase ATP microplate assay. These methods were used on sperm from field-collected *F. heteroclitus* sourced

from two historically contaminated US rivers (Christina River, DE, USA; Anacostia River, MD, USA) and from a clean reference location (Wye River, MD, USA). These systems have a history of urban legacy contaminants, including PCBs, PAHs, and other chemicals associated with industry. Ten male mummichogs were collected from each site on each river and their sperm motility recorded in the field for subsequent CASA. Samples for ATP analysis were cryopreserved and taken to the lab for microplate analysis. Compared against the Wye River reference, all historically impacted sites showed some level of decreased ATP stores, though this varied substantially between fish at each site. Total motility and movement characteristics were marginally higher in reference fish than exposed populations and correlated well with ATP quantity, both by sites and generally by fish. This indicates that in many instances, supplementing traditional CASA with ATP quantification can be useful for explaining decreased motility, however additional analysis is required to establish if impairment is related to malformed anatomy rather than inadequate energy stores.

1.07.P-Th054 Modification of the Comet Assay to Assess Sperm DNA Integrity in the Male Mummichog (Fundulus heteroclitus)

Sabine Malik[1]*, Carys Louise Mitchelmore*[2]*, Tyler Edward Frankel*[3]*, Candice Duncan*[1] *and Lance T Yonkos*[4]*, (1)University of Maryland, (2)Chesapeake Biological Laboratory, University of Maryland Center for Environmental Science, (3)Earth and Environmental Sciences, University of Mary Washington, (4)Environmental Science & Technology, University of Maryland*

As genomics advances in popularity, greater importance in the field of toxicology is placed on DNA integrity in response to common contaminants. This is particularly true of endocrine disruption research, as abnormal gene expression can disrupt hormone signaling and other normal processes. While promising and descriptive, these methods are costly and not yet widely accessible to labs for inclusion in general reproductive health damage assessments. To combat this, the Comet assay (single-cell gel electrophoresis) done on sperm cells can be used as an informative screening tool to assess for DNA damage in a particular system using standard laboratory equipment. While traditionally done on blood and liver cells, the Comet assay can be adapted for sperm cells by decreasing standard unwinding and electrophoresis times. These methods were used on sperm from field-collected mummichogs (*Fundulus heteroclitus)* sourced from two historically contaminated US rivers (Christina River, DE, USA; Anacostia River, MD, USA) and from a clean reference location (Wye River, MD, USA). These locations have a complex history of industry and legacy contamination, as well as continued urban inputs due to proximity to cities, with prominent chemical profiles of PAHs, PCBs, and potentially associated contaminants such as zinc. Ten male adults were collected from each site on each river and their sperm cryopreserved to conduct the Comet assay in the lab. Samples were stained, imaged, and processed using an open-source Comet scoring software. As compared to the control population, all historically impacted sites displayed significantly increased levels of DNA damage as measured by tail length and intensity, tail moment, and % DNA in the tail. Extent of the damage observed also correlated well with the most contaminated sites. Most severe damage was seen in the PAH-laden Hershey Run site on the Christina River, though the Anacostia had consistently high levels of damage at the Lower Beaverdam site, as well. While the reference population had little to no damage in any fish, another site on the Anacostia (Bladensburg) had variable levels of damage, with some severe and some nearly unimpacted fish. These results indicate the continued relevance and importance of the Comet assay for detecting basic DNA damage and its usefulness in complement with other sperm quality characterization techniques to fully understand the scope of damage in a particular system.

1.07.P-Th055 Pharmaceuticals and mixtures in the environment: a review on the use of zebrafish for neurotoxicity

Kevin di Domenico[1]*, Ines Lacchetti*[1]*, Giulia Cafiero*[2]*, Aurora Mancini*[3]*, Mario Carere*[1] *and Laura Mancini*[1]*, (1)Environment and Health, Italian National Institute of Health, Italy, (2)Environmental Risk Assessment, Wageningen University & Research, Netherlands, (3)Law, Roma Tre University, Italy*

The presence of neurotoxic chemical substances in the environment is an issue for both human and environmental health. Moreover, the interaction between different compounds mixed togheter is also a problem that can generate unpredictable effects and magnify the toxicity of the single chemicals. In this work we aim to summarise the use of zebrafish (*Danio rerio*) as a model for detecting the toxics effects of chemical mixtures. We decided to include in particular all the papers that between 2012 and 2023 focused on neurotoxicity, a widespread Mode of Action for many substances, through a behavioural approach.

This work was articulated in several steps: first, we elaborated a search string, then, we performed the bibliographic research on Embase. All the papers that resulted from the research were then analysed to determine if they met the criteria for inclusion in the final paper. All papers included were then summarised, statystical data was extrapolated and the results were reported.

The research, performed in September 2023, initially identified 779 papers that were later reduced to 171 by title and abstract reading. A screening based on the full-text reading furtherly reduced the final number to 101. All papers included were then grouped togheter and summarised based on the classes of chemicals involved. A statystical analysis was then performed, highliting a growing interest for the zebrafish model for this kind of application, a prevalence of short-term exposures and a balanced use of all developmental stages. This work also shows the use of a wide variety of different assays based on different senses, on the chemicals used and the developmental stages involved.

In conclusion zebrafish, that has already known a growing use in the biomedical research over the years, is proving to be an useful tool for the detection of the overall toxicity of simple and complex mixtures. As summarised in this work, there are numerous possibilities of applications with both zebrafish adults and embryos for neurotoxicity. The use of many different assays to evaluate the same endpoints however might show the need for a more standardized approach. A more widespread use of the early develpomental stages over the adult individuals should also be preferred when possible, in line with the current "3R" principle of animal experimentation.

1.07.P-Th056 Potential Triggering Effect of BPS for Diabetes by Dietary Condition in Zebrafish

***Yuna Kim*[1]**, *Ah-Reum Jo[2] and Kyungho Choi[2], (1)School of Public Health, Seoul National University, Seoul, Korea, Republic of, (2)School of Public Health, Seoul National University, Korea, Republic of (South)*

The escalating global prevalence of diabetes has been a significant societal and economic concern. Environmental factors, particularly chemicals suspected to disrupt metabolism, have drawn attention as potential player in the etiology of diabetes. Bisphenol S (BPS) is suspected as chemical risk factor that may be associated with type 2 diabetes in human populations. This study employs zebrafish (*Danio rerio*) as a model organism to elucidate the potential mechanisms by which exposure to BPS may impact the development of T2D, especially under different dietary conditions.

To this end, 6-8 months old male zebrafish were exposed to two different concentrations of BPS for 14 days, i.e., 0.013mM (labeled as 'BH'), and 0.004mM ('BL'), with different dietary conditions, i.e. normal fat diet with Artemia (labeled as 'NF') group and high fat diet ('HF') group with additional egg yolk powder. Plasma insulin and glucose levels were measured, along with the transcription of genes involved in diabetes pathway, insulin signaling, and glucose metabolism.

Following exposure, NF+BH group exhibited higher fasting glucose and insulin compared to NF, supporting that bisphenol S has a potential to develop diabetes in adult zebrafish. Significantly higher glucose was observed in HF+BPS group. This observation indicates that high fat diet may increase susceptibility of zebrafish to bisphenol S toward development of diabetes. The genes associated with both the insulin signaling pathway and the diabetes pathway (*insra, insrb, pik3ca, irs1*) exhibited general pattern of upregulation when dietary condition changed to more fat or chemical dose increased. Moreover, expression of genes related to glucose metabolism (*g6pca.1, gcgra, gcgrb, hk2*) was also disrupted, implying potential influence of BPS on glucose homeostasis.

The results of this study shows possible interaction of dietary condition in the diabetogenic effects of bisphenol S in zebrafish. Investigation to unravel the role of bisphenol S in etiology of diabetes should include intricate influence of dietary effects. Further study is warranted to screen similar effects for bisphenol A analogues.

This work was supported by Korea Environmental Industry & Technology Institute (KEITI) through "Core Technology Development Project for Environmental Diseases Prevention and Management", funded by Korea Ministry of Environment (MOE) (RS-2022-KE002173).

1.07.P-Th057 Subcellular effects of an antineoplastic agent and a nanomaterial to zebrafish

***Diana Isabel Oliveira Carneiro*[1]**, *Daniel Alexandre Bruno[2], Susana Loureiro[1], Roberto Martins[3] and Maria D Pavlaki[1], (1)University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Portugal, (2)University of Aveiro, Portugal, (3)CESAM-Centre for Environmental and Marine Studies and Department of Biology, University of Aveiro, Portugal*

Emerging contaminants (ECs) ECs interact with various compounds in aquatic environments, posing threats to ecosystems. Traditional hazard and risk assessment procedures often focus on individual compounds, but in the environment, organisms face intricate mixtures of stressors, highlighting the need for a comprehensive understanding. ECs, such as antineoplastics agents (AAs) and engineered nanomaterials (ENMs), present significant challenges in environmental risk assessment due to their limited regulation and understudied impacts. AAs, categorized as micropollutants, exhibit cytotoxicity at low concentrations, posing potential threats to aquatic organisms. Layered double hydroxides (LDHs) are stimuli-responsive nanomaterials with diverse applications, including as nanocarriers of drugs like AAs. This highlights the need for a comprehensive understanding of their combined effects, particularly at the subcellular level. Thus, this study aims to assess the biochemical and genotoxic joint effects of Mg-Al LDH and epirubicin in *Danio rerio*.

Danio rerio embryos, a well-established model organism, were exposed to no-effect concentrations of Epirubicin and Mg-Al LDH, in single and mixture exposures, according to the OECD 236 FET protocol. For the mixture exposure, a full factorial design was applied. DNA damage (evaluated through the comet assay) was assessed after 96 hours of exposure, while neurotoxicity and oxidative stress-related biomarkers were examined at the end of the 120-hour exposure period.

Epirubicin induced 15 – 25 % of DNA damage, as determined by the analysis of tail DNA, in zebrafish exposed to concentrations higher than 132 µg/L. The DNA damage caused by Mg-Al LDH was below 10 %. Epirubicin caused no neurotoxic or oxidative stress effects on *D. rerio* larvae at concentrations of up to 670 µg/L. No oxidative stress was observed after exposure to Mg-Al LDH, but larvae exhibited significant AChE activity inhibition at concentrations above 20 mg/L of Mg-Al LDH. These findings provide valuable insights of the subcellular effects promoted by mixtures of emerging compounds, like AAs and ENMs, in aquatic organisms and may assist in their future environmental hazard and risk assessment.

1.07.P-Th058 The impact of nano-polypropylene accumulation in the brain on behavioral changes in Zebrafish (Danio rerio)

Minji Kim[1] *and Sang Don Kim*[2]*, (1)Gwangju Institute of Science and Technology (GIST), Korea, Republic of (South), (2)School of Earth Science and Environmental Engineering, Gwangju Institute of Science and Technology (GIST), Korea, Republic of (South)*
Plastic pollution in the environment has emerged as a new contaminant with potential toxicological impacts on various organisms. Among them, nanoplastic, which has a small size and high bioavailability, and exist anywhere in the environment, poses a great threat to the ecosystem. Although research on the toxicity of nanoplastic is actively ongoing, our understanding remains limited. In this study, toxicity experiments were conducted using directly synthesized nano-polypropylene (PPNPs). The accumulation of PPNPs in the brina was confirmed, and the neurotoxic effects of accumulated PPNPs were investigated. Zebrafish (*Danio rerio*) were chosen as the experimental model due to their genetic and biological similarity to humans and comparable physiological characteristics with other animal models. Zebrafish exposed to four concentrations of PPNPs under optimal rearing conditions were used for analysis. The presence of PPNPs in the zebrafish brain was confirmed through pyrolysis gas chromatography-mass spectrometry and bio-transmission electron microscope. Behavioral monitoring assessed mobility and aggression, while enzyme levels of neurotransmitters and neural activity were measured. The accumulation of PPNPs in the brain, verified by TEM micrography, led to neurotoxicity, resulting in reduced mobility and aggressiveness. Changes in neurotransmitter levels and neural activity, associated with behavior further supported these findings. In conclusion, this study suggests that environmental plastic pollution can induce neurotoxicity in organisms, emphasizes the need for appropriate management of these materials.

1.07.P-Th059 Toxicity assessments of benzophenone-related derivatives in medaka fish
Pei-Jen Chen[1] *and Chan-Hao Hsu Mr*[2]*, (1)National Taiwan University, Taiwan, (2)Department of Agricultural Chemistry, National Taiwan University, Taiwan*
Benzophenones (BPs) are a category of chemicals with similar structures, commonly used as UV filters (e.g., BP itself and BP1-BP12) in personal care products such as sunscreens, skincare products, and body washes. Other BP-derivatives are often used as photoinitiators, binders, or additives in printing inks of food contact materials. Studies have shown frequent occurrence of certain BPs (as UV filters) in various environmental matrices and organisms. In particular, BP3 increases coral bleaching rates and exhibits estrogenic activity in aquatic life. However, much less studies report on ecotoxicity of 10 BP-derivatives. This study aims to analyze *in vivo* toxic effects of specific BPs-derivatives on medaka (*Oryzias latipes*) fish. The LC50 value from 96 hr-acute mortality of 7-day post hatching medaka larvae showed that DEAB was the most toxic compound and BP was the least toxic compound. With the 7 day-sublethal exposure, 4PBP and DEAB dose dependently increased larval mobility and oxidative stress responses at tested concentrations. We will further investigate the toxic mechanism of 4PBP and DEAB in medaka fish regarding fish behavior under environmentally relevant exposure conditions.

1.07.P-Th060 Transcriptomic alterations caused by progestogens during early zebrafish development
Liliya Sokalchuk Sokalchuk[1]*, Pol Broto*[2]*, Albert Menéndez-Pedriza*[1]*, Paula Medina*[3]*, Noelia Diaz*[3]*, Mercedes Blázquez*[3]*, Joaquim Jaumot*[1] *and Laia Navarro-Martin*[1]*, (1)Environmental Chemistry, Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain, (2)Chemical Engineering and Analytical Chemistry, University of Barcelona, Spain, (3)Institute of Marine Sciences, Spanish National Research Council (ICM-CSIC), Spain*
Evidence has shown that endocrine disruption chemicals (EDCs) can alter reproductive aspects in fish. These alterations affect their reproductive status, putting the continuity of the populations at risk and impacting biodiversity conservation. In the past decades, the effects of EDCs on fish reproduction have been the focus of increasing research. However, only a few studies have addressed their effects before pubertal onset and little is known about their precise mode of action. Synthetic progestagens and their derivatives, widely used for pregnancy maintenance in humans or as growth promoters in livestock, have proven ecotoxicological effects and appear as those with the highest environmental concern after synthetic estrogens such as ethinyl estradiol (EE2). It is well known that progestagens have a direct effect on the onset of meiosis and are considered key players in this process, however, the molecular mechanism by which they can alter puberty in fish still remains elusive. The purpose of our study was to determine the effects of progestagens, previously shown to alter steroidogenic genes at early zebrafish development stages, at the transcriptome and lipidome levels. Based on already published studies we first exposed embryos to 0.6 nM of progesterone (P4), levonorgestrel (LNG), and mifepristone (RU486) from 0 to 5 days post-fertilization (dpf). Results from RNA sequencing showed that exposure to this concentration did not provoke major alterations in the transcriptomic profile of fish. Therefore, a second exposure following a dose-response approach was performed exposing embryos to 0.2 nM - 16.2 nM of progesterone (P4), levonorgestrel (LNG), and mifepristone (RU486) from 0 to 5 days post-fertilization. At present, we are characterizing the transcriptomic response of embryos exposed to the progestogens by real-time RT-PCR. In the near future, we aim to perform lipidomic analysis by an untargeted liquid chromatography-high resolution mass spectrometry (LC-HRMS). Consecutively, we aim to study the long-term consequences of exposure to progestins during early development (0-5 dpf) by performing transcriptomic and lipidomic analyses in juvenile zebrafish to a better understanding of the modes of action of progestins, which leads to better protection of environmental health. The research leading to these results has received funding from the Spanish Ministry of Science and Innovation MCIN/AEI/10.13039/501100011033 (Grant PID2021-122929OB-C33).

1.07.P-Th061 Translocation and Toxicity of Additional Chemical Substances in Expanded Polystyrene Microplastics on Black Rockfish Sebastes schlegeli
Kwang-Min Choi[1]*, Seong Hee Mun*[2]*, Dongju Shin*[1] *and Jee hyun Jung*[1]*, (1)Korea Institute of Ocean Science and Technology (KIOST), Korea, Republic of (South), (2)Korea Institute of Ocean Science and Technology (KIOST), Yeongdo-gu, Korea,*

Republic of
Expanded polystyrene (EPS) has been manufactured by adding hexabromocyclododecane (HBCD), an organic flame retardant, but has been regulated due to the harmfulness and environmental problems caused by HBCD. However, numerous fragments originating from EPS products manufactured and recycled in the past are ubiquitous in the marine environment, and this study confirmed the biological effects of EPS-derived large MP (EPS-LMP) and added HBCD on black rockfish (*Sebastes schlegeli*), a commercially important fish species widely distributed along the coast of the South Korea. EPS-MP was made of 4.5 mm beads and 2 mm fragments and administered orally using gelatin capsules to determine toxic effects after 4 and 7 days. As a result, no deaths occurred during the 7 days of exposure, and no effects on growth were confirmed, but EPS-MP still existed in the gastrointestinal tract. Intrahepatic HBCD was detected in a concentration-dependent manner, and negative effects on cytotoxicity on leukocytes and intrahepatocyte toxicity indicators were confirmed in groups exposed to 100 mg of LMP. The exposure response and toxicity mechanism of black rockfish according to changes in size or concentration of EPS-LMP were verified through a multi-omics approach that analyzed transcriptome and metabolic changes. Our findings highlight the importance of the toxic effects of translocated MP in resident species in understanding the toxic effects through microplastic contamination.

1.07.P-Th062 Zebrafish as a Model for Screening Chemicals Linked to Preeclampsia Induction

Inhye Lee[1]*, Kyungho Choi*[2]*, Kyunghee Ji*[3] *and Jeon Hyelyn*[4]*, (1)Occupational and Environmental Health, Seoul National University, Seoul, Korea, Republic of, (2)School of Public Health, Seoul National University, Korea, Republic of (South), (3)Yong In University, Korea, Republic of (South), (4)Occupational and Environmental Health, Yong In University, Korea, Republic of (South)*
Preeclampsia is one of the pregnancy-related diseases accompanied by hypertension and proteinuria. In cases of early onset or severity, preeclampsia can lead to adverse outcomes such as premature placental abruption, miscarriage, and fetal death. Research on the etiology and adverse outcome pathways (AOPs) of pregnancy-related diseases is essential to prepare for the health of future generations and establish a precision public health. In this study, we explored the usefulness of zebrafish as an animal model to screen for chemicals associated with preeclampsia induction. A literature review was performed to identify AOPs in preeclampsia and to investigate molecular initiating events (MIEs) and key events (KEs). Among these, we explored biomarkers available in zebrafish, focusing soluble fms-like tyrosine kinase-1 (sFLT-1), soluble endoglin (sEng), vascular endothelial growth factor (VEGF), placental growth factor (PIGF), and transforming growth factor-β (TGF-β), which are used as angiogenic indicators, and investigated existing studies related to exposure to environmental pollutants. Preeclampsia is estimated to have heritability of approximately 55%, and is caused by imbalanced maternal nutritional status, lack of vitamins and minerals, and exposure to environmental pollutants (e.g., cadmium, bisphenol A, phthalates, flame retardants, and perfluorinated compounds). Impaired trophoblast invasion and spiral artery remodeling, placental ischemia and hypoxia, and changes in the renin-angiotensin-aldosterone system (RAAS) were identified as the MIEs and KEs of preecalmpsia. Although zebrafish does not have a placenta, they express genes and proteins (e.g., vegfa, sflt-1, and eng) related to the mechanism of preeclampsia. The results of this study indicate that zebrafish possesses genes and proteins related to the preeclampsia, and can be used as an animal model to screen for chemicals related to causing preeclampsia.

1.07.P-Th063 Effects of Differently Aged Tire-Wear Particle Suspensions on Danio rerio

Cátia Venâncio[1]*, Alexandra Savuca*[2]*, Alexandru Chelaru*[2]*, Joao Pinto da Costa*[3]*, Teresa Rocha-Santos*[4] *and* ***Isabel Lopes***[3]*, (1)Department of Biology, CESAM - Centre for Environmental and Marine Studies and Department of Biology, University of Aveiro, Portugal, (2)University of Iași, (3)University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Portugal, (4)Chemistry, Centre for Environmental and Marine Studies (CESAM) and Department of Biology, University of Aveiro, Portugal*
Tire wear particles (TWP) are formed when friction occurs between tires and the road surface. Adding to the physical damage that these TWP may cause to organisms, a simultaneous toxicity may be induced by the chemical compounds that constitute the TWP and are released over time into the environment. Thus, this study aimed to evaluate the toxicity of a TWP suspension at environmentally relevant concentrations (between 0.5 and 512 mg TWP/L), considering three ageing stages of the suspension: immediately after preparation, 7, and 30 days after preparation (0dA, 7dA, and 30dA, respectively), using *Danio rerio* as a model species. Due to the homology between this model and humans, inferences can also be made about the potential effects that TWP can cause in humans. The 96-h Fish Embryo Toxicity (FET) assays followed the OECD guideline 236 (OECD, 2013) using two life stage stages (embryos and post-hatching larvae) to determine potential different routes of uptake due to the occurrence of key events prior and post-hatching, such as eye and retina formation (in embryos) and protruding mouth development in larvae. Mortality and malformations, in addition to the determination of the heartbeat rate (HBR), total and interocular length (TL and IL, respectively), swim bladder area (SBA), and behaviour (total swim distance and time) were registered.

No significant mortality and malformations were registered in all assays with embryos and larvae (>10%). In embryos, HBR presented a pattern of tachycardia between concentrations of 0.5 and 8 mg TWP/L, whilst a pattern of bradycardia at higher concentrations (<32 mg TWP/L), for all ageing stages. The IL was significantly higher (p<0.05) in organisms exposed to tire wear particles concentrations equal to or higher than 8 mg/L in a non-aged particle suspension, whilst significantly higher in organisms exposed at the concentrations 0.5, 2, and 8 mg/L of a tire wear particle suspension aged for 7 days, with effects tending to disappear over time. In the post-hatching larvae, SBA decreased significantly (p<0.05) at all tested concentrations (except 0.5 mg TWP/L) compared to the control_0dA. The activity time of larvae from the embryo assay was close to zero. The results obtained highlight that further studies are needed to increase knowledge on TWP effects on understanding the impact that this type of particulate may have on ecosystems and, ultimately, human health.

1.08.P In Silico Ecotoxicology: Using Existing and Emerging Data to Characterize Chemical Impacts from Individuals to Ecosystems

1.08.P-Mo049 Assessing Chronic Effects of Chemical Pollution on Biodiversity Using Mean Species Abundance Relationships

Venja Sandrine Anna Margit Schoenke[1]*, Jiaqi Wang, MSc*[1]*, Paul van den Brink*[2] *and Jan A.J. Hendriks*[1]*, (1)Radboud University Nijmegen, Netherlands, (2)Wageningen University & Research (WUR), Netherlands*

Chemical pollution is a persistent threat to freshwater ecosystems and biodiversity. The long-term impact of chemical pollutants on our natural environments is a growing challenge requiring innovative methodologies to understand better and address the ecological risks associated with such pollutants. This research addresses the need for a predictive assessment of the long-term impacts of chemical pollution on biodiversity. We utilized the Mean Species Abundance Relationships (MSAR) methodology as a biodiversity measurement tool. This approach can provide the Mean Species Abundance as a function over the concentration of a chemical, allowing the interpretation of the impact of a chemical on biodiversity. This study aims to provide a tool to predict chronic Mean Species Abundance Relationships based on acute values.

The longer the exposure to a chemical, the less concentration is needed to result in a lethal effect. The resulting time-dependency can be described with the median Lethal Concentration (LC50). This method is based on the Critical Body Residue concept and, more precisely, the Lethal Body Burden approach and can be extended to other LC50-based tools. By fitting acute LC50 values to the time-dependent equation, LC50 values for any time point can be estimated and used to derive the Mean Species Abundance Relationships. Data from a case study with six freshwater arthropods exposed to imidacloprid was used to test the methodology for two different time points (days 21 and 28). Additionally, it was tested if chronic data is necessary to obtain a reasonable fit or if acute data is enough by including chronic values in the fitting up to the time point to be predicted. The chronic data was then used to validate the LC50 fits and MSAR.

For predicting LC50 values, the model overestimates the acute toxicity and underestimates the chronic toxicity of imidacloprid for certain species. This can be caused by the biotransformation of imidacloprid to the likewise toxic imidacloprid-olefin. However, the estimations of the chronic Mean Species Abundance Relationships are similar to the measured chronic MSAR. If only acute data were used for the estimation, the mean difference in Mean Species Abundance (MSA) between the prediction and the fitted MSAR is 6%. If chronic data was included, this difference lowered to 3% for day 21 and 2% for day 28.

1.08.P-Mo050 Integrating Time-Resolved Gene-Expression Data into TKTD Models to Approximate Toxicodynamic Damage

Florian Schunck[1]*, Bernhard Kodritsch*[2]*, Wibke Busch*[2] *and Andreas Focks*[1]*, (1)Institute of Mathematics, Osnabrück University, Germany, (2)Helmholtz Centre for Environmental Research (UFZ), Germany*

The immense productivity of the chemical industry requires an improved predictive risk assessment that can handle constantly evolving challenges. Integrating OMICs data into mechanistic models offers a promising solution by linking cellular processes triggered after chemical exposure with observed effects in the organism. The envisioned outcome of such approaches is the prediction of chemical effects for untested species–substance combinations and mixtures based on molecular data. However, its success hinges on the quantitative description of the temporal dynamics of molecular markers in response to chemical exposure.

The transcription factor *nuclear factor erythroid 2-related factor 2* (*Nrf2*) has been identified as a master regulator of the detoxification process and is tightly linked to chemical and oxidative stress in organisms. This makes *Nrf2* an optimal candidate for approximating the dynamic damage state in toxicokinetic-toxicodynamic (TKTD) models, thereby enabling the integration of OMICs data into mechanistic models.

In this work, we develop and apply a biologically anchored TKTD model, which describes the key processes in the *Nrf2* signalling pathway, linking the gene expression level of *nrf2* to detoxification and lethality. The model was fitted on time series of internal concentrations, *nrf2* gene-expression and lethality observed in zebrafish embryos exposed to diuron, diclofenac, and naproxen in over 200 experiments, using a Bayesian approach.

Nrf2-expression proved to be a reliable predictor of lethality for naproxen and diuron, accurately predicting lethality even in data-limited concentration ranges. In contrast, *nrf2*-expression was no good predictor for lethality under diclofenac exposure, possibly due to a differential expression pathway. By using *nrf2* as a predictor for lethality, highly similar lethality-related model parameters were obtained for different chemicals, opening the door for cross-substance extrapolation.

This study shows that *nrf2*, as a master regulator of the chemical and oxidative stress response, can serve as a proxy for lethality after exposure to different substances. Our findings highlight the advantage of the OMICs-TKTD integration in discerning stress response pathways based on the temporal dynamics in the molecular stress response. Finally, the work demonstrates the feasibility of integrating dynamic OMICs data into established TKTD models for approaching the goal of quantitative toxicity prediction across compounds.

1.08.P-Mo051 Forwarding maturation of Species Sensitivity Distributions using Machine Learning

***Pim Wassenaar**, Willie Peijnenburg, Jaap Slootweg and Leo Posthuma, National Institute for Public Health and the Environment (RIVM), Netherlands*

The characterization of impacts of chemical pollution in ecosystems is amongst others performed by a combination of exposure data with insights from Species Sensitivity Distributions (SSDs). SSDs are the statistical description of patterns in observed ecotoxicity endpoint metrics, such as NOECs, EC50s and LC50s. Despite the versatile application of this approach, we do not fully use available collections of ecotoxicity data to generate SSDs. This presentation ventures into a Machine Learning (ML) based additional approach to the derivation of SSDs from currently available data, and presents a suite of high-utility applications of outcomes of such SSDs derived by ML.

SSD models have different uses, classically ranging from the earliest uses in the derivation of protective, regulatory environmental quality standards and the characterization of the degree of harm causes by unintended ambient mixtures. Environmental concerns have resulted in vast collections of ecotoxicity test data, such as ECOTOX and REACH-database. Despite the wealth of information on chemical hazards there are still severe data gaps for many chemicals and the already available data has not yet been extensively used to identify the sensitivity patterns regarding chemicals and species in the broadest sense of the word. In our innovative versatile approach, we investigate the hidden patterns in these available ecotoxicity data sources and how these patterns can be applied to a wide variety of use cases. For this purpose, we use Machine Learning (ML) in the heart of the employed methods, to address, and potentially solve, the issue of data gaps. Particularly, the current data gaps are hampering the ecotoxicity assessments and are amongst the most pressing problems that limit the practical use of techniques such as Safe and Sustainable by Design.

Here, we aim to present the outputs of some example analyses, with the aim to highlight how we can derive SSDs based on both measured and ML-predicted ecotoxicity metrics. We show not only that we can derive SSDs for vastly more compounds based on existing data and underlying patterns, but also how those SSDs can be employed for at least three main purposes in environmental protection, assessment and management. We also show whether, how and to which extent the newly derived SSDs can be trusted as tools for practical purposes.

The authors thank Markus Viljanen and all others that work within or contribute to the the related projects at the RIVM

1.08.P-Mo052 The Effects of Pollution and Foraging Adaptation on the Stability of Ecological Communities

*Constanza Vega-Olivares[1], **Andreu Rico[1,2]**, Rodrigo Ramos-Jiliberto[3] and Pablo Moisset de Espanés[4], (1)Cavanilles Institute of Biodiversity and Evolutionary Biology, University of Valencia, Spain, (2)IMDEA Water Institute, Spain, (3)GEMA Center for Genomics, Ecology, and Environment, Universidad Mayor, Chile, (4)Centro de Biotecnología y Bioingeniería, Universidad de Chile, Chile*

The relationship between the adaptive responses of predators and the stability of communities has been previously analyzed only considering pristine environments, even though many ecological systems are exposed to pollutants, among other disturbances. Many pollutants tend to accumulate in the tissues of organisms, resulting in species present in trophic webs not only transmitting their effects among themselves, but also transmitting the pollutants through their trophic interactions. In this context, adaptive behavior, considered in this study as changes in prey preference, can inhibit pollutant transport through trophic networks without completely limiting biomass flow. In this study, the effectiveness of adaptive responses of predators in promoting the persistence and diversity of species in trophic networks subjected to stress from a bioaccumulative pollutant was evaluated. A community model based on the bioenergetic model was used, where the effects of the network topology (species richness and connectance), the pollutant concentration and the adaptive behavior over the species persistence and Shannon-Wiener diversity index were distinguished. In this work it was shown that adaptive behavior promotes species persistence and diversity in communities subject to stress from a bioaccumulative pollutant. Therefore, the adaptive responses of predators have a beneficial role on the stability of communities affected by bioaccumulative pollutants.

1.08.P-Mo053 Vitamin K 2,3-epoxide reductase molecular identity range the binding affinities to anticoagulant rodenticides of Rodentia

***Azucena Bermejo-Nogales**, Noelia Marin-Prat and David Hernandez-Moreno, Institute for Agricultural and Food Research and Technology, Spanish National Research Council (INIA-CSIC), Spain*

Rodents are notorious for being one of the pests with the greatest impact on agricultural production and public health. Anticoagulant rodenticides (ARs) are commonly used to control rodent populations by inhibiting the vitamin K 2,3-epoxide reductase (VKORC1) enzyme, which leads to internal haemorrhages and finally death of the animal. Docking analysis previously demonstrated that human VKORC1 variation is associated to anticoagulant resistance and affects binding interfaces (2). In rodents, research has been focused on the main pest species, such as the mouse, black rat, and grey rat. However, little is known about the influence of AR in other rodent species, despite the importance of this phylum in wild and agro-ecosystems. The hypothesis of this work is that rodent phylogenetic and structural differences among VKORC1 sequences do not range the binding properties of AR. To test this null hypothesis, we searched for complete VKORC1 sequences of different rodents in public databases and characterized the binding predictions by computational analysis. Rodentia phylum has differential sensitivity to second generation AR depending on species and families. The range of Rodentia sensitivity was (from highest to lowest) flocoumafen, difenacoum, brodifacoum, bromadiolone and difethialone. Long-tailed chinchilla is the most sensitive rodent to flocoumafen, difenacoum and brodifacoum, which bind very strongly to its enzyme (13 Kcal/mol). Guinea pig and Lesser Egyptian jerboa were also very sensitive to flocoumafen and difenacoum as binding affinities were above 12 Kcal/mol. Difenacum has binding affinities higher than 14 Kcal/mol in two Muridae and one Cricetidae. Among Cricetidae family, European snow vole had binding affinities higher than 14 Kcal/mol to brodifacoum. Specific sensitivities could be used to either control populations in case of rodent pests or to forbid the use of AR in ecosystems with protected species. The present work is a powerful *in silico* tool for pest control companies and biocides regulatory agencies.

1.08.P-Mo054 Using Comparative Genomics to Develop 'Digital Twins' to Support Ecotoxicological Predictions
Rama Krishnan[1]*, David Spurgeon*[2]*, Stephen James Short*[3]*, Bruno Campos*[4]*, Claudia Rivetti*[4]*, Claire Peart Dr*[5] *and Peter Kille*[1]*, (1)Cardiff University, United Kingdom, (2)UK Centre for Ecology & Hydrology (UKCEH), United Kingdom, (3)Pollution, UK Centre for Ecology & Hydrology (UKCEH), United Kingdom, (4)Unilever - Safety and Environmental Assurance Centre (SEAC), United Kingdom, (5)Safety and Environmental Assurance Centre (SEAC), Unilever, United Kingdom*
Our rapidly changing world is placing ecosystems under unprecedented pressure, including exposure to a wide range of chemical toxicants. Given the limited ability to test the impact of these toxicants across all species, it becomes crucial to unravel the intricate biological cascades that influence how different non-model organisms respond to such pollutants. By generating *in silico* representations of organisms and harnessing genomic data, this project seeks to reveal key characteristics underlying comparative ecotoxicological responses. From this we can predict species sensitivities to different toxicants, thereby protecting species critical for ecosystem processes or of high conservation value. We have developed an automated pipeline to streamline the process of quality assessment, pre-processing, *de novo* assembly, and annotation of publicly available transcriptomic data. This pipeline is optimised to operate within a Slurm-based system designed for high-performance computing (HPC) infrastructures and will be made available *via* GitHub. The transcriptome annotations are mapped to enzymes underpinning phase I metabolism to provide evidence to support relative Toxicokinetics (TK) and onto Adverse Outcome Pathways (AOPs), focusing on Molecular Initiating Events (MIE) and Key Events (KE) identified in eukaryotic organisms, to provide mechanistic insight into comparative Toxicodynamics (TD).

The pipeline has been deployed and evaluated against a diverse array of organisms to investigate the impact of laboratory vs wild population (*Enchytraeus albidus*), to compare *de novo* transcriptome vs genome (*Acyrthosiphon pisum* vs *Aphis fabae*) and to investigate organisms with large genomes with known transcript redundancy (*Porcellio scaber – genome size ~5.7 Gbp*). To augment this methodology, we are developing pipelines for analysing target receptor ortholog conservation across different species alongside applying *de novo*-based molecular docking techniques in evaluating receptor-ligand interactions. Further, we aim to transition these pipelines to a Nextflow framework to offer improved efficiency across heterogeneous HPC hardware. In conclusion, this study will develop a comprehensive automated data platform incorporating aspects of TK and TD and use mechanistically informed approaches to support AOP-based species sensitivities distributions (SSD) predictions.

1.08.P-Mo055 ADORE is for Lovers: A Benchmark Dataset for Machine Learning in Ecotoxicology
Christoph Schuer[1]*, Lilian Gasser*[2]*, Fernando Perez-Cruz*[2]*, Marco Baity-Jesi*[3] *and Kristin Schirmer*[1]*, (1)Environmental Toxicology, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (2)Swiss Data Science Center, Switzerland, (3)Siam, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland*
The use of machine learning for predicting ecotoxicological outcomes is promising, but underutilized. The curation of data with informative features requires both expertise in machine learning as well as a strong biological and ecotoxicological background, which we consider a barrier of entry for this kind of research. Additionally, model performances can only be compared across studies when the same dataset, cleaning, and splittings were used. Therefore, we provide ADORE, an extensive and well-described dataset on acute aquatic toxicity in three relevant taxonomic groups (fish, crustaceans, and algae). The core dataset describes ecotoxicological experiments and is expanded with phylogenetic and species-specific data on the species as well as chemical properties and molecular representations. The dataset spans Apart from challenging other researchers to try and achieve the best model performances across the whole dataset, we propose specific relevant challenges on subsets of the data and include datasets and splittings corresponding to each of these challenges as well as in-depth characterization and discussion of train-test splitting approaches and their relevance for this use-case.

1.08.P-Mo056 Identifying Molecular Endpoints to Assess the Biological Response of Contaminant of Emerging Concern in Marine Mammals: an In Silico Approach

Antonino Vincenzo Alessi[1], *Giacomo Limonta*[2], *Cristina Panti*[2] *and Maria Cristina Fossi*[2], *(1)University of Siena, Italy, (2)Department of Physical Sciences, Earth and Environment, University of Siena, Italy*
Due to their ecology marine mammals accumulate some of the highest levels of environmental contaminants of all wildlife. Contaminants of emerging concern (CECs) enter the environment from various anthropogenic sources and are distributed throughout environmental matrices. They have been detected in water at concentrations significantly higher than expected and their risk to human and environmental health may not be fully understood yet. CECs comprise a vast array of contaminants: pharmaceuticals such as personal care products (PPCPs), nonsteroidal anti-inflammatory drugs (NSAIDs), cardiovascular system drug (CVSD), steroidal hormones and antibiotics; Endocrine Disrupting Chemicals (EDCs) such as bisphenol A (BPA) phthalate esters, perfluoroalkyl and polyfluoroalkyl substances (PFAS) which are commonly spread in marine organisms ranging from benthic invertebrates up to top predators. The toxicological data of emerging contaminants on marine mammals is still scarce for several compounds and the toxicological impact of these contaminants needs further assessment. In silico models are a promising alternative to in vitro and in vivo methods to predict the toxicological effects of chemicals on mammalian model organisms (e.g. rat, human). These approaches continue to grow in capability and applicability to predictive toxicology. Numerous databases such as ChEMBL, EMBL-EBI and ECOTOX could be used as a comprehensive knowledge base providing data on the environmental toxicity of these chemicals on aquatic and terrestrial species. The aim of this study was to utilize in silico approaches such as Similarity Ensemble Approach (SEA), SwissADME and admetSAR, which are some of the most used in silico tools, in conjunction with literature research to identify specific endpoints strengthening our knowledge and our understanding of the biological effect of the CECs. The identified endpoints will be tested ex vivo (e.g. tissues/biopsies) on charismatic species such as: Balaenoptera physalus, Stenella coeruleoalba using Digital PCR assay (ddPCR).

1.08.P-Mo057 Developing an Ecosystem-Level Assessment Framework for Ecological Impacts of Accidental Chemical Exposure in Korean Freshwater: A Simulation-Based Approach Using the AQUATOX Model

Jaehoon Yeom[1] *and Sang Don Kim*[2], *(1)Gwangju Institute of Science and Technology (GIST), Korea, Republic of (South), (2)School of Earth Science and Environmental Engineering, Gwangju Institute of Science and Technology (GIST), Korea, Republic of (South)*
Recent ecological risk assessments (ERAs) encompass evaluations from the cellular to ecosystem levels. However, higher-level assessments, particularly at the ecosystem level, are often resource-intensive in terms of labor, cost, and time. Consequently, ecologists and environmental assessors are increasingly turning to modeling approaches. The United States Environmental Protection Agency (US EPA) has developed the AQUATOX model, an ecosystem-level risk assessment model designed to evaluate the effects of disturbances on freshwater environments, including chemical exposure, environmental changes, and ecological disruptions.

This study aims to conduct AQUATOX simulations and develop a library specifically tailored to the Korean freshwater system, with a focus on simulating the effects of phenol exposure. The target region for this study is the rivers in Korea. The Korean Ministry of Environment routinely investigates the ecological composition, phenol concentrations, and water quality of freshwater systems, periodically publishing the findings on the Water Environment Information System (WEIS, http://water.nier.go.kr/web). The model system is constructed using a substantial dataset of ecological information gathered from Korean rivers, considering the analyzed interactions between organisms in the food web of Korean freshwater and the ecological characteristics of domestic species in Korean rivers.

Monitored data covering the period from 2008 to 2020 from the WEIS system is utilized in model construction. The resulting model system and built library are validated using ecological monitoring data from regions exposed to phenol. The outcomes of this study will contribute to the development of a chemical assessment system for Korean rivers, utilizing an ecological model approach.

This work was supported by Korea Environment Industry & Technology Institute (KEITI) through Advanced Technology Development Project for Predicting and Preventing Chemical Accidents Project, funded by Korea Ministry of Environment (MOE) (2022003620001).

1.08.P-Mo058 Derivation of environmental quality standards for free cyanide in freshwater and marine surface waters by species sensitivity distribution including censored data

Stan de Groot[1], *Tom Aldenberg, Els Smit*[1], *Eric Verbruggen*[1], *Michiel Kraak*[3] *and P.L.A. van Vlaardingen*[1], *(1)National Institute for Public Health and the Environment (RIVM), Netherlands, (2)Sciencepark 904, University of Amsterdam (UVA), Netherlands*
The currently available Dutch environmental quality standards (EQSs) for free cyanide and cyanide complexes are regularly debated and considered to be outdated. Hence, there is an urgent need to update the EQSs for cyanide. The aim of the present study was therefore to derive new maximum acceptable concentrations (MAC) and annual average (AA) EQSs for free cyanide, following the 2018 version of the Technical Guidance for Deriving Environmental Quality Standards of the Water Framework Directive (WFD). To this end, ecotoxicity data were collected from previous national and international EQS derivations, supplemented with a literature search to gather additional ecotoxicity data generated since the publication of these reports. All collected ecotoxicity data were evaluated for reliability and compliance with strict standards, such as analytical verification. Data considered reliable were used for the derivation of the EQS values. The pooled freshwater and marine, acute

ecotoxicity data set consisted of reliable results for 35 species, distributed over 8 taxonomic groups. The pooled chronic ecotoxicity data set consisted of results for 13 species, distributed over 7 taxonomic groups. As both the acute and chronic dataset met the WFD criteria for deriving a species sensitivity distribution (SSD), a probabilistic approach was taken. However, the datasets include several censored data which are traditionally excluded when deriving an SSD. In the present paper, we present a solution for the censored data points using the R-package ETX 3.0-132, that provides functionality for fitting univariate SSD-related distributions to possibly censored toxicity data using a Bayesian simulation technique. The HC5 values derived from these acute and chronic SSDs were 17 and 0.66 µg CN-/L, respectively. Applying a default assessment factor of 10 to the HC5 from the acute SSD resulted in a MAC-EQS of 1.7 µg CN-/L for both freshwater and marine surface water. Applying assessment factors of 3 and 5 to the HC5 of the chronic SSD resulted in AA-EQSs of 0.22 µg CN-/L for freshwater and 0.044 µg CN-/L for marine surface waters, respectively. These MAC-EQS and AA-EQS values are generally in line with derivations by other (inter)national water authorities, but the present environmental quality standards have been derived in full accordance with the WFD guidance, using only reliable data and including censored values.

1.08.P-Mo059 Developing a Database for Comprehensive Assessment of Fish Reproductive Toxicity
Vid Modic Modic[1]*, Roman Li*[2,3]*, Stephan Fischer*[3]*, Katharina Klotz*[3]*, Kristin Schirmer*[2,4] *and Anže Županič*[1]*, (1)Department of biotechnology and systems biology, NIB, National Institute of Biology, Slovenia, (2)Environmental Toxicology, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (3)aQuaTox-Solutions GmbH, Switzerland, (4)Environmental Systems Science, ETH Zurich, Switzerland*
Traditional animal-based risk assessment of chemicals is struggling with the demands of 21st century safe and sustainable chemical development. In the project SAFE: Innovative Safety Assessment of Fish Adverse Effects, we are working to replace some of the costliest and most time-consuming tests in environmental toxicology - reproductive toxicity of chemicals to fish. Our approach incorporates computational (knowledge networks, machine learning) and experimental methods (molecular and cellular assays using permanent fish cell cultures). One of the main challenges of the development of such alternative tests is training the model and evaluating it against animal tests. The main reason being that it is expensive (and ethically problematic) to produce high quality *in vivo* validation data, while existing data are challenging to come by and sometimes difficult to interpret. This is why the very first step in our project was to collect and curate all available *in vivo* fish reproductive studies, especially those reporting reproductive endpoints and gene expression.

We collected fish reproductive toxicity data from EnviroTox (HESI) and EcoTox (US EPA) databases, the Gene Expression Omnibus (NCBI) and systematic literature reviews. When combining the gathered data into a unified database, we encountered several challenges: reproductive endpoints reported under non-standardized names, data reported across multiple publications, use of non-standard units, use of different statistical measures (LOECs, NOECs, ECs), missing metadata and data reported only in graphical format. We standardized the diverse information curated from the available resources to develop a unified database of fish reproductive toxicity. The next steps in our vision are to test permanent cell cultures and to build machine learning models that would be able to predict reproductive toxicity based on the fish cell assays and available historical data.

1.08.P-Mo060 In Silico Approaches to Characterize Chemical Impacts on Genetic Diversity
Marissa B Kosnik[1] *and Andreu Rico*[2]*, (1)Department of Environmental Toxicology, Eawag: Swiss Federal Institute of Aquatic Science and Technology, Switzerland, (2)Cavanilles Institute of Biodiversity and Evolutionary Biology, University of Valencia, Spain*
Population-level diversity is the bridge between individual organism and species-level effects. Within-species genetic diversity is susceptible to chemical pollution, and understanding the potential impacts of chemicals is essential to determine the resilience and adaptation potential of different species. However, of the three levels of biodiversity (genetic, species, and ecosystem), genetic diversity has been reported to receive the least attention. Field-based methods to assess genetic diversity depend on sequencing large numbers of organisms in a given population/geographic region or using environmental DNA. However, finding connections between these methods and chemical exposures is challenging, and difficult to do prospectively. Lab-based methods to assess genetic susceptibility to chemicals have also been used, but are impossible for all possible species/chemical combinations that may occur. We advocate that computational methods can be used to complement and enhance existing methods to assess chemical impacts on genetic diversity. We describe new opportunities to harness in silico approaches used in human health toxicology to inform genetic susceptibility to chemicals in non-human organisms. These include data integration approaches to form connections between chemicals, genetic data, and adverse outcomes in different species, and adverse outcome pathway (AOP)-based approaches. We propose that chemical pollution impacts on genetic diversity can serve as an early warning sign for more extreme adverse ecosystem effects (e.g., species loss), and thus combined environmental monitoring and computational methods can enable development of ecosystem protection and risk mitigation measures to prevent biodiversity loss from chemical pollution.

1.08.PC In Silico Ecotoxicology: Using Existing and Emerging Data to Characterize Chemical Impacts from Individuals to Ecosystems

1.09.A Invertebrate Species in Ecotoxicology: Challenges and Opportunities in a Global Change Scene

1.09.A.T-01 A Systematic Evidence Map of Molluscan Endocrinology and an Investigation of the Effects of a Pharmaceutical 5-alpha-Reductases Inhibitor, Dutasteride, on two Freshwater Gastropod Molluscs

***Konstantinos Panagiotidis, PhD candidate**, Nicola Beresford, Marta Straszkiewicz, Thomas Miller and Alice Baynes, Department of Life Sciences, Brunel University London, United Kingdom*

Molluscs, integral to ecosystems as habitat engineers and food sources, face unprecedented threats from pollution. Notably, the historical impact of tributyltin (TBT) causing 'imposex' by altering the sex organs of female snails, contributed to a global decline in marine snail populations. While molluscs can serve as early indicators for endocrine-disrupting chemicals (EDCs), current testing guidelines lack mechanistic understanding due to the intricate differences in molluscan endocrinology compared to vertebrates. Molecular investigations have demonstrated that molluscan genomes lack essential enzymes to induce vertebrate steroidogenesis as well as several nuclear steroid receptors. Some steroidogenic enzymes do appear to exist in mollusc genomes, but their function remains unknown. Most notably, the enzymes 5-alpha-reductases (5αR1, 5αR2) that metabolise testosterone to dihydrotestosterone in vertebrates, are present in molluscs. Previous work in our lab has shown that developmental exposure of *Biomphalaria glabrata* embryos to pharmaceutical 5αR disruptors (dutasteride or finasteride) results in a highly reproducible and dose-dependent disruption to development, resulting in altered shell morphology. However, the impact of dutasteride on adult gastropods remains unexplored. To fill this gap, two experimental systems are employed to investigate the effects of dutasteride on adult gastropods: a 21-day flowthrough exposure using *B. glabrata* snails and an OECD 243 static-renewal test using *Lymnaea stagnalis*, both with nominal exposure concentrations of 0, solvent control, 1μg/L, 3.2μg/L, 10μg/L, 32μg/L and 100μg/L Dutasteride. A systematic evidence map has also been developed to identify existing knowledge gaps in molluscan endocrine research. Findings from our systematic investigations suggest the existence of possible less intensively investigated hormonal pathways in molluscs, involving phytosterols (i.e. plant steroids), ecdysteroids (i.e. insect steroids) and thyroid hormones. These pathways could potentially be a target of chemical disruption that could interfere with their respective hormones, hormone-metabolising enzymes and/or hormone receptors, but currently remain underexplored. Our work aims to contribute valuable insights into the physiological role of 5-alpha-reductases in molluscs and identify novel endocrinological endpoints for ecotoxicological research that could enhance existing regulatory guidelines for testing chemicals.

1.09.A.T-02 Exposure of freshwater gastropod Lymnaea stagnalis to silver nanoparticles causes chronic and transgenerational effect

***Wei Liu** and Ting Wang, University of Geneva, Switzerland*

The traditional focus of ecotoxicological studies has been primarily on a single generation. Multigenerational research in ecotoxicological testing is needed to improve predictive approaches in ecological risk assessment. Given widespread use of silver nanoparticles (AgNPs), silver nanoparticles (AgNPs) are increasingly being detected in aquatic environments.

In this study, we investigated here the transgenerational effects of AgNPs on the life traits of the freshwater model gastropod *Lymnaea stagnalis* over two generations. Reversibility of the effects using recovery experiments was also performed. The results showed that AgNPs induced high Ag bioaccumulation throughout the soft tissues of *L. stagnalis* parents after 21 days of exposure. Increased ROS production and reduced condition index and fecundity were observed after exposure to AgNPs at 500 μg/L. These results underline that, upon exposure to AgNPs, adult gastropods may allocate more resources to resist oxidative stress rather than growth or reproduction. In addition, Ag accumulation and ROS production in egg clutches were significantly related to the duration and concentrations of parental exposure. On the other hand, exposure of single eggs, after transfer to a clean medium, similar Ag bioaccumulation and ROS production were observed from eggs whose parents had been pre-exposed to 50 and 500 μg/L AgNPs. demonstrated that biological effects were persistent for the next generation.

The current explicit consideration of offspring performance adds value to existing toxicity testing programs. There are important effects of parental exposure duration on offspring effects, and parental exposures can lead to transgenerational changes in resistance, which have significant implications for toxicity testing and adaptive responses. These transgenerational effects suggest the need for multigenerational testing to assess the environmental risks of MNPs in aquatic organisms.

1.09.A.T-03 Tracking Temporal and Spatial Ecotoxicological Effects of Suspended Particulate Matter in Lake Geneva

***Rébecca Beauvais**[1], Océane Lafargue[1], M. Carmen Casado-Martinez[2] and Benoit J.D. Ferrari[1], (1)Swiss Centre for Applied Ecotoxicology, Switzerland, (2)Swiss Centre for Applied Ecotoxicology Eawag (EPFL), Lausanne, Switzerland*

In aquatic environments, suspended particulate matter (SPM) contitutes an important interface between water and sediment and hence interacts with chemicals including toxic contaminants (adsorption, transport…). In contrast to bottom sediments, SPM reacts quickly to the surrounding conditions and can show temporal and spatial fluctuations. Here, we aim to study the ecotoxicological quality of SPM collected in Lake Geneva over different seasons and months. We investigated if SPM induced effects on two model invertebrates, the benthic insect *Chironomus riparius*, and the epibenthic ostracod *Heterocypris incongruens*. We assessed key biological parameters (mortality, growth and emergence) and explored the use of molecular and enzymatic biomarkers for a deeper interpretation. Lake SPM was trapped during two successive periods of 4.5 months in Spring to Fall 2021 and 2023. In 2023, additionnal traps were deployed to recover monthly SPM samples at 4 different depths: 10, 30, 50 and 100 m. The quality of SPM was characterized by physico-chemical analyses (grain-size, total organic carbon, S, N and P content and metals, including total Hg). SPM samples were also submitted to targeted GC-MSMS and non-targeted LC-HRMS screening. SPM-exposed larvae were digested for analysis of potentially bioaccumulated metals. In 2021, the emergence success of *C. riparius* was significantly impacted by the second season sample, while we noticed high larval mortality during the exposure of the first season sample. In 2023, in the ostracod bioassay, the mortality rate varied over the months and seasons but also with depth. Over 1,000 compounds were detected by LC-HRMS. Even though more substances were detected in Feb-July 2021 (172) than July-Nov 2021 (147), a large proportion of substances were detected in both periods, suggesting a clear anthropogenic impact of urban, industrial and recreational activities that contribute to the presence of micropollutants linked to lake SPM. Mesured concentrations of targeted pollutants however rarely exceeded sediment quality criteria. We showed that bioassays could be used to assess the ecotoxicological quality of SPM that was dynamic over time and space. Overall, we observed good agreement among toxicity tests for a same sampling and among tests for the different sampling strategy among years. In the future, effect-directed analyses could help to identify the natural or anthropogenic pollutants responsible for the observed ecotoxicity.

1.09.A.T-04 Chemical Characterization and Toxicity Assessment of Antifouling Coatings' Lixiviate: Implications for Biofouling Management

***Mar Santos-Simón*[1,2]**, *Edoardo Barbieri[1], Agnese Marchini[3], Nestor Etxebarria[1] and Maren Ortiz-Zarragoitia[1], (1)Research Centre for Experimental Marine Biology and Biotechnology (Plentzia Marine Station; PiE-UPV/EHU), University of the Basque Country (UPV/EHU), Spain, (2)University of Pavia, Italy, (3)Dep. Earth and Environmental Sciences, University of Pavia, Italy*

Antifouling coatings are commonly applied to minimize the growth of organisims on submerged artificial hard substrates. Biocide-based coatings (BC) are the most widespread ones and, currently, copper is the main biocide used in combination with other booster biocides. However, there is uncertainty regarding their performance and potential indirect environmental impact. Thus, new non-toxic coatings, such as foul-release coatings (FR), are being developed as a sustainable alternative.This study aimed to understand the effects of environmental conditions on the metal leaching from the coatings and to develop a screening procedure to assess their toxicity on selected marine species.

PVC panels with a standardized surface were coated, weighted and submerged in glass containers with 1L filtered sea water. Containers were placed in an incubator with an integrated shaker for 24h. Metal release was measured under 6 experimental conditions: 3 temperature scenarios (14, 20 and 30 ºC) at 33.5 PSU; 3 salinity scenarios (20, 33.5 and 37.5 PSU) at 20ºC. Additionally, uncoated PVC plates were used as reference. Metal release from the coated surfaces was measured in water samples with inductively coupled plasma mass spectrometry (ICP-MS). Lethal toxicity assays were done on three marine species: the amphipod Monocorophium insidiosum and the mussel Mytilus galloprovincialis pediveliger larvae, as biofouling target species, and the copepod Acartia tonsa as non-target species. Besides, A. tonsa was used to test the toxicity of the individual active coating compounds.

FR coating lixiviate did not have an effect on the survival of any of the tested species, while BC coating lixiviate lead to mortality at relatively low concentrations for A. tonsa, but higher concentrations are needed for the other two tested species, suggesting that the response is species specific. In fact, M. insidiosum was the most tolerant species to BC coating, a finding that could have important implications for biosecurity management. Ongoing chemical analysis of obtained lixiviates will allow us to better understand the chemical agents potentially involved in the observed toxic responses and the behaviour of coating paints in different environmental scenarios. In conclusion, this work sheds light into biofouling control, providing insights into coating selection, performance and environmental risks.

1.09.A.T-05 The tire rubber derived-contaminant 6-PPD-quinone and increased temperatures: too much for the freshwater snail Radix balthica

***Núria De Castro-Català*[1]**, *Isabel Muñoz[2], Catalina Lizama[2] and Jordi Serra[2], (1)Universitat de Barcelona, Spain, (2)University of Barcelona, Spain*

There is an increasing concern into the occurrence and fate of tire wear related compounds (TWCs) in the environment. One important class of TWCs are N, N'-disubstituted phenylenediamines, which are antioxidants added to tires to prevent the degradation of the rubber. They are highly reactive and this results in various transformation products. Among the globally used PPDs, N-(1,3-dimethylbutyl)-N′-phenyl-p-phenylenediamine (6PPD) is one of the most frequently used tire antioxidant [1]. Recently, Tian et al. (2022) [1] identified a highly toxic quinone transformation product of 6PPD, 6PPD-quinone (6PPD-Q), as the toxicant responsible for acute mortality of the Pacific Northwest coho salmon (*Oncorhynchus kisutch*). These chemical stressors may interact with other global stressors affecting aquatic systems. For example, within the context of climate change, high temperatures and lower river discharges will cause water warming. Warming combined with chemical stressors may result in lower fitness in natural populations.

In order to test the toxicity of 6-PPD-Q in invertebrates in the context of climate change, we carried out a 10 days microcosm experiment with the freshwater gastropod *Radix balthica.* We tested the effects of 30 µg/L of 6-PPD-Q at two different temperatures, 15 and 20°C. As preliminary results, negative sublethal effects of the exposure to 6PPD-Q on growth and reproduction have been observed. Although the concentration tested (30 µg/L) is higher than the levels detected in aquatic systems, the quantitave data for this contaminant are still scarce, and in the context of climate change, we can expect to find high levels of TWCs in the future. In fact, we have seen that the effects of exposure to this antioxidant are accentuated by the effect of the increased temperatures. Thus, climate change may worsen the negative effects of the contaminant and compromise the survival of *R. batlhica* populations in polluted aquatic systems.

1.09.B Invertebrate Species in Ecotoxicology: Challenges and Opportunities in a Global Change Scene

1.09.B.T-01 Enhanced Tolerance to Narcosis in Starved Daphnia magna Neonates
Sophie Steigerwald[1], *Yves Saladin*[1], *Roque Gastón Alurralde*[2], *Sebastian Abel*[3], *Ann-Kristin Eriksson-Wiklund*[1], *Anna Sobek*[1] *and Elena Gorokhova*[2], *(1)Environmental Science, Stockholm University, Sweden, (2)Department of Environmental Science, Stockholm University, Sweden, (3)Ecological Chemistry, Stockholm University, Sweden*
Daphnia magna is a standard model in ecotoxicity testing. The test protocols and guidelines specify the assay conditions, including feeding, during exposure to ensure reproducible test outcomes. In contrast, there is no explicit standardisation for pre-exposure feeding despite the recognised significance of test organisms' energy reserves in coping with various stressors, including organic pollutants with narcosis as the main mode of action. This gap in standardisation can contribute to inconsistent test outcomes undermining reliable hazard assessments.

Here, we examined whether the pre-exposure feeding regime of neonates (<24 h) of *D. magna* can affect the test outcome in an acute dose-response experiment with chemicals inducing narcosis. The neonates were subjected to two alternative feeding regimes during the pre-exposure: starved (food-free media) and fed (algae present). Following this treatment, the daphnids were exposed for 72 h to a mixture of polycyclic aromatic hydrocarbons and then allowed to recover for 48 h in clean media with algal food. We measured survival and individual protein content in the daphnids at the end of each part of the experiment, i.e., pre-exposure, post-exposure and post-recovery. There were significant effects of the pre-exposure feeding manifested as (i) lower and less variable individual protein content, (ii) higher survivorship, and (iii) greater potential for recovery in the starved individuals. These findings imply that feeding during the first hours of daphnid life rapidly increases metabolically active body mass, with downstream effects on stress tolerance. Therefore, the pre-exposure feeding regimen plays a pivotal role in experimental design, especially when inducing test outcomes through narcosis, exerting a substantial influence on both the effect concentrations and their variability.

1.09.B.T-02 Transgenerational effects of the fluoroquinolone Flumequine in D. magna: An In Vivo Whole-Transcriptomic Investigation
Edoardo Pietropoli[1], *Marianna Pauletto*[1], *Silvia Iori*[2], *Roberta Tolosi*[1], *Mery Giantin*[1], *Mauro Dacasto*[1] *and Marco De Liguoro*[1], *(1)Comparative Biomedicine and Food Science, University of Padova, Italy, (2)Department of Comparative Biomedicine and Food Science, University of Padua, Italy*
Flumequine (FLU), a long-standing antimicrobial widely used in aquaculture, lacks a comprehensive understanding of its toxicological effects on non-target species, especially long-term ones. This study delves into the potential transgenerational effects of FLU on *Daphnia magna*, a key crustacean model species in ecotoxicology. F0 generation was exposed for 21 days to two FLU concentrations (2.0 mg L^{-1} and 0.2 mg L^{-1}). Subsequent generations (F1 to F3) were kept for 21 days in pure medium. All the four generations (F0-F3) were subjected to phenotypic assessments, while the transcriptional profiles were investigated by means of RNA-sequencing in F0 and F3 generations. The results observed in the F3 generation were compared with those outlined in F0 and previously published. As to the FLU impact on phenotype, it decreased over generations. In contrast, in F3 generation, the transcriptional effects were exacerbated, suggesting a greater impact of FLU on progeny than on directly exposed organisms. Indeed, in F3 daphnids we observed 473 and 1187 differentially expressed genes (DEGs) following FLU 0.2 mg L^{-1} and FLU 2.0 mg L^{-1} exposure, respectively, while in F0 generations DEGs were 43 and 357 for low and high FLU dose, respectively. Functional analyses highlighted the upregulation of pathways related to cell duplication, nucleic acids binding, duplication and translation, coupled with the downregulation of pathways involved in the formation of the organism's nervous and structural systems.

These findings, indicating amplification of FLU transcriptional effects over generations upon reintroduction into a pure medium, suggest a potential adaptation to FLU contamination. It is worth noting that this potential adaptation was not appreciated at the phenotypic level, thus highlighting the importance of implementing molecular tools in risk assessment. Whether the observed differences in expression result from alterations at the DNA level (e.g., epigenetic factors) or a combination of other factors is still uncertain and worth of further investigations.

In conclusion, our research significantly contributes to understanding risks associated with the extensive use of fluoroquinolones in aquaculture and shows the potential transgenerational effects of environmental pollutants in aquatic systems.

1.09.B.T-03 An Open-Source Modular Workflow for Automated Daphnia Measurements of Sublethal Effects
Philipp Kropf[1], *Matthias Schott*[2] *and* ***Magdalena M. Mair***[3], *(1)University of Bayreuth, Germany, (2)Animal Ecology I, University of Bayreuth, Germany, (3)Statistical Ecotoxicology, University of Bayreuth, Germany*
Large standardized datasets are becoming increasingly important for early environmental screening and the comparison of effects across different pollutants. While standardized procedures are usually available for simple acute mortality (e.g. OECD guidance 202) and chronic reproduction (e.g. OECD guidance 211) tests, test setups for other sub-lethal endpoints are often more diverse and not standardized. In addition, the testing of sub-lethal effects is usually time-consuming and subjected to potential observer bias, which hampers the implementation in high- or medium-throughput workflows. New *in silico*-based automation techniques that allow for standardized and fast measurements are often following very specific tasks that restrict their application to specific research questions, or lack open and freely usable code.
We developed a free open image analysis framework that is able to achieve both, standardized time-efficient measurements of *Daphnia*, and the option for modular extensions to adjust the workflow to more specific research questions. We use a Fast

Region-based Convolutional Network (Fast-RCNN) algorithm to detect *Daphnia* body parts (whole daphnid, head, eye, body, spina base, spina tip, heart, brood cavity) and measure body size (body length, body width, spina length) with human precision. The workflow is packed into a user-friendly function that allows for the analysis of a batch of images in a single line of code. At its core, the output contains visualizations of annotated images and a simple csv file with measurements. In addition to this basic user level, we demonstrate how the workflow can be extended flexibly to answer additional research questions and how it can be connected to other automatized measurement approaches. The program is provided as docker image and as source code on github.

1.09.B.T-04 Investigating the fitness consequences of phenanthrene exposure in resurrected D. magna strains: a paleoecotoxicological study

Florian Gigl[1]*, Muhammad Abdullahi Mr*[2]*, Marianne Barnard*[2]*, Henner Hollert*[3] *and Luisa Orsini*[2]*, (1)Evolutionary Ecology & Environmental Toxicology, Goethe University Frankfurt, Germany, (2)School of Biosciences, University of Birmingham, United Kingdom, (3)Evolutionary ecology and environmental toxicology, Goethe University Frankfurt, Germany*

Polycyclic aromatic hydrocarbons (PAHs) are a ubiquitous class of chemicals formed by the incomplete combustion of wood, crude oil, coal, and gasoline. Due to their lipophilic properties, PAHs spread ubiquitously and are persistent in the environment. Because of their biochemical properties, PAHs can accumulate in animal tissue with mutagenic, carcinogenic, and reprotoxic effects. Since the industrial revolution, PAHs have increased in the environment considerably, with concentrations ranging between 0.159 to 33090 µg/kg in lake sediments worldwide. To date, many studies have investigated the acute and chronic effects of PAHs on freshwater organisms. However, the long-term impact of these contaminants on fitness and ecological endpoints has been largely ignored. Moreover, it is unclear how prior exposure to other contaminants in the environment may alter the toxic response of organisms to these ubiquitous contaminants. Here, we study the impact of Phenanthrene (PHE), one of the most abundant PAHs in aquatic environments, on the sentinel and keystone species *Daphnia magna*. Capitalizing on the long dormancy of this species, we expose *D. magna* strains with different history of exposure to chemicals to PHE and measure its impact on fitness-linked life history traits. The studied temporal populations of *D. magna* were resurrected from a lake with well-paced and well-described history of chemical exposure. This allowed us to study fitness responses of both strains naïve to chemical stress and strains that have experienced historical exposure to chemical stress. Our study shows that both naïve and experienced populations to chemical stress suffer a fitness cost following exposure to PHE, showing lower fecundity, a delay in maturation and smaller size.

1.09.P-Mo061 Toxicokinetic profiling of ZnO:Mn multicomponent nanomaterials in Daphnia magna

Marianne Houin[1]*, Maud Phillips*[1]*, Sébastien Cambier*[1]*, Johanna Ziebel*[1]*, Patricia M.A Farias*[2]*, Olavo D. F. Cardozo*[3]*, Andreas Stingl*[4]*, Arno C. Gutleb*[1] *and* ***Kahina Mehennaoui, PhD***[1]*, (1)Erin, Luxembourg Institute of Science and Technology (LIST), Luxembourg, (2)Postgraduate Program on Materials Science, PGMTR, CCEN, Federal University of Pernambuco, UFPE, Cidade Universitária, Brazil, (3)Phornano Brasil Ltda, Brazil, (4)Phornano Holding GmbH, Austria*

Multicomponent nanoparticles (MCNMs) are emerging nanomaterials (NMs) developed by combining individual nanoparticles (NPs) to enhance their properties. Despite their prevalence, there is limited knowledge about the behaviour, fate, and potential effects of MCNMs on aquatic organisms. Zinc oxide (ZnO) is a widely used NPs, particularly in cosmetics and sunscreens. When coupled with manganese (Mn) NPs, ZnO is anticipated to exhibit increased stability and potentially reduced toxicity. To explore this hypothesis, *Daphnia magna* were exposed for 72h to ZnO NPs and to a MCNMs consisting of ZnO:Mn NMs. Toxicokinetic profiles of Zn and Mn were assessed after a 72h exposure period.

Organisms were first exposed for 24h to 300 $\mu g.L^{-1}$ of ZnO and ZnO:Mn before being transferred to a clean medium for 48h. Survival, Zn and Mn bioaccumulation and/or depuration, and behavioural responses were investigated. This approach provides comprehensive insights about the short term effects, uptake, and potential recovery patterns of *D. magna* exposed to ZnO and ZnO:Mn.

A rapid uptake of Zn was observed in organisms exposed to ZnO NPs and ZnO:Mn with 400 $\mu g.g^{-1}$d.w. of Zn measured in organisms tissues after 1h of exposure and an uptake rate of 50.68 h^{-1} and 68.52 h^{-1} for ZnO NPs and ZnO:Mn respectively. Similarly, a rapid accumulation of Mn was observed after 1h of exposure of *D. magna* to ZnO:Mn with an uptake rate of 231.3 h^{-1}. After 24h of exposure, organisms were transferred into clean medium. No Zn elimination was observed in both exposure condition, while a slow but significant elimination of Mn was observed in organisms exposed to ZnO:Mn. A significant effect on *D. magna* behaviour was observed. Mobility of exposed organisms was significantly lower compared to the control group after 48 and 72h of exposure, suggesting a delayed effects of ZnO and ZnO:Mn. Similarly, *D. magna* velocity was significantly lower in exposed conditions when organisms were in clean medium. The application of a light stimuli had significant effects only on non-exposed organisms highlighting the impact of ZnO and ZnO:Mn on *D. magna* phototaxis. The current study gives a better understanding of the exposure kinetics of ZnO and ZnO:Mn and their potential toxicity on *D. magna*, as they may have deleterious effects on population dynamics which may alter the functioning of aquatic ecosystems.

1.09.P-Mo062 When Daphnia glow and tell us what's wrong: An Image-based screening method using Calcein AM in whole organisms for rapid assessment of chemicals

Amira Perez*, Cedric Abele, Paula Pierozan, Andrey Höglund, Oskar Karlsson and Magnus Breitholtz, Environmental Science, Stockholm University, Sweden*

More than 86 million tons of chemicals, potentially hazardous to the environment, are produced annually in Europe. This makes it nearly impossible to evaluate the adverse effects of each chemical in a realistic time frame. It is therefore fundamental to develop new tools capable of rapidly revealing adverse effects by quantifying relevant ecotoxicological endpoints.

New assessment methods (NAMs) such as image-based screening have started to evolve as an important predictive tool in ecotoxicology. Calcein AM is a lipophilic dye that permeates viable cells. Once in the cytoplasm it gets hydrolysed by the intracellular esterase into the fluorophore calcein, which emits a bright green signal. Cell viability as measured by intracellular esterase activity is a recognized parameter of cell health. Applying Calcein AM combined with automated image analysis in the model organism *Daphnia magna* is a novel approach that allows visualization of chemical effects in an intact organism. *D. magna* is a commonly used standard test species for ecotoxicological assessment of chemicals.

The aim of this project was to develop an image-based screening protocol for sublethal adverse effects in *D. magna* using Calcein AM. Esterase activity signal was analysed and quantified using Calcein AM after 24 hours exposure to three different model compounds known to have specific effects in *D. magna*: carbofuran and triphenyl phosphate interfering with the esterase activity and the insecticide methoxychlor, known to alter the viability and locomotor behaviour of *D. magna*. The signal intensity in each exposure was used to calculate EC_{50}-values, which were compared to corresponding EC_{50}-values obtained from the traditional OECD acute immobilization test.

Results showed a decreasing fluorescence intensity equal or similar to zero from Calcein AM with increasing concentration of Methoxychlor: 50-200 µg/L. These concentrations did not cause mortality. The EC_{50} obtained by the Calcein AM signal intensity was 28.9 µg/L compared to 171 µg/L from the OECD immobilization test, which demonstrates a higher sensitivity of the image-based screening method.

This novel whole organism image-based screening NAM offers a rapid and sensitive tool to asses sublethal ecotoxicological effects of chemicals.

1.09.P-Mo063 Impact of Antineoplastic Agents in the Survival and Cellular Homeostasis of Daphnia magna

*Ana Carolina Matias[1], **Madalena Vieira**[1], Andreia Rodrigues[2], Roberto Martins[3], Susana Loureiro[3] and Maria D Pavlaki[4], (1)University of Aveiro, Portugal, (2)CESAM & Department of Biology, University of Aveiro, Portugal, (3)CESAM-Centre for Environmental and Marine Studies and Department of Biology, University of Aveiro, Portugal, (4)University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Portugal*

Antineoplastic agents, which are vital components of cancer chemotherapy, are designed to inhibit tumor cell proliferation by interacting with DNA and modifying cellular growth factors. The release of these agents into municipal and hospital effluents has raised concerns regarding the potential risks to non-target aquatic organisms, particularly when they coexist in complex mixtures. This study aimed to investigate the effects of two distinct antineoplastic agents, doxorubicin (DOX) and oxaliplatin (OXA), on the acute effects of *Daphnia magna*, measuring immobilisation as an endpoint, and its sub-lethal antioxidant, biochemical, and neurotransmission responses, to evaluate the impact of their single and mixture toxic effects. Combined toxicities were predicted using two distinct models, Concentration Addition and Independent Action, along with possible deviations, such as synergism or antagonism, and effects dependent on “dose level” or those dependent on “dose ratio”. Acute effects of single exposure of the two antineoplastic agents to *D. magna* after 48 hours occurred at EC_{50}=0.79 mg/L of DOX and at EC_{50}=59.61 mg/L of OXA. Mixture exposure of DOX and OXA displayed a better fit for dose ratio deviation patterns for both models, showing synergism at higher OXA concentrations, whereas antagonism was mainly caused by increasing DOX concentrations. Biomarkers for neurotoxicity, oxidative stress, and cell membrane damage were evaluated in *D. magna* exposed to sublethal concentrations of DOX and OXA. Biomarkers included AChE, CAT, GPX, GR, GST, ETS, CYP c reductase, CYP3A4 activity, and LPO. Alterations in LPO were observed for DOX exposure, while CAT, GPx, GR, GST, and ETS showed changes with OXA exposure. Mixture exposure of DOX and OXA resulted in alterations in ETS and AChE. The ecotoxicological data presented in this study not only highlights the potential environmental risks associated with anticancer drugs, particularly concerning their synergistic effects but also emphasizes the importance of integrating statistical models to assess the environmental impact of these compounds, as their behaviour will be different from the impact of single stressors.

1.09.P Invertebrate Species in Ecotoxicology: Challenges and Opportunities in a Global Change Scene

1.09.P-Mo061 Toxicokinetic profiling of ZnO:Mn multicomponent nanomaterials in Daphnia magna

*Marianne Houin[1], Maud Phillips[1], Sébastien Cambier[1], Johanna Ziebel[1], Patricia M.A Farias[2], Olavo D. F. Cardozo[3], Andreas Stingl[4], Arno C. Gutleb[1] and **Kahina Mehennaoui, PhD**[1], (1)Erin, Luxembourg Institute of Science and Technology (LIST), Luxembourg, (2)Postgraduate Program on Materials Science, PGMTR, CCEN, Federal University of Pernambuco, UFPE, Cidade Universitária, Brazil, (3)Phornano Brasil Ltda, Brazil, (4)Phornano Holding GmbH, Austria*

1.09.P-Mo064 The Sub-lethal effects of Water Accommodated Fraction from chemically dispersed Marine Gas Oil on the North Atlantic copepod Calanus finmarchicus

Tamer Amr Hafez[1]*, Maren Ortiz-Zarragoitia*[2]*, Dag Altin*[3]*, Zdenka Bartosova*[4]*, Bjørn Munro Jenssen*[5] *and Tomasz Maciej Ciesielski*[4]*, (1)Zoology and Animal Cell Biology, CBET+, PiE, University of the Basque Country UPV/EHU, Spain, (2)Research Centre for Experimental Marine Biology and Biotechnology (Plentzia Marine Station; PiE-UPV/EHU), University of the Basque Country (UPV/EHU), Spain, (3)Research Infrastructure SeaLab, Norwegian University of Science & Technology (NTNU), Norway, (4)Norwegian University of Science & Technology (NTNU), Norway, (5)Department of Biology, Norwegian University of Science & Technology (NTNU), Norway*

Due to the maritime regulations to reduce sulfur emissions, there has been a shift in use of fuels with low sulfur content. As a result, the use of the low sulfur Marine Gas oil (MGO) has increased in the shipping industry. Although several studies have investigated the toxicity of MGO through Water Accommodated Fractions (MGO WAF), few investigated how chemically enhanced MGO WAF (MGO CEWAF), by the application the dispersant (FinaSol OSR52,10%), modifies the toxicity to marine organisms in cold environments. The copepod *Calanus finmarchicus* is an important component of the zooplankton communities of the North Atlantic and is a valuable food source for commercially important fish. In addition, *C.finmarchicus* has been extensively studied concerning hydrocarbon contamination, making it a model organism to investigate the effects of MGO CEWAF. Hence, the objective of this study was to investigate sublethal effects of MGO CEWAF on *C. finmarchicus*. Adult *C. finmarchicus* were exposed to a sublethal concentration of MGO CEWAF corresponding to 50% of the calculated LC_{50}-value after 96 hours of exposure (4.22% MGO CEWAF in seawater) for 24, 48, 72 and 96 hours. Sublethal responses were assesed by quantifying the transcription levels of several biomarker genes, activities of antioxidant enzymes, lipid peroxidation levels, and accumulation of the carotenoid astaxanthin. Gene transcription analysis showed significant downregulation of the biotransformation gene *cyp330A1* in all the exposed groups compared to control groups. Furthermore, changes in the gene transcription levels of elongase, fatty acid binding protein and ferritin suggested that exposure to MGO CEWAF affected lipid metabolism and consequently affect the copepods' ability to store energy and successfully complete diapause, an important phase in the copepod's life cycle. In addition, the significant reduction in activities of antioxidant enzymes, such as catalase, superoxide dismutase and total glutathione, suggests that exposure to MGO CEWAF induced oxidative stress. The reduced capabilities to oxidative stress regulation and changes in lipid metabolism will be further investigated through levels of lipid peroxidation and the amount of accumulated astaxanthin.

1.09.P-Mo065 Developing a Protocol for Measuring Viability and DNA Damage in Sperm Cells of Marine Amphipods

Marina Tenório Botelho[1] *and Gisela de Aragão Umbuzeiro*[2]*, (1)School of Technology – State University of Campinas, Brazil, (2)Faculdade de Tecnologia, Universidade Estadual de Campinas (UNICAMP), Brazil*

Adverse effects in germ cells are crucial endpoints to enable a comprehensive chemical hazard evaluation. Reduced sperm quality has been associated with negative effects at population levels in aquatic organisms. There is a lack of protocols for viability and DNA damage evaluation in sperm cells especially for marine invertebrates. *Parhyale hawaiensis*, a tropical marine amphipod, has been recognized as a promising model in ecotoxicology. So, this work aimed to optimize protocols to evaluate sperm viability and DNA damage (comet assay) using *P. hawaiensis* for *in vivo* experiments. Sperm viability and comet assay evaluations were performed after exposure of adults (8 months) to selected mutagenic compounds for 24h and 96h. Organisms were anesthetized and dissected to remove the testes, which were then dilacerated in artificial seawater to obtain sperm cell suspensions. To evaluate viability, sperm cells were stained with SYBR-14 and propidium iodide and counted under a fluorescent microscope after 24h exposure. To evaluate sperm cell DNA damage, standard alkaline comet assay protocol (EtBr stain) was used with organisms exposed for 24 and 96h. For viability, we evaluted the mutagen ethylmethane sulfonate (EMS) from 0.1 to 2 mM and dimethyl sulfoxide (DMSO) from 0.01 to 1%. We wanted to evaluate the maximum concentration that could be used without decreasing viability, since most organic toxicants use DMSO as solvent. No reduction in viability was observed for EMS and DMSO. To verify the best time of lysis and unwinding in the comet assay, we direct exposed sperm cells to EMS and UV radiation and verified that the used protocol provided satisfactory responses and the best conditions were 18h of lysis and 15 min of unwinding. When we compared the DNA damage responses of sperm cells and hemocytes for both mutagens at the same exposure times, sperm cells were more sensitive. Then, we exposed 12 males per concentration of EMS (0.1 to 2mM) for 24 and 96h. A clear concentration response was observed after 24h, but for 96h all concentrations provided high percentage of damage (>70%). Both viability and DNA damage protocols were successfully developed and will be now applied to evaluate mutagens that require metabolic activation, such as PAHs, azo and anthraquinones dyes. It seems that 24h exposure time is sufficient to detect DNA damage (comet assay) at least for direct mutagens as EMS. For other compounds different exposure times may be needed.

1.09.P-Mo066 Framework for Immunotoxicological Studies using the Marine Amphipod Parhyale hawaiensis: Hemocytes Characterization

Amanda dos Santos[1,2]*, Marina Tenório Botelho*[3]*, Willian Reina Joviano*[4]*, Vicente Gomes*[4]*, Jose Roberto Silva*[4] *and Gisela de Aragão Umbuzeiro*[5]*, (1)Center for Energy and Petroleum Studies - University of Campinas, Brazil, (2)School of Pharmaceutical Sciences - São Paulo State University, Brazil, (3)School of Technology – State University of Campinas, Brazil, (4)University of São Paulo (USP), Brazil, (5)Faculdade de Tecnologia, Universidade Estadual de Campinas (UNICAMP), Brazil*

Hemocytes are blood cells present in the hemolymph of amphipods and other crustaceans and are very important to the functioning of the immune systems. Given the importance of the amphipods as test organisms in ecotoxicological studies and the possibility of collecting hemolymph from them, several studies have used this matrix to assess DNA damage after different types of exposures. Nevertheless, the knowledge about the types of cells found in the hemolymph or their relative quantities from these investigations is limited. Hemocytes of the marine circumtropical amphipod *Parhyale hawaiensis* have been used for the evaluation of DNA damage and micronuclei, but they have not been characterized in the scientific literature. Thus, this investigation aimed to characterize *P. hawaiensis* hemolymph cells and examine their phagocytotic activity. Basic dyes, such as Rosenfeld and Sudan Black, were selected to differentiate the cell types and the presence of lipids. Three parameters were established: total hemocyte counts (THCs), the proportion of hemocyte types, and their size. To verify phagocytosis activity, hemolymph was exposed to *Escherichia coli*. We observed three distinct cell types in *P. hawaiensis* and all of them contained lipids. Granulocytes had an oval shape and size of 13.4 × 7.6 µm, semi-granulocytes also had an oval shape and a similar size (14.1 × 7.2 µm), and hyalinocytes had a round shape and a smaller size (9.6 × 7.2 µm). The proportions of the three cell types varied between males (64.8%, 31.1%, and 4.2%) and females (70.1%, 28.2%, and 1.7%). Males had significantly higher THCs than females (males: 9007 ± 3800 cells per individual; females: 4695 ± 1892 cells per individual). It was observed that hemocytes were able to phagocytose *E. coli*, indicating that assays based on phagocytosis could also be explored as an immunotoxicity endpoint. These results advance in the understanding of *P. hawaiensis* hemocytes and contribute to the framework for hemocyte-based immune responses as an endpoint in ecotoxicology.

1.09.P-Mo067 The toxic effect of plastic leachate on marine periwinkle Littorina littorea

Daria Bedulina[1]*, Frank Menger*[2]*, Mara Römerscheid*[3]*, Stefan Lips*[4]*, Lars Michael Hildebrandt*[5]*, Anette Tillmann*[6]*, Lanning Gisela*[7] *and Christian Bock*[1]*, (1)Alfred Wegener Institute Helmholtz-Center for Polar and Marine Research, Germany, (2)Department of Organic Environmental Chemistry, Helmholtz-Zentrum Hereon, Germany, (3)Department of Exposure Science, Helmholtz Centre for Environmental Research (UFZ), Germany, (4)Deparment of Bioanalytical Ecotoxicology, Helmholtz Centre for Environmental Research (UFZ), Germany, (5)Department of Inorganic Environmental Chemistry, Helmholtz-Zentrum Hereon, Germany, (6)Alfred-Wegener Institute, (7)Department of Integrative Ecophysiology, Alfred Wegener Institute Helmholtz-Center for Polar and Marine Research, Germany*

Plastic pollution poses a substantial threat to marine coastal ecosystems. Besides the physical effect of plastic debris and particles, plastic-associated chemical additives are continuously released from the polymeric matrix and can cause toxicity for marine benthic organisms. This release is enhanced by high coastal hydrodynamics and solar radiation. However, the way these complex mixtures of leached plastic-associated chemicals affect key littoral benthic species is still not fully understood. To investigate this, we exposed a common periwinkle, *Littorina littorea*, for three days to a dilution series of leachates prepared from UV-treated transparent polyethylene foil. The movements of snails were monitored by measuring the time of withdrawal from the shell, the time when tentacles appeared, and the time needed for the snails to rotate from the upward position. Additionally, the leachates were characterized using a set of complex analytical methods using liquid chromatography (LC) coupled to (high-resolution) mass spectrometry ((HR)MS). The results showed that the leachates suppressed the moving activities of snails in a dose-dependent manner. Metabolomic analysis using ^{1}H-Nuclear Magnetic Resonance (NMR) spectroscopy revealed that this suppression goes along with an increase in the concentration of biomarkers of anaerobic metabolism together with glucose depletion in pooled snail's tissues. This indicates a disturbed energy homeostasis induced by leachate exposure. The activity of acetylcholinesterase, a biomarker related to the nervous system, and levels of choline and serotonin changed after the exposure, indicating that the used leachate might have a neurotoxic effect on snails. This could explain the suppression of moving activity. The interconnection of the obtained results with the chemical composition of the used leachate is discussed in this intradisciplinary study.

1.09.P-Mo068 BPE exposure of the snail Lymnaea stagnalis: investigating effects in embryos, adults and after parental exposure

Gaëtan Tucoo[1]*, Henrik Holbech*[2] *and Jane Ebsen Morthorst*[2]*, (1)Biology, University of Southern Denmark, Denmark, (2)University of Southern Denmark, Denmark*

Bisphenols, such as Bisphenol A (BPA), have been used for decades in plastics and resins. After BPA has been considered toxic to reproduction and has been listed on the EU Candidate List of Substances of Very High Concern, BPA-alternatives, such as Bisphenol E (BPE), have been developed. The adverse effects of these alternatives are investigated within the European Partnership for the Assessment of Risks from Chemicals (PARC). The OECD published a *L. stagnalis* reproduction test guideline (OECD TG 243), but tests on embryos are yet to be developed. We investigated the effect of BPE, on both *L. stagnalis* embryos and adults. Embryos were exposed 21 days to 0.1, 0.5, 1, 2, 5, and 10 mg/L of BPE. For the reproduction test, adult snails were exposed in semi static conditions to five BPE concentrations, from 0.1526 to 1.6 mg/L, with a 3.2 factor. The BPE concentration was checked regularly in the exposure water using a UHPLC-3Q-MS/MS. We found that embryos exposed to 5 mg/L grew 21.5% less than the controls, and had significantly decreased heartbeat rate at day 6, but no death occurred. Embryos exposed to 10 mg/L grew 36.1% less than the controls. At this concentration, embryos didn't have heartbeat at day 6, and only 7% of the embryos had hatched after 21 days. However, in spite of severe malformations, no death occurred due to the exposure at 10 mg/L. For adults exposure, a range finding prior to the test showed a 100% mortality of the snails at 10 mg/L. The TG 243 experiment is ongoing. The chemical analysis results show a high instability of the BPE concentration, with down to only 20% of the nominal concentration left after 30h. During the reproduction test, eggs from exposed parents are collected in order to perform embryo tests, and evaluate the potential parental transfer of BPE toxicity. In conclusion, both *L. stagnalis* embryos and adults are sensitive to BPE. We also showed the importance of chemical analysis in exposure test to allow the comparison of results between laboratories and species. Results from embryo exposure tests are promising and will help evaluating the relevance of developing invertebrates embryo-based toxicity tests.

1.09.P-Mo069 Effects of Culturing Conditions on Metal Toxicity to Lymnaea stagnalis - Focus on Diet
Mariem Fadhlaoui[1]*, Osianna Williams*[2]*, Megan Mattsson*[3]*, Antoine Faure*[1]*, Léna Guimard*[1]*, Isabelle Lavoie*[4]*, Katrien Delebeke*[5]*, Stijn Baken, PhD*[6] *and Anne Cremazy*[1]*, (1)Institut national de la recherche scientifique (INRS), Canada, (2)Université d'Ottawa, Canada, (3)New Brunswick University, Canada, (4)Centre Eau Terre Environnement, Institut national de la recherche scientifique (INRS), Canada, (5)International Copper Association, Belgium, (6)European Copper Institute, Belgium*
Lymnaea stagnalis, a prevalent freshwater snail, plays a crucial role in aquatic ecosystems and is well-recognized for its sensitivity to metals, particularly copper (Cu). As a key model organism for assessing metal exposure risks in freshwater environments, understanding the factors influencing its sensitivity is important. This study consists of two sequential experiments to evaluate the impact of experimental conditions (diet quality) on the sensitivity of *L. stagnalis* to Cu. In the initial experiment, newly-hatched snails were exposed to a range of Cu concentrations (1, 2, 5, 10, 20, 50, and 100 μg/L) over 37 days to determine the EC50. The second experiment explored the influence of diet quality on snail sensitivity to Cu. Four distinct diets, including romaine lettuce, sweet potatoes, fish flakes, and periphyton, were tested under Cu-free and Cu-contaminated conditions at the selected EC50. Results from the first experiment indicated significant effects of Cu exposure on growth rate and mortality. A concentration of 15 μg/L was selected for the second experiment based on the EC50. Interestingly, this concentration did not impact growth rate. However, diet quality was found to be a critical factor influencing growth. Indeed, growth rate responded to diet quality depending on development stage.This study presents a contribution to the improvement of methodologies and enhances the reliability of toxicity assessments in *L. stagnalis,* thereby informing more accurate risk assessments in ecotoxicological studies.

1.09.P-Mo070 How can we Better Understand Ecosystem Scale Effects of Neuroactive Chemicals?
Joe D'Souza[1]*, Charles Tyler*[2] *and Fredric Windsor*[1]*, (1)Cardiff University, United Kingdom, (2)University of Exeter, United Kingdom*
Whilst we know neuroactive chemicals are pervasive in the environment, we know little of their impact within freshwater ecosystems. Existing toxicity tests are principally undertaken in controlled laboratory conditions on a small number of species and focus on the individual-level effect of chemicals. As a result, our understanding of sublethal and indirect effects, of which there are potentially many (e.g., reduced feeding activity and subdued predator responses), is limited. A major challenge, therefore, is to understand the effects of neuroactive chemicals at community and network scales within freshwater ecosystems. A multi-method approach will be used to understand the risk posed by neuroactive chemicals to freshwaters. Firstly, we will complete a systematic review into the fate and effects of neuroactive chemicals. Secondly, we will assess the concentrations of neuroactive chemicals in local river catchments across South Wales, UK. Thirdly, we will interrogate mammal, fish and invertebrate genomic databases to identify orthologues for receptors that different neuroactive chemicals interact with and determine the degree to which certain chemicals are likely to have impacts across freshwater ecosystems. By combining the findings of all three analyses we will be able to identify the most prevalent and potentially toxic chemicals at both the global and local scale.

Using the information from the above in silico and field assessments we will employ a combination of aquatic micro- and meso-cosm systems, seeking to address two main questions: (1) how do neuroactive chemicals alter ecological interactions (e.g., predation and competition) and the complex networks these interactions form; and (2) do changes to ecological networks result in alterations in ecosystem functioning? These experiments, assessing the impact of neuroactive chemicals as individual compounds and in mixtures within multi-species systems, will further our understanding of their effects on the complex interactions across trophic levels. Ultimately, by combining both empirical and in silico approaches, we aim to generate much needed policy-relevant and environmentally realistic data to highlight the importance of incorporating behavioural end points with standard ecotoxicological tests to inform chemical risk assessment, regulation and wastewater management.

1.09.P-Mo071 Assessing the Effects of Chemicals on UK-Relevant Freshwater Invertebrates
Amy Rose Ockenden*, Rana Aljaibachi, Anthony Turner, Nichola White and Lorraine Maltby, School of Biosciences, University of Sheffield, United Kingdom*
Freshwater macroinvertebrates are highly vulnerable to anthropogenic stressors such as chemical pollution, with one-third of freshwater insects under threat of extinction. However, macroinvertebrate species vary greatly in their sensitivity to different

chemicals, making it challenging to predict the impact of a given chemical on diverse freshwater invertebrate assemblages. Some of this interspecies variability is linked to a chemical's toxic mode of action (TMoA), wherein general acting chemicals (e.g., metals) exhibit smaller variations compared to specifically acting ones (e.g., insecticides). This interspecies variation in chemical sensitivity could result in variable assemblage sensitivity and associated risks from chemical exposure, a factor currently overlooked in existing assessments of chemical impacts. Given that it is not feasible to undertake toxicity tests for every species-chemical combination, our study introduces a novel strategy for obtaining effects data on high-priority chemicals for UK-relevant invertebrates, both laboratory cultured and field collected organisms. Our underlying hypothesis is that within a TMoA, the rank order of sensitivity of different species to chemicals remains constant, and the relative potency of chemicals across a TMoA is consistent. To test this hypothesis, we focused on six distinct chemical classes (metals, triazoles, polyaromatic hydrocarbons, synthetic pyrethroids, strobilurins), each characterized by a unique TMoA. We tested 3-4 chemicals from each class on an anchor species, *Daphnia magna* and tested 2-3 chemicals from each class on 10 distinct macroinvertebrate organisms. Macroinvertebrates were selected to represent the main taxonomic groups (e.g., arthropods, annelids, molluscs) and functional traits (e.g., detritivores, filter-feeders, grazers, predators) found within freshwaters assemblages. For each of these organisms, we conducted acute immobilization tests and investigated whether the rank order of sensitivity remains consistent within a chemical class. If our hypothesis is correct – that groups of similar species show consistent responses to particular chemical classes, this will facilitate the extrapolation of effects across species and chemicals. This will ultimately provide a more holistic and ecologically relevant perspective on the impact of chemicals on UK freshwater assemblages.

1.09.P-Mo072 Implications of WWTP Upgrade on aquatic organisms: Gammarids and NGS

Miriam Langer, *Verena Christen and Dominik Züger, University of Applied Sciences and Arts Northwestern Switzerland (FHNW), Switzerland*

Wastewater treatments plants (WWTP) are known point sources for micropollutants (MP) in surface water systems. To reduce the introduction of MP in Switzerland, WWTPs are currently upgraded with further treatment steps. To demonstrate the impact of this measures on the receiving streams, which is a huge financial investment for the involved partners, currently the removal efficiency of 12 tracer MP is recommended. This practice is not satisfying since it's not representing the impact of the water quality improvement for water organisms directly. The goal of this project was to demonstrate if increase of water quality can be represented by using actively monitored gammarids and next generation sequencing (NGS).

For several years adult male gammarids from the respective nearby ecosystem were selected and introduced in an active in situ monitoring up and downstream of WWTP outlets before and after an upgrade of a WWTP (monitored sites n=4, 1-3y). The gammarids were exposed for 1 month including food. After exposure the gammarids were counted, the RNA of the whole organisms were isolated and used for Next Generation Sequencing (Illumina NextSeq 550). A workflow based on the Galaxy platform (https://usegalaxy.org/) for the data evaluation was established including a transcriptome assembly. The project is currently still running, but initial results after the (partial) upgrade of the first two WWTP showed, that the number of significantly regulated transcripts between upstream and down streams are reacting towards the change in water quality. For example, after the upgrade with a PAK-Treatment, the number of significantly regulated transcripts between up- and down-stream was 3-times lower. The reduction pattern could be replicated in the subsequent year. Surprisingly, despite large biological variation, the number of significantly altered transcripts was comparable between up and down before and after removal at one site over 2 years.

At another WWTP a new biological treatment system has been activated, even with a still pending MP upgrade, a reduction of significantly regulated transcripts between up- and downstream could be demonstrated. For further analysis more WWTP upgrades are needed, but current results show that this "Non target" gene approach is showing a good responsiveness and could be an interesting indicator of water organisms health status, especially considering the high biological variance among populations and years

1.09.P-Mo073 Effects of Biodegradable Microplastics on the crustacean isopod Idotea balthica basteri Pallas, 1772

Amalia Amato[1], *Roberta Esposito*[2], *Thomas Viel*[2], *Francesca Glaviano*[3], *Loredana Manfra*[4], *Mariacristina Cocca*[5], *Giovanni Libralato*[6], *Maria Costantini*[2] *and Valerio Zupo*[3], *(1)Stazione Zoologica Anton Dohrn, Italy, (2)Stazione Zoologica Anton Dohrn, Department of Ecosustainable Marine Biotechnology, Italy, (3)Stazione Zoologica Anton Dohrn, Department of Ecosustainable Marine Biotechnology, Ischia Marine Centre, Italy, (4)Italian National Institute for Environmental Protection and Research (ISPRA), Italy, (5)Institute of Polymers, Composites and Biomaterials, National Research Council of Italy, Italy, (6)Department of Biology, University of Naples Federico II, Italy*

Plastic pollution is a remarkable environmental issue, being plastic widespread and characterized by long lifetime. Serious environmental problems are caused by the improper management of plastic end of life. In fact, plastic litter is currently detected in any environment. Biodegradable polymers are promising materials if correctly applied and managed at the end of life, to minimize environmental problems. However, poor data on BPs fate and toxicity on marine organisms limit their applicability. In the present work we tested the effects of biodegradable polymers (polybutylene succinate, PBS; polybutylene succinate-co-butylene adipate, PBSA; polycaprolactone, PCL; poly (3-hydroxybutyrates, PHB; polylactic acid, PLA) widely used in various anthropic activities. These polymers were fed for 35 days to adult individuals of the isopod *Idotea balthica basteri*, by adding fragments to formulated feeds at two concentrations, i.e., 0.84 and 8.4 g/kg feed. Our results showed that the polymers affected the survival rates of the isopods as well as the expression levels of eighteen genes (tested by Real Time qPCR) involved in stress response and detoxification process. Our findings demonstrated that *I. balthica basteri* is a convenient model organism to study the response to environmental pollution and to emerging contaminants in the aquatic environment, and highlight the need for the correct use of biodegradable plastic polymers.

1.09.P-Mo074 Salinity fluctuations impact behavior of copepods: in situ monitoring using the multispecies freshwater biomonitor

Mette Albreksen[1]*, Per Meyer Jepsen*[1] *and Henriette Selck*[2]*, (1)Science and Environment, Roskilde University (RUC), Denmark, (2)Roskilde University (RUC), Denmark*

Many organisms living in estuarine environments have evolved abilities to cope with changing salinities. The cyclopoid copepod *Apocyclops royi* are normally living in estuarine and coastal pond environments in e.g. Taiwan. Hence, they are during the monsoon season exposed to heavy rain falls and following decrease in salinity. At other times of the year, they experience longer heat periods and subsequent evaporating water, thus increasing salinities. This study examined the impact of salinity change on the activity and behavioral response of *A. royi*. More specifically we asked 1) how well does *A. royi* cope with extreme salinity changes (0 to 32 PSU), and 2) how long will it take to recover (from being inactive to be active again). Animal movements in the water generate specific frequencies, and the Multispecies Freshwater Biomonitor (MFB, Limco International) can estimate the percentage of time producing each frequency (from 0.5 to 8.5 Hz) by means of a stepwise discrete Fourier transformation. The chambers contain biosensors, which are placed on the inside wall. The biosensors come in pairs and there are two pairs in each chamber. One pair is sending out an alternating current through the water, which is then received by the other pair of sensors. If the chambers contain an animal, the movement of the animal will be detected by the change in amplitude of the signal sent by the first pair of sensors. MFB can be used in both marine- (0.1V) and freshwater (1V). *A. royi* was reared in a dark climate room in seawater (32 PSU) at 25°C and fed with the microalgae, *Rhodomonas salina* twice a week. Female *A. royi* with egg sacks was selected and placed individually in the experimental MFB chambers after addition of either DI- (0 PSU) or marine (32 PSU) water (n=8 chambers per salinity). Activity was recorded using the MFB: 1 V for 0 PSU and 0.1 V for 32 PSU. The MFB has 16 channels (8 for each salinity) and is based on the quadruple impedance conversion technique to record liv organism behavior. We found that *A. royi* decrease activity significant and is almost inactive initially when transferred from 32 to 0 PSU. Further, they appear to regain activity within hours suggesting that they will be able to handle extreme salinity stress. However, it is still to be examined how *A. royi* react to the combined stress of salinity change and contaminant exposure.

1.09.P-Mo075 Flow Cytometry as a Tool to Assess the Responses of Mytilus edulis Digestive Cells to Contaminants Present in the Arctic

Tania Gomes[1]*, Maria T. Hultman*[2]*, Samantha Eslava Martins, PhD*[1] *and Knut Erik Tollefsen*[2]*, (1)Norwegian Institute for Water Research (NIVA), Oslo, Norway, (2)Norwegian Institute for Water Research (NIVA), Norway*

Primary cell cultures from aquatic organisms are being increasingly developed for use in toxicity testing and mechanistic studies in response to xenobiotics. Whereas fish cells are commonly used, less is known about primary cells derived from aquatic invertebrates. Digestive glands play a key role in the metabolism and biotransformation of xenobiotics in mussels *Mytilus sp.*, making digestive cells relevant *in vitro* models for studying pathways and toxic mechanisms of xenobiotics. Flow cytometry (FCM) can be used as a tool to evaluate the toxicological effects of contaminants in individual cells close to an *in vivo* state. However, its potential use in integrated effects assessment and next generation risk assessment has not yet been fully explored. So, the aim of this study was to investigate the sensitivity of FCM to quickly screen the effects of model chemicals towards digestive cells isolated from *Mytilus edulis*. In a first assessment, the morphological, physiological and structural characteristics of digestive cells were determined using light microscopy, fluorescence microscopy and FCM. Several cell types were identified visually, comprised mostly of larger cells filled with lysosomes and smaller cells containing none to a few lysosomes or lipids. The presence of two main cell populations with different sizes and complexity was identified by FCM. Secondly, the integrity, viability and biochemical functions of isolated digestive cells were evaluated up to 24 hours post-isolation using FCM, for which mortality, cell viability, metabolic activity and neutral lipids and lysosomes presence were determined. Results obtained showed that digestive cells maintained their cellular integrity and biochemical functions over time, even though a small decrease in viability was seen at 24h post-isolation. Exposure experiments are currently ongoing, where digestive cells will be exposed to model chemicals, e.g., copper, pyrene, and the following endpoints determined by FCM: mortality, cell viability, metabolic activity, neutral lipids and lysosomes presence, ROS formation, membrane potential, lipid peroxidation and DNA content. Overall, the use of FCM seems to be a fast, accurate and reproducible cost-effective method to quickly assess a wide array of cellular functions in mussel digestive cells that can be integrated into assessment of contaminants present in the Artic. This work was supported by the EXPECT Project (#315969) funded by the Research Council of Norway.

1.09.P-Mo076 Can primary producers act as vector of nanoplastics bioaccumulation on small filter feeders?

Marisa Sarria Pereira de Passos[1]*, Guillaume Bucher*[2]*, Gabriella Schirinzi*[3]*, Vanessa Modesto*[4]*, Jessica Ponti*[5]*, Douglas Gilliland*[2]*,* ***Miguel-Ángel Serra***[5] *and Nicoletta Riccardi*[4]*, (1)European Commission - Joint Research Centre (JRC), Belgium, (2)European Commission - Joint Research Centre (JRC), Italy, (3)Joint Research Centre (JRC) - European Commission, Italy, (4)Water Research Institute - Italian National Research Council (IRSA-CNR), Italy, (5)European Commission - Joint Research Center (JRC), Italy*

Bioaccumulation is a key component for the assessment of nanoplastics risk to the environment. Within aquatic ecosystems, filter-feeding organisms are particularly relevant to sentinel for plastic contamination due to their highly specialized filtering structures. Although varying greatly among different zooplanktonic species on their biological filter-mesh size and sensory adaptability, the range limits seems to be set by the structure and function of the filtering apparatus used for trapping particles. It is therefore interesting to ask: does the biological filter mesh-size of small filter feeders matters when bio-concentrating nano-size plastic particles?

Within an environmental context, small filter feeders tend to be foodborne-exposed to the contaminants. It is therefore highly relevant to discuss the ecological role of phytoplanktonic species to try to understand if these can contribute as vectors of bioaccumulation, since as primary producers it would not be firstly anticipated that these microorganisms occupying the first trophic level of every trophic chains would have an "intent" to uptake nanoplastics.

In this work, relevant planktonic species were directly collected from Lake Maggiore (Italy) and exposed to three gold-doped nanoplastics for 24 h, considering nonstandard experimental designs. A non-axenic microalgae culture containing a mixture of species was used as foodvector for the nanoplastics exposure on freshwater cladocerans and copepods. Contact tests of freshwater microalgae to the nanoplastics were conducted at the exponential growth phase for 24 h and several relevant biomarkers were assessed. Metal-doped nanoplastics bioaccumulation on these microorganisms was assessed by ICP-MS analysis. Taken together, the obtained results pinpoint that zooplankton when fed with nanoplastics only (no microalgae) tend to accumulate significant levels on their bodies, however, when co-exposed with microalgae a decrease in the accumulated content was recorded. As microalgae directly exposed to the nanoplastics demonstrated high levels of metal content, it is reasonable to anticipate that the lower levels uptaken by the zooplankton was due to competition among species. Moreover, interesting differences on bioaccumulation levels among the two zooplanktonic species were observed, which seems to reflect their different biological filtering mesh-sizes. At last, differences on nanoplastics bioaccumulation were also demonstrated between different particles.

1.09.P-Mo077 Sublethal Effects On Planktonic Biota Of New Phosphorus Adsorbents Used For Lake Restoration
María Gómez-Pozuelos[1], *Eloisa Ramos-Rodriguez*[2], *Anja Svane Kolath*[3], *Anders Baun*[4] *and Inmaculada de Vicente*[2], *(1)Institute of Water Research (IdA), University of Granada (UGR), Spain, (2)Department of Ecology/Institute of Water Research (IdA), University of Granada (UGR), Spain, (3)University of Southern Denmark, Denmark, (4)DTU Sustain, Technical University of Denmark (DTU), Denmark*
Currently, it is well-known that eutrophication, characterized by an increase in the primary production of aquatic ecosystems, represents one of the major challenges for the quality of water resources worldwide. This also leads to a loss of biodiversity and disrupts aquatic ecosystems, emphasizing the importance of restoring these environments to aid in biodiversity recovery. Phosphorus is typically the primary limiting nutrient for primary production in most inland aquatic ecosystems. Therefore, reducing its concentration in water stands as the most crucial strategy to control eutrophication. In this context, short-term standardized laboratory tests were conducted to assess the sublethal effects on aquatic biota of two novel phosphorus adsorbents: carbonyl iron magnetic particles (HQ) and lanthanum-modified bentonite (Phoslock®). A series of toxicological tests were run by using species from two different trophic levels: primary producers such as *Desmodesmus* sp. (measuring algal growth rate inhibition) and primary consumers such as *Daphnia magna* (evaluating filtration and somatic growth rate). At this point, it is important to consider that adsorbent doses used in these experiments were much higher than doses expected to be used in a real scenario based on mobile sedimentary phosphorus and maximum adsorption capacity for phosphorus for each adsorbent. Therefore, if no effects on organisms are found at these high doses, no effects are likely to be expected at lower concentrations. Our results initially indicated that, in algal growth rate experiments, no inhibition was observed for HQ or Phoslock® despite the significant reduction (albeit still above the metabolic threshold) in phosphate concentrations upon adsorbent addition. *Daphnia* filtration rate experiments revealed that neither HQ nor Phoslock® had negative effects through indirect contact. However, a significant reduction in the somatic growth rate of *Daphnia* was observed when both adsorbents were directly added in all concentrations, particularly with Phoslock®, resulting in a more pronounced reduction at highest concentrations (1 and 2 g L-1). Nonetheless, indirect contact with both adsorbents did not yield any significant effects on the somatic growth of *Daphnia*. Overall, the addition of these adsorbents in a real lake-wide application is expected to cause minor sublethal effects in *Desmodesmus* and *Daphnia*.

1.09.P-Mo078 Indirect effects in mudsnails through dietary uptake?
Sophie Oster[1], *Patrick Fink*[2] *and Mirco Bundschuh*[3], *(1)Institute for Environmental Sciences, RPTU Kaiserslautern-Landau, Germany, (2)Department of River Ecology, Helmholtz Centre for Environmental Research (UFZ), Germany, (3)Institute for Environmental Sciences, RPTU Kaiserslautern-Landau, ., Germany*
Aquatic ecosystems are characterized by multiple connections within and among trophic levels. Chemical stress can disrupt these interactions and lead to shifts in structure and function. Pesticides or pharmaceuticals can enter surface waters via different pathways such as agricultural runoff or sewage treatment plants. Direct effects of these chemicals towards aquatic primary producers such as biofilms have been widely studied. Biofilms not only contribute to primary production, but also represent an important food source for grazing animals and host a large biodiversity including bacteria and algae. Studies of potential indirect effects towards higher trophic levels (primary consumers) are scarcer. We therefore hypothesized that species turnover in the biofilm community composition could in turn indirectly affect grazers feeding on biofilm. We studied river biofilms as food source for the grazing New Zealand Mudsnail *Potamopyrgus antipodarum* after exposure to chemical stress. *P. antipodarum* is a globally widespread invasive grazing gastropod, that lives in freshwater and consumes food via scraping off organic coatings. The mudsnail has been established and widely used in the OECD 242 reproduction test since 2016. In

terms of chemicals, we chose an herbicide to directly address the algal species and an antibiotic to address the bacterial community within the biofilm.

We collected biofilm from a small river in a natural reserve in Germany as an inoculum to colonise ceramic tiles in stream microcosms. After four weeks of colonisation, biofilms were chronically (14 days) exposed to 1) an unexposed control, 2) 10 µg/L of propyzamide, 3) 10 µg/L of ciprofloxacin and 4) to the mixture of both. In subsequent feeding assays, grazers were fed *ad libitum* with those biofilms for 21 days. Grazers were analysed regarding their physiological condition (fatty acid composition) and feeding activity, while the biofilm was analysed in terms of biomass, chlorophyll content, and fatty acid composition. The data is currently being analysed supporting a coherent interpretation of these indirect effects. Based on the above hypotheses, we expect chemically induced changes in the biomass and nutritional quality (less essential macronutrients such as highly unsaturated fatty acids) of the biofilm. Consequently, we also expect to see indirect changes in the snails based on an altered feeding rate and a similarly altered fatty acid profile compared to the control approaches.

1.09.P-Mo079 The Impact of Environmental Factors on the Growth and Development of a Laboratory Culture of Cloeon dipterum

*Katie Smith[1], **Hanna Samantha Schuster**[1], Charles Hazlerigg[2] and Nadine S Taylor[1], (1)Cambridge Environmental Assessments (CEA), United Kingdom, (2)Enviresearch Ltd., United Kingdom*

In the European Union (EU), non-standard test species are used in the refinement of aquatic risk assessments of plant protection products (PPPs). Representatives of EPT taxa (Ephemeroptera, Plecoptera and Trichoptera) are of particular interest as they are classed as sensitive and vulnerable to PPPs, however, they are known to be difficult to work with in a laboratory setting and the seasonality of their life cycle restricts the frequency and scale of ecotoxicity testing.

The mayfly *Cloeon dipterum* is a highly abundant species across the UK and Europe, residing in ponds and river margins in their larval stages and is a highly suitable taxa for Tier 2 testing in these regions. Yet little is known about how laboratory conditions affect sub-lethal endpoints such as emergence, larval stages and overall survival, resulting in difficulties with standardising testing. In the wild, individuals emerge across varied time periods and the emergence success rate and survival of larvae are largely unknown with many confounding factors contributing to growth and development.

Here, we present the results from non-standard bench-scale tests using wild-caught *C. dipterum* larvae. The larvae were subjected to different variations (from optimal to stress conditions) of environmental conditions, modifying temperature, photoperiod and food quantity. Data was collected for a range of developmental measurements, including body length, instar stage, feed intake, moults, time to emergence and survival were measured.

C. *dipterum* showed distinct trends in response to different conditions. In particular, sub-optimal temperature and food availability resulted in a significant impact on development and survival. Mortality increased with both low (16 ˚C) and high (22 and 24 ˚C) temperatures, and at the lowest food concentration. The increased mortality was mainly observed at instars L5 - L7. No clear trend was found for different photoperiods. A wider range of growth and development measurements, e.g., instar stages and body length was observed under optimum conditions (20 ˚C and higher food quantities) compared to the stress conditions. Ecologically speaking, variability in size and moults indicate different choices by individuals to invest in growth versus development which may have implications for population dynamics.

These results will be used to progress the reliability of mayfly testing in a regulatory context and inform future effect modelling.

1.09.P-Mo080 Effects of the UV filter 4-hydroxybenzophenone at the molecular level on the aquatic invertebrate Chironomus riparius

*Nuria Bosch[1], **Jose-Luis Martinez-Guitarte, PhD**[2] and Esther Gonzalez-Almela[1], (1)Universidad Nacional de Educación a Distancia, Spain, (2)UNED, Spain*

In recent years, UV filters have become ubiquitous environmental contaminants of increasing concern because of their extensive use, persistence, and bioaccumulation potential. The UV filter 4-hydroxybenzophenone (4HB) has been described to cause endocrine disruption in vertebrates and is found in natural aquatic environments. Here, the ability of aquatic invertebrates to manage the emerging contaminant 4HB is studied. To address this, the reference organism *Chironomus riparius* was in vivo exposed to three environmentally relevant concentrations of 4HB (0.1, 1 and 10 mg/L) for 8, 24 and 72 hours. The response was assessed by analyzing the differential expression of genes involved in detoxification, stress response, energy metabolism, drug resistance, and DNA damage repairing. The analysis was performed using a 16-gene real-time PCR array. The results suggest that exposure to 4HB stimulates the detoxification mechanisms and the toxicant export out of the cytoplasm causing an increase in the expression of the MRP1 transporter. Finally concluding that additional research is needed although the effects observed in this study suggest that it produces a weak response in the short-term.

1.09.P-Mo081 Toxicology Effects of Guanidinium Isothiocyanate In the Biological Model: Caenorhabditis Elegans

***Elin Yohana Manrique- J**[1] and Maria Cecilia Garcia-Espineira[2], (1)Universidad del Atlantico, Colombia, (2)Bolivar, University of Cartagena. Faculty of Medicine; Biomedical, Toxicological and Environmental Sciences Research Group*

(BIOTOXAM), Cartagena de Indias, Colombia., Colombia
Background**:** Guanidinium isothiocyanate (GITC) is a chaotropic agent that is used as the active ingredient in lysis buffers in nucleic acid extraction processes and whose use increased in laboratories during the pandemic (1,2). It is currently identified in the Network for Monitoring and Evaluation of Emerging Chemical Substances (Norman Network) on the list of suspects for Emerging Contaminants (3). Its inclusion as a suspicious substance is a cause for concern considering that this reagent is for use in the laboratory and must be discarded under special conditions and in accordance with the danger categories for “substances dangerous for the aquatic environment” of the Economic Commission to the United Nations for Europe. GITC is classified in category: acute toxicity 3, being toxic to some fish and crustaceans but not classified as a substance that generates chronic toxicity (4,5).
Objective**:** To evaluate the toxic effects at different concentrations of GITC in the Caenorhabditis elegans biological model.
Methodology: GITC concentrations that caused mortality in wild strains (Bristol N2) of exposed C. elegans were identified, estimating the LC 50. Growth, locomotion, and reproduction parameters were evaluated according to the exposure and changes in expression were established of stress response genes in transgenic strains of C. elegans.
Results: the concentrations used did not induce acute lethality. There was alteration in growth, locomotion, and reproduction. There was an increase in the expression of genes related to oxidative stress.
Conclusion: GITC generated effects on locomotion, growth and reproduction in the nematode, and oxidative stress enzymes were also expressed.

1.09.P-Mo082 A geometric framework approach to understand multi-metal toxicity on individual organisms to evaluate relative risks and benefits of pollution and mitigation
Eleanor Jane Phillips*, Biosciences, University of Sheffield, United Kingdom*
The essential nature of organic metals to organismal fitness makes them distinct from other common pollutants. The interdependence of these metals in cellular function, uptake, and excretion, are probable to make their dose-responses interdependent, whilst also being dependant on other environmental and physiological conditions. The potential for less than additive or antagonistic effects of certain metal combinations could have important implications in mitigating the impacts of organic metal toxicity in the environment. However, we lack a comprehensive assessment of multi-metal interactions, with most of our knowledge limited to studies of single or binary combinations of essential metals, across a narrow set of doses. We aim to generate a multivariate geometric framework, across multiple organic metals, as an intuitive means of mapping the effects of expose on phenotypic outcomes. We use the fruit fly (*Drosophila melanogaster*), an ideal high throughput model to achieve such an extensive assessment of candidate metals. Initial focus of the study will be on developmental and reproductive endpoints in flies exposed to combinations of copper, zinc, and phosphorus; elements important in shaping organismal health, that are also environmentally relevant pollutants. The protocols developed from this study can then be applied to a more extensive range of candidate metals to identify those that are highly interactive. In addition to other benefits of using a short-lived invertebrate model, the fly genome is comprehensively understood and easily manipulatable, making this species a particularly effective tool to explore the largely unknown mechanisms underlying the physiological effects of the interactions between metals. For example, metal toxicity effects have been studied in detail in the fly with a key regulatory role of the transcription factor MTF-1. Using flies mutant for this transcription factor will allow us to distinguish dysregulation of metal homeostasis from direct effects of metals and their interactions. Our work aims to provide a more comprehensive understanding of how organic metals shape organismal health and fitness on a fundamental level.

1.09.P-Mo083 Effects of three antibiotics (tetracycline, ciprofloxacin, sulfamethoxazole) on survival, growth, reproduction, behaviour and antioxidant enzymes of the earthworm Dendrobaena veneta
Jurate Zaltauskaite[1]*, Diana Miškelytė*[1]*, Gintare Sujetoviene*[2]*, Austra Dikšaitytė*[1]*, Giedrė Kacienė*[1]*, Irena Januskaitiene*[1] *and Renata Dagiliute*[1]*, (1)Vytautas Magnus University, Lithuania, (2)Vytautas Magnus University, Kaunas, Lithuania*
Antibiotics have been widely used in human and animal medicine and are identified as emerging aquatic and terrestrial contaminants. Veterinary antibiotics are used for disease prevention, control and treatment in food animal production. Worldwide demand for livestock production is expected to double by 2050 implying considerable use of antibiotics. A wide variety of antibiotics has been detected in aquatic and terrestrial environments, among which tetracyclines, sulfonamides and quinolones are the most frequently detected. Because of inherent biological activity antibiotics present in the soil may impact soil dwelling organisms, however their effects on soil dwelling organisms are still poorly understood. Adult earthworms *Dendrobaena veneta* were exposed to 1-500 mg/kg of tetracycline (TC), ciprofloxacin (CIP) or sulfamethoxazole (SMX) for 8 weeks. Mortality, body weight, cocoon production and biochemical responses including the activity of catalase (CAT), superoxide dismutase (SOD), glutathione reductase (GR), gluthathione-S-transferase (GST) and malondialdehyde (MDA) were examined. During the avoidance test, the earthworms were exposed to the same antibiotics concentration n the soil for 48 hours. The results showed obvious avoidance behaviour of D. veneta against CIP and SMX, though no avoidance was observed against tetracycline. The survival of the earthworm was affected only at the highest tested antibiotic concentration and only after eight weeks of exposure. Only SMX significantly affected the final earthworm weight, however, the pattern of body weight growth of earthworms exposed to different antibiotics was dissimilar. SMX has also shown toxicity to cocoon production and juvenile hatching. The activity of antioxidant enzymes (catalase, superoxide dismutase and gluthathione-S-transferase) was also affected by antibiotics.

1.09.P-Mo084 Assessment of Emerging Pollutants in Wastewater Impact on Fuente de Piedra Wetland: A Toxicological Study on a Native Species (Daphnia magna)

Emilio Moreno[1], *María Gómez-Pozuelos*[1], *Cristina Postigo*[2], *Inmaculada de Vicente*[3] *and José María Conde-Porcuna*[3], *(1)Institute of Water Research (IdA), University of Granada (UGR), Spain, (2)Civil Engineering / Institute of Water Research (IdA), University of Granada (UGR), Spain, (3)Department of Ecology/Institute of Water Research (IdA), University of Granada (UGR), Spain*
Wastewater discharges from local treatment plants in freshwater ecosystems are the main point source of emerging pollutants input into wetlands. The continuous input and presence of emerging pollutants like pesticides, stimulant and pharmaceutical compounds into freshwater and their potential effects on planktonic organisms are raising concern. Under this scenario, we investigated the presence of emerging pollutants in the Fuente de Piedra RAMSAR wetland (Málaga, Spain). We detected the presence of a total of 34 emerging pollutants in all water samples analysed over a period of six months. The most predominant contaminants were pharmaceuticals (13), followed by pesticides (11), drugs and stimulant substances (9), and personal care products (1). Among these, caffeine, the nonsteroidal anti-inflammatory drug naproxen and the neonicotinoid systemic insecticide imidacloprid showed the highest concentrations. Concentrations varied between 0.09 to 15.08 μg/L for caffeine and between nondetectable to 2.30 μg/L and 0.46 μg/L for naproxen and imidacloprid, respectively. According to the results obtained, we propose to carry out toxicological test to investigate their potential toxic effects on the native species from Fuente de Piedra *Daphnia magna*. Our approach is evaluating the potential ecological risk of caffeine, imidacloprid, and naproxen on *Daphnia magna* increasing concentrations (0, 0.1, 10, 100, 1,000, 10,000, 50,000, 100,000, 500,000 μg/L) and monitoring for acute effects. The concentrations selected cover a wide range to ensure a comprehensive evaluation of potential toxicity. Preliminary results indicate that caffeine, imidacloprid, and naproxen exhibit concentration-dependent effects on *Daphnia magna*, with immobilization as a primary endpoint.
The relevance of this study lies in its contribution to understanding the ecological consequences of wastewater-borne emerging pollutants on aquatic ecosystems. The findings provide valuable insights into the potential risks associated with specific pollutants, such as caffeine, imidacloprid, and naproxen, and their impact on *Daphnia magna*. This research provides insights into the adverse effects of emerging pollutants on planktonic native organisms for a better ecological risk assessment in contaminated areas. Subsequent efforts aimed at mitigating these effects should take our results into consideration.

1.09.P-Mo085 Acute and chronic toxicity of four short- and ultrashort-chain perfluoroalkyl substances in Daphnia magna and Hydra vulgaris

Marie Houédé[1], *Houda Hanana*[2], *Geneviève Farley*[2], *Pascale Bouchard*[2], *Roxane Sorel*[2], *Tuc Dinh Quoc*[3], *Sébastien Sauvé*[3] *and* ***Magali Houde***[2], *(1)University of Angers, France, (2)Environment and Climate Change Canada, Canada, (3)University of Montréal, Canada*
Perfluoroalkyl substances (PFAS) have been used for decades in industrial and commercial products and are detected worldwide in aquatic and terrestrial environments. Short substances (< 6C) such as perfluorobutanoic acid (PFBA), perfluorobutane sulfonic acid (PFBS), and trifluoroacetic acid (TFA) have been increasingly used by industry and are now detected in environmental matrices. We need to better understand the effects of these PFAS on aquatic organisms to be able to assess their risks. The first objective of this study was to investigate the acute toxicity of four short- and ultrashort PFAS - PFBS (4C), PFBA (4C), TFA (2C) and trifluoromethane sulfonic acid (TFMS, 1C) - in two aquatic invertebrate species: *Daphnia magna* and *Hydra vulgaris*. Two independent experiments were conducted with the same individual PFAS. In one experiment there was no pH adjustment of the solutions, whereas in the other experiment the test solutions were adjusted to pH of 6,5 to 8,5 corresponding to standard exposure media. The second objective was to assess the chronic toxicity of TFA in both species (treatments = 0, 0.01, 1, 10, 100 mg/L; 13 d exposure for *D. magna* and 7 d for *H. vulgaris*). Endpoints of immobility, mortality, reproduction, body size, and glutathion S-transférase (GST) as biomarker of oxidative stress were assessed in *D. magna* and development and reproduction were evaluated in *H. vulgaris* during and after exposure. Chemical analysis confirmed the presence and stability of the four PFAS in exposure media. Results from acute testing without pH adjustment (LC50 = 316 mg/L and 31,6 mg/L for *D. magna* and *H. vulgaris,* respectively) indicated that the four PFAS impacted the survival of both species at the highest concentration (1000 mg/L); results for all LC50 were > 1000 mg/L with pH adjustment. Results from chronic testing on *D. magna* indicated no effects on mortality, immobility, reproduction, and GST levels in comparison to controls. A size reduction was observed for *D. magna* with increasing concentrations for TFA during chronic testing. TFA exposure did not induce changes in the morphology of individual polyps and did not alter the reproduction of hydra. Overall, results suggest lower toxicity of these substances compared to longer-chain PFAS. However, the persistence of these short-chain PFAS in the environment and potential sub-lethal effects should be investigated.

1.09.P-Mo086 A High Throughput Adaptation of Standardized Ecotoxicological Exposure Tests in Daphnia magna and Other Invertebrates

Angel Daniel Ceballos Ramirez[1], *Mark Hodson*[1], *Colin Brown*[1], *Thomas G Preuss*[2] *and Elma Lahive*[3], *(1)University of York, United Kingdom, (2)Bayer AG - Crop Science Division, Germany, (3)UK Centre for Ecology & Hydrology (UKCEH), United Kingdom*
Modern mechanistic modelling can create extrapolations of chemical toxicity across multiple organisms; however, it tends to require large amounts of measurements. New technology and equipment have introduced the opportunity of using high-throughput testing techniques to facilitate the collection and automated processing of high volumes of experimental data assisted by Artificial Intelligence or specialized image analysis software.

The present project aims to adapt the *Daphnia magna* chronic OECD standard procedures to a High Throughput setting using a Cell imager and well plates. The method will then be extended to other invertebrates used in similar ecotoxicological tests, such as *Moina macrocopa, Thamnocephalus platyurus and Heterocypris incongruen*s. We aim to standardize high throughput methods, expose the organisms to different chemicals with varying modes of action and octanol-water partition coefficients, measure chronic toxicity responses and derive Dynamic Energy Budget Theory (DEB) Toxicokinetic – Toxicodynamic (TKTD) parameters.

In Initial experiments, *D. magna* was grown in Elendt M7 media in 2ml well plates. Growth, defined as head to tail length, matched observed values in the literature where OECD standards were followed. Lengths ranged between 1.8-3.0 cm after 14 days, with little mortality (<20%). Follow up experiments will feature cohorts of 60 organisms exposed to five different concentrations of 3,4-Dichloroaniline, 2,4,5-Trichloroaniline, 1,4-Dichlorobenzene and 3-Nitroaniline for 21 days, quantifying effects on their growth and reproduction. Experimental concentrations for the selected chemicals will be derived after an initial experiment to create a dose-response curve and obtain an EC50. For the presentation, results for *M. macrocopa, T. platyurus* and *H. incongruens* will also be included.

The next step will also include the exposure and culturing of all the species under different temperatures, food regimes and chemicals, in order to generate growth curves and derive DEB parameters, such data are currently unavailable for *T. platyurus and H. incongruens* in the Add-my-pet database. After this, the data generated will be inputted into a DEB-TKTD model to predict chemical toxicity across multiple species and chemicals with varying physicochemical properties and modes of action. Finally, the predictions of the model will be fitted to new experimental data.

1.09.P-Mo087 Nanoplastic-Induced Genotoxicity in Daphnia pulex

Thomas Nash*, Paul Kay and Laura Carter, School of Geography, University of Leeds, United Kingdom*

The presence of microplastics in freshwater systems are cause for concern, with many studies detailing harm caused to freshwater organisms resultant of exposure to microplastics at both an individual and community level. Exposure to microplastics is known to negatively impact daphnids, causing increased mortality and a range of sublethal effects including reduced reproduction and changes to swimming behaviour.

Genotoxicity testing can provide another useful endpoint in this regard since it can detect sublethal – but still potentially harmful – effects across varied timescales. Combined with other biomarkers, genotoxicity testing can improve understanding of the ecological consequences of environmental contamination.

In this study, *Daphnia pulex* neonates were exposed to 100nm polystyrene microparticles for 24 and 48 hours at doses ranging from 10 to 200 mg/L, with immobilisation and genotoxicity (comet assay) endpoints assessed following exposure. Results indicate that polystyrene microparticles at high concentrations induce genotoxicity within 48 hours, however immobilisation proved more sensitive to the presence of polystyrene microparticles at both lower concentrations and after just 24 hours. Further work will investigate the genotoxic impact of microplastics both in longer term (chronic) exposures and in combination with other pollutants.

1.09.P-Mo088 "An automated flow-through exposure system for the evaluation of challenging substances in the Daphnia reproduction test"

Anne Dupont, Armin Peither, Séverin Semal, ***Johannes Völker****, Stefan Josef Hoeger and Jörn Schreitmüller, Innovative Environmental Services (IES) Ltd., Switzerland*

The *Daphnia magna* reproduction test plays a crucial role in the regulation of chemical substances. The test involves exposing juvenile female Daphnia to the test substance over 21 days and assessing several reproductive parameters, including the number of offspring, time to the first brood, and the survival and growth (measured in length) of the parent organisms.

The frequency of medium renewal depends on the stability of the test substance. According to the test guidelines, medium renewal should be done at least three times a week. For challenging test substances that are volatile or tend to degrade quickly (such as hydrolysis, oxidation, and sorption), the OECD recommends more frequent medium renewal or the adoption of a flow-through test (OECD Guideline 211; OECD Guidance Document 23).

A flow-through exposure system enables the maintenance of stable exposure conditions and, thus, the assessment of difficult test substances. At IES, we use an automated flow-through dosing system with individual dosing units for each treatment. Based on the specific physicochemical properties of the test chemical, solubility tests and dosing pre-experiments are performed to determine and optimise appropriate dosing parameters including test medium flow and exchange rate as well as ensuring adequate nutrient supply.

Given the increasing demand for chronic toxicity testing of challenging test substances, the possibilities and various setting of the flow-through exposure system are presented, discussed, and compared with the semi-static approach. We will focus on the reproduction rate and the analytical results (recovery), as these two parameters are crucial for the acceptance of the test results for the risk assessment of biocides, plant protection products and industrial chemicals.

1.09.P-Mo089 JC-1 and High-Content Imaging to Quantify Mitochondrial Toxicity in Daphnia magna

Cedric Abele, *Amira Perez, Andrey Höglund, Paula Pierozan, Magnus Breitholtz and Oskar Karlsson, Environmental Science, Stockholm University, Sweden*

New approach methodologies are required to improve chemical risk assessment. Alternative endpoints are e.g. necessary to elucidate the toxic mechanism of a chemical towards organisms. Fluorescence microscopy and the development of molecular dyes offer new possibilities to detect changes in biochemical processes due to chemical stressors.

The aim of this study was to quantify the effect of the model compounds 2,4-Dinitrophenol (2,4-DNP) and carbonyl cyanide 3-chlorophenylhydrazone (CCCP) on mitochondria health in *Daphnia magna* by using the mitochondrial membrane potential dye JC-1 in combination with automated image-analysis.

D. magna were exposed to 2,4-DNP concentrations between 0.94 and 40 mg/L and CCCP between 0.5 and 2500 µg/L for 2 h and 24 h. Five daphnids per concentration were used and the experiments were conducted in triplicates. After the exposure, immobilization was measured and JC-1 was applied. Fluorescence images where acquired in an automated confocal high-content imaging system. The signal intensities in *D. magna* were measured using an established image analysis workflow. Dose-response relationships based on the change in fluorescence intensities were calculated.

In all experiments, effects on the mitochondrial membrane potential were detected at lower concentrations than immobilization. Moreover, the *D. magna* that showed altered JC-1 signal were fully mobile, showing that this effect is sublethal. In both experiments, the EC_{50}-values of mitochondrial membrane potentials after 2 h exposure were similar to their corresponding EC_{50}-values of immobilization after 24 h. After exposure to 2,4-DNP, mitochondrial effect concentration was three times lower compared to corresponding values for immobilization and up to 30 times lower after exposure to CCCP.

These results indicate that the image-based method is able to identify the difference in the test compounds' potency of uncoupling oxidative phosphorylation in mitochondria of *D. magna*. Furthermore, effects were measured at a much earlier stage and predicted organism death after 24h and 48h. In conclusion, this new approach provides an rapid and sensitive mechanistic approach to regular ecotoxicity testing of chemicals.

1.09.P-Mo090 The Effect of Wildland Fire-fighting Chemicals on the Reproductive Success of Ceriodaphnia dubia

Holly J Puglis, *Michael Iacchetta and Christina Mackey, U.S. Geological Survey (USGS)*

With wildfires increasing in frequency and intensity in the western United States, it is essential to understand how the chemicals used to suppress the spread of wildfire interact with the landscape. The effect on environmental health must be understood to use these chemicals safely and effectively in emergencies. Studies have recently been published on the lethality of fire-fighting chemicals currently used by the U.S. Forest Service; however, little is known about how these chemicals may impact the reproductive success of organisms affected by chemical intrusions. We investigated the reproductive success of a commonly tested cladoceran (*Ceriodaphnia dubia*). Specifically, female cladocerans were exposed to a concentration series of three current-use fire-fighting chemicals (LC95A-R, MVP-Fx, and 259-Fx) at two durations (15 or 60 minutes) and then held for seven days to determine effects on reproduction. There was a significant interaction between concentration and duration of exposure with a decrease in number of neonates produced per female in LC95A-R treatments after 60 minutes of exposure at 3,500 mg/L and greater concentrations compared to the control females. There was a similar pattern with MVP-Fx, although the interaction was not significant. In 259-Fx treatments, there was no interaction between duration of exposure and concentration, but fewer neonates were found in treatments with 60-minute exposures than in 15-minute exposure treatments. Measures of reproduction are a hallmark indicator of the ecological impact of chemical products on biota because impaired reproduction has significant consequences for the structure of natural populations, as well as for the stability of the food web. Further investigation of aquatic biota found in streams native to areas with high occurrence of wildfire should be studied to determine the potential population level changes that may occur from fire-chemical intrusion.

1.09.P-Mo091 Exploring mode-of-action for acute toxicity of primary aromatic amines with D. magna using differential gene expression analysis

Friedel Dewulf[1], ***Ilias Semmouri**[1]*, *Karel De Schamphelaere[2] and Jana Asselman[3], (1)Ghent University (UGent), Belgium, (2)Ghent University - GhEnToxLab, Belgium, (3)Blue Growth Research Lab, Ghent University (UGent), Belgium*

Organic pollutants, with their diverse structures and modes-of-action (MOAs), pose a significant challenge in understanding and predicting their toxic effects on the environment. Chemicals can be grouped according to toxicity in among others non-polar narcotics, polar narcotics, reactive chemicals, and specifically acting chemicals. Non-polar narcotics (baseline toxicants) act via a non-specific MOA, with their toxicity linked to hydrophobicity. Polar narcotics are slightly more toxic, while reactive and specifically acting chemicals show enhanced toxicity due to more specific MOAs and targets. The MOA of a chemical is also linked with its interspecies variation in toxicity: structurally analogous narcotics typically demonstrate limited interspecies variations in toxicity, while chemicals with a specific or reactive MOA display elevated interspecies variation, primarily attributed to the specific MOA in exceptionally sensitive species. In that respect, aromatic amines exhibit distinctive toxicity characteristics. Although they have been classified as 'polar narcotics', certain substitution patterns of the aromatically bound amino group result in a large interspecies variation in toxicity, due to their excess toxicity towards species such as *D. magna*. In this context, we investigated three primary aromatic amines (PAAs) in *D. magna*: 4,4'-MDA, 2,2'-MDA and 2,4-TDA.

Despite their structural and chemical similarities, they exert very distinct biological effects. Therefore, we studied their MOA by acute exposure experiments in the model organism *D. magna* to study its gene expression in response to PAA exposure. Our experimental design also included two reference compounds, a non-polar narcotic (1-octanol) and aniline. Our analysis showed, both in terms of acute immobility and gene expression patterns, very distinct biological MOAs for the three PAAs. While 4,4'-MDA treatment showed similar effects as aniline, its isomer 2,2'-MDA showed similar effects as 1-octanol. 2,4-TDA had an EC10 value in between the other two PAAs and did not induce any differential gene expression compared to the negative control at its EC10 concentration. These results indicate towards a specific influence of substituent positioning in PAAs on their toxicity and MOA towards *D. magna*.

1.09.P-Mo092 Alternative Assays for Routine Toxicity Assessment

Wouter Lanneau[1]*, Kirit Wadhia*[2] *and Kris Perdaen*[1]*, (1)Microbiotests, Belgium, (2)Environmental, NOV Inc, United Kingdom*

Substantial number of aquatic toxicity tests exist and are deployed in particular framworks. However, for routine screening of environmental samples and potential chemical formulation investigations, these conventional assays are not practical and hinder expeditious progress. The development of alternative small-scale bioassays referred to as microbiotests has significantly advanced throughput strategies. The microbiotest technology has several advantages in comparison to the "traditional" tests based on laboratory cultures, especially its independence of the stock culturing burden.

The Daphtoxkit is a prime example of a microbiotest that has been effective and has enabled implementation of projects worldwide otherwise not doable and has accelerated the advancement of research & development programs. Microbiotests offer new opportunities for effects monitoring of chemicals and environmental matrices (effluents, leachates, interstitial waters, etc). These can also contribute to increasing the cost efficiency and diagnostic potential of hazard assessment schemes.

Use of microbiotests is continuing to gather momentum for application in regulatory frameworks. Aquatic microbiotests, invaluable for screening and ranking ecotoxic effects, their intrisic features can contribute to novel applications enabling rapid detection and enhanced throughput.

Biological testing, and microbiotesting in particular, will indubitably increase significantly in environmental protection activities in the future. International recognition of biotesting, and more critically owing to limitations in regional testing infrastructure (lack of laboratories and culturing facilities), the implementation scope is globally significantly enhanced to facilitate environmental policies, regulations and guidelines. The imperative need for cost efficiency in environmental assessment continues to fuel the need for R & D concerning microbiotesting.

1.09.P-Mo093 Protection over Prediction: Daphnids Safeguard the Use of Alternatives to the Acute Fish Toxicity Test

Martin Paparella[1]*, Christoph Schuer*[2]*, Christopher Fassbender, PhD*[3]*, Gilly Stoddart*[3]*, Marco Baity-Jesi*[4] *and Kristin Schirmer*[5]*, (1)Medical Biochemistry, Medical University of Innsbruck, Austria, (2)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (3)PETA International Science Consortium Ltd., (4)Siam, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (5)Environmental Toxicology, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland*

The assessment of potential environmental impacts of chemicals traditionally involves acute aquatic toxicity tests using algae, daphnids, and juvenile fish, representing different trophic levels. As part of the international 3R goals, alternative tests like the acute fish toxicity test with the fish cell line RTgill-W1 and the zebrafish embryo acute toxicity test were developed to replace the juvenile fish test, which is in line with the European Chemical Strategy for Sustainability. A related OECD project to develop Integrated Approaches to Testing and Assessment (IATAs) for acute fish toxicity is ongoing.

Previous studies revealed the lower sensitivity of these alternative tests for some neurotoxic chemicals and allyl alcohol, which is biotransformed to the more toxic acrolein in fish. We analyzed historic toxicity data from the EnviroTox Database and found considerable variability in acute fish LC50s and acute daphnids EC50s, particularly for neurotoxic chemicals. Comparing sensitivity of these taxonomic groups according to different neurotoxicity classification schemes indicates that fish rarely represent the most sensitive trophic level, especially among chemicals with neurotoxic modes of action, except for a few cyclodienes, which are no longer relevant on the market and could be identified through structural alerts. Moreover, daphnids were more sensitive than fish for allyl alcohol toxicity. This analysis highlights the potential of the standard Daphnia acute toxicity test guideline in safeguarding the environmental protection level provided by alternative methods.

This research, rooted in decades of efforts to replace the juvenile acute fish toxicity test, expands the focus from predicting fish toxicity to emphasizing environmental protection. This broader perspective enables the complete replacement of the juvenile fish test within an IATA, standardized by the OECD. Furthermore, it paves the way for further eliminating vertebrate tests in environmental toxicology.

1.09.P-Mo094 Inorganic turbidity modifies the effect of glyphosate on Daphnia magna

Miriam Hernández Zamora[1]*, Laura Martínez-Jerónimo*[2] *and* ***Fernando Martínez-Jerónimo***[1]*, (1)Instituto Politécnico Nacional Escuela Nacional de Ciencias Biológicas, Mexico, (2)Escuela Nacional de Ciencias Biologicas, IPN, Mexico*

Nowadays, glyphosate is the most widely used post-emergent herbicide in the world. Although it is stated that the ecological risks of glyphosate on non-target species are minimal, the potential carcinogenic effect of this pesticide on humans has been demonstrated, as well as its toxic effects on aquatic biota. This situation has led to its use being banned in several countries. On the other hand, organic turbidity related to soil erosion due to deforestation and unsuitable agricultural practices contributes to an increase in inorganic turbidity in the aquatic environment, which affects non-selective filter-feeding zooplankton, such as cladocerans. In this study, the effect of the presence of clays (40 mg L^{-1}) on the acute and chronic toxicity (21 d) of the Faena® glyphosate formulation in *Daphnia magna* was evaluated. The sublethal concentrations assessed were 2, 4, and 6 mg L^{-1} as glyphosate. The presence of clay slightly reduced the acute (48-h) toxic effect (LC_{50}= 8.79 vs. LC_{50}=9.69 mg L^{-1}, respectively). For chronic exposure, the three concentrations of Faena® reduced accumulated progeny. When clay was added, the fecundity of *D. magna* was only reduced at the concentration of 6 mg L^{-1}. In controls, clay reduced total progeny. The number of clutches without clay was only lower at the highest concentration of glyphosate, and there were no differences at any concentration when clay was added. The age of first reproduction was merely delayed by clay in the control and the concentration of 2 mg L^{-1}. In the glyphosate-only assays, there was an increasing number of abortions in direct relation to the concentration. In contrast, in the clay experiments, abortions were only recorded in the control and the glyphosate concentration of 6 mg L^{-1}. Mortality was only significantly higher in glyphosate 6 mg L^{-1} with no clay. The results indicate a reduction in the toxic effects of the Faena® glyphosate formulation on *D. magna*, which could be due to a possible retention effect due to the mineral clay charges on some toxic ingredients of the formulation Faena®, in addition to glyphosate. However, it should be noted that both the toxicity of chemical pollution and the increase in inorganic solids in the aquatic environment produce adverse effects on the biota, in addition to affecting essential processes such as photosynthesis due to the interference with light by the increase in turbidity, and effects on filtration rates of zooplankton and benthic organisms.

1.09.P-Mo095 Prediction of the toxicity of 14 compounds on Daphnia magna by using cultures of the yeast Schizosccharomyces pombe

Consuelo Alvarez-Herrera, ***Sara Maisanaba****, María Llana-Ruíz-Cabello and Guillermo Repetto, Universidad Pablo de Olavide de Sevilla, Spain*

The aim of this work was to compare the toxicities on the wild strain of *S. pombe* and *D. magna* to compare the sensitivity and correlation among each experimental models. For all the compounds tested, the toxicity decreased in the following order: triclosan, carbendazim, propylparaben, rotenone, paraquat, chloroquine diphosphate, hydrogen peroxide, perfluorooctanoic acid, hydroxyurea, dibutylphthalate, carbamazepine, metoclopramide, melatonine and KCl.

Although *D. magna* is more sensitive than *S. pombe*, the correlation between the EC50 values obtained for the 14 compounds in the wild strain *of S. pombe* at 20h and for the crustacean *D. magna* exposed for 48h was quite good (R2=0.9282). Therefore, taking into account the limitations due to the small number of compounds tested, *S. pombe* allows the prediction of the range of toxicity of the substances to *D. magna*, and, viceversa.

It should be noted that the compound that is furthest from the trend line was rotenone, which presented much lower toxicity for *S. pombe* than for *D. magna*. This fact is understandable, since fission yeast does not have the main target of the toxic action of the pesticide, that is, complex I. Furthermore, short term *S. pombe* cultures can be applied to predict the range of toxicity on *D. magna.*

1.09.P-Mo096 Assessing the Toxicity of Cytarabine in Daphnia magna Through Apical and Cellular Endpoints

Madalena Vieira[1]*, Moslem Malek Shiri*[2]*, Ana Carolina Matias*[1]*, Susana Loureiro*[3]*, Marta Martins*[4] *and Maria D Pavlaki*[5]*, (1)University of Aveiro, Portugal, (2)Biology, Department of Biology, University of Aveiro, Campus Universitário de Santiago, Portugal, (3)CESAM-Centre for Environmental and Marine Studies and Department of Biology, University of Aveiro, Portugal, (4)MARE - Marine and Environmental Sciences Centre, NOVA School of Science and Technology, Portugal, (5)University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Portugal*

Due to the growing number of cancer cases, the occurrence of antineoplastic agents (AAs) in the environment is increasing, posing a significant threat to aquatic ecosystems. The primary sources of AAs' entry into the environment include hospital effluents, household discharges, and pharmaceutical manufacturing. Due to inadequate removal during wastewater treatment plant, AAs persist in surface, ground, and drinking water. AAs are one of the least studied groups concerning environmental impact and have been considered to represent specific risks to non-target aquatic species due to their mode of action. The aim of this study is to assess the effects of cytarabine (CYT) on the survival and reproduction output as well as analyze the biochemical alterations that it may induce to *Daphnia magna*. CYT is an AA that disrupts the DNA replication process, inhibiting the synthesis of deoxyribonucleic acid (DNA) in cells. To achieve this, *D. magna* individuals were exposed to a range of concentrations according to the OECD 202 and 210 guidelines and effects on their survival and reproduction were evaluated. For a more comprehensive understanding of the toxic effects of CYT, the activity of catalase (CAT), glutathione S-transferase (GST), acetylcholinesterase (AChE), and lipid peroxidation (LPO) were measured after 21 days of exposure. The results from the acute exposure showed no mortality at concentrations of up to 100 mg/L, while the reproduction test demonstrated a significant reduction in the offspring of *D. magna* across nearly all tested concentrations with the lowest concentration the exception. A 21 d EC_{50} of 20.65 ± 1.51 mg/L was obtained, with the highest concentration promoting almost a total inhibition to the offspring output. Regarding the biochemical determinations, no significant alterations were observed for CAT, GST and LPO, however, for AChE a decrease in activity was observed with significant differences at one of the concentrations tested. The results obtained in this study indicate that, despite not being able to induce alterations in short-term exposures, CYT can negatively impact the reproductive system of *D. magna* and compromise its offspring. Even though the chronic ecotoxicological data presented in this study highlight the potential risk associated with AAs, effects are observed at concentrations that are not environmentally realistic.

1.09.P-Mo097 Model species culturing made easier using an automated device: case study D. magna

Sizenando Nogueira Abreu[1,2]*, Fatima Jesus*[3]*, Ines Domingues*[3]*, Amadeu M.V.M. Soares*[3]*, Rui Martins*[2,4] *and Miguel Oliveira e Silva*[2,4]*, (1)CESAM & Department of Biology, University of Aveiro, Portugal, (2)TekenBio, Portugal, (3)CESAM - Department of Biology, University of Aveiro, Portugal, (4)Ieeta - Deti, University of Aveiro, Portugal*

The pollution of environmental components is being characterised by the appearance of new toxicants, multicomponent emissions and discharges, pollutants speciation in the air, water and soil, or other complex processes. Bioassays allow to determine the integral toxicity of the studied environment and extrapolate the data obtained to real ecosystems. To optimize results, it is necessary to consider the sensitivity of the biological species to toxicants, the adaptive capabilities of organisms in the environment, as well as the action of a complex of abiotic (temperature of cultivated water, its chemical composition, season of the year) and biotic factors (such as seeding density). The need to combine chemical methods and bioassays is a generally recognised trend in planning environmental studies. One of the key points to optimisation resides on the culture of model species, where standardisation of the conditions for test organisms have been promoted; however, routine monitoring of cultures requires effort and time.

This work aims to evaluate an automated computerised device assisting culture monitoring of model species, leading to easy routine monitoring. The work presents a case study using *Daphnia magna*, and considering some life history traits of *D. magna***,** such as survival time, body length at maturation, and offspring per female.

The counting of neonate production can be easily achieved by using automated device, contrary to what is required by manual counting. Some other life history traits, such as time to maturation, time to first brood, and time to next brood, are also evaluated using the automated computer device. The discussed approach can be applied assisting routine monitoring model species demographic characteristics, complementing already implemented procedures of test-cultures standardisation, selecting organisms of similar size, saving time, avoiding human error, and improving culture synchronisation, by predicting the time when offsprings might occur.

1.09.P-Mo098 Daphnia magna as an Indicator for Aquatic Species in the Non-target Risk Assessment of Genetically Modified Maize

Michael Peter Meissle*, Research Division Agroecology and Environment, Agroscope, Switzerland*

Similar to pesticides, genetically modified (GM) GM crops are regulated worldwide and environmental risk assessment is one requirement for environmental release. As a surrogate for aquatic species, non-target tests of GM crops often include *Daphnia magna*. Developing suitable test protocols for GM plants and *D. magna* has been challenging, because plant material needs to be ingested by the test organisms (oral mode of action). We here present laboratory studies with insect-resistent GM maize producing multiple Cry proteins from the bacterium *Bacillus thuringiensis*. Our experiments address several difficulties with such studies, including the suitability of crop plant material as food for *D. magna*, the separation of Bt protein-effects from plant background effects, and the interpretation of effects in the context of biological relevance and natural range of variation. *Daphnia magna* can survive, grow and reproduce when fed only maize materials, although the performance was poorer than when fed algae, which indicates nutritional stress. Adverse effects were observed for *Bt* maize flour, originating from different production fields and years, but not for leaves or pollen, produced from plants grown concurrently in the glasshouse. Because leaves contained eight to ten times more Cry protein than flour, the effects of the flour were probably not caused by the Cry proteins, but by compositional differences between the plant backgrounds. Larger differences in life table and population parameters of *D. magna* were observed among 5 different non-GM maize lines, which were tested in a similar way to obtain a natural range of variation for each parameter. The protocols established for testing GM crops on *D. magna* could also be adapted for other orally active substances including, e.g., systemic or RNAi-based pesticides.

1.09.P-Mo099 Dearbhla, the Daphnia, and her research highlights

Katie Reilly[1] *and Iseult Lynch*[2]*, (1)University of Birmingham, United Kingdom, (2)School of Geography, Earth and Environmental Sciences, University of Birmingham*

Daphnia are a fantastic model for research, but also for research communication. The Daphnia Detectives project, was developed to communicate our research findings on the impacts of microplastics in freshwater environments using Daphnia as a model organism. The project consists of a bank of open access online resources that cover the topic of microplastics and Daphnia, from experimental design stages through to example results and data sets that can be used to explore data analysis themes within the high school curriculum context.

A pillowcase, some pegs and pink particles form an integral element of the Daphnia detective's activities, and are a good example of how every day and specialist items can be blended to fit science communication needs. Some of the key lessons from this project was to have a range in the level of detail and complexity, as not all schools or groups have the same baseline level of understanding. Through engaging the pupils, it also highlighted aspects of the research that we don't give a second though to, such as the ethical consideration of research designs. Although this is a standard part of the research process, it is refreshing to reconsider and evaluate the developments in this area, demonstrating that science communication and public engagement isn't just disseminating information but is a valuable experience for researchers too.

The importance and use of model organisms with research communication can further be supported through the Dearbhla Daphnia mascot, which showcases an interactive and creative way to quite literally bring Daphnia into the public domain and spark discussions on the importance of water quality, moving beyond an anthropocentric view to explore the ecosystem level consequences of this in an engaging and novel way. A unique mascot design, and project approach, facilitates discussions beyond those which would conventionally take place within Daphnia, or environmental, research and can bring this research and the big challenges being explored to audience which perhaps would not have traditionally engaged. This project showcases a range of medium and platforms focussed on Daphnia, that can be used to disseminate but also engage people in research from the conception of projects and experimental designs, which could be of interest to other people working with the Daphnia domain.

1.09.P-Mo100 Development of a Transcriptomics-based Testing System to Identify Environmental Stressors in Freshwater Invertebrates using Daphnia pulex as a Model Organism

Jake Bowley[1]*, Rob McFarling*[1]*, Anke Lange*[1]*, Sarah Woodsford*[1]*, Gregory C Paull*[1]*, Ceri Lewis*[1]*, Aaron Jeffries*[1]*, Jonathan Ray Newman*[2] *and Eduarda Santos*[1]*, (1)University of Exeter, United Kingdom, (2)Environment Agency (England), United Kingdom*

Chemical pollutants alone and as part of complex mixtures are a key challenge for aquatic freshwater ecosystems, especially when they occur in combination with other biotic or abiotic stressors. Freshwater catchments often receive complex mixtures of chemicals, including pesticides associated with farming activities. Assessing the impact that these chemicals may have on aquatic organisms continues to be challenging and this knowledge gap is particularly notorious for aquatic invertebrates.

In collaboration with the Environmental Agency in the UK, we set out to develop a novel approach to assess the potential adverse effects that chemicals associated with farmland catchments may have on freshwater invertebrates. To do so, we selected *Daphnia pulex* as a model species given its widespread range in the UK and across many temperate regions worldwide, the ease of culture in the laboratory and the genomic resources available. We set out to use whole body transcriptomics to assess the molecular effects of a selection of pesticides of concern both individually and as part of complex mixtures. This information will then be utilised to design a transcriptomics based assay capable of detecting low levels of stress following chemical exposures in this species. This methodology will function as an early warning system for adverse effects of chemical contamination in freshwater ecosystems and support management and conservation decisions in the future.

1.09.P-Mo101 Long-term Consequences of a Mosquito Control Agent on Insect Emergence – Insights From a Four Year Mesocosm Study

Agnes Schöndorfer[1]*, Sara Kolbenschlag*[1,2]*, Peer Bauspiess*[3] *and Mirco Bundschuh*[4]*, (1)University of Kaiserslautern-Landau (RPTU), Germany, (2)nEcoTox GmbH, Germany, (3)Eusserthal Ecosystem Research Station, RPTU Kaiserslautern-Landau, (4)Institute for Environmental Sciences, RPTU Kaiserslautern-Landau, ., Germany*

Specialized riparian predators rely mostly on aquatic derived food. Changes in the emergence pattern of aquatic insects may thus have substantial consequences on prey availability for these predators with potential risks for associated terrestrial foodwebs through bottom-up and top-down regulation. Bti (*Bacillus thuringiensis* var. *israelensis*), a commonly used non-chemical pesticide applied to control mosquito outbreaks in floodplain areas, is known to also affect non-target insects including Chironomidae. This effect is particularly concerning as Chironomidae can contribute up to 90% to emergence in some ecosystems. To understand the long-term consequences of Bti exposure we employed the so-called floodplain pond mesocosm (FPM) system monitoring insect emergence over the course of 4 years. During these 4 years, we collected emerging insects using emergence traps from the ponds with Bti application at field relevant levels, although using different application intervals, being the independent factor (stressor). Emergence was collected between April and August starting in 2020 until 2023. Equal seasons of the investigated years are compared to understand long-term consequences of varying application intervals. While most samples are still under evaluation, data from the first year of exposure uncovered a shift of the peak emergence by 10 days combined with a 25% reduction in Bti treated ponds. We expect to see a habituation of emergence dynamics in the second and third year where treatment intervals are kept similar to the first year followed by a stronger reduction on the emergence of Chironomidae with shorter treatment intervals.

1.09.P-Mo102 Beyond Microplastics: Water Soluble Synthetic Polymers Exert Sublethal Adverse Effects In The Freshwater Cladoceran Daphnia magna

Simona Mondellini[1]*, Matthias Schott*[2]*, Martin G.J. Löder*[1]*, Seema Agarwal*[3]*, Andreas Greiner*[1] *and Christian Laforsch*[4]*, (1)University of Bayreuth, Germany, (2)Animal Ecology I, University of Bayreuth, Germany, (3)macromolecular chemistry II, University of Bayreuth, Germany, (4)University of Bayreuth, Animal Ecology I, Germany*

Plastic contamination can be considered a driver of global change. Nevertheless, polymer contamination is not limited exclusively to microplastic (MP). Water soluble polymers (WSP) are in fact a class of highly employed compounds whose prevalence and impact have been neglected until recent years. WSP are used in several industrial, dietary, domestic and medical products and are often applied for waste water treatment. Despite they cannot be seen washing up on shores like MP do, WSP are found to be present in the environment and hence can potentially interact with the biota. In this work we exposed the freshwater cladoceran Daphnia magna to five commonly used WSP. For our investigations we relied upon a 48h acute toxicity test and a 21d chronic toxicity test at the end of which we analyzed the levels of reactive oxygen species and life history parameters. Furthermore, we developed a heartrate acute assay to assess any early stage physiological alteration. Our results highlight that the employed WSP do not exert any acute effect, however they did induce life history alterations together with an altered oxidative status. The recorded effects not only can potentially alter D. magna's population dynamics, and thereby, given this species relevancy in lentic ecosystems, impact also higher trophic levels and the biological community. Therefore, further investigations on WSP's effects are highly desirable and their inclusion in hazard assessment regulations is urgently needed.

1.09.P-Mo103 The effects of Dexmedetomidine on the behaviour of crustaceans: lab to field approach

Elea Giraud[1], Susanne Vogeler[2], Daniela Famoso[1], Matthew Parker[3], Samuel Robson[1] and ***Alex Ford[1]****, (1)University of Portsmouth, United Kingdom, (2)School of Biological Science, University of Portsmouth, United Kingdom, (3)University of Surrey, United Kingdom*

Dexmedetomidine is an α2-adrenergic receptors agonist and was originally authorised as a human/veterinary sedative but is now an active ingredient in antifouling paint for boats. In crustaceans, it is known to bind to octopamine receptors, which like other neurohormones, cascade to control many biological functions including behaviour. The aim of this study was to determine whether exposure to Dexmedetomidine can alter the behaviour of marine amphipods (*Echinogammarus marinus*) and juvenile crabs (*Carcinus maenus*) under laboratory conditions using both Zantiks and Daniovision behavioural analysis. Amphipod specimens were exposed to concentrations between 0.1 and 100µg/L with behaviour recorded at 24h, 72h, 96h, 7d, and 14d of exposure and compared to controls and octopamine exposed individuals. Exposure significantly increased activity and distance travelled of individuals compared to controls in both amphipods and juvenile crabs, with an interesting non-monotonic concentration effect observed. Using acoustic telemetry, we then set out to determine whether these results could be replicated in the field to test how effects recorded in the laboratory may relate to in situ ecology. To do so, adult *C. maenas* crabs were sampled in Portsmouth, UK and gradually acclimated to 24‰ salinity before being exposed 1 and 100µg/L of Dexmedetomidine and 1µg/L of octopamine and serotonin. Individuals were tagged using V5 180Khz tags and released into a saline lake, where their position was estimated using four HR2 receivers (Innovasea) deployed 200 meters apart. Preliminary results indicate that the distance travelled by adult shore crabs was increased for individuals exposed to Dexmedetomidine in the first 96 hours, effects consistent with those observed in laboratory experiments performed on juveniles *C. maenas* crabs and *E. marinus* amphipods. Increased activity was persistent over the 12-week in situ period, for individuals exposed to the highest concentration of 100µg/L. Increased activity was also translated in an increase of home range area used by *C. maenas* exposed to 100µg/L of dexmedetomidine. Further results will aim to determine whether exposure to Dexmedetomidine may affect other aspects of their ecology, such as their mortality and diurnal rhythms. The field experiment represents the first acoustic telemetry project with crabs, looking into the behavioural effects of an environmental contaminant.

1.10.A Legacy and Emerging Contaminants in Wildlife: Recent Advancements in Ecotoxicology and Risk Assessment

1.10.A.T-01 Per- and polyfluoroalkyl substances levels and effects in Finnish Waterbirds

Céline Arzel[1]*, Sunniva Frøyland[2], Silje Peterson[2], Elise Lunde[3], Prescillia Lemesle[2], Anne-Fleur Brand[2], Amalie Ask[1], Seyyed Sajjad Vakili[4], Junjie Zhang[2], Tomasz Ciesielski[5], Alexandros G. Asimakopoulos[2], Bin-Yan Hsu[6], Kristina Noreikiene[7], Suvi Ruuskanen[8], Juho Jolkkonen[8], Titiksha Peetumber[1], Salla Lahdentausta[1], Eeva-Riikka Vehniäinen[1,8], Katja Anttila Anttila[1], Kang Nian Yap[2], Mary Ann Ottinger[9], Stefan Björkman[10], Nora M. Wilson[11], Christian Sonne[12], Sanna Koivisto[13], Tapio Eeva[1], Martin Hansen[14] and Veerle L. B. Jaspers[2], (1)Department of Biology, University of Turku, Finland, (2)Norwegian University of Science & Technology (NTNU), Norway, (3)Department of Biology, Norwegian University of Science and Technology (NTNU), Norway, (4)Dept of Biology, University of Turku, Finland, (5)Department of Biology, Norwegian University of Science & Technology (NTNU), Norway, (6)University of Turku, Finland, (7)Institute of Veterinary Medicine and Animal Sciences, Estonian University of Life Sciences, Estonia, (8)University of Jyväskylä, Finland, (9)University of Houston, (10)Faculty of Veterinary Medicine, University of Helsinki, Finland, (11)Faculty of Science and Engineering, Åbo Akademi University, Finland, (12)Bioscience, Aarhus University, Denmark, (13)Finnish Safety and Chemicals Agency (Tukes), Finland, (14)Aarhus University, Denmark*

The increased presence of endocrine disrupting chemicals (EDCs) in our environment poses a significant threat to wildlife. In the Baltic region, the common eider (*Somateria mollissima)* and the common goldeneye (*Bucephala clangula*) breeding populations have been declining in recent decades. While predation plays a significant role in this decline, other stressors may also contribute to this process. Notably, there is a growing sex ratio bias towards males in the adult populations of these 2 species as in several other species, high hatching failure in monitored eider colonies and general decline in the breeding success of both species. These observations have raised the question of whether EDCs might be involved in these processes.

We investigated the presence of 41 Per- and polyfluoroalkyl substances (PFAS) among other EDCs in eider (plasma and eggs) and goldeneye (plasma). Our research confirms the presence of a variety of PFAS in breeding females of both species. We are currently assessing if the PFAS exposure is associated with thyroid hormone levels; results will be presented at SETAC. We further assessed the link between PFAS and Avian Influenza Virus (AIV) occurrence in breeding females. Among the 45 sampled individuals, 75% were positive to AIV. Preliminary results did not show a relationship between PFAS exposure and presence of antibodies for AIV. We demonstrated a transfer of PFAS from female eiders to their eggs (18 PFAS among the 41 tested). In addition we have uncovered a positive correlation between the sum of 5 PFAS, among which perfluorododecane sulfonic acid (PFDoDS), and androstenedione (androgen and sex hormone precursor) in eggs with female embryos raising concern on PFAS endocrine disrupting effects on female embryos. Following these results, an *in ovo* injection experiment with perfluoro-4-ethylcyclohexane sulfonic acid (PFECHS), PFDoDS and perfluorooctane sulfonic acid (PFOS) was carried out at NTNU, Norway with farmed mallard (*Anas platyrhynchos*) eggs. Results from different oxidative stress endpoints will be presented.

Our findings underscore the need for further studies on PFAS in waterbirds and their population level impacts.

1.10.A.T-02 Urban Stressors on Avian Immune Defenses: Impact of pollution on Viral challenge via Poly I:C in great tit and blue tit nestlings

Shivani Ronanki[1]*, Matteo Schiavinato*[2]*, Ignacio Miro Estruch*[3] *and Nico van den Brink*[4]*, (1)Department of Toxicology, Wageningen University & Research (WUR), Netherlands, (2)University of Padova, Italy, (3)Toxicology, Wageningen University & Research (WUR), Netherlands, (4)Wageningen University & Research (WUR), Netherlands*

Rapid urbanization driven by human population growth alters landscapes, increases emissions, and disrupts habitats. This affects biodiversity, especially in birds adapted to city life, where chemical exposure is an indirect outcome. Most physiological research often focuses on human and poultry interactions, leaving gaps in understanding of how free-living birds respond to environmental chemicals. Urban areas have elevated air pollution, encompassing ozone, metals, nitrogen oxides, and particulate matter. Exposure to which induces oxidative stress, disrupting cellular balance.The innate and acquired immune system, regulated by antioxidant systems, becomes susceptible to oxidative stress. While most studies showed baseline immune parameters impacted in urban areas, few employ standard approaches, like immune challenges, to assess pollution's impact on pathogen response. Notably, studies of this nature used LPS and to our knowledge no study has explored how urban birds respond to viral challenges. Given the rising rates of avian influenza, understanding how pollutants affect birds' ability to establish anti-viral responses is crucial. To address this, we conducted a field experiment on great tits (*Parus major*) and blue tits (*Cyanistes caeruleus*) breeding in polluted (Rhenen) and clean (Wageningen) sites in the Netherlands. Pasive NO_2 samplers were installed at each box. On days 8 and 15 post-hatch, mass, tarsus, and wing were recorded to estimate body condition. On day 13, four chicks within each box were selected, with two receiving a Poly I:C injection, and two a saline as control. Two days later, a blood sample was extracted, and the four chicks were euthanized for further analysis. Immune parameters, including haptoglobin (acute phase protein), immune cell counts, and Poly I:C specific gene expression (TLR3, RIG-1, IL-6, & IRF-7) were assessed and related to NO_2 levels. Preliminary results suggest that the atmospheric NO_2 levels were four fold higher in polluted site compared to the clean site and the NO_2 was positively correlated to baseline haptoglobin. However, when challenged with Poly I:C, nestlings in clean site exhibited a more robust immune response, with increased haptoglobin and higher immune cell counts compared to nestlings challenged in urban site. Additional analyses are pending, including the assessment of internal heavy metal concentrations and the incorporation of immune gene expression to explore the mechanistic pathways of Poly I:C.

1.10.A.T-03 Quantify Exposure Levels of Non-persistent Chemicals in Wildlife from Tissue Concentrations, by Reverse Dosimetry Modelling using PBK-Models

Bohan Hu[1] *and Nico van den Brink*[2]*, (1)Toxicology, Wageningen University & Research (WUR), Netherlands, (2)Wageningen University & Research (WUR), Netherlands*

Wildlife is exposed to different chemicals in the environment. To assess risks that such chemicals may pose, it is essential to have quantified insight in exposures. Monitoring of exposures in wildlife can be based on e.g., non-destructively collected samples or by using samples obtained from animals found dead. Historically, this has focused on legacy chemicals, including POPs for which interpretation of tissue concentrations is relatively straightforward. Their concentrations are directly related to (historic) uptake and often increase over time. Therefore, measured concentrations in tissues cover current and historic exposures and hence, risks. However, Contaminants of Emerging Concern (CECs) include chemicals that are less persistent, which can be metabolized by wildlife. For these, concentrations in tissues may decrease over time, making interpretation of (historic) exposure levels based on tissue concentrations difficult, often resulting in underestimation of risks. For such chemicals tissue concentrations are depending not only on levels of exposure but also on the capacity of the organism to metabolise it and the time between collection of the samples and the actual exposure. Physiological Based Kinetic (PBK-) models have been developed to quantify tissue concentrations of chemicals in organisms, based on exposure levels. In the current paper we present PBK-models for non-persistent pesticides, imidacloprid and carbendazim, for mouse (*Mus* musculus) and rat (*Rattus norvegicus*), and we will discuss the need for species specific and chemical specific rate constants for uptake and metabolism. These models include phase I metabolism, both total depletion of the parent compound as well as the formation of major phase I metabolites, and also the depletion of the phase-I metabolite, by phase II metabolism. This allows to quantify time-trends of concentrations of both parent compound as well as major metabolites. We will use these PBK-models for an innovative reverse dosimetry approach, which can be used to quantify oral exposures based on internal tissue concentrations. For this, the time between exposure and sample collection will be assess based on the ratios of the concentrations of parent compound/metabolites, which increase over time, and can be used to base the reverse modelling of the exposures. We will apply the approach on experimentally obtained data for wood mouse (*Apodemus sylvaticus*) and discuss the applicability of this new approach.

1.10.A.T-04 EXPOSO-METER: Characterizing the lifelong exposure (exposome) to environmental mixtures of pollutants at high trophic levels in Arctic marine mammals

Elisa Rojo-Nieto[1]*, Eva Barbara Reiter*[1]*, Angelina Miller*[2]*, Chistian Sonne*[3]*, Rune Dietz*[3] *and Annika Jahnke*[2,4]*, (1)Department*

of Ecological Chemistry, Helmholtz Centre for Environmental Research (UFZ), Germany, (2)RWTH Aachen University, Institute for Environmental Research, Germany, (3)Department of Ecoscience, Aarhus University, Arctic Research Centre (ARC), Denmark, (4)Department of Exposure Science, Helmholtz Centre for Environmental Research (UFZ), Germany
EXPOSO-METER aims to provide access to the exposome by offering practical, economical and easy-to-use *chemometers* that allow for the identification, characterization and direct comparison of mixtures of environmental pollutants from multiple organisms, species and matrices. The *chemometer* approach is based on passive equilibrium sampling, and EXPOSO-METER aims to combine *chemometers* with advanced chemical profiling to integrate the lifelong exposure of environmental organisms to mixtures of pollutants. As *chemometers* are defined as a common reference phase, the chemical concentrations in the *chemometers* at equilibrium can be directly compared between organisms, circumventing normalizations. In this work, silicone *chemometers* have been used to analyze legacy and emerging hydrophobic organic pollutants (HOCs) present in 84 lipid-rich tissues from Arctic marine mammals collected in the sorroundings of Tasiilaq and Kulusuk, at the southeast coast of Greenland. Samples of pilot whales, white-sided dolphins, white-beaked dolphins, narwhales, orcas and polar bears were analyzed. Circa 100 compounds were quatified (by gas chromatography coupled to high-resolution mass spectrometry), including polycyclic aromatic hydrocarbons (PAHs), polychlorinated byphenyls (PCBs), polybrominated diphenyl ethers (PBDEs), pyrethroids (PYRs), chlorinated hydrocarbons (CHCs), organochlorine pesticides (OCPs), musk compounds, UV filters and antioxidants., and sex- and size/age-related patterns and intraspecies differences of contaminant exposure were investigated.

The results indicate that considering the fraction of each group of compounds in the total mixture, PCBs and OCPs were there predominant compound groups in all species, showing large variety between species, e.g. PCBs ranging from 35% in white-beaked dolphins to 68% in polar bears. Other groups of chemicals, like musk compounds, PAHs or PYRs show largely differing percentages in the different species that ranged across 2 orders of magnitude. The results also indicate interspecies differences in contaminant exposure, but no clear intraspecies differences, evaluated as sex- or size-related patterns. Within this project, *chemometers* will help to capture and understand the lifelong exposure of environmental organisms to mixtures of pollutants to strengthen the study of the exposome.

1.10.B Legacy and Emerging Contaminants in Wildlife: Recent Advancements in Ecotoxicology and Risk Assessment

1.10.B.T-01 Pesticide contamination in bats: a case study on Greater Mouse-eared Bat in an agricultural and natural area in Southern Poland

Olha Timofieieva[1] *and Ryszard Laskowski*[2]*, (1)Biology, Jagiellonian University, Poland, (2)Jagiellonian University, Poland*
Agricultural production across the world is highly dependent on the use of pesticides, which can be extremely dangerous to non-target arthropods, and especially to predators, which feed on insects, such as bats. According to the legal regulations in the EU, farmers are obliged to spray insecticides exclusively after sunset to limit the hazard to bees and other pollinators on the flowering cultures (e.g. oil-seed rape), which is the time when bats start to forage, potentially exposing them to high contamination risk.

The primary ways of poisoning bats with pesticides are the ingestion of contaminated food and water, inhalation and dermal contact**.** Taking into account that the activity of bats coincides with the recommended insecticide application time (evening and night) and considering the extremely high metabolic rate of bats as well as the large surface area of the wing membrane, we wanted to check if bats are directly exposed to pesticides.

To answer this question, we collected samples of insects and bat fur in two study areas – agricultural and natural ones in Southern Poland during May and June 2022 and 2023. Additionally, 15 carcasses of bats were collected for analysis from the agricultural area for pesticide screening in internal organs, such as kidneys and liver and also wing membrane. An agricultural area, where pesticides are regularly applied, was Ślężany village with a summer roosting colony of greater mouse-eared bat (*Myotis myotis)* in the school building. Our control site was in Sokole Góry nature reserve, where a large colony of *M. myotis* inhabits the Studnisko Cave. We used chromatographic analysis (GC/MS and HPLC/MS) to screen bat fur, wing membrane, kidneys and the liver and *Carabidae* beetles for the presence of pesticides.

We found in bat tissues and beetles 42 pesticides among 423 substances screened of which 23 were fungicides; 17 – insecticides and 2 were herbicides. Among these, 4 substances are currently banned in the EU: hexachlorobenzene, dieldrin, DDT (DDE, DDD) and chlorpyrifos. DDT and its metabolites (DDD and DDE) were present in bats and carabids from both the agricultural and natural areas, confirming the extremely long residence time of these compounds in the environment. Fortunately, in a comparison with concentrations found by other researchers in insectivorous bats which were poisoned by pesticides, the concentrations found in our study were lower and probably did not affect bat survival.

1.10.B.T-02 Calibration of mechanistic effect models for amphibians - challenges and solutions

Simon Ewald Hansul *and Andreas Focks, Institute of Mathematics, Osnabrück University, Germany*
Mechanistic effect models (MEMs) serve multiple useful purposes in a holistic risk assessment (RA) of chemicals to amphibian populations. A pivotal step in the development of MEMs is the development of physiological baseline models, which will have a large impact on the accuracy of predicted chemical effects. Generic models, such as Dynamic Energy

Budget (DEB) models, require adaptations to account for the specific life-history of amphibians. These deviations introduce difficulties in the estimation of DEB parameters from life table-data. Without manual intervention, common calibration routines often fail to correctly predict the timing of life stage transitions. We therefore provide an approach to calibrate mechanistic effect models, specifically developed for amphibian models. This approach is designed to minimize the necessity for manual intervention by modelling experts during the calibration, propagate uncertainties of parameter estimates and allow for varying levels of detail in the calibration data. We implemented a model based on Dynamic Energy Budget (DEB) theory, including adaptations to account for amphibian physiology. The calibration scheme progresses in multiple steps, where the starting point is a set of correlated probability distributions of DEB parameters which match the distributions of central physiology and life-history characteristics across a variety of amphibian species. This is followed by multiple parameter estimations, dealing successively with different life stages and transitions between life stages. Through the use of Approximate Bayesian Computation, the parameter uncertainty is propagated throughout the parameter estimation scheme. This scheme was applied in a case study using available *Xenopus laevis* growth data and resulted in a good fit to the data, including the timing of metamorphosis. Completing the calibration for a few data-rich species allows to use the gathered information to perform calibrations for data-poor species. At the minimum, estimates of age and body mass at life stage transitions are needed to perform parameter corrections for data-poor species. The approach will further be extended to the calibration of toxicity submodels, yielding whole life-cycle models which can be used to address risk assessment questions. This increases the applicability of the calibration approach to a wide range of species, helping to improve the environmental relevance of mechanistic effect models in the application of RA.

1.10.B.T-03 Selenium accumulation and effects on freshwater turtle species from Tablas de Daimiel National Park (Spain)

María Mercedes Andres[1]*, Manuel Ortiz Santaliestra*[2] *and Rafael Mateo*[3]*, (1)Toxicology, Institute for Game and Wildlife Research, IREC (UCLM-CSIC), Spain, (2)Instituto de Investigación en Recursos Cinegéticos (IREC) CSIC-UCLM-JCCM, Spain, (3)Wildlife Toxicology, Instituto de Investigación en Recursos Cinegéticos (IREC) CSIC-UCLM-JCCM, Spain*

The Tablas de Daimiel National Park (TDNP) is a Mediterranean alluvial plain formed by Cigüela and Guadiana rivers, located in the semi-arid region of central-southern Spain. It is declared a Biosphere Reserve, listed as a Wetland of International Importance by the Ramsar Convention and belongs to the European Natura 2000 Network. The wetland is threatened by the overexploitation of freshwater resources, aggravated by climate change. Pollutants reach the wetland through water seepage from surrounding agricultural lands and upstream WWTP discharges. Thus, high concentration of metals and metalloids of anthropogenic origin could be expected in the Park, as shown by previous studies detecting high levels of Se in sediments and biota. Although Se is an essential element due to its antioxidant properties, at toxic levels it interferes with sulfur-containing molecules and causes different effects like reproductive failure or abonrmalities in the tegumentary. We hypothesize that freshwater turtles from TDNP affected by increased Se accumulation could suffer shell malformations because of the high proportion of sulfur-rich amino acids in the keratin covering the carapace. In July 2018, we captured 6 European pond turtles (*Emys orbicularis*). In October 2023, we captured 18 Iberian pond turtes (*Mauremys leprosa*) from the area within the Park with highest Se levels. All individuals were sexed, weighed and measured for shell curvature, and 1 mL blood was taken from the occipital sinus together with a sample of carapace scales to determine Se levels by ICP-MS. High incidence of *E. orbicularis* individuals with keratinization abnormalities and loss of shell keratin plates was detected. Turtles showing these abnormalities had close-to-significantly higher levels of Se than unaffected ones in both blood (p=0.06). Se levels in blood and scales were correlated (p=0.036). Our results suggest that Se exposure could be the reason for the observed abnormalities and allow us to determine that the malformations in *E. orbicularis* carapace are susceptible to occur blood Se levels above 6.1 mg/kg d.w.

1.10.B.T-04 ELSATA: Update on a Thyroid-Focused Alternative to the Larval Amphibian Growth and Development Assay (LAGDA)

Lennart Weltje, Prof. Dr.[1]*, Jeffrey C. Wolf*[2]*, Brittanie Peake*[3] *and Douglas J. Fort*[3]*, (1)Agricultural Solutions - Ecotoxicology, BASF SE, Germany, (2)EPL, Inc., (3)Fort Environmental Laboratories, Inc.*

The Larval Amphibian Growth and Development Assay (LAGDA, OECD TG 241) was designed as a higher tier in vivo assay meant to provide data on adverse effects of substances on thyroid-mediated endpoints. As a level 4 test within the OECD Conceptual Framework on Endocrine Disrupters Testing and Assessment, it is a final step of testing in the ECHA-EFSA testing scheme for the thyroid modality, to be utilised in case a Level 3 Amphibian Metamorphosis Assay (AMA, OECD TG 231) indicates thyroid activity of a substance and thus, the need for the generation of additional data. However, the LAGDA is not limited to generating endpoints related to the thyroid modality, as the second half of the study is focused on the estrogen, androgen and steroidogenic (EAS) modalities. Considering that the triggering of a LAGDA is based on concerns around the thyroid axis, questions have been raised as to the value of this additional 10-week period in the study for identifying any additional effects related to (anti)thyroidal activity of substances. Initiation at NF stage 8-10 considers embryo-larval and pre-metamorphic development, already providing a means for assessing potential alternative modes of action and discriminating non-endocrine from endocrine toxicity. Additionally, for the purpose of an assessment on the thyroid modality, generating unrelated data causes needless animal welfare concerns. In an effort to focus on the core strength of LAGDA, we have investigated a modified version of the study, named the ELSATA (Early Life Stage Amphibian Thyroid Assay), which only considers endpoints related to the thyroid modality. In doing so, animal welfare is emphasized, as fewer individuals are used for a shorter total duration, and without decreasing the amount of thyroid-specific data generated. Two thyroid-active substances, benzophenone-2 (BP-2) and perchlorate (study ongoing) are used to evaluate the practicability of the ELSATA model.

1.10.P Legacy and Emerging Contaminants in Wildlife: Recent Advancements in Ecotoxicology and Risk Assessment

1.10.P-We036 Pipping, Hatching, Sex Ratio and Gene Expression Changes in Ducklings Exposed In Ovo to Emerging Per-/Poly-Fluoroalkyl Substances

Anne-Fleur Brand[1]*, Junjie Zhang*[1]*, Tomasz Ciesielski*[2,3]*, Céline Arzel*[4]*, Veerle L. B. Jaspers*[1]*, Kang Nian Yap*[1] *and Silje Peterson*[1]*, (1)Norwegian University of Science & Technology (NTNU), Norway, (2)Department of Biology, Norwegian University of Science & Technology (NTNU), Norway, (3)University Centre in Svalbard (UNIS), Norway, (4)Department of Biology, University of Turku, Finland*

Effects of per- and polyfluoroalkyl substances (PFASs) have been observed in wildlife for various endpoints such as oxidative stress, neurotoxicity, immunotoxicity, endocrine disruption, reproduction, and biomass reduction. Although many studies show that environmental PFASs concentrations adversely affect the health of wildlife species, the establishment of a clear link between PFASs exposure and its toxicity is often hampered by unknown effects of additional factors such as environmental conditions, occurrence of co-contaminants, and age and sex of the investigated species. Therefore, exposure experiments under controlled laboratory conditions are needed to plausibly link PFASs exposure to effects in wildlife.

Here, we studied the effects of two unregulated PFASs compounds; perfluoro-4-ethylcyclohexane sulfonic acid (PFECHS) and perfluorododecane sulfonic acid (PFDoDS), alongside the regulated perfluoro octane sulfonic acid (PFOS). Both compounds have been detected in samples from wild bird species. Furthermore, a sex ratio bias towards males has been found in wild ducks. Various PFASs have been shown to interfere with transcriptional pathways linked to growth, development, and reproduction. MicroRNAs are a class of small noncoding RNAs that are involved in the regulation of gene expression at the posttranscriptional level. For certain microRNAs, expression changes have been found after exposure to PFOS and other pollutants. However, the effects of PFASs exposure on microRNA profiles during ontogeny of birds are not well understood.

The aim of this study was to assess PFECHS and PFDoDS developmental effects alongside PFOS, using the mallard duck (*Anas platyrhynchos*) as a model species. We investigated hatching success, sex ratios, and liver microRNA profiles in ducklings exposed *in ovo* to PFOS, PFECHS and PFDoDS.

We observed a lower hatching success in the PFECHS and PFDoDS groups compared to the control and PFOS groups. In addition, the sex ratio in the control group is skewed towards females, while the PFOS group showed a bias towards males. PFECHS and PFDoDS groups have a more balanced sex ratio. Gene expression data will be obtained early in 2024 and will be presented at the conference.

The results of this experiment will not only increase our understanding of the toxicological mechanisms of PFECHS and PFDoDS at a gene expression level during ontogeny of birds, but also will be meaningful for environmental risk assessment and management.

1.10.P-We037 PERSISTENT ORGANIC POLLUTANTS AND THE ROLE OF ANTHROPIC SOURCES IN THE DIET OF AVIAN SCAVENGERS

Juan Munoz-Arnanz[1]*, Ainara Cortes-Avizanda*[2]*, Iñigo Donázar-Aramendia*[3]*, Eneko Arrondo*[4]*, Pere Colomer Vidal*[1]*, Olga Ceballos*[5]*, Begoña Jiménez*[1] *and Jose Antonio Donázar*[4]*, (1)Institute of Organic Chemistry, Spanish National Research Council (IQOG-CSIC), Spain, (2)Department of Plant Biology and Ecology, Faculty of Biology, University of Seville, Spain, (3)Laboratorio de Biología Marina, Seville Aquarium R + D + I Biological Research Area, Department of Zoology, Faculty of Biology, University of Sevilla, Spain, (4)Department of Conservation Biology, Estación Biológica de Doñana, CSIC, Spain, (5)UGARRA, Avda. Carlos III 1, Spain*

Vultures, face declines due to various factors, including anthropization and changes in farming systems. However, there is limited research on the detailed relationship between contaminant levels and individual foraging behavior, especially in scavenger birds exploiting "risky" trophic sources like landfills.This research aimed to assess POPs such as polychlorinated biphenyls (PCBs) and organochlorine pesticides (OCPs), on Egyptian and griffon vultures, examining their association with the scavenger's diet and trophic strategies using stable isotopes.

In 2021, blood samples were collected from fledging Egyptian (EV, n=14) and griffon (GV, n=15) vultures inhibiting a Natural Park in Navarre, northen Spain, within an area heavily humanized, with shifts in agriculture and livestock practices. Blood's plasma was analyzed for their POP content. Additionally, mantle feathers and hair samples, from vultures' prey , were gathered for stable isotope analyses ($\delta^{15}N$ and $\delta^{13}C$).

Low concentrations of pollutants were found in both vulture species, with median values within the sub-ppb range. This stands in clear contrast to concentrations reported in other regions worldwide, and below the levels previously recorded for these species in the same study area in earlier decades. Specifically, PCBs were higher in EVs compared to GVs, with medians of 0.564 pg/µL and 0.282 pg/µL, respectively. Conversely, OCPs were similar in EVs (median: 0.349 pg/µL) and GVs (median:

0.350 pg/μL), although broader pollutant ranges in GVs were observed due to two specimens with exceptionally high concentrations. Dietary models based on isotopic signatures indicated that both species were globally relying on the same food resources. However, a diet more based on carcasses of intensive farming and landfills was associated with higher PCBs, as it was found for Egyptian vultures.

In conclusion, low PCB and OCP concentrations in northern Spain's avian scavengers suggest effective implementation of restrictive regulations, minimizing expected negative effects on fitness. Yet, surveillance is advised, particularly for Griffon vultures exhibiting some high OCP levels, highlighting potential individual exposure variation. This study also underscores stable isotopes' utility in gauging avian scavengers' exposure to contamination sources, especially PCBs, which is crucial in a changing food source landscape with declining extensive livestock and increasing dependence on landfills.

1.10.P-We038 Putting Individual Effects into the Context of Natural Variability. Using Dynamic Energy Budget (DEB) Modelling in Amphibians to assess the Normal Operating Range for Metamorphosis

***Joachim Ulrich Kleinmann*[1]*, Carlo Romoli*[2]*, Erik B Muller*[2]*, Lennart Weltje, Prof. Dr.*[3] *and Pernille Thorbek*[4]*, (1)BASF SE, Germany, (2)ibacon GmbH, Germany, (3)Agricultural Solutions - Ecotoxicology, BASF SE, Germany, (4)Apd/EE, BASF plc, United Kingdom*

Amphibian assays are important tools in the assessment of thyroid activity of plant protection products. While for human health adversity is considered on the individual level, for non-target species the population is the protection goal. However, it is still unclear how adversity on the population level should be assessed.

EFSA suggested the concept of assessing effects on a population level relative to the normal operating range (NOR) in a report from 2021 on the natural variability of honeybee hives and considered similar approaches also for several mammal species (e.g. common vole, wood mouse) to derive specific protection goals. However, for processes which are plastic even on the organism level, like amphibian metamorphosis, we believe a first step is to assess an individual level NOR. We consider if effects in laboratory studies are within this NOR of individuals, they are not relevant on the individual level and, following this logic, by definition not relevant on the population level.

To assess the NOR of amphibian metamorphosis, a Dynamic Energy Budget (DEB) model was developed which explicitly includes the plasticity of metamorphosis. In an extensive literature review, the most relevant environmental conditions determining metamorphosis rate, and so the natural variability, were assessed. The most relevant factors were included in the DEB model. Additionally, the model has been expanded to reproduce the restructuring of biomass during the metamorphosis climax. In this way we can explicitly simulate the natural variability of the metamorphosis rate on an individual level and potential impacts of plant protection products can be assessed for their relevance in this context. If effects are borderline in the context of natural variability on an organism level, the developed model can also be included in a population model to assess the relevance of these individual effects on a population level.

Since this approach combines models and concepts which were accepted by EFSA for addressing similar issues in other taxa, we believe that this approach can be a way forward in determining the adversity of endocrine-mediated effects on a population level.

1.10.P-We039 Chronic exposure of amphibian aquatic stages to pesticides: a case study with flupyradifurone

***Manuel Ortiz Santaliestra** and Pedro Peiró, Instituto de Investigación en Recursos Cinegéticos (IREC) CSIC-UCLM-JCCM, Spain*

Amphibians are not routinely considered as part of environmental risk assessment of pesticides, which raises uncertainty about the efficacy of this regulatory process to protect them. As vertebrates, alternative approaches to animal testing like extrapolation from surrogate taxa and effect modelling from pesticide impacts, bring increasing interest. While acute toxicity of chemicals to aquatic stages can be estimated from fish-generated data [2,3], there is little support about the validity of surrogates to cover long-term toxicity. Amphibian development has unique features, including a period of complete starvation during metamorphosis that challenges the development of energy-based effect models. We monitored survival and growth, as a proxy of energetic balance, during a long-term exposure (up to 76 days) of larval green frogs to 0, 0.01, 0.1, 1, 10 or 100 mg/l of the insecticide flupyradifurone applied as Sivanto Prime®. The exposure cause a dose-dependent reduction of larval survival during the initial stages ($p=0.006$), with mortality rates of up to 60% at the highest insecticide level. During the metamorphosis transition, percentage of successful individuals was also reduced at the highest flupyiradifurone level, although in a non-significant manner ($p=0.425$), which reflects that the stress during larval stage could make that only the strongest individuals reach metamorphosis. Larval growth did not significantly differ among treatments, but a clear trend for arresting growth towards the end of the larval period was seen at concentrations ≥10 ppm. These results suggest that the period after metamorphosis climax (no energy uptake) is less sensitive to the toxic action than the pre-climax period (positive energetic balance). This pattern should be considered in energy-based models like DEB in amphibians, and also in population models because completing metamorphosis in optimal conditions is essential for juvenile survival and in turn for population dynamics. Funded by EFSA through the project AMPHIDEB (contract OC/EFSA/SCER/2021/12).

1.10.P-We040 Amphibians Provide Unique and Sensitive Models in Ecotoxicology: Arguing for Advanced Propagation and Integration in Risk Assessment

Werner Kloas[1]*, Ilka Lutz*[1]*, Andrea Ziková-Kloas*[2] *and Mathias Stoeck*[1]*, (1)Leibniz-Institute of Freshwater Ecology and Inland Fisheries, Germany, (2)German Environment Agency (UBA), Germany*

The unique vertebrate class *Amphibia* is covering the transition to partial terrestrial life style and consists of the three orders *Anura* (frogs), *Urodela* (salamanders), and *Gymnophiona* (caecilians). They developed manifold life styles to inhabit nearly all ecosystems and are very sensitive to environmental factors including chemical substances. Although information about ecotoxicology are available for all three orders, ecotoxicological research has mostly been performed in frogs representing the classical models for endocrinology and developmental biology. In addition, for practical reason research is focusing on lab models such as *Xenopus* but also wildlife species with seasonality should be at least checked for relevancy of lab based results. Classical ecotoxicological tests investigating acute toxicity by lethality without assessing modes of action (MOA) have past and are rarely done for instance the FETAX (Frog Embryo Teratogenesis Assay *Xenopus*) because they are taken over by fish egg tests.

However, a great revival for amphibians as model organisms in ecotoxicology came along with the emerging issue of endocrine disruption (ED) because the endocrine systems of amphibians and other vertebrate classes including humans are quite similar. Starting with endocrine active compounds affecting reproductive physiology of amphibians quite sensitively during larval exposure the establishment of the amphibian metamorphosis assay (AMA) is the most sensitive standardized test guideline (OECD 231) for determining thyroid system disrupting effects. Further test guidelines to assess ED are XETA (*Xenopus* Eleutheroembryonic Assay; OECD 248) and LAGDA (Larval Amphibian Growth and Development Assay; OECD 241), the latter one determining impacts on both, reproduction as well as thyroid system. Recent advancements direct towards an extended AMA that could assess all developmental impacts on reproductive physiology and thyroid system more efficiently and sensitively than any other test. In addition, integrating new approach methods allow to increase the sensitivity as well as the determination of MOA being exemplified by two AMA exposures with the weak antithyroidal compounds Carbamazepine and Tetrabromobisphenol A. Furthermore, amphibians provide phantastic models for assessing ED by using non-invasive behavioural parameters.

1.10.P-We041 Anticoagulant Rodenticides in Wildlife: A Risk for Game Meat Consumers?

Rafael Mateo*, Wildlife Toxicology, Instituto de Investigación en Recursos Cinegéticos (IREC) CSIC-UCLM-JCCM, Spain*

Game animals are at risk of exposure to anticoagulant rodenticides (ARs), either by the direct ingestion of anticoagulant baits or by the consumption of carcasses of animals poisoned by ARs. Granivorous or herbivorous species such as partridges, ducks, pigeons, hares and rabbits can ingest AR-treated grain or baits because they associate these as potential food resources. Omnivorous species such as wild boar can be also exposed through the consumption of AR-poisoned animals. In New Zealand, second-generation ARs (SGARs) have been detected in the liver of several large game species, and in the case of the feal pigs with hepatic concentrations that can affect blood coagulation of the animals. In Spain, first-generation ARs (FGARs) have been detected in small game species during large scale treatments against voles, and SGARs have been detected in 45% and 12% of the liver and muscle samples, respectively, of wild boar hunted in Barcelona province. Although the observed concentrations in liver and muscle were below those that are likely to be lethal or to affect blood clotting in humans after acute exposures, there is still a need of improving the environmental risk assessment of chronic exposures to SGARs in game meat consumers. In some areas in Spain, SGARs are used to control rabbit overabundance, which may increase the risk of exposure to toxic doses in the consumers of these animals. The high capacity of SGARs to bioaccumulate in liver, the extremely high toxicity of SGARs and the high percentage of human population with an antithrombotic treatment must be considered in the refinement of their risk assessment. This study compiles the information about SGAR prevalence and concentrations in edible tissues of game species as a first step for this assessment. The study also identifies current gaps that should be filled to improve the evaluation of the risk on game meat consumers and the recommendations for risk mitigation. This study is developed under the framework of the Cost Action CA22166 - Safety in the Game Meat Chain (SafeGameMeat).

1.10.P-We042 Anticoagulant rodenticide exposure of two mammal species, American badger and fisher from British Columbia Canada.

John E. Elliott[1]*, Sofi Hindmarch*[2]*, Rich Wier*[3]*, Sandi Lee*[1] *and France Maisonneuve*[1]*, (1)Environment and Climate Change Canada, Canada, (2)Fraser Valley Conservancy, Canada, (3)British Columbia Ministry of Environment*

There are increasing reports from many jurisdictions of mammalian carnivores with elevated exposure to anticoagulant rodenticides (ARs). A proportion of animals tested have exhibited symptoms of anti-coagulant poisoning. Most of those samples from the literature, but not all, were from locations near to agricultural or urban development. For the present study, we tested 69 samples of two species of mammal, the American badger *Taxidea taxus,* an endangered species in British Columbia, and a furbearer, the fisher *Pekania pennanti,* collected over the period 2004 to 2018 from locations in southern British Columbia, Canada. Of 59 badgers analyzed, 46% (27) contained residues of both second generation (SGAR) and first generation (FGAR) compounds, with 10% (n=6) exposed to only SGARs, and 14% (n=8) exposed to just FGARs. The mean total exposure was 0.20 μg/g while the geometric mean was 0.15 μg/g, (range: 0.004-2.138 μg/g ww). Of the exposed badgers (n=41), 73% (n=30) are exposed to at least two AR compounds, 49% (n=20) are exposed to at least three AR compounds. The breakdown of exposure by compound was: bromadiolone (n=33), brodifacoum (n=21), chlorophacinone (n=20), diphacinone (n=17), warfarin (n=12), difethialone (n=12). Of the badger liver samples, 17 contained > 0.100 μg/g ww ∑ ARs with a range of 2.14 – 0.146 μg/g ww. Six females were lactating all of which were exposed to ARs. Fishers were collected over an earlier timeframe, 2003 – 2009. They were less exposed, with 2 out of 10 individuals testing positive, one of which was exposed to warfarin (0.05 μg/g) and high levels of bromadiolone (0.528 μg/g), and the second individual tested positive for brodifacoum (0.013 μg/g). We discuss likely exposure pathways and toxicological implications of these results for badger conservation and population recovery.

1.10.P-We043 Anticoagulant Rodenticides in Birds of Prey in Switzerland – Towards an Appraisal of Threshold Values

Sibylle Xenia Maletz[1]*, Daniel Olbrich*[1]*, Carolin Riegraf*[1]*, Marion Junghans*[1]*, Sarah Albini*[2]*, Saskia Keller*[3]*, Petra Kunz*[4] *and Etienne Vermeirssen*[1]*, (1)Swiss Centre for Applied Ecotoxicology, Switzerland, (2)Institute for Food Safety and Hygiene, University of Zurich, Switzerland, (3)Institute for Fish and Wildlife Health, University Bern, Switzerland, (4)Biocides and Plant Protection Products Section, Federal Office for the Environment, Switzerland*

Due to their widespread use for rodent pest control, the presence of anticoagulant rodenticides (ARs) in the environment is ubiquitous. These substances, especially the second generation ARs, have persistent, bioaccumulative and toxic properties that can lead to secondary poisoning of non-target organisms. Exposure of non-target organisms, such as small predators or birds of prey, to ARs is well documented internationally. However, the situation in Switzerland had so far only been scantly investigated. To fill this gap, a reliable and sensitive analytical method (LC-MS/MS) to quantify ARs in liver samples was established and a first set of wildlife liver samples was analyzed for seven approved substances (brodifacoum, bromadiolone, coumatetralyl, difenacoum, difethialone, flocoumafen, warfarin). Samples included livers of foxes, birds of prey, hedgehogs and fish. In almost all samples analyzed, up to four different ARs were detected with maximum liver concentrations of 1100 ng/g (fox), 450 ng/g (bird of prey), 2 ng/g (hedgehog) and 40 ng/g (fish). A comparison with data collated from literature showed similar exposure in biota from surrounding countries.

To date, there is no broad consensus as to which AR concentrations lead to toxicosis and must therefore be considered problematic. Some experimental toxicity data are available from studies in which animals were fed food or prey laced with AR. However, only a few species have been studied in this way, often with low numbers of animals and only testing single substances and not mixtures. Another approach to derive threshold values involves the combination of measured AR liver burdens and the determination of the cause of death by means of pathological examinations. For this reason, we started a new project where we focus on birds of prey that died during care in bird rehabilitation centers. We aim to extend monitoring of AR exposure in Switzerland and combine it with pathological examinations of birds. The data obtained will then be fed into established models to determine AR threshold values and allow for improved risk assessment concerning non-target organisms. Additional data are also crucial to assess future trends in AR exposure and for evaluating the efficiency of possible future changes to AR application strategies.

1.10.P-We044 Anticoagulant Rodenticide Contamination and Coagulation Capacity Assessment in Long-Eared Owls (Asio otus) from a Mediterranean Agricultural Landscape

Livia Spadetto[1]*, Pilar Gomez-Ramirez, PhD*[1]*, José Manuel Zamora-Marín*[2,3,4]*, Mario León-Ortega*[3]*, Antonio Zamora-López*[2,3]*, Sarah Díaz-García*[3]*, Fernando Tecles-Vicente*[5]*, José F. Calvo PhD*[6]*, José Fenoll-Serrano*[7]*, Juana Cava-Artero*[7] *and Antonio Juan Garcia-Fernandez, DVM, PhD*[8]*, (1)Toxicology Research Group, Faculty of Veterinary Medicine, University of Murcia, Spain, (2)Department of Zoology and Physical Anthropology, Faculty of Biology, University of Murcia, Spain, (3)Ulula Research Group, Spain, (4)Department of Applied Biology, Miguel Hernández University of Elche, Spain, (5)Interdisciplinary Laboratory of Clinical Analysis (Interlab-UMU), Faculty of Veterinary Medicine, University of Murcia, Spain, (6)Department of Ecology and Hydrology, Faculty of Biology, University of Murcia, Spain, (7)Instituto Murciano de Investigación y Desarrollo Agrario y Alimentario (IMIDA), Spain, (8)Toxicology Research Group, Faculty of Veterinary Medicine, Universidad de Murcia-IMIB, Spain*

Anticoagulant rodenticides (ARs) are chemical compounds widely employed for rodent population control in various anthropogenic landscapes. These highly toxic substances, known for their bioaccumulative nature in the tissues of consuming individuals, not only induce mortality in target rodents but also pose a threat to the populations of predators and scavengers that feed on these contaminated prey. Here, the long-eared owl (*Asio otus*) is used as a biomonitoring species to assess the presence and distribution of ARs in different agricultural landscapes within a Mediterranean semiarid region of southeastern Spain. Blood samples were extracted from 69 nestlings belonging to 38 nests in the Region of Murcia and analysed using HPLC/MS/MS. Additionally, plasma samples were obtained to evaluate clotting function through prothrombin time (PT) testing as a biomarker of exposure and effect. Our analysis revealed an almost absolute prevalence (98.6%), with no variation across different agricultural landscapes and multiple ARs detected in most samples (82.6%). The most commonly detected ARs were second-generation compounds (SGARs), particularly flocoumafen (88.4%). Total concentration (ΣARs) ranged from 0.06 to 34.18 ng mL^{-1} and the highest levels were found in a study site dominated by intensive agriculture. However, no correlation was found between ΣARs and the different land uses calculated within 1 and 1.5-km buffers around each nest, which was established as a proxy of the adults' home range. Furthermore, blood ΣAR levels showed a positive correlation with PT values measured in the corresponding plasma samples (*Rho*= 0.547, *p*= 0.000), highlighting the presence and quantifiable effects of these compounds even at low blood concentrations. These findings underscore the widespread presence of ARs across the study area, indicating early exposure in long-eared owl nestlings. Our results also suggest that exposure in this owl species is chronic, which could potentially lead to medium or long-term toxic effects due to the progressive accumulation of

ARs in the organism. Moreover, the long-eared owl proved to be an excellent sentinel species for monitoring environmental contamination in agricultural landscapes, suggesting that other wildlife from the same area may also be exposed and affected by the detrimental effects of AR compounds. This study emphasizes the urgent need for effective strategies to mitigate the impact of ARs on ecosystems and protect non-target wildlife.

1.10.P-We045 Environmental Factors Influencing Anticoagulant Rodenticide Exposure in Common Kestrels (Falco tinnunculus) and Barn Owls (Tyto alba) from Southeastern Spain

__Livia Spadetto__[1], Antonio Juan Garcia-Fernandez, DVM, PhD[2], Antonio Zamora-López[3,4], José Manuel Zamora-Marín[3,4,5], Mario León-Ortega[4], Sarah Díaz-García[4], José Fenoll-Serrano[6], Juana Cava-Artero[6], José F. Calvo PhD[7] and Pilar Gomez-Ramirez, PhD[1], (1)Toxicology Research Group, Faculty of Veterinary Medicine, University of Murcia, Spain, (2)Toxicology Research Group, Faculty of Veterinary Medicine, Universidad de Murcia-IMIB, Spain, (3)Department of Zoology and Physical Anthropology, Faculty of Biology, University of Murcia, Spain, (4)Ulula Research Group, Spain, (5)Department of Applied Biology, Miguel Hernández University of Elche, Spain, (6)Instituto Murciano de Investigación y Desarrollo Agrario y Alimentario (IMIDA), Spain, (7)Department of Ecology and Hydrology, Faculty of Biology, University of Murcia, Spain

Anticoagulant rodenticides (ARs) act by disrupting blood clotting and causing fatal haemorrhages in target rodents. Previous studies have demonstrated their widespread occurrence in the environment, moving through the food chain and accumulating in top predators such as birds of prey. These predatory birds also display higher sensitivity to ARs compared to other avian species, raising concerns about their potential impact on raptor populations, particularly for species inhabiting agricultural landscapes near human activities. Here, we aimed to assess the exposure to second-generation ARs (SGARs) in two farmland bird of prey species with different foraging habits. For that purpose, we blood-sampled barn owl (*Tyto alba*, *n*=54) and common kestrel (*Falco tinnunculus*, *n*=70) nestlings in the Region of Murcia (southeastern Spain), during the breeding seasons of 2021 and 2022. Samples analyzed using HPLC/MS/MS revealed high prevalence in both species - 50% in *T. alba* and 68% in *F. tinnunculus* - with the presence of multiple ARs in 16% and 32.9% of the individuals, respectively. Flocoumafen was predominant in kestrels, while bromadiolone in barn owls, with SGAR levels (ΣSGARs) ranging from 0.07 to 11.52 ng mL^{-1} in the kestrel and 0.03 to 3.75 ng mL^{-1} in the barn owl. Environmental variables that could affect the prevalence (study site, land uses, livestock farms, and human population density) were analysed within a 1-km buffer around each nest. This study revealed that SGAR prevalence in kestrels was related to the extension of artificial surfaces (roads, buildings, industrial areas, parkings, etc.), with no significant differences observed among study sites. In contrast, barn owls showed the higher prevalence in the most densely inhabited study site, with human population density emerging as the most explanatory factor. Hence, it seems that the kestrel - with a more generalist and flexible diet - frequently forages near buildings and urban centers where it would be prone to come into contact with AR contaminated prey. Conversely, the barn owl, although primarily feeding on rodents, often hunts in open spaces away from settlements. Therefore, contamination risk would be greater for owl nests located near urban areas, with higher presumed AR use and presence of target rodents such as rats (*Rattus sp.*). Our findings emphasize the need for responsible application practices and conservation efforts to safeguard raptor populations in Mediterranean agricultural regions.

1.10.P-We046 Impact of Changes in Governance for Anticoagulant Rodenticide Use on Non-target Exposure in Buzzards (Buteo buteo)

Elizabeth Ann Sharp[1], __Megan Galloway__[1], Louise Ann Mocogni[1], Laura Marie Melton[1], Steve Campbell[2] and Sheila George[2], (1)Chemistry Section, SASA, United Kingdom, (2)Wildlife Management Unit, SASA, United Kingdom

Birds of prey are susceptible to non-target exposure to anticoagulant rodenticides (ARs) used in pest management. An industry-led stewardship scheme introduced new rules on the use and sale of rodenticide products across the UK in 2016, with the aim of reducing this risk. To determine if this intervention was effective, exposure to second generation anticoagulant rodenticides (SGARs) was measured in buzzards. Liver samples from 790 buzzards collected between 2005 and 2022 were analysed and the percentage presence and concentrations of SGARs from pre-stewardship and post-stewardship samples were compared.

There was no statistically significant change in the percentage of buzzards exposed to bromadiolone, difenacoum or summed SGAR residues after the introduction of stewardship. The percentage of buzzards exposed to brodifacoum increased significantly post-stewardship, from 8% to 27%. There were no significant changes in the concentrations of individual SGARs post-stewardship but concentration of summed SGARs increased significantly post-stewardship. Buzzards were significantly more likely to be exposed to multiple SGARs post-stewardship.

These findings echo similar findings in other wildlife monitoring studies and suggest that the industry-led stewardship scheme has not yet had the intended impact of reducing SGAR contamination in non-target wildlife.

1.10.P-We047 Exposure of piscivorous avian predators to second-generation anticoagulant rodenticides

__Julia Regnery__[1], Hannah Schmieg[2], Hannah Schrader[2], Olaf Zinke[3], Julia Bachtin[1], Christel Möhlenkamp[1], Stefanie Jacob[4] and Anton Friesen[4], (1)Federal Institute of Hydrology (BfG), Germany, (2)Bavarian Environment Agency (LfU), Germany, (3)Museum of the Westlausitz Kamenz, Germany, (4)German Environment Agency (UBA), Germany

Exposure of wildlife to anticoagulant rodenticides (ARs) has been extensively monitored worldwide for a variety of terrestrial species directly or indirectly linked to pest rodents via the terrestrial food web. In recent years, the scientific focus of environmental AR monitoring extended to AR emissions to the aquatic environment, demonstrating the relevance of aquatic exposure pathways such as sewer baiting and bait application in close proximity of surface water bodies. Hence, in regions with pronounced rodent control measures in Germany, biocidal ARs were frequently detected in Eurasian otters (*Lutra lutra*), a primarily piscivorous mammalian predator, in spite of strict regulations regarding the sale, supply, and use of ARs. Here, we present additional evidence that second-generation ARs entering the aquatic environment and accumulating in native freshwater fish, are transferred along the aquatic food chain, possibly posing a threat to piscivorous predators. Liver samples of 96 cormorants (*Phalacrocorax carbo sinensis*), an exclusively piscivorous, migratory avian predator, were analyzed regarding residues of all eight active ingredients used in biocidal ARs in Germany. All of the randomly investigated cormorants from different German regions (Bavaria, Rhineland-Palatinate, Saxony) had been shot for nature conservation reasons based on state-specific species protection exception regulations between 2020 – 2023 (outside breeding season). In summary, hepatic residues of biocidal ARs were detected in 46% of investigated cormorants (max. individual total hepatic AR concentration of 35 ng/g based on liver wet weight). Second-generation AR active ingredients brodifacoum, difenacoum, and bromadiolone were detected almost exclusively, reflecting their estimated market share in Germany. Without doubt, improvements of regulatory measures will be required to mitigate the almost ubiquitous occurrence of hepatic second-generation AR residues in non-target wildlife as the potential ecotoxicological consequences thereof are yet unknown.

1.10.P-We048 Biomonitoring of metals and second-generation anticoagulant rodenticides at the pan-European scale from 1996 to 2021 with wild Common Buzzards (Buteo buteo)

Avian predators have been widely used for biomonitoring due to their long lifetime and large foraging areas. However, many data from top-predator monitoring are temporally or regionally fragmented, which complicates long-term and large-scale chemical risk and hazard assessments. To fill this knowledge gap in the assessment of chemicals in the terrestrial compartment at a large scale, we conducted a pan-European scale biomonitoring using Common Buzzards (*Buteo buteo*) as sentinel species. We present here our initial results on the temporal trend of two types of chemical contaminants posing threats to terrestrial wildlife, heavy metals and second-generation anticoagulant rodenticides (SGARs).

We collected buzzards found dead or dying in the wild from 11 European countries from 1996 to 2021. Livers from several individuals within a region of a country were pooled to increase sample mass for multiple-contaminant analysis. Concentrations of three metals (mercury, cadmium and lead) and five SGARs (bromadiolone, difenacoum, brodifacoum, flocoumafen and difethialone) were measured in 64 pooled samples and compared between countries. The spatiotemporal trend of each contaminant and the number of samples exceeding a threshold referred from the literature were modelled.

Except for cadmium, which was significantly lower in Spain than in Germany, no significant difference between countries was observed in metal and SGAR concentrations. There was no significant temporal trend in metal concentrations, while summed SGAR concentrations (ΣSGARs) decreased from 1997 to the end of the 2000s and then increased. Regarding each SGAR, only brodifacoum showed a similar temporal trend as ΣSGARs, but no other SGAR significantly varied over time. Meanwhile, the proportion of samples exceeding the threshold of at least one metal or SGAR significantly differed between before and after 2015. For each contaminant, the same result was observed only in brodifacoum.

Overall, metals in buzzards showed a spatial variation but did not change over time. In contrast, SGARs did not spatially vary but changed over time. Potential health risks from the analysed chemical contaminants on buzzards increased around the middle of the 2010s, mainly due to high brodifacoum concentrations. Interpretation of these findings needs to consider the chemical regulation changes over time in Europe, the potential disparity in the regulatory authorities, and the variety in the ecology of the bird between countries.

1.10.P-We049 Lead Exposure of Scavenging Birds Due to Accidental Ingestion of Lead Ammunition: Geographic and Species Variation in Canada

*John Chetelat[1], **John E. Elliott**[1], Kirsty Gurney[1], Christine McClelland[1], Shane R. deSolla[2], Jamille McLeod[1], Guy Fitzgerald[3], Stephane Lair[3], Megan Jones[4], Laura Bourque[4], Heather Fenton[5], Dayna Goldsmith[6], Sandi Lee[1], Jane Harms[7], Maude Henaff[7], Kristenn Magnusson[7], Erin Moffatt[8], Lenny Shirose[9], Melanie Whalen[10] and M Zimmer[8], (1)Environment and Climate Change Canada, Canada, (2)Wildlife and Landscape Science Directorate, Environment and Climate Change Canada (ECCC), Canada, (3)University of Montréal, Canada, (4)University of Prince Edward Island, (5)Government of Northwest Territories, (6)University of Calgary, Canada, (7)Government of Yukon, (8)University of Saskatchewan, Canada, (9)University of Guelph, Canada, (10)Calgary Wildlife Rehabilitation Centre*

Multiple bird species, including raptors and corvids, accidentally ingest spent lead ammunition while scavenging on gut piles of hunted game, which can result in acute and chronic toxicological effects. This phenomenon has been reported worldwide and for some bird species is associated with population-level impacts. To evaluate lead poisoning of scavenging birds across Canada, we initiated a national scale study in 2018, with the objective of using a pan-Canadian database to (i) assess the extent of lead exposure of scavenging birds and (ii) identify bird species and regions at higher risk. Through a collaboration between Environment and Climate Change Canada, the Canadian Wildlife Health Cooperative, territorial governments, and other partners, a sample set of close to 1000 livers has been obtained from dead and moribund birds brought to wildlife organizations. Currently, bald eagle is the most sampled species (n = 423) followed by red-tailed hawk (n = 139), common raven (n = 101), great horned owl (n = 90), golden eagle (n = 50), merlin (n = 38), American crow (n = 35), and turkey vulture (28). Measurement of lead burdens in the livers is on-going, though preliminary concentration data (n = 792) were compared to an established threshold of 20 mg/g dry weight (dw) associated with a high risk of clinical lead poisoning. Bald eagle, golden eagle, and turkey vulture showed the greatest lead exposures, with 12-15 % of birds having liver concentrations in exceedance of 20 mg/g dw. A few individuals of red-tailed hawk and great horned owl also showed exceedances of that threshold, though at a lower frequency of 1-2 %. None of the corvid species had liver concentrations of lead above the threshold (maximum concentrations £ 5 mg/g dw). A comparison of bald eagle lead concentrations among regions of Canada showed considerable geographic variation in exposure, with threshold exceedances ranging from 4-23%. Antimony concentrations of bird livers were also examined because antimony is used as a hardener in lead ammunition alloys. A positive correlation was found between bird liver concentrations of antimony and lead, which is consistent with lead ammunition being a dominant source of lead exposure to the birds. This national-scale Canadian dataset will provide a baseline to track long-term trends in lead exposure of a representative suite of raptors and corvids.

1.10.P-We050 Feathers to the Rescue: A Non-Destructive Tool for the Detection of Metals and Metalloids

***Martin Emilo Pereda Solis**[1], Manuel Armando Salazar Borunda[1], José Martínez Guerrero[1], Patricia Carrillo Buentello[2], Fernando Flores-Morales[1], Andrea Vargas Duarte[1] and Jaime Rendón-von Osten[3], (1)Universidad Juarez del Estado de Durango, Mexico, (2)Pronatura Noreste, (3)Autonomous University of Campeche, Mexico*

Heavy metals and other inorganic elements are widely distributed in the environment through the geological cycle. Additionally, they are released due to various human activities such as industrialization, combustion, smelting processes, vehicle emissions, mining, agricultural runoff, and oil activities, among others. Some inorganic elements, such as Zn, Cu, and Se, are essential for organisms, playing a crucial role in their biological functions. In contrast, elements like Cd, Hg, and Pb are non-essential and have been shown to have adverse effects on birds. These inorganic elements occur naturally in the environment, implying a constant level of exposure. Birds have developed adaptations to cope with this exposure, and concentrations of essential elements typically remain in balance in birds unless the exposure is significantly high and disrupts normal homeostatic processes. The aim of this study was to assess the presence of inorganic elements in the feathers of green-winged teals and snow geese wintering in Laguna de Santiaguillo, Durango, Mexico, and also to evaluate the usefulness of feathers as indicators of exposure to these contaminants.

During the hunting season 2021-2022, 27 specimens of snow geese (Anser caerulescens) and 30 green-winged teals (Anas crecca) were collected. Feathers were taken from the collected birds, and the determination of metals was carried out using the voltammetry technique.

The concentrations of inorganic elements showed the following pattern: In A. crecca: As > Cr > Cu > Ni > Hg > Zn > Sn > Pb > Al > Cd, while in A. caerulescens: Ni > Cr > Cu > As > Hg > Al > Sn > Zn > Pb > Cd. For both species, Cr and Cu were the elements observed with higher concentrations, and Cd was the lowest concentration; the rest of the elements were distributed differently between the species. Although the average concentrations of inorganic elements in both species do not suggest significant exposure, some individuals with particularly high concentrations of Pb and Hg were observed.

The use of feathers as biomarkers of exposure to metals and metalloids is highly beneficial since when these elements circulate in the blood, they adhere to the proteins present in the feathers. Thus, they accumulate throughout the development and growth process of feathers. Once feather growth ceases, it seals, ceasing to interact with the bird's physiology, reflecting the levels of metals accumulated during its growth or molt period.

1.10.P-We051 The Red-billed Chough (Pyrrhocorax pyrrhocorax) as a Sentinel Species for the Input of Heavy Metals from the Tajogaite Volcano into the Environment of La Palma, Canary Islands

*Isabel Navas DVM,[1], Guillermo Blanco PhD[2], Martina Carrete PhD[3], Sara Gutiérrez[4], María Belén Nieto[5], Pedro María-Mojica DVM,[5] and **Antonio Juan Garcia-Fernandez, DVM, PhD**[6], (1)Health Sciences-Faculty of Veterinary-IMIB, Universidad de Murcia-IMIB, Spain, (2)Evolutionary Ecology, MNCN-CSIC, Spain, (3)Physical, Chemical and Natural Systems, Universidad Pablo de Olavide, Spain, (4)Public Sciences-Toxicology, Universidad de Murcia, Spain, (5)Health Sciences, Faculty of Veterinary, Universidad de Murcia, Spain, (6)Toxicology Research Group, Faculty of Veterinary Medicine, Universidad de Murcia-IMIB, Spain*

Geothermal activities, such as volcanic eruptions, represent one of the most important natural sources of metal emissions. These events can have an impact on the health of ecosystems incorporating large amounts of different pollutants.
On September 19th of 2021, in Cumbre Vieja (La Palma, Canary Islands), began the most recent volcanic eruption in Spain (Tajogaite volcano), which ended on December 25th of the same year. Being such a recent event, the effects of ash exposure on wildlife and humans have been scarcely studied.
The red-billed chough (*Pyrrhocorax pyrrhocorax*) is considered a symbol or "flagship species" of the island's natural values. Knowledge of the impact that the Tajogaite volcano may have had on its population is essential to assess the present and future conservation status of this species.
The main objective of this study is to evaluate the exposure to levels of contamination by heavy metals in wildlife in the area after the eruption.
To this end, the red-billed chough (*Pyrrhocorax pyrrhocorax*), named locally as “graja” has been considered as a monitoring species by using moulted wing feathers as monitoring tool of heavy metals exposure. Feathers collected before and after the eruption were used to compare both pollution scenarios.
Twenty-nine red-billed chough feathers were sampled (15 before and 14 after the eruption), on which the following metals were analyzed by IPC-MS: Al, Sr, Fe, Cu, Zn, Co, Ni, Cr, As, Cd, Pb, V, Se, Hg. Samples of ashes from the volcano eruption were also analyzed.
Most of the metals except of Cu, Zn, As and Pb, showed significant lower concentrations before than after the eruption, suggesting a common origin for most of the metals studied, which could be directly related to the recent eruption. Moreover, the metal and mineral profiles in feathers and volcanic ashes were very similar.
As a complement, a study of the levels of the same metals in internal organs of chough carcasses found dead before and after the eruption is being carried out in order to obtain more information on the possible consequences not only for the health of this species, but also for other species, including humans.

1.10.P-We052 Why are flamingo eggs not good indicators of environmental pollution?

*Hindrik Bouwman[1], **Velesia Lesch**[1] and Nicole van Gesselen Mrs[2], (1)Zoology, North-West University, South Africa, (2)Geography, North-West University, South Africa*

We present the first report on metallic element concentrations in egg contents of any flamingo species worldwide. Lesser Flamino Eggs *Pheoniconaias minor* were sampled at Kamfers Dam, Kimberley, South Africa. As one of the longest-lived bird groups (up to 50 years), we expected birds of the Family Phoenicopteridae to accumulate metals from the highly saline waters where they feed and transfer them to their eggs. However, the concentrations of metals were lower than expected when compared with shorter-lived large aquatic birds from the same region, possibly indicating maternal physiological processes that protects the embryo. Large inter-egg variations reflect their wide-ranging nomadic movements. Strontium concentrations in eggshells exceeded toxic reference values, and copper concentrations in egg contents may cause reproductive stress. Although there was no molar association between selenium and mercury, selenium was in excess. We identified various mechanisms by which flamingos have evolved to potentially remove metals from their bodies, such as excretion through feathers, salt glands, uropygial glands, and crop milk. In many respects, they could be considered marine birds. While embryonic flamingos chicks may be protected *in ovo*, we identified post-hatching routes of uptake by the chicks not previously recognised. Chicks consume their eggshells to an amazing extent, and the parents feed them crop milk akin to breast milk in mammals. We consider neither *P. minor* egg contents nor eggshells as good indicators of environmental metallic pollution. Our findings suggest a more nuanced approach to monitoring and protecting Phoenicopteridae from pollution.

1.10.P-We053 Compound-specific Stable Isotope Analyses of Amino Acids Reveal Drivers of Mercury Concentrations in Steller Sea Lions and their Prey

*Michelle Trifari[1], Matthew Wooller[1], Lorrie Rea[2], Todd O'Hara[3], Gretchen Lescord[4], Amy Bishop[5], Andrew Parnell[6] and **Benjamin D Barst**[2], (1)University of Alaska Fairbanks, (2)Institute of Northern Engineering, University of Alaska Fairbanks, (3)Texas A&M University, (4)School of Forest Fisheries, and Geomatics Sciences, University of Florida, (5)University of Alaska Anchorage, (6)Maynooth University, Ireland*

Total mercury concentrations ([THg]) exceed thresholds of concern in some Steller sea lion (*Eumetopias jubatus*) tissues from certain portions of the Aleutian Islands, Alaska (USA). We applied compound-specific stable isotope analyses (CSIA-AA) of both carbon and nitrogen in amino acids from fish muscle tissue to quantify the proportional contributions of primary production sources and trophic positions of eight prey species (n = 474 total) that are part of Steller sea lion diets. THg analyses of fish muscle, coupled with monomethylmercury analyses of a subset of samples, substantiated previous findings that fishes from the west of Amchitka Pass, a discrete oceanographic boundary of the Aleutian Archipelago, have higher muscle Hg concentrations relative to fishes from the east. The $\delta^{13}C$ values of essential amino acids (EAAs) in fish muscle demonstrated that although most fishes obtained their EAAs primarily from algae, some species varied in the extent to which

they relied on this EAA source. The $\delta^{15}N$ values of phenylalanine (0.9 to 7.8 ‰), an indicator of the isotopic baseline of a food web, varied widely within and among fish species. Trophic position estimates, accounting for this baseline variation, were higher from the west relative to the east of the pass for some fish species. Trophic magnification slopes using baseline-corrected trophic position estimates indicated similar rates of Hg biomagnification to the east and west of Amchitka Pass. Multiple linear regression models revealed that trophic position was the most important driver of fish muscle [THg] with less variation explained by other parameters. Thus, higher trophic positions but not the rate of Hg biomagnification to the west of Amchitka Pass may play a role in the regional differences in both fish and Steller sea lion [THg]. Although, differences in Hg contamination and uptake at the base of the east and west food webs could not be excluded. To better identify the drivers of observed temporal patterns in Steller sea lion [THg], we also performed CSIA-AA of nitrogen on Steller sea lion whiskers. Results indicate cyclical variation in the isotopic baseline along whiskers (i.e., over time), suggesting Steller sea lions are foraging and obtaining Hg from different locations seasonally. The application of CSIA-AA to Steller sea lions and their prey is allowing for a more nuanced perspective of Hg pathways in this remote region of Alaska.

1.10.P-We054 Dietary shift in Southeast Alaskan wolf populations leads to increased mercury exposure

***Angela R Gastaldi**[1], Gretchen H Roffler[2] and Benjamin D Barst[3], (1)University of Alaska Fairbanks, (2)Alaska Department of Fish and Game, Division of Wildlife Conservation, (3)Institute of Northern Engineering, University of Alaska Fairbanks*

Although all wolves (Canis lupus) express a high degree of dietary plasticity, the coastal wolves in Southeast Alaska, USA (*Canis lupus ligoni*) have demonstrated an extremely diverse diet dominated by ungulates but including marine resources opportunistically throughout their range. Recent studies have shown a drastic dietary shift towards sea otters (*Enhydra lutris*) in the region near Glacier Bay National Park and Preserve (GLBA), specifically for the wolves inhabiting Pleasant Island and the Gustavus Forelands. Sea otter populations were decimated by the fur trade prior to their protection in 1911. Following their reintroduction to Southeast Alaska in the 1960s, sea otters have since increased in numbers, especially near GLBA. This recovery has allowed the ranges of sea otters and wolves to overlap, resulting in a shift in wolf diet from terrestrial herbivores (ungulates such as deer and moose) to a marine predator (sea otters). As monomethylmercury is produced and biomagnifies mainly in aquatic food webs, we expected to find higher concentrations of total mercury in wolves with strong connectivity to marine food webs. To determine baseline contamination and identify the trophic transfer of mercury, we measured total mercury concentrations and the stable carbon and nitrogen isotope ratios ($\delta^{13}C$ and $\delta^{15}N$ values) in fur from wolves and sea otters, as well as in the tissues of intertidal fishes and invertebrates from Pleasant Island and the Gustavus forelands. We also compared stable isotope and total mercury concentrations of Pleasant Island/Gustavus wolves with data from wolves (n=118) across Southeast Alaska. Our results indicate substantial variation in fur total mercury concentrations (0.05 to 17.1 ppm) and $\delta^{13}C$ (-26.4 to -14.6‰) and $\delta^{15}N$ (4.5 to 14.0‰) values. Both $\delta^{13}C$ and $\delta^{15}N$ values were tightly correlated with fur total Hg concentrations demonstrating that dietary reliance on marine resources is a major driver of Hg exposure for wolves across Southeast Alaska. Due to their predation of sea otters, wolves from Pleasant Island had the highest total Hg concentrations, which may ultimately affect their health.

1.10.P-We055 Uncovering Effects with Molecular Techniques and Primer Design: Chronic Mercury Exposure and gene expression in Svalbard Reindeer

***Tove elizabeth Petersson**, University of Gothenburg, Sweden*

Despite its remote Arctic location, Svalbard has significant levels of Mercury contamination, (Hg). Hg travels to the Arctic via long-range atmospheric transport, from industrialised areas all over the world. As a result, the Arctic cryosphere is the second-largest sink of legacy mercury on Earth. As temperatures rise in the Arctic, historically stored mercury may remobilise to other environmental compartments. The Svalbard reindeer (*Rangifer tarandus platyrhynchus*) is the largest herbivore of the archipelago, and an essential part of the terrestrial ecosystem. They consume vascular vegetation, moss, and lichen, which take up Hg from air and water. Top predators include humans, polar bears, and Arctic foxes.

This project investigates low-level, chronic effects in Svalbard reindeer following a life-long exposure to environmental concentrations of mercury. This is done by assessing the regulation of genes associated with oxidative stress and mercury detoxification in liver and muscle samples from Svalbard reindeer. Genes of interest include metallothionine, selenoprotein, glutathione reductase and hepcidin. The project includes primer design development and thus the creation of new primers that can be used for further research. The results from the genetic expression will be compared to the mercury concentration in these tissue samples.

To extend the project and support assumptive expression results, bioassays and blood smear analyses will also be included.

1.10.P-We056 The Chemical Load of Pilot Whales in Arctic Waters

***Halla Weihe Reinert** and Katrin Hoydal, Environmental Protection, Faroese Environment Agency, Faroe Islands*

Long-finned pilot whales in the North Atlantic Ocean are burdened by vast quantities of chemicals transported by air and water from distant places. Due to its position in the food web, these chemicals are bioaccumulated to a high degree. The pilot whale has been a staple diet of the Faroese people for centuries, yet concerns have been raised about its chemical profile for decades.

The Faroese participation in the Arctic Monitoring and Assessment Programme (AMAP) began in 1997, focusing on the monitoring of heavy metals and persistent organic pollutants (POPs) in selected animals, including the pilot whale, along with supporting parameters. One of the main objectives is the generation of temporal trend analyses of contaminants in different tissues in different animals as indicators of environmental pollution. Retrospective analyses have also been done to complement already existing data.

Temporal trends were analysed using a robust regression approach to detect trends as well as an ordinary log-linear regression. The analyses were successfully applied to individual time-series for 59 compounds in four different tissues, resulting in 73 time-series. Of these, 29% show an increasing trend, 36% show a decreasing trend, and 18% show no detectable trend. However, only 34 time-series have a statistical power over 80%, which indicates the need for continued monitoring.

1.10.P-We057 Ultraviolet Absorbents and Industrial Antioxidants in Tissues of the Canadian Arctic Wildlife
Alejandra Granados Galvan, Ph.D. Student[1]*, Jennifer F Provencher*[2]*, Mary Gamberg*[3]*, Mark Mallory*[4]*, Amila O. De Silva*[5]*, Derek C.G. Muir*[6]*, Xiaowa Wang*[5]*, Magali Houde*[7]*, Robert J. Letcher*[8]*, Lisa L. Loseto*[9]*, Bonnie Hamilton*[10]*, Chelsea Rochman*[10]*, Cory J.D Matthews*[9]*, Florentine Malaisé*[11]*, Winny Pan*[12]*, Alice Guillot*[12] *and Zhe Lu*[11]*, (1)Institut des Sciences de la Mer de Rimouski, University of Quebec at Rimouski (UQAR), Rimouski, Canada, (2)Ecotoxicology and Wildlife Health Division, Environment and Climate Change Canada (ECCC), Canada, (3)Gamberg Consulting, Canada, (4)Department of Biology, Acadia University, Canada, (5)Aquatic Contaminants Research Division, Environment and Climate Change Canada, Canada, (6)Air Quality Processes Research Section, Environment and Climate Change Canada, Canada, (7)Environment and Climate Change Canada, Canada, (8)Ecotoxicology and Wildlife Health Division, Environment and Climate Change Canada, Canada, (9)Arctic Aquatic Research Division, Fisheries and Oceans Canada, Canada, (10)Department of Ecology and Evolutionary Biology, University of Toronto, Canada, (11)Institut des Sciences de la Mer de Rimouski (ISMER), University of Quebec at Rimouski (UQAR), Canada, (12)University of Quebec at Rimouski - Institute of Marine Sciences (UQAR-ISMER), Canada*
Ultraviolet (UV) absorbents and industrial antioxidants are plastics associated contaminants and they have been detected in the environment and are known to cause different types of toxicities in exposed organisms. However, the distribution of these contaminants in Arctic wildlife remains poorly understood, hindering comprehensive risk assessment and policy development. This study analyzed benzotriazole UV stabilizers (BZT-UVs), UV filters (UVFs), synthetic phenolic antioxidants (SPAs), and secondary amine antioxidants (Ar-SAs) in the liver, muscle, or blubber of seabirds, marine mammals, and fish from the Canadian Arctic (*n*=278 samples) collected between 2017 and 2021. Contaminants were analyzed via gas chromatography-mass spectrometry. Seabirds in eastern Nunavut showed elevated levels of BZT-UVs, UVFs, Ar-SAs, and 26DTBP (2,6-di-*tert*-butylphenol) in the liver compared to other species. UV328 (2-(2H-benzotriazol-2-yl)-4,6-di-*tert*-pentylphenol), recently added to Annex A of the Stockholm Convention, exhibited higher accumulation in thick-billed murre livers (mean concentration 45±18 ng/g wet weight; *n*=28) than reported in seabirds' liver or egg from other Arctic regions. This suggests higher potential exposure of murres in this colony to UV328, warranting further investigation. The southern Hudson Bay polar bear population was more contaminated with 26DTBP, UV329 (2-(2H-benzotriazol-2-yl)-4-(1,1,3,3-tetramethyl butyl) phenol), and 4MBC (4-methylbenzylidene camphor) compared to the western population. Liver UV329 levels were approximately twice as high as the levels in Svalbard polar bears' blood. Eastern Beaufort beluga and sea-run Arctic char from Northwest Territories and Nunavut, respectively, had relatively the lowest contamination levels of the target contaminants. Regarding mammal tissue distribution, walrus and ringed seals showed higher ∑BZT-UVs in blubber than muscle or liver, with no trend for ∑UVFs and ∑Ar-SAs. On the contrary, ringed seals from Northwest Territories displayed higher levels of ∑SPAs in the liver than the blubber. Interestingly, no correlation was found between the microplastic accumulation reported in the gastrointestinal tract and target contaminant concentrations in these tested species. These findings establish a baseline for monitoring UV absorbents and industrial antioxidants in the Arctic, which is crucial for comprehensively understanding the plastic pollution in the Arctic food web.

1.10.P-We058 Time trends (1996-2021) in PCB and PBDE congeners and in ΣPCBs and ΣPBDEs residue concentrations in the common buzzard Buteo buteo in 11 European countries in relation to restrictions on chemicals use
Paola Movalli[1]*, Alessandra Cincinelli*[2]*, Shinji Ozaki, PhD*[3]*, Tania Martellini*[2]*, Saul Santini*[2]*, Chiara Sarti*[2]*, Nikiforos Alygizakis*[4]*, Alexander Badry*[5]*, Koos Biesmeijer*[1]*, Rene Dekker*[1]*, Guy Duke*[6]*, Georgios Gkotsis*[7]*, Natalia Glowacka*[4]*, Jan Koschorreck*[5]*, Maria-Christina Nika*[8]*, Peter Oswald*[4]*, Jaroslav Slobodnik*[4]*, Nikolaos S. This study aims to explore the utility of long-term contaminant monitoring in raptors as sentinels to assess the effectiveness of chemicals restrictions in Europe. EU regulations, notably Directive 96/59/EC on PCBs, Directive 2003/11/EC on certain PBDEs and the REACH Regulation EC 1907/2006, together with the Stockholm Convention (2001), have been introduced to reduce the threats posed by persistent, bioaccumulative and toxic substances to human and wildlife health, although their transposition or ratification and implementation has varied by country.

Top predators (also called apex species) such as raptors are frequently used as sentinels for bioaccumulating chemicals, with potential for regulatory applications including early warning of emerging contaminants, chemicals risk assessment and assessment of efficacy of chemical risk management measures. Such applications offer substantial promise in relation to EU ambition to limit harm from chemicals to both wildlife and human health. However, little research has explored the potential for such applications at Europe-wide scale, in particular assessment of efficacy of risk management measures.

This study used the common buzzard *Buteo buteo*, an apex species, which is widely distributed in Europe and has been suggested as a suitable species for systematic monitoring of contaminant trends in terrestrial food webs at large spatial scales. We analysed for 31 PCBs and 23 PBDEs in 64 buzzard livers from 11 European countries (Austria, Belgium, Finland, Germany, Greece, Italy, Portugal, Romania, Slovenia, Spain, Switzerland) for the period 1996-2021 using GC-MS. We explored time trends for the number of PCB and PBDE congeners and for residue concentrations. We also explored differences in time trends between substances and countries. In particular, we assessed possible explanations for any observed reductions in the numbers and/or residue concentrations of PCBs and PBDEs over time, at pan-European and at national scales, subsequent to restrictions on these substances. We discuss implications for the further application of monitoring of chemicals in terrestrial apex species to assess the effectiveness of regulatory restrictions at pan-European and national scales.

1.10.P-We059 Title: From soils to apex species: chemical pathways, effects and impacts on terrestrial biodiversity and ecosystem services and applications for better chemicals management

Guy Duke[1]*, Nikiforos Alygizakis*[1]*, S. Thomaidis*[10]*, Gabriele Treu*[9]*, Martina G. Vijver*[2]* and Jaroslav Slobodnik*[1]*, (1)Environmental Institute, Slovakia, (2)Institute of Environmental Sciences (CML), Leiden University, Netherlands, (3)Naturalis Biodiversity Center, Netherlands, (4)Leiden University, Netherlands, (5)Chemistry, National and Kapodistrian University of Athens, Greece, (6)Quantitative Sustainability Assessment, Department of Environmental and Resource Engineering, Technical University of Denmark, Denmark, (7)Environment Agency Austria (EAA), Austria, (8)Department of Environmental Toxicology, Eawag: Swiss Federal Institute of Aquatic Science and Technology, Switzerland, (9)German Environment Agency (UBA), Germany, (10)National and Kapodistrian University of Athens, Greece, (11)Technical University of Denmark (DTU), Denmark*
TerraChem (*From soils to apex species: chemical pathways, effects and impacts on terrestrial biodiversity and ecosystem services and applications for better chemicals management*) is a three-year collaborative project running from November 2023.

The European Commission's *Chemicals Strategy for Sustainability* aims to minimise the risk of chemicals to wildlife (and human) health. However, the number of chemicals in use far exceeds capacities of conventional risk assessment, registration data is often inadequate and risk assessment does not consider damages to biodiversity and ecosystem services. Real-world contaminant monitoring and in silico modelling can help to assess exposure and effects and damages on biodiversity and ecosystem services, and are increasingly recognised as important in the prioritisation of substances for environmental risk assessment. However, their application in the terrestrial environment has to date been limited.

TerraChem addresses this gap by aiming to develop, demonstrate and apply a novel systems approach, integrating monitoring, environmental modelling, data management, analytical tools and user guidance to better understand exposure of terrestrial abiotic media (soil, soil pore water) and biota across trophic levels (plants to primary and secondary consumers to apex species) to the universe of environmentally-relevant anthropogenic chemicals and resulting damage to biodiversity and ecosystem services. TerraChem will enable more efficient environmental risk assessment of chemicals in the terrestrial compartment and more effective prevention and mitigation, accelerating achievement of the EU's zero pollution ambition.

TerraChem's objectives include: (1) understanding routes of exposure to chemicals in wildlife, including routes and extent of trophic transfer, for selected food chains in representative terrestrial biomes across Europe; (2) modelling source-to-receptor pathways of selected chemical contaminants for terrestrial ecosystems, and link organism and species effects to damage on genetic and functional diversity and on relevant ecosystem services; (3) developing tools and guidance for regulatory and practice uptake of TerraChem output to optimise current environmental risk assessment of chemicals and improve risk management measures, thereby reducing damage to biodiversity; and (4) developing a TerraChem Data Management System and Dashboard as a One-Stop Shop for data on contaminants in terrestrial biodiversity in Europe.

1.10.P-We060 The TerraChem approach to monitoring chemicals exposure and mixture effects in real-world terrestrial food chains

Paola Movalli[1], *Koos Biesmeijer*[1], *Nikolaos S. Thomaidis*[2], *Maria-Christina Nika*[3], *Georgios Gkotsis*[4], *Martina G. Vijver*[5], *Laura Scherer*[5], *S. Henrik Barmentlo*[5], *Annetrude Boeije*[6], *Philipp Kropf*[6], *Gabriele Treu*[7], *Oliver Machate*[7], *Peter Fantke*[8], *Susan Oginah*[9], *Marissa B Kosnik*[10], *Nikiforos Alygizakis*[11], *Guy Duke*[11], *Natalia Glowacka*[11], *Peter Oswald*[11], *Jaroslav Slobodnik*[11] *and Tom Nolte*[1], *(1)Naturalis Biodiversity Center, Netherlands, (2)National and Kapodistrian University of Athens, Greece, (3)National and Kapodistrian University of Athens, Greece, (4)Chemistry, National and Kapodistrian University of Athens, Greece, (5)Institute of Environmental Sciences (CML), Leiden University, Netherlands, (6)Leiden University, Netherlands, (7)German Environment Agency (UBA), Germany, (8)Quantitative Sustainability Assessment, Department of Environmental and Resource Engineering, Technical University of Denmark, Denmark, (9)Technical University of Denmark (DTU), Denmark, (10)Department of Environmental Toxicology, Eawag: Swiss Federal Institute of Aquatic Science and Technology, Switzerland, (11)Environmental Institute, Slovakia*

Knowledge on exposure to and effects of chemicals in terrestrial ecosystems in Europe is limited. TerraChem is a collaborative 3-year project running from November 2023. The overall objective of Work Package 1 (WP1) is to understand routes of exposure to chemicals in wildlife, including extent of trophic transfer, for selected food chains (soil and soil water – plants – primary and secondary consumers – apex species) in representative terrestrial biomes. WP1 specific objectives are: (1) to detect and determine chemicals and predominant chemical mixtures present; (2) to understand routes of exposure, including extent of trophic transfer and magnification; (3) to explore patterns for individual contaminants and predominant mixtures in terrestrial trophic chains; (4) to elucidate toxic effects of chemical mixtures using an effects-based approach; and (5) to identify and collate secondary data on contaminants along trophic chains in terrestrial ecosystems in Europe.

WP1 involves six one-country cases in Europe, across representative biomes (e.g. farmland, woodland, grassland) and food chains (e.g. carnivorous mammal, insectivorous mammal), plus one pan-European case study (barn owl *Tyto alba* food chain, six countries). Food chain samples will be analysed by wide-scope target analysis (>2400 substances) and suspect and non-target screening (>95000 substances) using LC- and GC-HRMS, covering the more-or-less full universe of environmentally-relevant anthropogenic chemicals, their transformation products and metabolites. We will explore patterns of individual contaminants and of contaminant mixtures. Routes of exposure and trophic transfer and magnification will be further elucidated using compound-specific amino acid isotope analysis. Mixture effects, at the level of the individual organism, will be explored using a battery of bioassays.

WP1 primary data (and secondary data on contaminants in terrestrial food chains, extracted from previous landscape-scale studies in Europe) will be used in WP2 to train models on source-to-damage chemical pathways in terrestrial ecosystems. WP1 and WP2 outcomes will be used to improve current risk assessment practice and measures (WP3) to better protect biodiversity in Europe. WP1 data will be made available through a new TerraChem database for contaminant data in terrestrial biota in Europe, hosted by NORMAN.

1.10.P-We061 Unveiling the chemical fingerprint of xenobiotics in different otter tissues through HRMS-based targeted and untargeted workflows

Antigoni Konomi[1], *Georgios Gkotsis*[2], *Maria-Christina Nika*[2], *Elizabeth Chadwick*[3], *Emily O'Rourke*[3], *Chloe Farrington*[3], *Elaine Potter*[4], *Carsten Baessmann*[5] *and Nikolaos S. Thomaidis*[1], *(1)National and Kapodistrian University of Athens, Greece, (2)Chemistry, National and Kapodistrian University of Athens, Greece, (3)Cardiff University, United Kingdom, (4)NERC Centre for Ecology & Hydrology, United Kingdom, (5)Bruker Daltonics GmbH, Germany*

Anthropogenic activities are one of the main contributors to the introduction of chemicals in the environment and research findings indicate a constantly increasing number of xenobiotics, which are distributed in various environmental compartments. Through their systematic monitoring, insights on their potential harmful properties can be revealed, making their prioritization for the addition in the future legislation more efficient. Apex predators, such as Eurasian otters (*lutra lutra*), are commonly used as sentinels to assess the effectiveness of chemical regulations, since they possess many key characteristics that make them ideal organisms for detecting and evaluating contaminants in the environment. The conventional biomonitoring strategies focus on investigating the occurrence of priority pollutants or specific chemical classes, such as Per and Poly- Fluoroalkyl Substances (PFAS). Thus, many organic micropollutants remain uninvestigated and the chemical exposure of biota species is not explored to a high extent.

In the framework of this study, otter samples gathered from the United Kingdom were analyzed to investigate the different accumulation profiles of chemicals in seven different tissues collected during postmortem of road-killed otters (muscle, liver, kidney, pelt, blood, fat and fecal samples), through wide-scope target analysis. The sample preparation was conducted by applying generic protocols for the extraction of LC- and GC- amenable compounds with different physicochemical properties, whereas the analysis was conducted using complementary chromatographic techniques coupled to HRMS. For the detected analytes, the investigation of the simultaneous presence of transformation products was conducted using suspect screening.

In total, 91 micropollutants, from different chemical classes, were determined during the targeted analysis. The most abundant class of contaminants were pharmaceuticals, followed by plant protection products and PFAS. Pelt accumulated the highest number of compounds with 45 contaminants detected, most of which were pharmaceuticals, followed by liver samples with 42 compounds, the majority of which were PFAS. Therefore, pelt, which could be potentially acquired non-invasively, may be of interest for the systematic monitoring of polar and semi-polar chemicals (including pharmaceuticals) in otter samples. Moreover, based on our results, liver and fecal samples seem to accumulate plant protection products.

1.10.P-We062 Pilot study: Seasonal pesticide exposure and corresponding metabolomic changes identified by non-target analysis of plasma samples obtained from hares in Austria.
*Julia Atterbury[1,2], Karoline Schweitzer[3], Anna Kübber-Heiss[1], **Romana Hornek-Gausterer**[4] and Herbert Oberacher[5], (1)Research Institute of Wildlife Ecology (FIWI), University of Veterinary Medicine Vienna, Austria, (2)Institute of Legal Medicine and Core Facility Metabolomics, University of Veterinary Medicine Vienna, Austria, (3)University of Applied Science Technikum Wien, Austria, (4)Environment Agency Austria (EAA), Austria, (5)Institute of Legal Medicine and Core Facility Metabolomics, Medical University of Innsbruck, Austria*
The population dynamics of the European brown hare (*Lepus europaeus*) have exhibited a consistent downward trend over the past few decades, disregarding isolated regional deviations. Although the reasons for this decline are complex, some factors like chemical pressure may not have been adequately addressed. The use of pesticides has become essential in agriculture, and despite strict authorisation procedures, it is often not known whether and to what extend adverse effects on non-target organisms occur. In this study, plasma samples from 42 brown hares across different regions in Austria were analysed using non-targeted liquid chromatography-tandem mass spectrometry. Data mining included screening for pesticides potentially applied in the regions sampled. The samples include specimens from autumn 2020 and summer 2021, illustrating a distinct seasonal exposure pattern regarding the active substances of the applied plant protection products, as well as respective transformation products. While no pesticides or degradation products were detected in any of the animals taken in autumn, at least one pesticide was identified in more than 50 % of the samples taken in summer. In total, eight active substances of plant protection products and five metabolites were identified in 18 animals, with some individuals displaying a simultaneous exposure of up to eight different substances. Further statistical analyses revealed significant differences in the metabolomes of contaminated and uncontaminated hares. These results highlight the acute seasonal pesticide exposure in European brown hares and offer a valuable foundation for in-depth research into the metabolic effects and potential health consequences of pesticide exposure in European hares.

1.10.P-We063 A Spatial Assessment of Neonicotinoid Exposure in Common Goldeneyes in Finland
***Amalie Ask**[1], Pilar Gomez-Ramirez, PhD[2], Veerle L. B. Jaspers[3], José Fenoll-Serrano[4], Juana Cava-Artero[4], Seyyed Sajjad Vakili[5], Prescillia Lemesle[3], Tapio Eeva[1], Martin Hansen[6] and Céline Arzel[1], (1)Department of Biology, University of Turku, Finland, (2)Toxicology Research Group, Faculty of Veterinary Medicine, University of Murcia, Spain, (3)Norwegian University of Science & Technology (NTNU), Norway, (4)Instituto Murciano de Investigación y Desarrollo Agrario y Alimentario (IMIDA), Spain, (5)Dept of Biology, University of Turku, Finland, (6)Aarhus University, Denmark*
Neonicotinoids are widely used insecticides in agriculture and veterinary medicine. While the primary scientific and public concern has been on the effect of neonicotinoids on pollinator populations, these contaminants have also been linked to adverse effects in farmland-associated birds. However, recent research shows that birds not directly linked to agricultural areas are also exposed to neonicotinoids. Many important rivers flowing into the Baltic Sea run through agricultural areas and are thus potential transmitters of neonicotinoids to the aquatic environment. As Finland both continues to use neonicotinoids and has several declining populations of waterbirds, it is pressing to examine whether these species are exposed to neonicotinoids. Here, we chose to investigate the occurrence of neonicotinoids in the common goldeneye (*Bucephala clangula*) as this bird can be found throughout Finland and can act as a proxy for more endangered waterbird species as well as being a good model species for assessing contamination of the aquatic environment. We collected blood plasma samples from incubating female goldeneyes (n = 51) in 2022 from five different regions of Finland (Tornio, Seinäjoki, Maaninka, Helsinki, and Velkua) to assess if these compounds are present at quantifiable concentrations in this species and whether there is a spatial pattern to the concentrations and profiles linked to land use. The five regions follow a north-south gradient and are either predominantly agricultural or urban as well as including both inland and coastal areas. The target analytes are imidacloprid, acetamiprid, clothianidin, thiacloprid, thiamethoxam, nitenpyram, and dinotefuran. The samples have all been extracted and are scheduled for instrumental analysis in December-January, so the results will be ready to present at SETAC Seville.

1.10.P-We064 Exploring 46 Years of Temporal Trends and Interspecific Patterns of Perfluoroalkyl Substances (PFASs) in 4 Seabird Species from Canada’s Pacific Coast
***Robert Kesic**[1], John E. Elliott[1], Kyle Elliott[2], Sandi Lee[1] and France Maisonneuve[1], (1)Environment and Climate Change Canada, Canada, (2)McGill University, Canada*
Spatial and temporal trends of perfluoroalkyl substances (PFASs) have been well documented in marine food webs in the Atlantic, Indian, and Arctic oceans. However, much less is known about long-term trends of PFASs in the North Pacific Ocean, a region that remains largely understudied in coastal North America and is often subject to long-range transport (LRT) of PFASs and other contaminants from various North American and Asian sources. Here, we examined longer-term temporal

trends (1973-2019) of 4 PFSAs and 13 PFCAs, as well as stable isotopes of carbon ($\delta^{13}C$) and nitrogen ($\delta^{15}N$), in the eggs of 4 seabird species sampled along a nearshore-offshore gradient; double-crested cormorants (*Nannopterum auritum*), pelagic cormorants (*Urile pelagicus*), rhinoceros auklets (*Cerorhinca monocerata*), and Leach's storm-petrels (*Hydrobates leucorhous*) from the Pacific coast of British Columbia, Canada. PFOS was the most abundant PFSA (79-94%) detected, with the highest concentrations, on average, measured in auklet eggs (mean PFOS = 58 ng/g, range = 11-286 ng/g ww) collected from relatively remote colonies. PFUdA and PFTriDA were the dominant long-chain PFCAs (≥30% combined). The majority of PFSAs (including PFOS) are statistically declining ($p < 0.001$) in the eggs of all 4 species with half-lives ranging from 2.6-7.8 years. Concentrations of long-chain PFCAs exhibited a trajectory comprised of linear increases (primarily due to PFNA, PFUdA, and PFTriDA) as well as second-order declines ($p < 0.001$) in recent years, suggesting that the rate of uptake of these PFCAs is slowing or levelling off in our species. However, egg values for $\delta^{13}C$ and $\delta^{15}N$ across species were nonlinearly correlated with lnΣPFASs, suggesting that diet and foraging behaviour in nearshore/offshore areas may have influenced temporal trends. Nonetheless, these trends are consistent with the voluntary ceased production of PFSAs and their precursors by 3M circa 2000-2003 and are among the first from Canada to indicate a positive response to North American legislative restrictions (e.g. US EPA, Health Canada) on PFCAs from facility emissions and product content.

1.10.P-We065 PFAS accumulation and associations with reproduction in songbirds living near a hotspot

Thimo Groffen, *Jodie Buytaert, Els Prinsen, Lieven Bervoets and Marcel Eens, University of Antwerp, Belgium*

The area around 3M in Zwijndrecht, Belgium, has been well characterized to contain exceptionally high PFAS concentrations due to historical and recent emissions, making it an ideal site to study wildlife toxicity. Reproductive effects of PFAS on birds have been primarily studied under laboratory conditions, and field studies on PFAS (other than PFOS) are still relatively scarce. If present, they provide contradictory results, suggesting species-specific differences. In this study, we determined PFAS concentrations in eggs and blood plasma of chicks of both great tit (*Parus major*) and blue tit (*Cyanistes caeruleus*) in the vicinity of this fluorochemical plant. Furthermore, we associated accumulated PFAS concentrations to various breeding success parameters, including hatching and fledging success, survival, clutch size, and egg shell thickness. Nest-building and breeding was followed-up at three sites (i.e., 3M, the adjacent nature reserve Blokkersdijk, and Vlietbos, a forest area approximately 1.5 km from 3M) during the breeding season of 2022. When three eggs were present in a nest, a random egg was collected. Hereafter, the aforementioned breeding success parameters were determined. Blood samples were taken 14d after hatching, and were pooled among all chicks within a clutch to obtain sufficient plasma for PFAS analysis. Our preliminary results (further analysis will be conducted early 2024) reveal differences in PFAS accumulation profiles between blood plasma and eggs. Perfluorooctane sulfonate (PFOS) was the dominant PFAS in the eggs, with concentrations ranging between 34.5 and 67916 ng/g ww, whereas both PFOS (bLOQ – 15448 mg/L) and perfluorobutane sulfonate (PFBS; 41.3 – 24385 mg/L) were dominant in the blood plasma. Concentrations tended to decrease with distance from the 3M site, which is in agreement with previous studies in the area. Based on the field observations and earlier studies, limited effects of PFAS on breeding success are expected in both species, despite the high PFAS concentrations, although this still has to be confirmed by further statistical analysis.

1.10.P-We066 Assessment of Persistent Organic Pollutants (POPs) in Common Kestrel Eggs from Urban and Rural Areas in Rome, Italy

Pere Colomer Vidal[1], *Juan Munoz-Arnanz*[1], *Laura Giovanetti*[2], *Gianluca Damiani*[3], *Giacomo Dell'Omo*[3], *David Costantini*[4], *Ilaria Caliani*[2], *Silvia Casini*[2] *and Begoña Jiménez*[1], *(1)Institute of Organic Chemistry, Spanish National Research Council (IQOG-CSIC), Spain, (2)University of Siena, Italy, (3)Ornis italica, Italy, (4)Muséum National d'Histoire Naturelle, France*

The common krestel is a diurnal raptor undergoing a moderate decline and chemical pollution represent a well known stressor for this species. In this study we investigated the presence of Persistent Organic Pollutants (POPs) in common kestrel eggs from urban (Aniene Park) and rural (Castel di Guido) locations in Rome, Italy. These locations represent diverse environmental conditions, offering insight into potential POPs exposure.

Gas chromatography coupled to high-resolution mass spectrometry (GC-HRMS) and low-resolution tandem mass spectrometry (GC-MS/MS) techniques were used for the quantificaton of selected POPs (OCPs, PCBs, PBDEs and PCDD/Fs). Our findings showed a varied concentration range of ∑POPs (17.4 to 975 ng/g ww) in common kestrel eggs, significantly higher in Aniene Park compared to Castel di Guido. PCBs dominated the POPs profile in both locations, followed by OCPs and then PBDEs, with low levels of PCDD/Fs. A higher contribution of OCPs to total POPs was found in Aniene Park.

Urban environments exhibited higher concentrations of ∑DDTs, ∑endosulfan, and PeCB. Particularly, pp'-DDE emerged as a significant contributor to ∑DDTs and OCPs in both locations. HxCB and ∑HCHs depicted relatively high contributions, particularly in Castel di Guido. Isomeric analysis of ∑HCHs revealed notable differences between locations: in Castel di Guido, the α and γ isomers displayed similarity, contrasting with the significant contribion of the β isomer in Aniene Park. ∑endosulfan showed a minimal presence. Concerning industrial and non intentional POPs, PCBs, PBDEs, PCDD/Fs, and PCDFs showed significantly higher median values in Aniene Park compared to Castel di Guido. No significant differences were observed for ∑PCDDs. The PCBs profile in both locations was dominated by PCB-118, followed by PCB-153. In the case of PBDEs, PBDE-153 was the predominant compound in both locations. However, PBDE-99 emerged as the subsequent prominent compound in Aniene Park, while PBDE-209 held that position in Castel di Guido. PCDD/F profiles varied between locations: in Aniene Park, 12378-PeCDF dominated, followed by 2378-TCDF, while in Castel di Guido, an equal dominance was seen for 2378-TCDF and 23478-PeCDF.

This study provides crucial insights into the prevalence and distribution of POPs in common kestrel eggs across urban and rural areas, emphasizing the need for continued monitoring and targeted mitigation strategies to safeguard avian populations in diverse habitats.

1.10.P-We067 Difference in Toxicokinetics and Maternal Tranfer between Lipophilic and Proteinophilic Halogenated organic pollutants in Laying Hens

Xiao-Jun Luo, *Guangzhou Institute of Geochemistry, Chinese Academy of Sciences, China*

Halogenated organic chemicals such as PCBs, PBDEs, DPs, and PFASs are pollutants with high envrionmental concerns. PCBs, PBDEs, and DPs are tradition lipophilic POPs while PFASs are well known as proteinophilic chemicals. BDE209 also exhibited some extent protein binding in biota. In the present study, the toxicolinetics and maternal transfer of PCBs, PBDEs, DPs, and PFCAs (C4-C18) in laying hen were investigated by exposuring hens to spiked food. The highest uptake efficiencies were found for PCB congeners (>90%) and the lowest were found for BDE209 (21%). The uptake efficiencies of long chain PFACs (C>9, 76%-91%) were comprable with those of tetra-BDE to hex-BDE congeners (70%-91%) but were significant higher than those of short chain PFACs (C<8, 30%-50%) . The depuration rate (kd) of PFCAs were higher than those for PCB, PBDEs, and DPs and an inverted "U" relation between kd and carbon chain was found while a "V" relation was found between kd and log KOW for other chemicals. The bioaccumulation curves of PFACs can be divided into three groups (C4-C8, C9-C16, and C18) and other chemicals can be divided into two groups (all PCB and PBDE congeners without BDE209 as a group and BDE209 and DPs as a group). Adipose are main organ where all PCB and PBDE congeners without BDE209 deposited while BDE209 and DPs prefer to diposite in heart and muscle tissues. Yolk and brain are main organ/tissues where PFACs deposited and a tissue-specific affinity to specific carbon-chain PFCAs such as C9 for serum and liver, C18 for muslce, C14 for brain was observed. When different maternal tissues were chose to calculate maternal transfer potential of chemicals, the correlation between calculated maternal transfer potential and chemical property (log KOW or catbon chain length) exhibited various, which indicated single maternal tissues is inappropriate to assess the maternal transfer potential of chemicals. The percentage of chemicals in egg to total chemicals in maternal body indicated that the maternal transfer potential of PFCAs (>80%） were significantly higher than those of BDE209 and DPs (about 30%) and the lowest maternal transfer potental were found for PCB and PBDE congeners without BDE209 (<10%). Exposure status (uptake or depuration phase) also affect the maternal transfer potential of chemicals. The results implied that lipophilic chemical have high bioaccumulation but lower maternal transfer potential and vice versa for proteinophilic chemicals.

1.10.P-We068 Carbamazepine Acts as Endocrine Disruptor of the Thyroid System in the Amphibian Xenopus laevis

Andrea Ziková-Kloas[1], *Ilka Lutz*[2], *Mathias Stoeck*[2], *Julia Bindl*[2], *Sascha Behrens*[2] *and Werner Kloas*[2], *(1)German Environment Agency (UBA), Germany, (2)Leibniz-Institute of Freshwater Ecology and Inland Fisheries, Germany*

Carbamazepine (CARB) is a widely used pharmaceutical to treat epilepsy and neuropathic pain and furthermore as adjunctive medication of schizophrenia and bipolar disorder. Due to its common medication CARB is excreted at high concentrations and ends up via sewage treatment plants in surface waters reaching levels in the range of µg/L. CARB is known to affect hepatic enzymes and herewith it has been suggested to affect the thyroid system via an increased clearance rate of thyroid hormones (TH) by the liver. In order to assess the thyroid disrupting potential of CARB the amphibian metamorphosis assay (AMA) according to OECD test guideline 231 has been performed using CARB concentrations of 5.44, 54.4 and 544 µg/L. The AMA comprises as endpoints mainly gross morphological parameters, such as staging and hindlimb length, and after 21 d at the end of exposure also thyroid histopathology. All gross morphological endpoints revealed only a significant inhibition for staging after 7 d at the highest CARB concentration. Thyroid histopathology, however, resulted in moderate but significant effects even at the lowest concentration of 5.44 µg/L. Therefore, the proposed combination of gross morphological endpoints and classical thyroid histopathology reveals a great sensitivity regardless the mode of action for endocrine disruption of the thyroid system because TH agonists have only minor effects on thyroid histology but affect strongly gross morphological endpoints. The results are in accordance with the hypothesis that CARB increases elimination of TH by hepatic enzyme stimulation and reveal a significant dose dependent inhibition of stage development after 7 d. However, at the end of exposure after 21 d no significant effects are found neither at staging nor at any further gross morphological endpoint suggesting that the endogenous endocrine counter measure can balance the induced moderate impairment of metamorphosis via stimulation of the thyroid as seen by histology. In addition, whole tadpoles and target tissues such as pituitary, thyroid, liver, tail and eye have been excised to process them for transcriptomics and gene expression of established thyroidal biomarkers to get a deeper insight concerning modes of action and the potential for detecting new sensitive biomarkers. Acknowledgement: Funding by the European Union’s Horizon 2020 research and innovation programme under grant agreement No. 825753 (ERGO).

1.10.P-We069 Acute Dermal Toxicity of Pesticides to Terrestrial Metamorphs of the Spotted Salamander (Ambystoma maculatum)

Lennart Weltje, Prof. Dr.[1], *Scott M Weir*[2] *and Jon M Davenport*[3], *(1)Agricultural Solutions - Ecotoxicology, BASF SE, Germany, (2)Queens University of Charlotte, (3)Appalachian State University*

Most of the toxicological research on amphibians focuses on anurans and on aquatic rather than terrestrial stages. For terrestrial stages, birds are often used as surrogates. However, bird studies focus on dietary exposure, while dermal exposure of amphibians is likely the more important exposure route.

Therefore, the goal of this study was to assess dermal toxicity of five insecticides (resmethrin, terbufos, endosulfan, bifenthrin, flufenoxuron) and two herbicides (pendimethalin, triclopyr) to terrestrial life stages of spotted salamanders (*Ambystoma* *maculatum*) using the up-and-down testing procedure. We estimated LD_{50} values through dorsal skin application of an active substance dissolved in a small volume of solvent (acetone, propylene glycol or polyethylene glycol) for each pesticide (depending on its solubility).

We also compare our results with standard dermal mammalian (rat) data and with outcomes of a dermal acute estimation model, originally developed for anurans, extrapolating from fish toxicity and bioconcentration data.

Of the seven pesticides tested, four appeared to have significant toxicity (LD50 < 1750 µg/g), while flufenoxuron and the two herbicides were non-toxic (LD_{50} > 1750 µg/g). LD_{50} values for bifenthrin and endosulfan ranged from 5.5 to 17.5 µg/g, depending on the solvent. LD_{50} values for terbufos ranged from 9.3 to 55 µg/g, depending on solvent, while for resmethrin both acetone and polyethylene glycol LD_{50} values were 310 µg/g. When comparing toxicity across solvents within the same pesticide, there was only one instance where acetone appeared to increase toxicity (propylene glycol *versus* acetone for terbufos).

Our results suggest that mammalian dermal LD_{50} values may underestimate sensitivity for terrestrial salamanders for the insecticides resmethrin, bifenthrin, and endosulfan. The calculations for the dermal acute estimation model are ongoing. Our study fills a knowledge gap regarding dermal acute toxicity to terrestrial life stages of amphibians and will help in estimating potential risk to amphibians due to dermal exposure.

1.10.P-We070 Incorporating Mechanistic Effect Models into the Risk Assessment for Amphibians and Reptiles
Simon Ewald Hansul[1]*, Manuel Ortiz Santaliestra*[2] *and Andreas Focks*[1]*, (1)Institute of Mathematics, Osnabrück University, Germany, (2)Instituto de Investigación en Recursos Cinegéticos (IREC) CSIC-UCLM-JCCM, Spain*
The incorporation of mechanistic effect models (MEMs) is a central aspect of developing an environmentally relevant framework for the environmental risk assessment of pesticides in amphibian and reptiles.
As information is currently scattered, there is need to assess the state-of-the-art of MEMs for amphibians and reptiles and define a roadmap, ensuring that model development prioritizes activities which improve the applicability of MEMs to risk assessment.
For this reason, a workshop was held in Osnabrück on September 15 and 16 at Osnabrück University, Germany.
It was found that the development of organism-level models for amphibians and reptiles is already in an advanced state, with multiple models being developed for Amhpibians for the purpose of modelling whole life-cycle effects as well as plasticity in the timing of metamorphosis.
Population models for amphibians are in a less mature state and can currently only be applied to simplistic scenarios.
Population models for reptiles have already been applied in more complex contexts, such as in combination with food web models.
The adoption of MEMs for the application in risk assessment requires agreement between the model functioning and the specific use of models, as well as validation against data. This is in contradiction with the availability of data. However, this further motivates the use of models as tools for exploration of possible effects and behavior of systems. Models might thus be a useful tool to prioritize a limited set of scenarios which require empirical testing.
Regarding the applicability of models, we differentiate between short-term applicability (“fit for purpose”) and long-term perspectives. On the short term, organism-level models may be fit for purpose to support risk assessment, for example to extrapolate across exposure scenarios or integrate apical endpoints. On the long term, we expect population models to be invaluable tools for risk assessment, but solutions need to be developed to resolve the conflict between the need for validation and the availability of data.
Within PERIAMAR, we further aim to increase the feedback between risk assessors and model developers. Proposed actions include the conduction of a survey among risk assessment agents to acquire an overview of the most useful model applications in risk assessment. This could form the basis of highly targeted development processes.

1.10.P-We071 Amphibians in the Agricultural Landscape - Risk Reduction in Plant Protection and Promotion of Populations
Annette Aldrich[1]*, Gregory Churko*[2]*, Erich Szerencsits*[3] *and Benedikt R. Schmidt*[4]*, (1)Federal Office for the Environment (FOEN), Switzerland, (2)Biodiversität-Umwelt-Interaktionen, Agroscope, Switzerland, (3)Agrarökologie und Umwelt, Agroscope, Switzerland, (4)Department of Evolutionary Biology and Environmental Studies, University of Zurich, Switzerland*
This poster presents risk mitigation measures (RMM) for the terrestrial life stages of amphibians that can be recommended independently of the authorization of plant protection products (PPP). These measures should reduce the risk of PPP exposure, promote amphibians in agricultural areas and compensate for negative effects of PPP at the population level.

With the help of a literature review and expert surveys, potential RMM were compiled and evaluated in terms of their effectiveness in protecting or promoting amphibians, their feasibility on a farm and their controllability. In particular, existing measures for ecological compensation and PPP risk reduction were evaluated, but changes in agricultural practice were also taken into account. A total of 30 measures would be conceivable in Switzerland. Of these, nine RMM are proposed for practical application, whereby forward-looking and constructive cooperation between agriculture and amphibian conservation is important for their implementation. Some of the measures are already being implemented or promoted, but can be adapted even more specifically for amphibians based on this work. In principle, the effect can be increased by combining measures.

GIS analysis and modeling provided a scientific basis for the selection of locally adapted measures with the greatest effect on amphibian populations. Models for the dynamics of populations and metapopulations of amphibians indicated that measures for the protection of tadpoles and especially juveniles (after metamorphosis) appear to have the greatest protective effect on the population. Regionally, the creation of new breeding sites (with suitable terrestrial habitat) is the most efficient measure. At the local level, small structures in terrestrial habitats or on seasonal migration routes are considered to be effective. Furthermore, we analyzed the use of agricultural landscapes by amphibians on a national scale and show where populations potentially live on agricultural areas with pesticide use. This work provides the basic information on where and when which species and life stages can be best protected and how. RMM should be selected and implemented on a species-specific basis. For example, a field study observed how natterjack toads used arable land as terrestrial habitat, as they prefer open ground. Biodiversity promotion areas with open soils would therefore be a promising enhancement measure to promote natterjack toads.

1.10.P-We072 Evaluating Pesticide-Induced Risks to Amphibians in Agricultural Waters: A Case Study in Arroyo Pergamino, Argentina

***Samuel González López**[1], Natalia Belén Godoy[2], Ana Clara Caprile[2], Diego Cristos[2], Manuel Ortiz Santaliestra[1] and Julie Brodeur[2,3], (1)Instituto de Investigación en Recursos Cinegéticos (IREC) CSIC-UCLM-JCCM, Spain, (2)Instituto Nacional de Tecnología Agropecuaria, Argentina, (3)Consejo Nacional de Investigaciones Científicas y Técnicas (CONICET), Argentina*

The evaluation of the risks that pesticides pose to amphibians has become increasingly important, given the ongoing decline in amphibian populations. This issue is particularly pressing in countries such as Argentina, where agricultural production is predominant and large extensions of land are treated with pesticides many times per year. Amphibians are highly dependent on water bodies, and their ability to avoid pesticide exposure from contaminated water sources is limited due to habitat loss and fragmentation. Here, we evaluate the environmental risk of pesticides for amphibians in Arroyo Pergamino, a medium-sized stream that flows through the heart of the agricultural Pampa Region in Argentina. To do so, comprehensive pesticide residue data obtained from a year-long monitoring study were used. Pesticide data were obtained in four locations along the stream. These values were compared to toxicity data of the substances detected in the water, both for native and non-native amphibian species. When sufficient toxicity data was available, amphibian-specific acute and chronic predicted no effect concentrations (PNEC) were calculated by dividing the Lethal Concentration 50 (LC50 within 96 hours) and No Observed Effect Concentration (NOEC within 21 days) of the most sensitive amphibian species by an assessment factor (AF) of 10. Then, we calculated Risk Quotients (RQ) by dividing measured environmental concentrations of each single substance by their respective PNEC. To determine the risk threshold derived from acute toxicity data, we used the maximum measured concentrations of each site, while for the risk derived from chronic toxicity data, we used concentration means of the residues found in the monitoring studies. We used RQ to rank pesticides based on single substance risk and their contribution to mixture risk. Besides, we aimed to identify native amphibian species potentially vulnerable to pesticides detected in the stream. The result revealed that pesticides detected in Arroyo Pergamino pose a risk to amphibian health. However, the current lack of toxicity data for non-model species presents challenges in providing a definitive assessment across various species and regions. Despite this limitation, the results of this evaluation are expected to serve as a proof-of-concept risk assessment for amphibians inhabiting waters affected by agricultural activities.

1.10.P-We073 Risk assessment screening step for dermal toxicity in terrestrial phase amphibians

***Valentin Mingo**[1] and Lennart Weltje, Prof. Dr.[2], (1)Corteva Agriscience, Germany, (2)Agricultural Solutions - Ecotoxicology, BASF SE, Germany*

Although currently considered covered by surrogate bird and mammal Environmental Risk Assessment (ERA) schemes, concerns for amphibian risk assessment have arisen regarding dermal exposure to pesticides in the terrestrial phase, primarily due to the high permeability of their skin and the lack of a protective layer such as fur or feathers. This, coupled with the uncertainties regarding differences in amphibian toxicity when compared to birds and mammals are currently considered the main hindrances for addressing amphibian-specific risks of plant protection products.

Toxicity data for terrestrial life-stages of amphibians are lacking. While this is true both for acute and chronic toxicity, some acute data are available which can be compared to bird, mammal, or fish data. Based on this information, extrapolation methods have been described with which acute toxicity endpoints (LD_{50}) can be extrapolated for adult (terrestrial) amphibians. Similarly, although considered of high importance, dermal exposure data in amphibians are very scarce and limited to a few compounds. However, exposure can be estimated using toxicokinetic models, which allow to predict body burdens resulting from dermal exposure due to contact with contaminated surfaces, such as soil.

By combining these two methods, a screening assessment for dermal exposure can be described based on already available regulatory data. The goal of such a screening step would be to identify plant protection products of low and high concern for amphibians, in order to prioritize risk assessment efforts. At the same time, extrapolation and modelling approaches will help in reducing unnecessary animal testing and suffering, while allowing risk evaluation despite the lack of amphibian-specific data.

Here, we present a screening approach in which acute risk to amphibians was evaluated for selected pesticides based on the abovementioned toxicity and exposure estimation methods.

1.10.P-We074 Suggestion of Focal Species of Amphibians in the Context of Environmental Risk Assessment of Pesticides in Brazil

Marcelo Augusto Pereira Coelho Dias[1], *André Sartori*[2], *Ester Obrecht Bensadon*[2], *Monica Vasques Mangas Pereira*[2], *Ubirajara Fidelis Da Silva*[2], *Alessandro Ribeiro de Morais*[3], *Marcella Gonçalves Santos*[4], *Rogério Pereira Bastos*[5], *Thiago Pereira Mendes*[6], *Eduardo Alves Almeida*[7], *Suelen Cristina Grott*[7], *Raquel Fernanda Salla Jacob*[8], *Guarino Rinaldi Colli*[4] *and Juliane Silberschmidt Freitas*[9], *(1)Brazilian Institute of Environment and Renewable Natural Resources (IBAMA), Brazil, (2)Instituto Brasileiro do Meio Ambiente e dos Recursos Naturais Renováveis (IBAMA), Brazil, (3)Instituto Federal Goiano - campus Rio Verde, Brazil, (4)Universidade de Brasília, Brazil, (5)Universidade Federal de Goiás, Brazil, (6)Universidade Federal do Pará, Brazil, (7)Fundação Universidade Regional de Blumenau - FURB, Brazil, (8)Universidade Federal de São Carlos (UFSCar), Brazil, (9)Universidade do Estado de Minas Gerais, Brazil*

Amphibians have the highest proportion of threatened species among vertebrates and exposure to pesticides has been identified as one of the potential causes for population declines of several species. This study aimed to identify a potential focal species of amphibians that could be used in the Environmental Risk Assessment (ERA) of pesticides in Brazil. The appraisal was based on (1) exposure potential due to the ecological characteristics of the species and the overlap of their distribution with agropastoral lands and (2) their relative sensitivity to pesticides, compared to fish. For step 1, distribution maps for 1106 amphibian species were constructed. Then, the maps were superimposed with Brazilian maps of agropastoral lands, totaling 805 species possibly occurring in such areas. Later, data was filtered to consider only highly abundant species with no associated taxonomic issues and widely distributed in Brazil – resulting in 76 species. Ecological data were then collected for these species and a Non-metric Multidimensional Scaling was carried out, resulting in 30 possible focal species. For step 2, systematized searches on the USEPA “Ecotox Knowledgebase” database and in Web of Science and Google Scholar platforms were performed for ecotoxicological studies with herbicides on larval stages of amphibians in Brazil. Among the 115 active substances of herbicides registered in the country, only 16 presented LC50 data for native species of amphibians and 17 for model species. LC50 values of the same herbicides were also compiled for model fish species. LC50 for fish and amphibians were then combined to construct Species Sensitivity Distribution (SSDs) curves. Due to data availability, SSDs were constructed for only seven herbicides. Amphibian species showed less sensitivity to acetochlor and ametrine than fish. For atrazine, glyphosate, glyphosate-isopropylamine salt, picloram, and 2,4-D, the species *Physalaemus centralis, P. cuvieri, P. nattereri*, and *P. albonotatus* were more sensitive than the standard fish species *Oncorhynchus mykiss*. The evident sensitivity of *Physalaemus* spp., associated with their occurrence on the focal species list suggested in Step 1 indicates that this genus contains species potentially sensitive to the toxicological effects of pesticides, which could be important vertebrate bioindicators for neotropical areas. This study is a pioneer in indicating a possible focal species for the ERA of pesticides for amphibians in Brazil.

1.10.P-We075 Mass spectrometry imaging of the developing amphibian brain as a tool to discover bioindicators of developmental neurotoxicity.

Rikke Poulsen[1,2], *Helena Petrosova*[1,2], *Emma M Field*[2], *Haley Kuecks-Winger*[2], *Angela M Jackson*[1], *David Goodlett*[1,2] *and Caren C. Helbing*[2], *(1)University of Victoria Genome BC Proteomics Centre, Canada, (2)Department of Biochemistry and Microbiology, University of Victoria, Canada*

Neurodevelopment is highly conserved across animal species and is a vulnerable choreography of events that unfolds to construct highly complex organs. Exposure to neurotoxic substances can lead to failure in proper spatial and temporal organization of neural tissues. Despite this, the current guidelines are insufficient to properly identify chemicals that are toxic for the developing brain.

Amphibians are exceptional alternative model organisms for uncovering neurotoxicity during postembryonic development because the reorganization of a tadpole brain during metamorphosis has direct parallels to the developing human brain during the last trimester and the first weeks of life. Herein we are utilizing a representative of true frogs, the cosmopolitan tadpole model American bullfrog (*Rana [Lithobates] catesbeiana*) and mass spectrometry imaging to discover bioindicators of neurodevelopmental toxicity.Mass spectrometry imaging is a unique technology that adds spatial information to mass spectrometry analysis, allowing mapping of specific biomolecules in the tissue. This is particularly relevant in the brain, where different tissue regions have different functions.

We examined three distinct postembryonic life stages: premetamorphic tadpoles (Gosner stage 31-33), tadpoles at metamorphic climax (Gosner stage 41-44) and froglets (Gosner stage 46). Cryosections of the head, including the olfactory system and brain, were obtained, and analyzed by Matrix-Assisted Laser Desorption/Ionization coupled to a Time-of-Flight mass spectrometer (MALDI-TOF) for non-targeted analysis focussed on lipid metabolites. Brain lipids are of particular interest as they are critical for the health of the brain and its activities such as structural development, neurogenesis and in myelin sheath formation. We found that several lipids varied in their spatial location and relative concentration between the developmental stages. These compounds represent candidates for neurodevelopmental bioindicators and may serve as valuable, quantifiable key events in future identification of chemicals causing developmental neurotoxicity.

1.10.P-We076 Aquatic Risk Assessment of Pesticides in Swiss Habitats of National Importance
Etienne Vermeirssen[1], *Marion Junghans*[1], *Christoph Moschet*[2] *and Lukas Kohli*[3], *(1)Swiss Centre for Applied Ecotoxicology, Switzerland, (2)Inter Cantonal Laboratory, Switzerland, (3)Hintermann & Weber, Switzerland*
In 2017, Switzerland adopted an action plan covering plant protection products (PPP) with one of its aims: a reduction of risks that PPP pose to the aquatic environment. Long-running monitoring programmes provide good data coverage of streams in areas with agricultural and urban land use. However, similar investigations are lacking for PPP in smaller standing waters, particularly those classified by law as habitats of national importance which are often listed as spawning areas for amphibians. In our study, listed habitats were included for preselection based on proximity to agricultural land use using a 2 x 2 km^2 grid. Selected areas were then classified in low, medium and high risk categories based on i.a. the proportion to agricultural land use and their proximity to such land use. Six water bodies, two of each risk category, were sampled in 2020; six further water bodies were sampled in 2021. At each location, grab water samples were taken on a monthly basis for either 6 months in 2020 or 8 months in 2021. Chemical analyses of samples encompassed some 100 compounds, mainly PPP, transformation products, biocides and pharmaceuticals. Observed concentrations were evaluated against chronic and acute water quality criteria provided in the Swiss Water Protection Ordinance (WPO) as well as those available from own research. Results show that in half of the studied water bodies at least one compound exceeded either chronic or acute WPO criteria. When including the wider set of criteria, two further sites showed exceedances. Exceedances were not linked to the site’s risk category. Main drivers for exceedances were pyrethroid insecticides and the maximal exceedance of WPO criteria was 25 fold for cypermethrin. A chronic water quality criterion derived for deltamethrin of 1.7 pg/L (not yet included into the WPO) was exceeded at most sites with a maximum exceedance of ca. 1200 fold. Although populations of amphibians were not specifically monitored for this study, the multiple and partially large exceedances of water quality criteria indicate that effects on aquatic wildlife cannot be excluded. Even if amphibians may not be directly affected by the observed concentrations of monitored compounds, effects on biodiversity or food webs may impact amphibian populations. The observed significant occurrence of PPP in the studied habitats warrants further study by expanding the studied locations and investigating PPP entry pathways to address possible mitigation measures.

1.11 New Approach Methodologies (NAMs) – Robust Predictions for Addressing Regulatory Challenges in the Field of Ecotoxicology

1.11.P-Th064 Machine Learning-based Prediction of Fish Acute Mortality: Implementation, Interpretation, and Regulatory Relevance
Christoph Schuer[1], *Lilian Gasser*[2], *Fernando Perez-Cruz*[2], *Kristin Schirmer*[1] *and Marco Baity-Jesi*[3], *(1)Environmental Toxicology, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (2)Swiss Data Science Center, Switzerland, (3)Siam, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland*
The use of historic data and chemical properties for the prediction of ecotoxicological outcomes has a long tradition within the realm of ecotoxicological research, for the most part in the form of quantitative structure-activity-relationship (QSAR) models. However, recent developments of machine learning (ML) in terms of accessibility, software packages, and computational power have led to them presenting a viable option for the inclusion in predictive ecotoxicology. A significant advantage of these methods lies in their ability to integrate data beyond chemical properties and descriptors, thus enabling researchers to include species-specific and experimental data, expanding their applicability beyond limited species and chemical domains. Our work aims to assess the potential and limitations of applying machine learning to predict ecotoxicological outcomes in fish. After data curation we coupled several state-of-the-art ML regression models with 6 molecular representations and applied this toolbox to a dataset focused on 140 fish species and 1,905 chemicals. The two decision-tree-based models RandomForest and XGBoost performed best and the linear-regression-based LASSO model performed worst. Comparisons of the 6 molecular representations did not yield a definitive winner, even though the best performing combination was the MACCS fingerprint in conjunction with the XGBoost model. Globally, this combination was able to predict the log-transformed LC50 within one order of magnitude, while local model performances varied more widely. Additionally, we performed an analysis of residuals and feature importances. These led to the conclusion that chemical properties influence the model performance the most, while taxonomic features do not consistently show up as important. However, if we train models only based on the most important features, those perform markedly worse than those based on the whole feature space. Following this broad modeling approach, we adapted the workflow towards optimized predictions of single fish species, mimicking the OECD test guideline used for regulatory hazard assessment. By limiting the taxonomic space we achieved better model performances and make the model output transparent and discuss it through the lens of hazard assessment.

1.11.P-Th065 Connecting the Dots: A Bottom-Up Approach to Link Liver Fibrosis with Key Events through Text Mining and Topic Modeling in AOP Development
Achilleas Karakoltzidis, *Ilias Frydas, Spyros Karakitsios and Dennis Sarigiannis, Aristotle University of Thessaloniki, Greece*
A novel methodology for the construction of AOPs is introduced, with liver fibrosis serving as the paradigm. Our approach integrates cutting-edge models for biomedical text mining and employs two distinct techniques for topic modeling, namely LDA and BERTopic. The utilization of two different algorithms enabled a cross-validation between the topics obtained from the two different methods. These techniques enhance the understanding of complex relationships within biological processes, thus providing a systematic and data-driven approach for constructing AOPs. Following a literature review, a set of keywords related to liver fibrosis was initially identified. Instances of the keywords included Cytokines, Ehr, chemokines, among others. Afterwards, a search on PubMed was conducted, collecting all available abstracts. A total of 195748 abstracts were collected.

Afterwards duplicates were removed and the total number of abstracts remaining for analysis was 191029. The abstracts organized in tabular form from. They were tokenized and cleaned by removing stop words and lemmatized. After processing the abstracts, the topic modeling results were organized into a network. This facilitated the identification of nodes and connections between the significant factors associated with liver fibrosis. Examples encompass liver diseases like HVB/C, inflammation, exposure to specific chemicals, oxidative stress, and cellular death, among others. It is worth noting that many literature reports have documented the presence of patients suffering from both liver fibrosis and insulin resistance. The identified topics will enable us to refocus the literature review on specific points, intentionally constructing an AOP. Consequently, the next phase entails acquiring new articles based on keywords identified through topic modeling. The collected publications will undergo two distinct text mining methods: biological entity recognition, and biological entity extraction The goal is the systematic construction of an AOP for liver fibrosis, employing a bottom-up approach. Simultaneously, articles categorized with significant topics relevant to the present study will be included in the subsequent analysis. It is noteworthy that in the ensuing step, after reapplying topic modeling to the newly collected articles and preserving the relevant ones, is to proceed to a comprehensive full text analysis.

1.11.P-Th066 High-Throughput Transcriptome in Zebrafish Embryos towards Adverse Outcome Pathway Network-Based Screening of Environmental Neurotoxicants

Pu Xia[1]*, Yuwei Xie*[2]*, John K. Colbourne*[3]*, Luisa Orsini*[3]*, John Giesy*[1] *and Xiaowei Zhang*[4]*, (1)University of Saskatchewan, Canada, (2)Nanjing Institute of Environmental Sciences, China, (3)School of Biosciences, University of Birmingham, United Kingdom, (4)Nanjing University, China*

The increasing presence of neuroactive chemicals in the environment poses a significant threat to the developing nervous systems of both humans and wildlife. To address this concern, there is an urgent need for new methodologies that are fast, cost-effective, and accurate in testing developmental neurotoxicity. High throughput screening (HTS) approaches have emerged as a potential solution. Current in vitro assays focus on targeted biological pathway responses at the biomolecular level but are limited by known biological endpoints, which account for less than 3% of neurodevelopment-related aspects. In vivo assays, particularly using small animals like zebrafish, offer high-throughput screening of phenotypic profiles but lack the ability to elucidate the molecular mechanisms underlying neurotoxicity.

Omics approaches, such as high-throughput transcriptomics (HTT), provide a genome-scale understanding of biological pathways affected by chemical exposure. However, interpretation of omics responses into apical effects has traditionally relied on expert-based manual explanations. The Adverse Outcome Pathway (AOP) framework offers a promising approach to bridge the gap between molecular-level perturbations and regulatory concerns' apical effects.

This study incorporates zebrafish transcriptomics and behavioral assays to develop an AOP network-based approach for assessing environmental neurotoxicants. Dose-dependent transcriptomics across multiple time points were conducted to identify neurotoxic modes of action for model neurotoxicants at specific developmental stages. The study aims to evaluate the AOP network-based approach's ability to qualitatively identify neurotoxic modes of action and quantitatively derive genomics-based points of departure comparable to behavior-based points of departure. Additionally, the research explores the potential of the AOP network-based approach for screening neurotoxic chemicals using dose-dependent transcriptomics in zebrafish embryos.

1.11.T-01 Commission Roadmap towards Phasing out Animal Testing for Chemical Safety Assessments

Georg Streck*, European Commission - DG GROW, Belgium*

On 25 July 2023, the European Commission published a Communication, with which it committed to develop a roadmap towards ultimately phasing out animal testing for chemical safety assessments. The purpose of this presentation is to provide an overview of the process of the development of the roadmap and to outline possibilities for stakeholders from the research community, industry and non-governmental organisations to provide input to the work.

The European Union has a long-standing policy that aims to phase out all animal use for research and for regulatory purposes in the EU, if and whenever it is scietifically possible. In the last years, the question of how to reach this ultimate goal has gained more and more political attention, e.g. as evidenced by a resolution of the European Parliament. Notwithstanding the progress made in developing non-animal methods, an answer to the question has not yet been found and animal testing is still needed, e.g. to assess chemicals for complex toxicities. The roadmap has the purpose to outlilne the path towards phasing out animal testing for chemical safety assessments.

The cornerstone of the roadmap is a plan outlining of how to phase out animal testing for each area of concern (toxicity, (eco-)toxicological endpoint), starting with a gap analysis. For some areas of concern, short-term solutions are available (e.g. fish acute toxicity, bioaccumulation), while for others long-term action points might be necessary to define data requirements in legislation differently so that non-animal methods can be used to fulfil the ultimate regulatory goal of protecting human health and the environment.

The roadmap will also seek for solutions of how to accelerate the validation of methods. In addition, there is a need to speed up the regulatory acceptance of methods. In this context, the Commission is analysing the need and feasibility of an expert scientific committee to provide advice on the development and regulatory application of non-animal methods. This analysis goes along with analyising the strengths and weaknesses of the current landscape of advisory bodies on non-animal methods.

An exchange in paticular with the scientific community is vital for developing the roadmap. The presentation will therefore outline how stakeholders can get involved in the shaping the path towards phasing out animal testing for chemical safety assessments.

1.11.T-02 Building an alternative fish to improve current environmental risk assessment schemes for chemicals
Kristin Schirmer[1]*, Ksenia J Groh, PhD*[2]*, Melanie Fischer*[2]*, Jarno Hoekman*[3]*, Stephan Fischer*[4]*, Roman Li*[5]*, Bernhard Truffer*[6]*, Colette vom Berg*[7] *and Anže Županič*[8]*, (1)Environmental Toxicology, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (2)Eawag - Swiss Federal Institute of Aquatic Science and Technology, Switzerland, (3)Utrecht University, Netherlands, (4)aQuaTox-Solutions GmbH, Switzerland, (5)aQuaTox-Solutions/Eawag, Switzerland, (6)Eawag/Utrecht University, (7)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (8)National Institute of Biology, Slovenia*
Because of their importance in aquatic ecosystems and as human food source, fish receive great attention in the environmental risk assessment of chemicals. However, current animal-centric testing paradigms cannot keep pace with the demands of chemical safety assessment and the societal desire to reduce or replace animal testing. It is, therefore, our vision to build an alternative fish: a modular assemblage of fish cell line-based assays, alone or combined with computational models. Such an alternative fish represents a new method that promises to overcome some of the limitations of the traditional testing approach and holds tremendous opportunity for industrial innovation. Yet, validation of the new approaches takes years and uptake is slow. We, therefore, argue that regulatory routines and procedures, as well as industrial innovation practices, need to be considered in the design of such alternative approaches to accelerate their acceptance and implementation into practice.

Pursuing this vision, we have demonstrated that it is possible to use a rainbow trout (*Oncorhynchus mykiss*) cell line to predict the impact of chemicals on two *in vivo* apical endpoints: short-term survival and growth. Short-term survival is predicted using the RTgill-W1 cell line assay, which as reached global acceptance as ISO standard 21115 and OECD Test Guideline 249; it hence comprises the first complete module of our envisioned alternative fish. Prediction of reduced fish growth measures cell proliferation as a proxy for fish cell number/weight. We further expand these concepts to modules for neuro- and reproductive toxicity, and to subcellular markers with a documented link to adverse outcomes in fish, and have implemented an array of computational models to extrapolate cell line-derived information to predict *in vivo* outcomes.

We propose to co-develop the alternative fish platform with the relevant stakeholders from the start by applying a socio-technical perspective. The goal is to create a common understanding of the challenges and opportunities and to identify the needs and capabilities of different stakeholders to accelerate uptake.

Using the alternative fish framework as a test case, we aspire to initiate a paradigm shift in the socio-technical testing regime from single animal replacement options and assay-by-assay validation to a flexible framework that enables a more rapid transition towards the replacement and reduction of animals in environmental risk assessment.

1.11.T-03 Integration of Endocrine Modalities into an Existing Mechanism of Action-based In Silico Scheme for use in Environmental Risk Assessment
James Firman[1]*, Franklin Bauer, PhD*[2]*, Geoffrey Hodges*[3]*, Gaspard Levet*[2]*, Bruno Campos*[3]*, Jayne Roberts*[3]*, Steve Gutsell*[3]*, Homa Basiri*[1]*, Paul Thomas*[2] *and Mark Cronin*[1]*, (1)Liverpool John Moores University, United Kingdom, (2)KREATiS SAS, France, (3)Unilever - Safety and Environmental Assurance Centre (SEAC), United Kingdom*
The adoption of *in silico* methodologies for the inference of toxic potential has been advanced as a means through which challenges associated with data scarcity, as relates to chemical risk assessment within the environmental context, might be addressed. Previously, we have reported upon the development of mechanism of action-centred, structural alert-based profiling/classification schemes (MechoA and Sapounidou-Firman), facilitating the assignment of likely mechanisms of toxic action in a variety of taxa. However, it is recognised currently that there is a paucity of alerts permitting the identification of substances which may be considered to act specifically upon the endocrine system.

As such, we have sought to expand the scope of these tools so that they might integrate alerts covering many further endocrine-associated pathways. An account of progress to-date is presented – incorporating description of processes behind the preliminary identification of molecular initiating event (MIE) targets, and the subsequent organisation and placement of these within the existing scheme. To this end, a tiered system of classification was adopted, grouping MIEs in accordance with shared downstream key events. More than 25 sites of action have been identified as forming suitable candidates for inclusion. These range from key hormone binding receptors (e.g., androgen, thyroid), to enzymes essential within hormone synthesis (e.g., 5α-reductase, thyroperoxidase), to proteins mediating hormone distribution (e.g., transthyretin). Represented within this number are pathways relevant in mammalian, fish and arthropod species.

With reference to selected MIE targets, we further illustrate application of workflows assisting the derivation of the novel structural alerts. Incorporated within are stages spanning both the sourcing of appropriate data, and the subsequent identification of key chemical features selectively associated with activity.

1.11.T-04 Predicting Aquatic Toxicity of Surfactants Using Simulated Coarse-Grained Membrane-Water Coefficient Derived QSARs

Andrea Gredelj[1,2], *Jayne Roberts*[1], *Elin Barrett*[3], *Eoin Kearney*[4], *Nicola Haywood*[1], *Mark Miller*[4] *and Geoffrey Hodges*[1], *(1)Unilever - Safety and Environmental Assurance Centre (SEAC), United Kingdom, (2)Norwegian Geotechnical Institute (NGI), Norway, (3)Safety and Environmental Assurance Centre, Unilever Research, United Kingdom, (4)Department of Chemistry, Durham University, United Kingdom*

Recent developments in regulatory landscapes have been encouraging a shift away from generating *in vivo* data towards the use of *in vitro* and *in silico* approaches to support New Approach Methodologies (NAM) based non-animal alternatives. Quantitative Structure-Activity Relationships (QSAR) models are well-established within regulatory guidelines as a means for predicting (eco)toxicity endpoints. The octanol-water partitioning coefficient (K_{ow}) is commonly applied as a predictor variable for (eco)toxicity, but its applicability for surfactants has been criticised based on experimental challenges in its determination and the lack of biological relevance. The membrane-water distribution coefficient (D_{mw}) has been demonstrated previously as a potentially suitable alternative for surfactants, with established experimental methods appropriate for surfactants (and ionisable chemicals) as well as its applicability as a bioaccumulation proxy.

Here, the application of D_{mw} in building QSARs for predicting (eco)toxicity of fish and *Daphnia* species will be demonstrated for the group of hydrocarbon- and perfluorocarbon-based anionic surfactants. D_{mw} values were generated by the coarse-grained simulation method, which was successfully developed further for both of these surfactant groups. These predicted values were compared with existing and newly generated experimental D_{mw}s, demonstrating a good fit for anionic surfactants with different functional groups and backbones.

While developed QSARs have high relevance for use in Environmental Risk Assessment (ERA) in both regulatory and non-regulatory applications, the new simulation method and its validation for these and other ionisable chemical groups provides another *in silico* approach that will make D_{mw} predictions more reliable and readily available.

Furthermore, to our knowledge, those are the first QSARs that incorporate different anionic surfactant groups into a single QSAR and the first (eco)toxicity QSAR derived for different (legacy and novel) perfluorinated surfactants that are based on membrane-water partitioning as an (eco)toxicity proxy. This work also presents a step forward towards increasing the application of *in silico* NAMs for surfactants which are in general high tonnage, high usage types of chemicals and commonly registered under REACH.

1.11.P New Approach Methodologies (NAMs) – Robust Predictions for Addressing Regulatory Challenges in the Field of Ecotoxicology

1.11.P-Th064 Machine Learning-based Prediction of Fish Acute Mortality: Implementation, Interpretation, and Regulatory Relevance

Christoph Schuer[1], *Lilian Gasser*[2], *Fernando Perez-Cruz*[2], *Kristin Schirmer*[1] *and Marco Baity-Jesi*[3], *(1)Environmental Toxicology, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (2)Swiss Data Science Center, Switzerland, (3)Siam, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland*

The use of historic data and chemical properties for the prediction of ecotoxicological outcomes has a long tradition within the realm of ecotoxicological research, for the most part in the form of quantitative structure-activity-relationship (QSAR) models. However, recent developments of machine learning (ML) in terms of accessibility, software packages, and computational power have led to them presenting a viable option for the inclusion in predictive ecotoxicology. A significant advantage of these methods lies in their ability to integrate data beyond chemical properties and descriptors, thus enabling researchers to include species-specific and experimental data, expanding their applicability beyond limited species and chemical domains. Our work aims to assess the potential and limitations of applying machine learning to predict ecotoxicological outcomes in fish. After data curation we coupled several state-of-the-art ML regression models with 6 molecular representations and applied this toolbox to a dataset focused on 140 fish species and 1,905 chemicals. The two decision-tree-based models RandomForest and XGBoost performed best and the linear-regression-based LASSO model performed worst. Comparisons of the 6 molecular representations did not yield a definitive winner, even though the best performing combination was the MACCS fingerprint in conjunction with the XGBoost model. Globally, this combination was able to predict the log-transformed LC50 within one order of magnitude, while local model performances varied more widely. Additionally, we performed an analysis of residuals and feature importances. These led to the conclusion that chemical properties influence the model performance the most, while taxonomic features do not consistently show up as important. However, if we train models only based on the most important features, those perform markedly worse than those based on the whole feature space. Following this broad modeling approach, we adapted the workflow towards optimized predictions of single fish species, mimicking the OECD test guideline used for regulatory hazard assessment. By limiting the taxonomic space we achieved better model performances and make the model output transparent and discuss it through the lens of hazard assessment.

1.11.P-Th065 Connecting the Dots: A Bottom-Up Approach to Link Liver Fibrosis with Key Events through Text Mining and Topic Modeling in AOP Development

Achilleas Karakoltzidis, *Ilias Frydas, Spyros Karakitsios and Dennis Sarigiannis, Aristotle University of Thessaloniki, Greece*

A novel methodology for the construction of AOPs is introduced, with liver fibrosis serving as the paradigm. Our approach integrates cutting-edge models for biomedical text mining and employs two distinct techniques for topic modeling, namely LDA and BERTopic. The utilization of two different algorithms enabled a cross-validation between the topics obtained from the two different methods. These techniques enhance the understanding of complex relationships within biological processes, thus providing a systematic and data-driven approach for constructing AOPs. Following a literature review, a set of keywords related to liver fibrosis was initially identified. Instances of the keywords included Cytokines, Ehr, chemokines, among others. Afterwards, a search on PubMed was conducted, collecting all available abstracts. A total of 195748 abstracts were collected. Afterwards duplicates were removed and the total number of abstracts remaining for analysis was 191029. The abstracts organized in tabular form from. They were tokenized and cleaned by removing stop words and lemmatized. After processing the abstracts, the topic modeling results were organized into a network. This facilitated the identification of nodes and connections between the significant factors associated with liver fibrosis. Examples encompass liver diseases like HVB/C, inflammation, exposure to specific chemicals, oxidative stress, and cellular death, among others. It is worth noting that many literature reports have documented the presence of patients suffering from both liver fibrosis and insulin resistance. The identified topics will enable us to refocus the literature review on specific points, intentionally constructing an AOP. Consequently, the next phase entails acquiring new articles based on keywords identified through topic modeling. The collected publications will undergo two distinct text mining methods: biological entity recognition, and biological entity extraction The goal is the systematic construction of an AOP for liver fibrosis, employing a bottom-up approach. Simultaneously, articles categorized with significant topics relevant to the present study will be included in the subsequent analysis. It is noteworthy that in the ensuing step, after reapplying topic modeling to the newly collected articles and preserving the relevant ones, is to proceed to a comprehensive full text analysis.

1.11.P-Th066 High-Throughput Transcriptome in Zebrafish Embryos towards Adverse Outcome Pathway Network-Based Screening of Environmental Neurotoxicants

Pu Xia[1], *Yuwei Xie*[2], *John K. Colbourne*[3], *Luisa Orsini*[3], *John Giesy*[1] *and Xiaowei Zhang*[4], *(1)University of Saskatchewan, Canada, (2)Nanjing Institute of Environmental Sciences, China, (3)School of Biosciences, University of Birmingham, United Kingdom, (4)Nanjing University, China*

The increasing presence of neuroactive chemicals in the environment poses a significant threat to the developing nervous systems of both humans and wildlife. To address this concern, there is an urgent need for new methodologies that are fast, cost-effective, and accurate in testing developmental neurotoxicity. High throughput screening (HTS) approaches have emerged as a potential solution. Current in vitro assays focus on targeted biological pathway responses at the biomolecular level but are limited by known biological endpoints, which account for less than 3% of neurodevelopment-related aspects. In vivo assays, particularly using small animals like zebrafish, offer high-throughput screening of phenotypic profiles but lack the ability to elucidate the molecular mechanisms underlying neurotoxicity.

Omics approaches, such as high-throughput transcriptomics (HTT), provide a genome-scale understanding of biological pathways affected by chemical exposure. However, interpretation of omics responses into apical effects has traditionally relied on expert-based manual explanations. The Adverse Outcome Pathway (AOP) framework offers a promising approach to bridge the gap between molecular-level perturbations and regulatory concerns' apical effects.

This study incorporates zebrafish transcriptomics and behavioral assays to develop an AOP network-based approach for assessing environmental neurotoxicants. Dose-dependent transcriptomics across multiple time points were conducted to identify neurotoxic modes of action for model neurotoxicants at specific developmental stages. The study aims to evaluate the AOP network-based approach's ability to qualitatively identify neurotoxic modes of action and quantitatively derive genomics-based points of departure comparable to behavior-based points of departure. Additionally, the research explores the potential of the AOP network-based approach for screening neurotoxic chemicals using dose-dependent transcriptomics in zebrafish embryos.

1.11.P-Th067 Addressing the challenges of Acute Toxicity Hazard Classification using a non-animal Defined Approach

Donna S. Macmillan[1], *Pravin Ambure*[2], *Yannick Bayona*[3], *Vera Bonderovic*[4], *James Dawick*[5], *Nicolas Fabre*[3], *Stephan Fischer*[6], *Geoffrey Hodges*[7], *Ágata Llobet Mut*[2], *Sophie Loisel-Joubert*[3], ***Jayne Roberts***[7], *Eva Serrano Candelas*[2], *Blanca Serrano*[8], *Claudia Rivetti*[7], *Kristin Schirmer*[9] *and Ricky Stackhouse*[10], *(1)HSI, (2)ProtoQSAR, Spain, (3)L'Oreal Research & Innovation, France, (4)BioRevivo, (5)Innospec Limited, United Kingdom, (6)aQuaTox-Solutions GmbH, Switzerland, (7)Unilever - Safety and Environmental Assurance Centre (SEAC), United Kingdom, (8)ECETOC, Belgium, (9)Environmental Toxicology, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (10)Sasol*

The current regulatory landscape for assessing chemical safety is driven by a historic requirement for *in vivo* testing. Specifically, current regulatory frameworks for classification and labelling (C&L) and Persistence, Bioaccumulation and Toxicity (PBT) and very Persistent, very Bioaccumulative (vPvB), drive the need for aquatic toxicity studies involving fish, amphibians (for endocrine properties), birds (for pesticides) and mammals. However, this is incongruous with the current societal and ethical shift towards non-animal testing. In response to this circumstance, there are increasing signs of change in some regulatory landscapes such as REACH. For example, there have been significant efforts in recent years to reduce or eliminate the number of vertebrates, such as fish, in regulatory assessments, by applying the 3Rs. Notably, there has been progress in opportunities to replace some *in vivo* tests with *in vitro* assays, such as RTgill-W1 (OECD TG 249) assay, or developing read-across, weight of evidence (WoE) and Integrated Approaches to Testing and Assessment (IATA) approaches to support chemical registration. However, to date there is no clear agreement on how to move these opportunities towards the greater use of non-animal New Approach Methodologies (NAMs) so that they could be fully integrated into regulatory frameworks such as EU Classification, Labelling and Packaging (CLP) and United Nations Globally Harmonized System of Classification and Labelling (UN GHS) frameworks.

Here we present a modular score-based *in silico* defined approach, which could be used to address the current requirements for *in vivo* acute aquatic toxicity under the CLP and UN GHS frameworks. The approach was developed using a curated, high-quality, literature based/publicly sourced dataset of existing *in vivo* and *in vitro* data, Mode of Action (MoA) assessment and predictions from several different *in silico* models to predict classifications of acute aquatic toxicity. Several case studies are presented which incorporate the defined approach prediction, physicochemical parameters and existing data to support the classification in a WoE.

1.11.P-Th068 Development of an Ontology-Driven In Silico Profiler for the Evaluation of Potential Endocrine Disruptors

Mark Cronin[1]*, Homa Basiri*[1]*, Franklin Bauer, PhD*[2]*, Bruno Campos*[3]*, James Firman*[4]*, Steve Gutsell*[3]*, Geoffrey Hodges*[3]*, Gaspard Levet*[2]*, Jayne Roberts*[3] *and Paul Thomas*[2]*, (1)Liverpool John Moores University, United Kingdom, (2)KREATiS SAS, France, (3)Unilever - Safety and Environmental Assurance Centre (SEAC), United Kingdom, (4)School of Pharmacy and Biomolecular Sciences, Liverpool John Moores University, United Kingdom*

The identification of xenobiotics with potential to cause endocrine disruption is a process likely to draw heavily upon the use of new approach methodologies (NAMs). *In silico*, or computational, NAMs will be applied early in any screening process. This investigation describes the development of an *in silico* screening tool based upon known mechanisms of endocrine disruption. Specifically, we present here a novel ontology for endocrine disruption, categorising more than 25 molecular initiating events (MIEs), was used as its foundation. The ontology builds upon previous work categorising acute mechanisms of ecotoxicity, and allows for association of MIEs with species-specific adverse outcomes within well-defined chemical domains. To develop the profiler, data relating to the MIE were retrieved from publicly available resources such as Tox21 and ChEMBL. The data were curated and allocated in line with specific outcomes such as agonism, antagonism and inhibition. Chemical descriptors and properties were calculated, along with ToxPrint fingerprints. Subsequently, data were subject to chemoinfomatic analysis using machine learning techniques, enabling groups of similar molecules to be identified. Approaches adopted included hierarchical clustering (based upon shared structural features) and the extraction of Murcko scaffolds. Collections of the grouped substances related directly to MIEs were considered to form the starting points for structural alert development. Each cluster and scaffold-sharing group is described fully in terms of the nature and type of data from which it is derived, the aspects of the applicability domain (such as the range of physico-chemical properties and types of molecular substituents) associated with it, and the overall confidence score (representing the numbers and quality of active data) which may be attributed. The *in silico* profiler will be made publicly available in the form of a computational workflow, the application of which will serve as a first-pass rapid screening tool to highlight possibility of compounds being associated with endocrine disruption MIEs. This could form the basis of a testing strategy, for instance informing the use of *in vitro* NAMs, or else may facilitate other *in silico* approaches such as read-across.

1.11.P-Th069 MechoA+: use, versatility and structural diversity

Gaspard Levet[1]*, Franklin Bauer, PhD*[1]*, James Firman*[2]*, Bruno Campos*[3]*, Steve Gutsell*[3]*, Jayne Roberts*[3]*, Mark A. Bonnell*[4]*,* ***Paul Thomas***[1]*, Mark Cronin*[2] *and Geoffrey Hodges*[3]*, (1)KREATiS SAS, France, (2)Liverpool John Moores University, United Kingdom, (3)Unilever - Safety and Environmental Assurance Centre (SEAC), United Kingdom, (4)Department of Environment and Climate Change, Canada*

In silico and computational approaches offer an efficient option for supporting safety decision making of chemicals. Mode and/or Mechanism of Action (MoA/ MechoA) profilers linked to robust quantitative structure-activity relationships (QSARs) and quantitative structure-property relationships (QSPR), provide valuable opportunities to reduce the need for in vivo studies. Last year one such tool, **MechoA+** was introduced and **MechoA Premium** (based on MechoA+ but with further additions and refinements) was implemented in iSafeRat® Desktop. This tool is a structure activity relationship (SAR) model developed to detect the molecular initiating events (**MIE**), the first step in the adverse outcome pathway by which substances induce adverse effects and some subsequent key events for a wide domain of species. Knowledge of the mechanisms is key to understand, predict and limit the impact of chemicals on humans and ecosystems. When entering the SMILES of substances in the tool, it detects if the substance potentially has a structural pattern known to be related to a given hazardous MIE and species. Using this knowledge, this SAR model has shown to have very versatile uses from product development stages to final steps of substances registrations. As such, it can:

- Raise alerts for undesired toxic mechanisms during the product development stage;
- Ensure mechanistic similarity in Read-Across approaches to fill regulatory dossiers data gaps;
- Select appropriate QSAR models to reliably predict (eco)toxicological outcomes;
- Rationalise toxicological effects observed in experiments.

Case studies of the use of MechoA+ in one or the other of these cases will be presented in the poster, e.g. Read-Across study, uses of the batch mode for Safe & Sustainable by Design (SSbD) process.

In this presentation, the structural applicability domain of the scheme will be challenged with a large variety of organic chemicals (e.g. common organics, biocides, plant protection products and pharmaceuticals) to demonstrate how much MechoA+ can cover. The results obtained will be presented.

1.11.P-Th070 How Well QSAR(s) Predict Aquatic Toxicity of REACH Registered Substances?

Lale Carstensen, Tatiana Netzeva, Doris Hirmann, Romanas Cesnaitis and ***Anna-Maija Nyman****, European Chemicals Agency (ECHA), Finland*

Information on aquatic toxicity is required under REACH Annex VII, Section 9.1.1 (Short-term toxicity testing on aquatic invertebrates) and 9.1.2 (Growth inhibition study on aquatic plants), Annex VIII, Section 9.1.3 (Short-term toxicity testing on fish), Annex IX, Sections 9.1.5 and 9.1.6 (Long-term toxicity testing on aquatic invertebrates and fish) [1]. All these standard information requirements can be adapted by a reliable and relevant QSAR adaptation (Annex XI, Section 1.3). The computational methods such as QSARs may not always carry information on all the effects measured in a e.g. OECD TG 210 study (hatching and survival, abnormal appearance, abnormal behaviour, weight, length). The purpose of this study was to assess if the use of QSARs would estimate hazards differently to standard experimental studies and whether any differences would affect regulatory decision-making. We collected aquatic toxicity data which were conducted after a Compliance Check (CCH) and Testing Proposal (TP) processes, and was accepted as being reliable in these processes. We predicted aquatic toxicity (EC50, EC10/NOEC) by QSAR models ECOSAR and VEGA for the substances for which new data was received. The experimental values were compared to the modelled predictions. At the end, we checked if there are substances that are predicted better or worse than the average. Moreover, we assessed if any deviation between experimental data and prediction would bring any effect in regulatory risk management by exceeding the specific thresholds (e.g., CLP classification criteria [2]). Initial results show that the predictions are in line with experimental data for some substances but for some, the prediction may differ significantly from the experimental effect concentrations. For some substances the differences between prediction and experimental data may also have an impact on regulatory risk management.

1.11.P-Th071 Predicting species sensitivities to corticosteroids

Fernando Calahorro Nunez Dr[1]*, Matloob Khushi Dr*[2] *and Nicolas Bury*[1]*, (1)Ocean and Earth Science, University of Southampton, United Kingdom, (2)College of Engineering, Design and Physical Sciences, University of Brunel, United Kingdom*

Both biodiversity loss and concentrations of novel entities have exceeded planetary boundaries for future human generations to thrive. A key goal for humanity is to establish the link between these two –planetary boundaries and identify those chemicals of greatest concern and the species most vulnerable to reduce the impact on biota. This is a daunting task with a reported 350,000 synthetic chemicals produced globally and billions of existing species. However, the advancement in High Performance Computing (HPC) capacity, accessibility of genome and chemical databases and performance of high throughput in vitro screenings, offers an opportunity to discriminate differences at species level in molecular initiating events (MIE) leading to adverse outcomes. We have used the fish corticosteroid system as an exemplar of such an approach. We have shown that using protein structure prediction tools such as AlphaFold, and ligand binding docking programmes such as Kdeep, there are distinct difference in the predicted binding affinities (pKd) and Gibb free-energy of ligand binding (deltaG) between glucocorticoid receptor 1 and 2 and the mineralocorticoid receptor from over 50 species in response to both natural and synthetic corticosteroids. Furthermore, using an in vitro transactivation assay we have demonstrated that the EC50 values for gene transactivation correlates to the predicted pKd and deltaG values providing support to the use of computational methods as predictive tools for species sensitivities to environmental corticosteroids.

1.11.P-Th072 Can Fish Toxicity Data Reliably Predict Toxicity to Aquatic Stages of Amphibia – Re-evaluation of a Dataset by Formulation

Heino Christl[1]*, Eva Gryglewicz*[1] *and Anja Russ*[2]*, (1)Tier3 Solutions GmbH, Germany, (2)tier3 solutions GmbH, Leverkusen, Germany*

A future risk assessment for amphibia will have to cover acute and chronic risk to aquatic and terrestrial stages. There are publications indicating that fish and tadpoles react similar to toxicants, but also papers claiming that amphibia might be more sensitive than fish. Toxic endpoints of both organism groups are listed in Appendix K of the supporting EFSA document (Ortiz-Santaliestra et al. 2017). Based on this dataset, the EFSA Panel proposed to apply an additional assessment factor (AF) of "at least 100" if acute fish-endpoints were used as a surrogate for acute amphibia endpoints. The dataset in Appendix K can however be improved, if matching fish endpoints (of the very formulation used in the amphibian test) are paired. These acute fish endpoints are available for virtually every formulation as a fish LC50 is a core data requirement. When updating the database accordingly, only few cases remained with fish less sensitive than amphibia, none by a large margin, and only these would justify a high additional AF to bridge between fish and amphibian LC50-endpoints. If an additional AF of 100 were included in any future Guidance Document on top of the AF of 100 for acute fish endpoints, amphibian endpoints would have to be a factor of 10000 higher than the matching PEC. This would result in a very conservative risk assessment, so trigger many additional experiments with amphibia. Contradicting current efforts to reduce animal testing, EFSA even proposed to generate more experimental data with amphibia, until there was more evidence available. However, based on the revision of the existing data by formulation we conclude that there is already extensive evidence, indicating that acute risk to amphibians can be reliably predicted from fish endpoints, and hence additional acute animal tests are considered dispensable. An additional assessment factor of 100 to bridge between fish and aquatic amphibia stages should not be needed either. The data situation is similar to the one between cold-water- and warm-water-fish, the latter are no longer tested, as generally - though not always – less sensitive than cold-water fish, and no additional assessment factor was introduced for them. Also aquatic amphibia are generally less sensitive than (cold-water) fish, so no regular testing should be needed, neither an additional assessment factor.

1.11.P-Th073 In vitro effects of plastic additives and their mixtures with pharmaceuticals on fish liver cell line
María del Mar García Pimentel[1]*, Michela Panni*[2]*, Matteo Vitale*[3]*, Juan Antonio Campillo*[1]*, Victor M. León*[1] *and Daniela Maria Pampanin*[3]*, (1)Institute of Oceanography, Spanish National Research Council (IEO-CSIC), Spain, (2)Polytechnic University of Marche (UNIVPM), Italy, (3)Chemistry, Bioscience and Environmental Engineering, University of Stavanger, Norway*
Wastewater treatment plants (WWTPs) effluents have been identified as a major route for release a large variety of contaminants into waterbodies particularly contaminants of emerging concern such as pharmaceuticals (PhACs) and microplastics (MPs). MPs in the marine environment can provoke direct physical effects, and act as dispersal vector for plastic additives, such as UV-filters or antimicrobians, that can be leached to the surrounding environment during physical disintegration processes., It can induce adverse biological effects, including synergistic or antagonistic interactions that may occur when organisms are exposed to mixtures of compounds with different modes of action. The main interaction between chemicals and organisms takes place at cellular levels, therefore cell systems are used as suitable early tools for detection of chemical exposure and toxicity.

Considering the key role of the liver in detoxification mechanisms, fish hepatocytes are often chosen as in vitro model systems. The use of permanent cell lines have several advantages over the use of animals in vivo exposure, such as their easy culture, availability and reproducibility. One well established permanent fish cell line is PLHC-1, derived from topminnow (*Poeciliopsis lucida*) hepatocellular carcinoma, which have been successfully used to assess the cytotoxicity, genotoxicity and oxidative stress of xenobiotics.

The present work developed in PHARMASEA project aimed to assess cytotoxicity and ability to counteract oxidative stress (through reactive oxygen species (ROS) and mitochondrial membrane potential (MMP) assays) in fish liver cells exposed to 4 plastics additives from different nature (octocrylene, triclosan-TCS, bisphenol S-BPS and acetyl tributyl citrate-ACETYL) and their mixtures with citalopram, bezafibrate and carazolol at environmentally relevant concentrations. In addition, the wound healing assay was carried out to observe cells ability to growth and migrate until new cell-to-cell contacts are established.

The results obtained showed that none of treatment affected the wound healing. The differents PhACs-ACETYL and PhACs–BPS mixtures had sinergistic behaviour respect to individual compounds, while PhACs–TCS mixtures had antagonics behaviour respect to individual compounds. The decrease of MMP in the single and mixtures at low concentrations, supported the hypothesis that there was an environmental risk due to their presence in the possible mixtures.

1.11.P-Th074 In vitro effects of pharmaceuticals at environmental relevant concentrations on fish liver cell line
María del Mar García Pimentel[1]*, Michela Panni*[2]*, Matteo Vitale*[3]*, Juan Antonio Campillo*[1]*, Victor M. León*[1] *and Daniela Maria Pampanin*[3]*, (1)Institute of Oceanography, Spanish National Research Council (IEO-CSIC), Spain, (2)Polytechnic University of Marche (UNIVPM), Italy, (3)Chemistry, Bioscience and Environmental Engineering, University of Stavanger, Norway*
Pharmaceuticals (PhACs) have been quantified in marine environmental matrices at low concentrations (ng/L) and their occurrence in marine organisms raises concerns about harmful effects. Chemical analyses should always be combined with biological measurements in order to evaluate environmental risks. Therefore, it is very important to evaluate both PhAC bioavailability, as well as possible biological adverse effects, including synergistic or antagonistic interactions that may occur when organisms are exposed to mixtures of compounds. The main interaction between chemicals and organisms takes place at cellular levels, therefore cell systems are used as suitable early tools for detection of chemical exposure and toxicity.

Considering the key role of the liver in detoxification mechanisms, fish hepatocytes are often chosen as *in vitro* model systems. The use of permanent cell lines have several advantages over the use of animals in *in vivo* exposure, such as their easy culture, availability and reproducibility. One well established permanent fish cell line is PLHC-1, derived from topminnow (*Poeciliopsis lucida*) hepatocellular carcinoma. PLHC-1 liver cells have been successfully used to assess the cytotoxicity, genotoxicity and oxidative stress of xenobiotics.

The present work developed in PHARMASEA project aimed to assess cytotoxicity and ability to counteract oxidative stress (through reactive oxygen species (ROS) and mitochondrial membrane potential (MMP) assays) in fish liver cells exposed to the antidepressant citalopram, the lipid regulator bezafibrate, and the cardiovascular drug carazolol, and their mixtures at environmentally relevant concentrations. In addition, the wound healing assay was carried out to observe cells ability to growth and migrate until new cell-to-cell contacts are established.

The results showed that none of treatment affected the wound healing. As single compound exposure, carazolol didn't provide significantly different results compared to the control in the selected assays. Bezafibrate and citalopram induced the ROS production at low doses. Citalopram was the PhAC that most affected the normal functioning of cells. The different PhACs mixtures intensified the responses at lower concentrations. However, there were no diferences in the responses obtained between tested concentrations in the mixtures. The decrease of MMP in the tertiary mix suggest that there is an environmental risk of PhACs due to their presence as mixtures.

1.11.P-Th075 Quantitative Adverse Outcome Pathway Assisted Formulation of Integrated In vitro Testing Strategies for Identification of Mitochondrial Uncouplers

***Maria T. Hultman*[1]*, Yang Cao[2], Xueqi Fan[3], Prem Chand[4], Jan Thomas Rundberget[1], Maria Christou[1], Hongling Liu[5] and You Song, PhD[1], (1)Norwegian Institute for Water Research (NIVA), Norway, (2)Clinical Epidemiology and Biostatistics, Orebro University, Sweden, (3)School of Environment, Tsinghua University, China, (4)Ecotoxicology and risk assessment, Norwegian Institute for Water Research (NIVA), Norway, (5)Department of Environmental Sciences, Nanjing University, China*

There is an urgent demand for cost-effective new approach methodologies (NAMs) that fully align with the 3R principles (Replacement, Reduction, and Refinement), crucial for advancing current chemical risk assessment and regulatory processes. This case study aligns the AOP concept with the 3Rs, employing NAMs alongside a quantitative AOP network (qAOPN) to assess environmentally relevant uncouplers. Given the diverse impact of chemicals on mitochondrial functions, uncoupling of oxidative phosphorylation (OXPHOS) is a common mode of action for mitochondria toxicants, raising regulatory concerns such as growth inhibition and reproductive failure. This study demonstrates how integrating NAMs with qAOPN enhances the testing strategy, improving the cost-efficient hazard assessment of mitochondrial uncouplers. A qAOPN, using piecewise structural equation modeling (PSEM), was developed by quantifying key events (KEs) temporally in the zebrafish liver (ZF-L) cell-line. *In vitro* data, guided by AOP #263 & 264, utilized the model uncoupler carbonyl cyanide m-chlorophenyl hydrazone (CCCP). Validation involved a 96-hour fish embryo test and a 28-day fish early life stage test using zebrafish with overlapping CCCP concentrations. Measured KEs included OXPHOS, ATP level, cell death (metabolic activity, cell membrane integrity), and cell proliferation (CP). ZF-L was subsequently exposed to five environmentally relevant uncouplers (Perfluorooctanesulfonamide (PFOSA); 2,4-dinitrophenol (2,4-DNP); 2-(tert-butyl)-4,6-dinitrophenol (DTB); Chlorfenapyr (CFP) and Triclosan (TCC)) at 1×10-3 - 3×10-7 M. Temporal and concentration-dependent responses of ZF-L cells to CCCP were observed for KEs. Direct *in vitro* to *in vivo* comparison was challenging due to differing effect concentration by over one order of magnitude. PSEM generated 105 models, the most suitable testing strategy was ranked No. 1 and reported temporally regulated KE: OXPHOS 2h, ATP 6h, CP 24h, and Cell death at 24h, exhibiting strong predictability. Using this strategy, the study assessed the five uncouplers, revealing decreased mitochondrial potential, ATP, cell proliferation, and viability. The data will challenge the CCCP-based qAOP model, evaluating its predictive power for later KEs (CP and cell death) with environmental uncouplers. The study highlights the effective combination of (q)AOP and *in vitro* NAMs in screening mitochondrial uncouplers, offers novel causal knowledge and a workflow for qAOPN construction.

1.11.P-Th076 Transcriptomic Points of Departure in Early-life Stage Rainbow Trout Exposed to Diverse Chemicals for 24 hr

***Emily Boulanger**, Hugo Marchand, Krittika Mittal, Jessica Head and Niladri Basu, McGill University, Canada*

There is great interest in the development, validation, and application of New Approach Methods (NAMs) in the field of toxicity testing that are considered to be more cost-effective, ethical, and efficient. Transcriptomic points of departure (tPODs) are emerging as a promising approach for evaluating the toxicity of environmental contaminants while simultaneously obtaining mechanistic data. Here, the objective was to evalulate whether we could use a rapid 24 hr microplate-based embryo bioassay coupled with transcritomics to assess the sensitivity of a chemical in rainbow trout (RT) alevins and generate tPODs. Briefly, individual RT alevins (1-2 day post-hatch) were placed into single wells (24-well plates) and exposed for 24 hr to a solvent control (fish water or 0.5% DMSO) and 11 concentrations of a chemical of interest (total of 12 individuals per concentration group). After the 24 hr exposure, alevins were pooled (n=3) to create 4 replicates per concentration group for differential gene expression and dose-response analyses. Presently, 25 chemicals have been tested using this microplate-based assay and we are currently in the process of generating tPODs for many of them. So far, RNA Sequencing (RNA-Seq) has been performed on RT samples for two chemicals of interest (i.e. ethinylestradiol (EE2) and 6PPD quinone (6PPD)). Significant genes (| log2FC |=1 and adjusted p-value <0.05) were fitted with a curve to determine the gene-level benchmark dose (BMD). From the distribution of all genes with BMDs, a tPOD was calculated on ExpressAnalyst. A transcriptomic point of departure was observed and tPODs were generated for EE2 (4.9 ng/L) and 6PPD (3.7 ng/L). The EE2 values are similar to a recent study in which RT hatchlings were exposed to EE2 from hatch to four days post hatch, following which RNA-Seq analysis of whole embryos yielded tPOD values ranging between 0.2 and 3.6 ng/L. Taken together, these findings will lend support to the notion that 24 hr microplate-based bioassays with RT alevins coupled with RNA-seq can yield molecular data that can provide insights into mechanisms of action and are also conducive to benchmark dose modelling to derive quantitative tPODs.

1.11.P-Th077 Transcriptomic Points of Departure in Rainbow Trout Exposed to Ethinylestradiol: A Comparison of Approaches in Different Model Systems

***Emily Boulanger**, Hugo Marchand, Krittika Mittal, Jessica Head and Niladri Basu, McGill University, Canada*

To help move away from whole animal acute toxicity testing involving fish, there is interest in the development of alternatives to animal methods (e.g., early-life stage (ELS) and in vitro tests) that are high-throughput and can also derive quantitative transcriptomics point of departure (tPOD) values. To understand the variance in tPOD values across a range of experimental systems and conditions, here we examined different exposure models (cell line, embryo, juvenile) and transcriptomic methods (EcoToxChips, UPXome, RNA-sequencing) involving rainbow trout exposed to ethinylestradiol (EE2). In study #1, individual rainbow trout hatchlings alevins (1-2 day post-hatch) were placed into single wells (24-well plates) and exposed for 24 hr to a solvent control (0.5% DMSO) and 11 concentrations of EE2: 0.003, 0.01, 0.03, 0.1, 0.3, 1, 3, 10, 30 and 100 ng/L (12 individuals per group). After the 24 hr exposure, alevins were pooled (n=4) to obtain 3 replicates per dose group for gene expression analysis using the 384-gene Rainbow Trout version 0.1 EcoToxChip. Differential gene expression analysis and dose-response analysis methods were performed on EcoToxXplorer. In addition, RNA-Sequencing (RNA-Seq) was performed on the same set of samples and the data was analyzed using ExpressAnalyst. No mortalities or deformities were observed following EE2 exposure. Most differentially expressed genes (DEGs) from the EcoToxChip data were found in the 1 ng/L treatment group, and common DEGs included vitellogenin-like and estrogen receptor genes as would be expected with EE2 exposure. A tPOD was derived from EcoToxChips (4.86 ng/L) and RNA-Seq (4.80 ng/L) data. These values are similar to recently published studies in which rainbow trout: a) hatchlings (study #2; Alcaraz et al.) were exposed to EE2 from hatch to four days post hatch, following which RNA-Seq analysis of whole embryos yielded tPOD values ranging between 0.2 and 3.6 ng/L; and b) juveniles (study #3; Pagé-Larivière et al.) were exposed to EE2 from fry (60 days post-fertilization) for 76 days, following which microarray analysis of gonadal tissue yielded a tPOD value of 3 ng/L. Study #4 is underway with the rainbow trout gill cell line (RT gill-W1) exposed to similar concentrations of EE2 for 24 hr. Taken together, the findings from this case study of rainbow trout and EE2 lend support to the notion that tPODs generated from alternative to animal models can reflect tPODs from more involved animal studies.

1.11.P-Th078 Exploiting Single Cell Sequencing to Evaluate the Efficacy of Primary Gill Cell Cultures as Tools for Deriving Pharmaceutical Toxicological Mechanisms

***Owen Robert Paul Trimming**[1], Aya Takesono[2], Charles Tyler[3], Stewart Owen[4] and Peter Kille[5], (1)Cardiff University, Cardiff, United Kingdom, (2)Faculty of Health and Life Sciences, University of Exeter, United Kingdom, (3)University of Exeter, United Kingdom, (4)AstraZeneca UK Ltd, United Kingdom, (5)Cardiff University, United Kingdom*

New *in vitro* and genomic approaches are increasingly being incorporated into ecotoxicology. Such advances can be utilised to address novel challenges posed by emerging pollutants, in a way which is both representative and in line with the principles of the 3Rs. Even at environmentally relevant concentrations, some pharmaceuticals can elicit transcriptomic changes which can result in adverse outcomes. As vertebrates, fish share more drug target orthologues with humans than any other aquatic life and are at the most risk from this pollution. Repeated alterations to gene expression may cause chronic health issues, that are not necessarily detected by traditional acute toxicological assessment methods. Furthermore, these changes in the mRNA abundance can have a disproportionate impact on different cell populations. Thus, sensitive approaches are required to identify cell-specific molecular initiating events (MIEs) which drive subsequent adverse outcomes. Single-cell RNA sequencing (scRNA-Seq) is a promising technique for defining the precise mechanisms underpinning toxicity in individual cells. However, commonly used fish cell cultures are immortalised cell lines made up of one cell type, which can be genetically dissimilar to the original tissue. Alternatively, *Oncorhynchus mykiss* (rainbow trout) double-seeded gill inserts are a three-dimensional primary cell culture composed of different cell types, including small molecule transporters. These properties are why this culture is often utilised to study pharmaceutical toxicokinetics at the point of xenobiotic uptake. However, for this culture to also be used to study toxicodynamics through the lens of transcriptomic changes, it must first be demonstrated that mRNA profiles of the different cell populations are comparable to that of the original tissue. In this work, we aim to use scRNA-Seq to analyse the transcriptomic fingerprint in both the double-seeded gill model and the original gill tissue to identify if there are significant differences in cell type abundances and transcriptomes. If this model proves to be sufficiently representative, further scRNA-Seq could be conducted to elucidate the subtle low-dose effects that pharmaceuticals are having on specific cell populations, without the need for *in vivo* study. Employing scRNA-Seq in aquatic ecotoxicology can improve the mechanistic understanding of toxic effects, in a way that is highly suitable for deriving the mode of action of pharmaceutical pollutants.

1.11.P-Th079 Exploring the genome of the oribatid mite, Oppia nitens

***Adedamola Ayodeji Adedokun**[1], Hamzat Fajana[2], Kayode Jegede[3], Austin Hammond[4], Stephanie Kvas[5], Derek Smith[5], Juliska Princz, PhD[5] and Steven Siciliano[2], (1)University of Saskatchewan, Saskatoon, Canada, (2)University of Saskatchewan, Canada, (3)Soil Physics and Land Management, University of California Davis (UC Davis), (4)Global Institute for Food Security, Canada, (5)Environment and Climate Change Canada, Canada*

Oribatid mites are one of the most abundant group of microarthopods in soil. *Oppia nitens*, belonging to the family Oppiidae, one of the largest and diverse families of oribatid mites, has been developed as a standardized model test organism for the assessment of soil contamination and habitat adaptation. However, the limited availability of genomic information for this species hinders our understanding of its physiological adaptation and sensitivity to chemical stress and soil habitat quality. We present the annotated *O. nitens* draft genome assembled using both Oxford Nanopore Technologies and Illumina sequencing platforms.

The sequences assembled into 65 scaffolds spanning 125.4Mb with a 24.5% GC content, a N50 length of 4.41Mb, and a maximum scaffold length of 6.36 Mb. Genome quality and completeness were checked using arthropod Benchmarking Universal Single Copy Orthologs (BUSCO) analysis, which identified: 96.9 % - 93.5 % complete single-copy orthologs, 3.4% complete but duplicated orthologs, 0.5% fragmented, and 2.6% missing orthologs (n=2934). The mitochondrial genome was also recovered and assembled. We found 15,369 protein-coding genes, 16, 969 mRNA, and 14, 938 proteins.

Here, we describe the *O. nitens* reference genome and discuss its utility as a genetic basis for further investigations and understanding of the molecular mechanisms and physiological functions in adaptations to environmental change, especially exhibited tolerance of *O. nitens* to metal stress.

1.11.P-Th080 Sub-lethal Transcriptomic Points of Departure and Toxicity Pathways of Legacy and Emerging Perfluoroalkyl Substances Determined Using New Approach Methods

***Hannah Mahoney**[1], Phillip Ankley[2], Yutong Zhou[1], Alicia Lamb[1], Catherine Roberts[2], Matthew Schultz[2], John Giesy[1] and Markus Brinkmann[2], (1)University of Saskatchewan, Canada, (2)Toxicology Centre, University of Saskatchewan, Canada*

Per- and poly-fluoroalkyl substances (PFAS) have unique, amphiphilic properties that extend them to many uses in industry and commercial products. As a result, some PFAS have become ubiquitous in the environment. Recently, several 'replacement' PFAS have been produced and are beginning to emerge in the environment. Two such emerging compounds, perfluorobutane sulphamide (FBSA) and perfluoroethylcyclohexane sulphonate (PFECHS) are becoming widely detected, however, little to no information regarding their effects at either the molecular or apical levels is available. Therefore, this study investigated the toxic potency and mechanisms of toxicity of these substances at sub-lethal effect concentrations related to perfluorooctane sulphonate (PFOS). Zebrafish (*Danio rerio*) embryos were chosen as the experimental model to investigate three apical endpoints: (1) mortality, (2) abnormalities, and (3) growth, as well as to be sequenced using mRNAseq to obtain transcriptomic datasets. The embryos were exposed from 24 to 96 hours post fertilization (hpf) to seven exposure concentrations from 0.0001 – 5 mg/L plus a solvent control of each compound individually, with a subset extracted for total RNA, which was then sent to Genome Quebec Inc. for RNA sequencing. Each compound resulted in a maximum mortality rate < 20%, with the order of compound potency being PFOS > PFECHS > FSBA. Focusing on the highest treatment versus the solvent control, the PFOS exposure resulted in 539 differentially expressed genes (DEGs), the PFECHS exposure resulted in 24 DEGs, and the FSBA exposure resulted in 630 DEGs. However, only 497, 6, and 2 genes followed dose-response relationships for PFOS, PFECHS, and FSBA, respectively. The low amount of DEGs recorded for PFECHS and FSBA can likely be associated with the relatively low apical toxicity observed under these two compounds. As a result, only tPoDs for PFOS could be determined and gene level benchmark doses (BMDs) were calculated as 0.00012, 0.00016, and 8.7e-5 mg/L for the 20th gene, max 1st peak, 10th percentile BMDs, respectively. The DEGs for PFECHS and FSBA were related to adrenergic signalling in cardiomyocytes, suggesting this pathway may be driving the enrichment signal for the gene sets identified. Determining the toxic potency of emerging replacement PFAS is an important step that will help better inform the viability of replacements as a strategy for PFAS management in the future.

1.11.P-Th081 The Induction of Nuclear Receptor Pathways Plays a Role in Hepatic Thyroid Hormone Metabolism in Zebrafish (Danio Rerio) Embryos

***Maximilian Rinderknecht**[1], Andreas Gado[2], Thomas Broschard[2], Lisa Annie Baumann[3] and Thomas Braunbeck[1], (1)Centre for Organismal Studies, University of Heidelberg, Germany, (2)MerckGroup, Germany, (3)Environmental Health and Toxicology, Vrije University Amsterdam, Netherlands*

Conjugation of thyroid hormones (TH) as biotransformation phase II metabolization can be divided into two major pathways: Glucuronidation by UDP-glucuronosyltransferases (UGTs) and sulfation by sulfotransferases (SULTs). These reactions primarily increase water solubility and thus facilitate biliary excretion of THs. While disruption *via* hepatic induction as part of an adverse outcome pathway (AOP) has been observed in multiple mammalian species, it has thus far not been explored in detail in fish. The expression of these conjugation enzymes is influenced by a variety of nuclear receptors most commonly associated with the detection of xenobiotics. Examples include the aryl hydrocarbon receptor and the pregnane x receptor. These accept a wide range of potential agonists, and their activation generally leads to an increase in the expression of enzymes involved in the metabolization of xenobiotics. As an off-target effect, UGT and SULT expression can also be increased to levels that negatively affect TH homeostasis.

In the context of the 3R principles, it would be highly beneficial to determine whether fish and other lower vertebrates are also sensitive to TH system disruption *via* this mechanism. Specifically, the applicability of zebrafish (Danio rerio) embryos as a predictive model would help to reduce mammalian animal testing. First exposure experiments provided strong indication towards this being the case, showing effects of hepatic inductors on the morphological level. To appropriately investigate this mechanism, further experiments are necessary to properly evaluate the induction of hepatic TH metabolism in zebrafish. These range from tests on the molecular level to the assessment of possible behavioural changes resulting from altered TH signalling. For this end, wildtype zebrafish were exposed to different known agonists of the nuclear receptors involved in UGT and SULT expression to cover different molecular key events. These experiments assessed endpoints related to molecular events and possible behavioural changes resulting from altered TH signalling and involve endpoints like TH levels, eye histopathology, swim bladder inflation and visual motor response. The experiments aim to deepen the understanding of hepatic TH metabolism in zebrafish embryos. Comparisons with data from other vertebrates will reveal similarities and differences among species and vertebrate classes.

1.11.P-Th082 Navigating truth and truce: Validation as institutional entrepreneurship in regulatory science

*H.M. Tuihedur Rahman[1], **Gordon Hickey**[1] and Steven Maguire[2], (1)McGill University, Canada, (2)University of Sydney, Australia*

Regulators responsible for national and international chemicals management need New Approach Methodologies (NAMs) to overcome the ethical and technical limitations of prevailing animal-based risk assessment approaches. Validation – a process based on sound scientific principles to establish the reliability and relevance of a test method (OECD, 2005) – is an important step towards regulatory acceptance and adoption of NAMs (and NAM-generated data) in chemicals management decision making. However, risk assessment of chemicals is a highly institutionalized field of professional practice, with the methods, routines and tools used by risk assessors – and widely accepted by regulators and industry actors – largely taken for granted, even if practitioners recognize their shortcomings. As a result, these entrenched practices are difficult to change, and doing so requires "institutional entrepreneurship" – "activities of actors who have an interest in particular institutional arrangements and who leverage resources to create new institutions or to transform existing ones" (Maguire et al., 2004: 657). This presentation draws on a case study of the entrepreneurial activities of members of a NAM innovation project team– referred to as NAMTEAM — which aims to develop a low-cost, and reliable toxicogenomic technology. We collected qualitative data from the project's initial proposals, monthly updates, recorded yearly meetings, validation plan, publications, workshop reports, and other correspondences related to validation activities. Our analysis reveals that regulatory actors' understandings about validation are diverse but can be broadly grouped under two ideal types in tension: a "scientific logic" in which validation signifies 'truth' vs a "political logic" in which validation signifies an end of contestation and social acceptance or 'truce'. Institutional entrepreneurs navigate this tension in a variety of ways. Since validation activities are not value neutral and may change with scientific advances, validation plans and activities need to be reflexive and adaptive. The findings of this study can inform multi-level efforts to advance the use of NAMs in regulatory science and risk assessment processes.

1.12 Omics Beyond Transcriptomics: Leveraging Proteomics and Metabolomics to Improve Mechanistic Understanding of Responses to Environmental Stressors

1.12.T-01 Metabolomics response kinetics of a periphytic community to mixture of pesticides to unravel short term molecular mechanisms involved in long term structural and functional impairment

*Maelle Baillergeau[1], Chloe Bonnineau[1], Melissa Eon[2], Antoine Tourret[1], Soizic Morin[1] and **Nicolas Creusot**[1,3], (1)INRAE UR EABX, France, (2)INRAE UR EABX; Plateforme Bordeaux Metabolome, France, (3)Plateforme Bordeaux Metabolome, France*

Agriculture leads to the release of multiple pesticides into aquatic ecosystems that might be harmful for exposed organisms such as periphytic microbial communities playing a key role in ecosystem functions. Despite evidence about the effect of these chemicals on the structure and functions of periphytic biofilms, there is still a paucity of knowledge about the kinetic of responses. In particular, there is a need to unravel how short term molecular responses are involved in long-term impairment at the functional/structural levels to support the discovery of biomarkers allowing the early and sensitive detection of long term alteration of ecosystem function(s). To this end, untargeted meta-metabolomics is a cutting edge approach since it provides a comprehensive picture of the molecular phenotype of the whole community, as a result of interactions with the environment. In this context, this study aims to characterize the link between the response at the molecular level and the responses at the physiological/function and structural levels of periphytic biofilms exposed during one month to mixture of insectide (fenoxycarb,FNX), herbicide (glyphosate, GLY) and its metabolite (AMPA). At the structural level, normal increase of the biomass was observed between 13 and 28 days in control and FNX conditions while the growth was lower in condition with GLY+AMPA and the mixture. In parallel, there is a decrease of cyanobacteria in control and FNX conditions while they increase following exposure to GLY+AMPA and the mixture. At the physiological level, significant discrepencies were noted for the photosynthetic yield with a decrease after 13 and 28 days of exposure to GLY+AMPA, FNX and the ternary mixture. At the molecular level, HCA showed a clustering of the features according the time as soon as after 4h of exposure. At this time, the effect of the conditions GLY+AMPA is already visible in comparison to other conditions. Further comparison of the significantly modulated features highlighted few overlap between the tested conditions suggesting that specific metabolic pathways were involved in the response. Altogether, our results highlight that the microbial community metabolome changed strongly over time and also responded very quickly to pesticides exposure. This study also suggests specific metabolic pathways involved in the response to FNX vs GLY+AMPA vs FNX+GLY+AMPA, and so likey specific adverse outcome pathways leading to ecological functions impairment.

1.12.T-03 Xenometabolome of Early Life Stage Rainbow Trout Exposed to 6PPD-quinone

***Phillip Ankley**[1], Catherine Roberts[1], Evan Kohlman[1], Mawuli Amekor[1], Natacha S Hogan[1], Markus Hecker[2] and Markus Brinkmann[1], (1)Toxicology Centre, University of Saskatchewan, Canada, (2)Toxicology Centre and School of the Environment and Sustainability, University of Saskatchewan, Canada*

N-(1,3-Dimethylbutyl)-N′-phenyl-p-phenylenediamine-quinone (6PPDq) is toxic to several salmonid species. The differences in metabolism of this compound in fishes is an emerging area of research, as it leads to detoxification or potential activation of the analyte. Mass spectrometry can prioritize metabolites of concern while using data-dependent acquisition (DDA) for suspect screening novel metabolites and understanding potential impacts on the endogenous metabolome. This study used targeted and untargeted metabolomics to determine the metabolism of 6PPDq in larval rainbow trout and assessed the effects of 6PPDq exposure on the metabolome. Larval rainbow trout tissue was extracted for targeted 6PPDq metabolite analysis using a full MS/parallel reaction monitoring method with analyte separation using Vanquish UHPLC and positive scans using QETM HF Quadrupole-Orbitrap™ mass spectrometer with HESI ion source (Thermo Scientific). Untargeted analysis utilized a DDA to acquire ddMS2 top 5 data, and the resulting DDA data was analyzed using mzMine3 for spectral preprocessing and feature detection before exporting to GNPS for feature-based molecular networking (FBMN) and to SIRIUS for molecular formula prediction and annotation. Greater levels of hydroxylated 6PPDq were detected in larval fish tissue compared to 6PPDq glucuronide conjugate. Metabolites of 6PPDq detected via FBMN and Cytoscape were found to be associated with the precursor 299.1746 m/z (6PPDq) for hydroxylation transformation to form an alkyl hydroxylation transformation product (m/z = 315.169), aromatic ring hydroxylation, and a double hydroxylation (m/z = 331.1644). Another network detected for phase II biotransformation of 6PPDq included glucuronidation of single hydroxylation (m/z = 491.2014) and double hydroxylation (m/z = 507.1965). An additional phase II transformation product was detected for sulfonation of single hydroxylation (m/z = 395.1265). PLS-DA revealed the separation of the concentrations in multivariate space, and several metabolites were important in driving these differences in a dose-response manner. The next steps include further identification of dysregulated metabolites in larval rainbow trout and characterization of the metabolism of 6PPDq in larval fathead minnow, brook trout, and brown trout, allowing for comparison of the metabolism of 6PPDq in greater phylogenetic space and in nonsensitive species.

1.12.T-04 Phosphoproteomics-Based Investigation of the mTOR Pathway Signalling Reveals its Role in Mediation of Chemical Effects on Fish Cell Culture Growth

*Nikolai Huwa[1], Rene Schonenberger[1], **Ksenia J Groh, PhD**[2] and Adele Blatter[2], (1)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (2)Eawag - Swiss Federal Institute of Aquatic Science and Technology, Switzerland*

Many signalling cascades in the cells are regulated by (de)phosphorylation at specific protein sites. Several initiator kinases can respond to diverse stressors, including chemical exposure. However, mechanistic exploration of chemical effects on protein phosphorylation has received little attention in predictive (eco)toxicology so far, likely due to technical limitations. For example, in non-mammalian model organisms, suitable antibodies are often lacking. To address this limitation, we worked to develop a mass spectrometry-based targeted (phospho)proteomics method, using the zebrafish (*Danio rerio*) PAC2 cell line model and focusing on the mTOR kinase pathway, which is known to regulate growth and could also play a role in mediating chemical effects on growth. The optimized workflow includes fast cell lysis with 5% SDS, S-Trap™ protein isolation and digestion, followed by NTA-Fe phosphopeptide enrichment. Currently, abundance and/or phosphorylation status can be monitored for 21 protein targets within the mTOR pathway simultaneously. We used this method to study the mTOR pathway responses to pharmacological inhibition of the mTOR kinase by Torin2 as well as nutrient deprivation stress and exposures to chemicals known to inhibit fish growth. As an example, Torin2 showed no acute toxicity but caused a strong reduction in cell culture growth in chronic scenario. Protein abundance was affected only slightly, while protein phosphorylation changes in response to exposure were more dynamic and suggested impacts on several upstream regulators of the mTOR pathway activity. Ongoing study investigates whether early responses on the (phospho)protein level can be used to predict reduced growth as measured at a later time point, through gaining a time-resolved view into mTOR pathway dynamics in response to chemicals known to inhibit fish cell culture growth and/or fish growth *in vivo*. Collectively, our results suggest that the mTOR in fish plays a similar role in the regulation of cellular growth and proliferation as that known in mammals. In a broader context, this study demonstrates the applicability of the mass spectrometry-based targeted (phospho)proteomics as a feasible and versatile approach to study chemical disruption of phosphorylation-based signalling in different organisms. Better understanding of the roles played by signalling pathways could allow identifying novel mechanistic targets and exploring their suitability as predictive markers of toxicity.

1.12.P Omics Beyond Transcriptomics: Leveraging Proteomics and Metabolomics to Improve Mechanistic Understanding of Responses to Environmental Stressors

1.12.P-We077 Is Toxicophenomics The New Omics?

***Valentine Guzniczak**[1] and Signe Marie Jensen[2], (1)Copenhagen University, Denmark, (2)Plant and Environmental Sciences, University of Copenhagen, Denmark*

Risk assessment (RA) aims to characterize the response of organisms to a stressor, which can be achieved at different levels, through different methods, and with different data types. However, not all levels, methods, and data types have received the same attention. Within the omics field, this is the case for phenomic data. Phenomics, defined as the “acquisition of high-dimensional phenotypic data on an organism-wide scale”, has great potential for predicting important biological outcomes, but it is not fully exploited as technological advances have been limited. In the context of environmental stressors and toxicological research, toxicophenomics are of great interest, as it combines phenomics and toxicology. However, the limited advances in phenomics also create a knowledge gap in toxicophenomics.

This study aims to extend the knowledge of toxicophenomic data, its opportunities, and its challenges. We hypothesize that toxicophenomic data will convey extra knowledge and deepen our understanding of responses to environmental stressors. This knowledge will be useful to improve RA.

The toxicophenomics data used for this study originates from a dose-response experiment where seven non-target plant species were exposed to glyphosate. The plants were monitored in a fully automated high-throughput phenotyping platform. Non-destructive measurements were performed repeatedly during the experiment and destructive measurements were obtained at the end of the experiment.

The data will be analyzed in R using the “drc” and “bmd” packages for fitting dose-response models and extracting benchmark doses. The analysis will shed light on the information that can be extracted from such data. As an example, the porometer measurements, such as stomatal conductance, can provide insights on the efficiency of photochemistry, and stress recovery. Data from thermal imaging can provide information on responses to biotic and abiotic stress, for example, to detect diseases. Multispectral imaging can be used to quantify growth rates and study early responses to drought stress. The chlorophyll content provides insights on photosynthesis efficiency, while the anthocyanin and flavonol contents can be used to study response to stress, e.g. drought resistance.

This study will shed light on the unique knowledge that can be acquired through toxicophenomic data. This will enable the integration of toxicophenomics in RA procedures and will provide novel knowledge that can improve RA.

1.12.P-We078 Coupling Uncoupling: Deciphering the Molecular Symphony – Exploring the Impact of Mitochondria Uncoupling Chemicals on the Transcriptome and Metabolome of Zebrafish Embryos

***Maria Christou*[1]**, *Daniel Ng[2], Kai Xiang Kuah[3], Lene Hermansen[4], YeonKyeong Lee[5], Jan Thomas Rundberget[1], Maria T. Hultman[1], Camila Esguerra[6], Jorke Kamstra[7], Adam Lillicrap[8] and You Song, PhD[1], (1)Norwegian Institute for Water Research (NIVA), Norway, (2)International Food and Water Research Centre (IFWRC), Canada, (3)International Food and Water Research Centre (IFWRC), Waters Pacific, Singapore, (4)The Imaging Centre, Norwegian University of Life Sciences, Norway, (5)Norwegian University of Life Sciences (NMBU), Norway, (6)Center for Molecular Medicine, University of Oslo (UiO), Norway, (7)Utrecht University, Netherlands, (8)Norwegian Institute for Water Research (NIVA), Oslo, Norway*

Mitochondrial uncoupling chemicals manifest their effects by disrupting oxidative phosphorylation (OXPHOS), a main metabolic pathway that produces ATP. Uncoupling of OXPHOS can cause reduced ATP production and cell proliferation and adverse effects of regulatory concern, such as growth inhibition. Uncoupling of OXPHOS leading to growth inhibition (AOPWiki, AOP #263) has been proposed as a key adverse outcome pathway (AOP) in eukaryotes and endorsed by the Organisation for Economic Cooperation and Development for potential regulatory use. This study aims to utilise new approach methodologies (NAMs), in particular the zebrafish embryo model as an alternative to fish testing, to generate in-depth systems biology and quantitative understanding to support AOP #263, develop and standardize new NAM testing strategies and expand this AOP to a more complex AOP network (AOPN). Zebrafish embryos were exposed to different concentrations of the reference mitochondrial uncoupler carbonyl cyanide m-chlorophenyl hydrazone (CCCP) from 3 to 96 hours post fertilisation (hpf). Targeted bioassays (uncoupling of OXPHOS, ATP pool, cell proliferation and growth), histopathological analysis and a regulatory toxicity protocol (i.e., Fish Embryo Toxicity Test, OECD TG 236), multi-OMICS (transcriptomics and metabolomics) as a high-content NAM was used to generate new knowledge on the temporal and concentration-dependent stress response patterns in response to mitochondrial uncoupling. Furthermore, a multi-OMICS point of departure (POD) estimation using benchmark dose (BMD) modelling will be performed to support the AOP and identify new key events (KEs) in a larger AOPN. ATP pool and growth were affected in a concentration-dependent manner Significant effects on ATP pool were observed in 48hpf and 72hpf embryos. Significant growth inhibition was observed in 96 hpf embryos. OMICS analysis revealed a high number of commonly affected genes and metabolites across concentrations and time. Pathways such as ECM-receptor interaction, retinol metabolism and apoptosis are found to be highly enriched. In the next step, BMD modelling and subsequent functional enrichment analysis will be performed to support AOP #263 in terms of temporal and dose concordance. This study uses combined multi-OMICS and phenotypic bioassays, as NAMs to generate systems toxicological data in zebrafish embryo exposed to a model mitochondrial uncoupler and the results will be used to expand the current AOP to an AOPN.

1.12.P-We079 Metabolomic changes in juvenile coho and Chinook salmon exposed to the vehicle tire associated chemical 6PPD-quinone

***Bonnie Lo*[1]**, *Vicki Marlatt[1] and Tanya Brown[2], (1)Simon Fraser University, Canada, (2)Fisheries and Oceans Canada, Canada*

N-(1,3-Dimethylbutyl)-*N'*-phenyl-*p*-phenylenediamine-quinone (6PPD-quinone, 6PPD-Q), an ozonation product of the tire rubber antioxidant 6PPD, has been identified as an important driver of urban runoff mortality syndrome. This phenomenon affects adult coho salmon (*Oncorhynchus kisutch*) upon entry into urban streams and results in high rates of pre-spawn mortality. Studies have reported a wide range of sensitivity to 6PPD-Q in several fish species. Our recent study revealed more than 3 orders of magnitude difference in the LC50 values between newly feeding juvenile Chinook (*Oncorhynchus tshawytscha*) and coho, with coho being the most sensitive. Both etiology and sublethal effects of 6PPD-Q are not well understood, although capillary leak and disruptions of the blood brain barrier have been associated with 6PDD-Q induced coho mortality. Here we investigated the sublethal effects of 6PPD-Q in newly feeding juvenile coho and Chinook salmon using a targeted metabolomic platform in a subset of samples collected during our recent acute 24h exposure. Sample exposure concentrations ranged from 11.9-38.5 ng/L for coho, and 3 112-25 808 ng/L for Chinook. Up to 530 and 556 metabolites of the 633 targeted panel were detected in juvenile coho and Chinook, respectively. Our preliminary results reveal altered metabolite profiles in both species in response to 6PPD-quinone concentrations, which differ between the two species, and may be consistent with their varied sensitivities. Ongoing metabolomics data analysis in the two salmonid species will identify the main metabolic pathways involved in the sub-lethal responses to 6PPD-Q exposure.

1.12.P-We080 Omics-Based Biomarker Selection for Difenoconazole and Metalaxyl Toxicity in Zebrafish Embryos.
Fatma Marghany[1]*, Steve Uwa Ayobahan Dr.*[1]*, Gabriela Salinas*[2]*, Christoph Schaefers*[3]*, Henner Hollert*[4,5] *and Sebastian Eilebrecht*[1]*, (1)Ecotoxicogenomics, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (2)NGS - Integrative Genomics Core Unit, Germany, (3)Ecotoxicology, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (4)Environmental Media Related Ecotoxicology, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (5)Goethe University Frankfurt, Evolutionary Ecology and Environmental Toxicology, Germany*
Due to increasing application of fungicides in agricultural, veterinary and medicinal practices, relevant concentrations of fungicide residues in the environment as well as crops have been detected by previous studies. Beside the reported adverse effects of fungicides on different organisms inhabiting the ecosystem, such observations prioritise developing efficient and sensitive approaches for predicting environmental hazards of fungicides. In this study, we applied OMICs analysis to identify substance-specific biomarker candidates which may act as early indicators for ecotoxicity of difenoconazole (sterol biosynthesis inhibitor) and metalaxyl (nucleic acid metabolism inhibitor). Zebrafish embryos were exposed to the fungicides according to a modified protocol of the OECD test guideline No. 236, terminated by simultaneous RNA and protein extraction in order to analyse the whole transcriptome and proteome. Consequently, a positive exposure-response correlation was detected at differentially expressed gene (DEGs) and differentially expressed protein (DEPs) levels in all test concentrations for both fungicides. Moreover, a positive correlation between the obtained transcriptome and proteome responses was observed, denoting the persistence of the detected molecular responses. From the detected DEGs, candidate biomarkers specific for difenoconazole (*apoa1b, gatm, mylpfb* and *acta1b)* and metalaxyl (*lgals2b, abat*, *fabp1b.1* and *myh9a)* were selected, and their biological functions were discussed to assess the predictive potentiality of our approach. The developed biomarker panels may act as early indicators for environmental hazards of chemical substances under development. Furthermore, the integration of OMICs techniques in ecotoxicology can enhance our understanding of key events (KE) and key event relationships in an Adverse Outcome Pathways (AOPs).

Key words: Zebrafish Embryo, Fungicides, Transcriptomics, Proteomics, Biomarkers, RNA Seq

1.12.P-We081 The Effects of Hypoxia on Fathead Minnow Behaviour and 'Omics
Raina Hubley*, Aisha Pasha, Meghan Allen, Theresa Warriner and Denina B.D. Simmons, Ontario Tech University, Canada*
Behaviour is a useful parameter for monitoring the health of vertebrates in the context of environmental changes. Behavioural monitoring is non-invasive and could be utilized as a refinement for fish studies in both the lab and field environments. Traditional 'omics methods can be utilized to determine changes in fish protein, metabolite, and lipid abundance due to toxic exposures. Dissolved oxygen fluctuations in water bodies have become more prevalent due to climate change and these fluctuations can lead to increased frequency and intensity of hypoxic conditions. We aimed to combine non-invasive methods with traditional methods to determine the effect of hypoxia on Fathead minnow (*Pimephales promelas*) behaviour and 'omics. We exposed 60 Fathead minnows to hypoxic (2.10-2.80 mg/mL DO) and normoxic (5.80-7.00 mg/mL DO) conditions over a 7-day period. Fish were video recorded on days 1, 3, 5, and 7. Three blind observers analyzed the videos for fish tank location activity, foraging behaviour, and novel object behaviour. On day 8, we anaesthetized fish with 100 mg/L MS-222 and collected mucus, plasma, gill, and brain samples and also measured blood glucose. We found that hypoxia altered Fathead minnow activity levels over the course of the 7-day treatment. In this presentation, we will share the integrated results of fish behaviour, brain 'omics, mucus 'omics, and blood glucose levels

1.12.P-We082 Non-targeted multi-omic analyses of blood plasma for health exploration of namew (lake sturgeon, Acipenser fulvescens) in an intact and an impacted watershed in the Moose Cree Homeland
Keisha A Deoraj[1]*, Jennifer Simard*[2]*, Constance O'Connor*[3]*, Claire E Farrell*[3]*, Jacob Seguin*[3] *and Denina B.D. Simmons*[1]*, (1)Aquatic Omics Lab, Faculty of Science, Ontario Tech University, Canada, (2)Resource Protection, Moose Cree First Nation, Canada, (3)Ontario Northern Boreal Program, Wildlife Conservation Society Canada, Canada*
Namew (nah-may-yo) or lake sturgeon (*Acipenser fulvescen*s), are large, long-lived, benthivorous fish that are ecologically and culturally significant to many Indigenous communities. Historically, they were found throughout most of North America's Hudson Bay, St. Lawrence, and Mississippi drainage basins. Overexploitation and extensive habitat loss and alteration since the 1800s caused massive declines in Lake Sturgeon abundance over much of its range. The Moose Cree Homeland includes a diversity of rivers for namew, some of which are heavily impacted by hydroelectric development, forestry, mining, and other impacts, while others are free-flowing and without any development. Therefore, these internationally endangered fish face impacts and threats at varying levels of severity within the Moose Cree Homeland. The People of the Moose River Basin have compiled over a century of knowledge regarding the impacts of hydroelectric development and activity on Moose Cree Peoples, including declines in namew in some areas of the Moose Cree Homeland. Our collaborative team examined fine scale measures of namew health and condition in the Mattagami River, which has been impacted by hydropower, forestry, and other industrial development, and the free-flowing and unimpacted North French River, both tributaries of the Moose River system. We used non-targeted metabolomics, lipidomics, and proteomics to profile and investigate location-specific variation among detected biomolecules, before functionally characterizing biomolecules to identify possible health effects for namew in these

two river systems. We present our findings from one sampling season and discuss our future non-targeted multi-omic approaches.

1.12.P-We083 Untangling Defensomes: Omic Comparisons Across Species and Chemical Mode of Action to Aid Species Sensitivity Prediction.

*Stephen James Short[1], Melanie Gibbs[2], Alex Robinson[3], **David Spurgeon**[3], Amaia Green Etxabe[3] and Peter Kille[4], (1)Pollution, UK Centre for Ecology & Hydrology (UKCEH), United Kingdom, (2)Biodiversity, UK Centre for Ecology & Hydrology (UKCEH), United Kingdom, (3)UK Centre for Ecology & Hydrology (UKCEH), United Kingdom, (4)Cardiff University, United Kingdom*

Terrestrial invertebrate groups are declining, with pollution thought to be a major driving factor. Faced with the challenge of translating model species data into predictions for the wider range of species in ecosystems, risk assessment would be improved with accurate prediction of species sensitivity that incorporates a deeper molecular understanding of species-toxicant interactions. Current research characterising such molecular biology has (for good reasons) largely focussed on toxicant receptors (i.e. the initiation event that triggers downstream consequences) and cross-species comparisons of adverse outcome pathways. However, other factors (not adequately incorporated into existing approaches) can also dictate chemical toxicity to non-target organisms, such as including a species' capacity to mount an orchestrated response to exposure. This response (defensome) includes modulating the genes linked with chemical detoxification, elimination, damage mitigation and repair. The diverse evolutionary paths and life histories across species means defensomes will not be equal, with some species possessing more or less optimal responsive capacities to varied chemical and environmental stress. To leverage such defensomic data, major questions need to be answered for many invertebrate groups. For example, to what extent do defensome responses vary across chemicals within the same species, as well as across species for the same chemical. And, just as critically, to what extent do such differences explain (and therefore predict) sensitivity. We have characterised the transcriptomic responses of the annelid *Enchytraeus crypticus* across time (6 time points from 1hr-24hrs) exposed to equivalent sub-lethal doses of pesticides (EC_{50} for reproduction) that act via varied modes of action. As well as revealing both the core (i.e. common to all chemicals) and pesticide-specific defensomes, we score defensomes in terms of differential inducibility and magnitude of response, correlating these scores with sensitivity. Furthermore, to compare defensome scores across species, we have sequenced the transcriptomes of larval *Mamestra brassicae* (Cabbage Moth) following sub-lethal exposure to a subset of the same pesticides. We discuss our findings in the context of understanding the contribution varied defensomic responses make to a species' sensitivity, as well as the challenge of defensome characterisation in species that are relatively poorly studied at the molecular level.

1.12.P-We084 Development of Proteomics Modules for the OECD Omics Reporting Framework

***Ksenia J Groh, PhD**[1], Premkumari Kumarathasan[2], Steve Uwa Ayobahan Dr.[3], Davide Degli Esposti[4], Verónica I. Dumit[5], Sebastian Eilebrecht[3], Vera Engelbrecht[6], Salvador Fernandez Arroyo[7], Nico Jehmlich[8], Predrag Kukic[9], Isabel Karkossa[8], Thibaut Leger[10], Arnaud Salvador[11], Johannes Schmidt[12], Kristin Schubert[8], Joshua Austell Harrill[13], Magdalini Sachana[14] and Alexandra Schaffert[15], (1)Eawag - Swiss Federal Institute of Aquatic Science and Technology, Switzerland, (2)Analytical Biochemistry and Proteomics Laboratory, Mechanistic Studies Division, Environmental Health Science and Research Bureau, Healthy Environments and Consumer Safety Branch, Health Canada, Canada, (3)Ecotoxicogenomics, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (4)Laboratoire d'écotoxicologie INRAE, France, (5)Federal Institute for Risk Assessment (BfR), Germany, (6)PETA Science Consortium International e.V., Germany, (7)EURECAT, Spain, (8)Molecular Systems Biology, Helmholtz Centre for Environmental Research (UFZ), Germany, (9)Unilever, United Kingdom, (10)Fougères Laboratory, ANSES, French Agency for Food, Environmental and Occupational Health & Safety, France, (11)University of Lyon, France, (12)Fraunhofer Institute for Cell Therapy and Immunology, Germany, (13)U.S. Environmental Protection Agency (US EPA), (14)Environment Health and Safety Division, Environment Directorate, Organisation for Economic Co-operation and Development (OECD), France, (15)Regulatory Toxicology, Institute of Medical Biochemistry, MUI Medical University Innsbruck, Austria*

The OECD Omics Reporting Framework (OORF) was developed to facilitate the regulatory use of omics data from laboratory-based toxicology studies, which is achieved by means of (i) increasing transparency and reproducibility, and (ii) supporting standardization and harmonization. The latter can in turn improve the efficiency of data sharing and promote its use in systematic reviews and meta-analyses. The OORF consists of a narrative guidance and reporting templates that cover the study design and data generation, processing and analysis stages. Additional modules focusing on selected application cases, such as read-across, can also be included.

The first edition of OORF, released in November 2023 (ENV-CBC-MONO(2023)41.en), focused on transcriptomics and metabolomics studies, while proteomics was not covered due to less frequent use in the past. However, since technological capabilities for proteomics analysis have greatly improved recently, the number of studies providing protein-data based insights into toxicity mechanisms and effects is expected to increase rapidly. Therefore, in order to support the use of proteomics data for regulatory purposes, this project aims to develop respective proteomics modules for inclusion in the OORF.

Based on the initial scoping survey, we prioritized the development of two proteomics-relevant Data Acquisition & Processing Reporting Modules (DAPRMs), namely (1) mass spectrometry-based proteomics (including both global and targeted acquisition, as well as label-free and label-based quantification methods), and (2) affinity proteomics. Gel-based proteomics were excluded from the scope, as this technique is rarely used for regulatory toxicology studies, if at all. In addition, the Data Analysis Reporting Modules (DARMs) currently present in the OORF will be reviewed and updated to enable their application for reporting proteomics data as well.

The inclusion of proteomics-specific modules in the OORF is expected to facilitate the maturation of proteomics-based toxicity assessment methods and allow regulatory consideration of proteomics data. This contributes to delivering on the original vision of building a comprehensive OORF that covers the major omics data types most frequently collected in chemical toxicity studies, thus enabling an efficient and unbiased use of these data streams in chemical hazard and risk assessments performed by regulators, industry and other stakeholders. *This abstract does not reflect US EPA policy.*

1.12.P-We085 Unravelling the Modes of Action of Antibacterial Agent Triclosan and Novel Alternatives in Human Macrophages by Untargeted Proteomics

Stefanie Raps[1]*, Laura Bahr*[1]*, Manuela Rossol*[2]*, Martin von Bergen*[1,3,4] *and Kristin Schubert*[1]*, (1)Molecular Systems Biology, Helmholtz Centre for Environmental Research (UFZ), Germany, (2)Molecular Immunology, Brandenburg University of Technology Cottbus-Senftenberg (BTU), Germany, (3)Faculty of Biosciences, Pharmacy and Psychology, Institute of Biochemistry, Faculty of Biosciences, Pharmacy and Psychology, University of Leipzig, Germany, (4)German Centre for Integrative Biodiversity Research (iDiv) Halle-Jena-Leipzig, Germany*

Triclosan (TCS) is an antibacterial active agent, which regulatory agencies in Europe and the US restricted due to its diverse effects on human health, rendering substitution products more relevant. TCS influences the immune metabolism in macrophages by activating the NLRP3 inflammasome, but effects on the molecular level are not entirely understood and knowledge about the alternatives is rare. Hence, we aimed to unravel the potential adverse effects of TCS and its substitutes in human macrophages.

To decipher the underlying modes of action of the antimicrobials, endotoxin-stimulated THP-1 macrophages were treated with TCS or the alternatives, including chlorhexidine (CHX) benzalkonium chloride, benzethonium chloride, chloroxylenol and cetylpyridinium chloride. First, the cytokine release was analysed using ELISA, showing significantly higher TNF and IL-1β in TCS-treated cells than the control. In contrast, CHX completely abolished cytokine release. A reduction of TNF and IL-1β was determined among the other investigated alternatives, and IL-6 was reduced among all treatments.

Molecular changes were studied using untargeted LC-MS/MS-based proteomics applying tandem mass tags (TMT), and effects on the pathway level were determined using Ingenuity Pathway Analysis®. TCS and CHX showed the strongest response at the protein and signalling pathway levels after 24 h of treatment. Due to oxidative stress conditions, both agents inhibited signalling pathways related to metabolism, like glycolysis, TCA cycle and oxidative phosphorylation. While TCS was responsible for mitochondrial dysfunction resulting in inflammasome activation, CHX induces translational arrest. Therefore, the formation of stress granules was determined in CHX-treated cells using fluorescence microscopy. Besides, podosome formation was observed, potentially resulting in ECM degradation. Likewise, small and large ribosomal proteins and proteins related to the actin cytoskeleton were identified as putative key drivers by a networked-based analysis (WGCNA).

The obtained data showed significant alterations of the inflammatory response in macrophages by TCS and substitute exposure, especially CHX. The results illustrate the need to understand molecular mechanisms for developing strategies to minimise adverse effects.

1.12.P-We086 Acetylation and Phosphorylation are Dynamically Involved in Adipocyte Differentiation and Provide Insight on their Response to the Emerging Plastic Additive DINCH

Alix Sarah Aldehoff[1]*, Isabel Karkossa*[2]*, Sontje Krupka*[3]*, Cornelius Goerdeler*[2]*, Beatrice Engelmann*[2]*, Nora Klöting*[3]*, Matthias Blüher*[3]*, Ulrike Rolle-Kampczyk*[2]*, Kristin Schubert*[2,4] *and Martin von Bergen*[2,4,5,6]*, (1)Helmholtz Centre for Environmental Research (UFZ), Germany, (2)Molecular Systems Biology, Helmholtz Centre for Environmental Research (UFZ), Germany, (3)Helmholtz Institute for Metabolic, Obesity and Vascular Research HI-MAG, Helmholtz-Centre Munich at the University of Leipzig and University Hospital, (4)* Authors contributed equally, (5)Faculty of Biosciences, Pharmacy and Psychology, Institute of Biochemistry, Faculty of Biosciences, Pharmacy and Psychology, University of Leipzig, Germany, (6)German Centre for Integrative Biodiversity Research (iDiv) Halle-Jena-Leipzig, Germany*

Obesity is a major public health burden impacting life quality and expectancy of more than one billion people worldwide. Factors beyond genetic predisposition and modern sedentary lifestyle may facilitate the development or progression of obesity. Metabolism-disrupting chemicals (MDCs) ubiquitously present in our environment are external factors that can promote obesogenic onset by interfering with endocrine regulation yet causing metabolic conditions. The molecular mechanisms underlying the exposure to MDCs in adipose tissue are incompletely understood. Especially for emerging contaminants, fundamental knowledge about their modes of action is lacking. Proteins critically control biological processes, with their post-translational modifications (PTMs) serving as proxies of cellular signalling.

Hence, we analysed the PTMs acetylation (AcK) and phosphorylation (PP) during adipocyte development and during exposure to the emerging plastic additive DINCH (1,2-cyclohexanedioic acid diisononyl ester) and its active metabolite MINCH (monoisononylcyclohexane-1,2-dicarboxylic acid ester), to gain insight into molecular events triggered upon exposure. We combined mass-spectrometry based proteomics with PTM enrichment strategies on human SGBS and murine 3T3-L1 adipocyte cell lines as well as visceral, subcutaneous, brown adipose tissue and liver of C57BL/6N mice following dietary exposure to DINCH for 16 weeks.

During healthy adipogenesis of SGBS and 3T3-L1 cells, we observed a dynamic involvement and distinct time-dependent profiles of the acetylome and phosphoproteome. AcK was dominantly involved in core metabolism while PP was found important for cell structural organization and insulin signalling, both with great relevance for the development of metabolic co-morbid conditions. MINCH exposure of SGBS adipocytes altered the PTM profiles of glycolysis/gluconeogenesis (AcK) and insulin signalling (PP) and pointed to the Rab effector WDR44 as relevant phosphorylation target. Dietary exposure to DINCH *in vivo* indicated no distinct phenotype, but appeared to be associated with distinctive liver damage, inflammation and disturbed lipid metabolism at the cellular level.

This data contributes to a better understanding of the ways MDCs affect adipogenesis and adipose tissue depots, thereby aiding the development of adverse outcome pathways (AOPs) and regulatory risk assessment.

1.12.P-We087 Multiomic Analysis of Tributyltin-Exposed Adipocytes Reveals Omic-Related Signatures Associated with Metabolic Syndrome

Dayna Schultz[1], *Ilias Frydas*[1], *Nafsika Papaioannou*[1], *Thanasis Papageorgiou*[1], *Catherine Gabriel*[1], *Martin Wabitsch*[2], *Jan Kucera*[3], *Spyros Karakitsios*[1] *and Dennis Sarigiannis*[1], *(1)Aristotle University of Thessaloniki, Greece, (2)Division of Pediatric Endocrinology and Diabetes, Ulm, Germany, (3)Masaryk University, Czech Republic*

Metabolic syndrome is a cluster of frequently co-occurring conditions linked to various health outcomes, increasingly attributed to exposure to endocrine-disrupting chemicals (EDCs). Specifically, EDCs may impact the normal development and function of adipose tissue, once considered an inert storage depot. However, mounting evidence suggests that it is a complex and metabolically active organ with a considerable influence on the regulation of metabolism and energy homeostasis. To explore relevant effects of EDCs, Simpson-Golabi-Behmel syndrome (SGBS) pre-adipocytes were exposed to tributyltin (TBT), a known lipogenic substance, to map the omic signature associated with metabolite and transcript dysregulation. SGBS pre-adipocytes were grown to near confluence and incubated in differentiation medium for four days, followed by cultivation in maintenance medium for six days. The differentiation medium of TBT-exposed cells was additionally supplemented with 25nM TBT during the initial four days. Cells were harvested at day 10 of differentiation and TBT-exposed and differentiated controls were compared. Samples for untargeted metabolomics were analyzed using Reversed Phase (RP) and Hydrophilic Interaction (HILIC) Liquid Chromatography in positive and negative ionization modes. Transcriptomic analysis was performed using Agilent microarrays to determine differentially expressed genes (DEGs) between treatment groups. Data preprocessing, batch correction, and statistical analyses were conducted in R using *xcms*, *IPO*, *PMCMRplus*, and *xMSannotator* packages for metabolomics, and *limma* for transcriptomics. An integrated omics analysis pipeline was employed, using univariate and multivariate approaches in *mixOmics* and *MetaboAnalystR*, aimed at enhancing the depth of understanding of multiomic mechanisms. This approach highlights both individual molecular changes and their integrated effects on cellular pathways. Across analyses, perturbations in pathways linked to metabolic dysfunction, including dyslipidemia, obesity, and inflammation, were identified consistently. The consistent identification of key features and shared perturbed pathways provides a foundation for further mechanistic investigations and potentially informs strategies for mitigating the adverse effects of these exposures. Future studies will delve deeper into the adipocyte 'ome', seeking indications of susceptibility or early warning signs specific to health outcomes such as metabolic syndrome.

1.12.P-We088 Concomitant Investigation of Protein Expression, Neurotransmitter Levels and Locomotor Behavior in Zebrafish Larvae upon Exposure and Depuration from Neuroactive Pharmaceuticals Fentanyl and Buspirone

Ksenia J Groh, PhD[1], *Samira Senft*[1,2], *Melissa von Wyl*[3], *Severin Ammann*[3], *Rene Schonenberger*[3] *and Colette vom Berg*[3], *(1)Eawag - Swiss Federal Institute of Aquatic Science and Technology, Switzerland, (2)Institute of Biogeochemistry and Pollution Dynamics, ETH Zurich, Switzerland, (3)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland*

Pharmaceutical residues can contaminate aquatic environment due to incomplete removal during wastewater treatment. Exposure to these compounds can cause various effects in non-target species, such as changes in fish behavior. This could occur either due to specific disruption of normal functioning of the nervous system (since many molecular targets of neuroactive compounds are well conserved across vertebrates), or through non-specific mechanisms, such as physiological disturbance or depletion of energy reserves.

Zebrafish (*Danio rerio*) larvae are often used to test for neurotoxicity of diverse compounds by studying their effects on locomotion. However, such chemical-induced alterations of locomotor behavior were often observed to be transient (reversible) in nature, and hence their ability to reflect specific changes in the nervous system remains unclear. In order to investigate the persistency and reversibility of chemical-induced behavioral changes, we developed a test setup where behavior is first assessed at 6 days post fertilization (dpf) in zebrafish larvae continuously exposed to test chemicals from birth. To assess recovery potential, some fish are then transferred to clean water, followed by daily re-testing of behavior in depurated and continuously exposed individuals until 9 dpf.

Exposure to non-toxic levels of two neuroactive pharmaceuticals, fentanyl and buspirone, caused strong hypoactivity at 6 dpf for both compounds and in both light and dark conditions. Upon depuration, reduced activity in the dark rapidly recovered to non-exposed levels already after one day (at 7 dpf) for both substances. In contrast, reduced locomotion in the light persisted until 8 dpf for fentanyl, and did not recover even at 9 dpf (i.e., after three days of depuration) for buspirone.

To investigate molecular changes underlying these responses, we carried out concomitant molecular analyses that included global proteomics by nanoLC-MS/MS with data-independent acquisition mode and targeted metabolomics for a set of 16 neurotransmitters and precursors. Interestingly, both pharmaceuticals reduced the levels of catecholamines epinephrine and norepinephrine, and differentially affected several other metabolites. The analysis of proteomics data set is currently ongoing with the goal to identify potential protein markers which could be predictive of recovery potential in the dark and/or of persistent hypoactivity in the light, observed in response to these compounds.

1.12.P-We089 Proteomic Analysis of Short-Chain Perfluorinated Alkyl Substance (PFAS) Exposure in Fathead Minnows (Pimephales Promelas)

***Cristina Henriques**, Theresa Warriner and Denina B.D. Simmons, Ontario Tech University, Canada*

Perfluoroalkyl substances are widely used anthropogenic compounds with many structures and applications. Over the years, there has been a great concern regarding their usage as exposure can result in liver toxicity, endocrine disruption and bioaccumulation, thus resulting. As of recently, the presence of short-chain PFAS within commercial products and within the environment has risen. Current research focuses on legacy long-chained PFAS, with very little information available for the health and environmental risks of short-chain PFAS. Therefore, more information on short-chained PFAS toxicity is required as their prevalence increases. To determine the toxicity of short-chain PFAS in comparison to its' long-chained counterparts, fathead minnow (Pimephales promelas) were exposed to PFOS (5ug/L), PFHxS (5ug/L), PFBS(5ug/L) as well as an environmentally relevant mixture (PFOS: 110ng/L, FHxS:10ng/L, PFBS: 20ng/L) for 28 days. Post exposure, mucus, blood and brain were collected and stored at -80°C for future proteomic analysis. Muscle was also collected to determine bioaccumulation. Proteins from samples were digested with heat and formic acid, and analyzed with a LC-QTOF (Agilent 1260 LC and 6545 QTOF) using data-dependent acquisition (DDA) to create a spectral peptide library, and then MS1 filtering was performed using Skyline software and their DDA workflow. In this presentation, preliminary results from the mucus, blood and brain proteomes will be presented.

1.12.P-We090 Leveraging Multi-Omics Analyses to Explore the Toxicity of Urban Road Runoff Contaminants in Juvenile Salmonid Species

Miranda Elizabeth Jackson[1], Chloe Fender[2], Stacey L Harper[2] and ***Manuel Garcia-Jaramillo**[2]*, *(1)Environmetnal and Molecular Toxicology, Oregon State University, (2)Oregon State University*

Urban roadway runoff is correlated to escalating pre-spawn mortality (PSM) events in Pacific Northwest salmon populations. Recently, a chemical derived from tires, N-(1,3-Dimethylbutyl)-N'-phenyl-p-phenylenediamine-quinone (6PPD-q), was isolated from roadway runoff and observed to induce acute mortality in salmonids, however sensitivity among salmonid species is varied. It is predicted that exposure to 6PPD-q will enhance salmonid sensitivity to other cooccurring contaminants commonly detected in surface waters, such as the polycyclic aromatic hydrocarbon 9,10-Anthraquinone (AQ). To determine sublethal concentrations, juvenile salmonid species (chinook, coho, and rainbow trout) were exposed to a range of concentrations of 0 – 10 µg/L 6PPD-q for 24-hours. A targeted multiple reaction monitoring (MRM) method was developed in a triple quadrupole mass spectrometer, coupled to an ultra-high-performance liquid chromatography system to quantify 6PPD-q and AQ in water samples. To better understand the mechanisms of toxicity of 6PPD-q, fish were exposed to established sublethal concentrations of 6PPD-q and AQ separately and in combination over a five-day period. AQ and 6PPD-q quantification in water tanks were validated and measured within a 15% margin of error. Coho and rainbow trout exhibited PSM symptoms leading to mortality at 6PPD-q concentrations after 24-hour exposure to 0.01 µg/L and 10 µg/L, respectively. PSM symptoms and mortalities were observed in coho and rainbow trout, but not chinook. Non-targeted mass spectrometry-based metabolomics analyses were performed on brain and liver samples from exposed and non-exposed fish. Using in-house and open-source spectral libraries we annotated 290 and 260 metabolites in the brain and liver tissues, respectively, with high level of confidence. A larger number of significant changes were observed in the liver tissues within each specie when compared to the brain tissues (Wilcoxon rank sum test, $p < 0.05$). Fatty acid biosynthesis was the pathway most significantly affected by 6PPD-q exposure in coho salmon, as revealed by metabolic pathway enrichment analysis. QuantSeq 3' mRNA-sequencing transcriptomics analysis will be integrated with the metabolomics data. This study aims to clarify the impact of prioritized urban road runoff contaminants on salmonids health, contributing to a deeper understanding of the observed variations in toxicity among different salmonid species and mechanisms of action.

1.12.P-We091 The Use of Concentration Ranges Inducing Defense and Damage Responses as a Promising Approach to Overcome Database Gaps in Metabolite Annotation in Ecotoxicology

***Simon Colas**[1], Benjamin Marie[2], Claude Fortin[3] and Séverine Le Faucheur[1], (1)Universite de Pau et des Pays de l'Adour, E2S-UPPA, CNRS, IPREM, France, (2)UMR 7245 CNRS/MNHN « Molécules de Communication et Adaptation des Micro-organismes », Muséum National d'Histoire Naturelle, France, (3)Centre Eau Terre Environnement, Institut National de la Recherche Scientifique – Eau Terre Environnement, Canada*

The use of untargeted metabolomic data by liquid chromatography-high resolution mass spectrometry (LC-HRMS) enables the characterization of families and functions of molecules within biological systems without making an *a priori* decision on the molecules to be identified. However, this approach has some limitations. Indeed, the proportion of annotation of untargeted metabolomic features with the use of databases proved to be very low (~5% of the chemical signal). The trends in the dose-response model of the untargeted metabolomic feature are a biological parameter that can reflect the metabolome responses of a biological system exposed to a contaminant without the need for an annotation step. Following a meta-analysis of response trends (*i.e.* biphasic: bell- and U-shaped, monotonic: decreasing and increasing) of known biomarkers of defense and damage that we performed on 156 selected articles, 2,595 dose-response curves were interpreted from exposure experiments to inorganic and organic contaminants on 18 phyla, representing four kingdoms. The results of multinomial logistic models showed that defense biomarkers mainly describe biphasic trends, while damage biomarkers follow monotonic trends. Based on these observations, we have characterized the metabolomic response of river biofilms exposed to cobalt, using dose-response modeling, benchmark-dose calculations and characterization of response trends. The trends in the dose-response curves obtained for all untargeted metabolomic features revealed a concentration range in which the biofilms were likely to exhibit a defense response (predominance of untargeted metabolomic features with a biphasic trend) and a range in which the biofilms would instead exhibit a damage response (predominance of untargeted metabolomic features with a monotonic trend). Following these observations, we proposed a new concept of concentration range inducing defense responses (CRIDeR) and concentration range inducing damage responses (CRIDaR). This holistic approach makes it possible to use the entire chemical signal of the metabolome without being restricted by the metabolite annotation step. It can also be used to monitor the effects of exposure time with the characterization of a time range inducing defense responses (TRIDeR) and a time range inducing damage responses (TRIDaR). This approach represents a promising avenue for the development of a robust and sensitive tool for environmental risk assessment.

1.12.P-We092 Analyzing the Metabolic Effects of Nitrobenzene Exposure in Japanese Medaka (Oryzias latipes) with Consideration of Reproductive Cycle

***Jaehyeon Park** and Sang Don Kim, School of Earth Science and Environmental Engineering, Gwangju Institute of Science and Technology (GIST), Korea, Republic of (South)*

The analysis of fish metabolites is a widely adopted research methodology aimed at scrutinizing diseases and detecting anomalies in diverse conditions. In this study, we seek to investigate the metabolic perspective of chemical exposure and toxicity in fish through the utilization of metabolic analysis. To accomplish this, we made a decision to investigate metabolic alterations in a manner that accounts for the potential impact of gender and reproductive cycle on metabolic changes. We chose the Japanese medaka (*Oryzias latipes*) as the experimental species due to its brief reproductive cycle that permits daily egg-laying under favorable circumstances. Furthermore, we selected a sampling method to acquire samples from both the control and experimental groups as a singular entity, involving the concentration and measurement of extracorporeal metabolites released into the media over a designated time interval. We sampled the medaka three times a day in accordance with their reproductive cycle to verify metabolic changes that are dependent on the reproductive cycle, which is characterized by daily ovulation. Nitrobenzene, a chemical commonly used in industry, was the initial chemical used in the experiment due to its potential for exposure to water systems in case of an accident and prior research highlighting its toxic effects on fish. In this study, an investigation of the impact of both the reproductive cycle and nitrobenzene exposure on the extracorporeal metabolites of medaka was undertaken. Utilizing PLS-DA for data analysis, it was discerned that the metabolites emitted by medaka underwent alterations within reproductive cycle. Moreover, a distinctive identification of metabolites that exhibited a notable decrease post nitrobenzene exposure, as compared to their pre-exposure state, indicated an encompassing influence on the reproductive cycle. To delve further into these effects, enumeration and annotation of metabolites displaying significant changes in each analysis will be conducted. Subsequently, from the metabolites influenced by sampling time and nitrobenzene exposure, we will identify biomarkers to differentiate changes attributed to the reproductive cycle and those induced by nitrobenzene exposure. By elucidating the biological characteristics of these metabolites, we aim to foresee potential transformations within the medaka.

1.12.P-We093 Optimization of simultaneous metabolomics and lipidomics analysis to improve reliability of multi-omics and reduce zebrafish animal use

*Eun Ki Min and **Kitae Kim**, Seoul National University of Science and Technology, Korea, Republic of (South)*

Recent toxicological studies have employed multi-omics analysis to identify the underlying molecular mechanism. However, preparing individual animal samples for each omics analysis has the problem of increasing exploratory animal use. To overcome this limitation, we aimed to develop a novel approach for simultaneous analysis of both metabolomics and lipidomics. We collected 5 days post-fertilization zebrafish larvae, with pooling size of 15, 30, 50, and 100, and biological replicate of 4. Metabolites and lipids of zebrafish larvae were extracted with methyl *tert*-butyl ether (MTBE). To compare solvent effects, the metabolites of 15 larval group was further extracted with chloroform and methanol. Moreover, untargeted metabolomics employed to cover diverse metabolites, while targeted lipidomics applied to enhance identification of lipid species. Metabolomic profiles with MTBE extraction were similar to those with chloroform or methanol extraction, indicating that MTBE extraction performance was sufficient for metabolome analysis. The metabolomic profiles of 15, 30, 50, and 100 larvae contained 202, 234, 248, and 305 metabolites and 47, 45, 47, and 50 pathways. Of 54 pathways, 39 pathways were overlapped regardless of pooling size while 15 larval groups covered 86% of the pathways enriched in 100 larval group. Similarly, the lipidomic profiles of 15, 30, 50, and 100 larvae contained 274, 283, 285, and 290 lipids. The lipids identified in 100 larvae included those identified in all pooled groups, and 15 larval group was covered 94% of the lipids measured in 100 larval group. MTBE-based simultaneous extraction strategy was newly proposed for zebrafish toxicology. We showed that both metabolomics and lipidomics can be performed at least 15 larvae and demonstrated that analyzing biomolecules of multiple layers is possible in a single sample, which will improve the reliability of omics, more importantly, reduce animal use.

1.12.P-We094 Lipidomic Profiling of Coral Exposed to Phthalate Demonstrates a Microplastic Pollution-Deriving Environmental Risk in the Ocean

Chuan-Ho Tang[1], *Ting-Ju Liu*[2] *and Ching-Yu Lin*[3], *(1)National Museum of Marine Biology and Aquarium/National Sun Yat-sen University, Taiwan, (2)National Sun Yat-sen University, Taiwan, (3)National Taiwan University, Taiwan*

Microplastics increase the bioaccessibility of chemical additives, such as plasticizers, for suspension feeders, leading to concerns regarding what detrimental effects would be induced on coral health. As a foundational role in various cellular processes, the lipidome can represent the change in the health of an organism. Untargeted lipidomic profiling of coral exposed to di(2-ethylhexyl) phthalate (DEHP) less than 2.0 μg/L for 10 days was therefore performed to gain insight into the health impacts in this study. Decreasing saturated and polyunsaturated (22:6-possessing species especially) triradylglycerols featured predominantly in coral exposed to DEHP, but increasing some of the triradylglycerols including shorter saturated and 20:5 fatty acid chains was additionally observed during the early exposure. These results indicated that DEHP can induce activation of mitochondrial and peroxisomal β-oxidation and the host-mediated storage lipid biosynthesis of symbiotic algae in the coral. Potentially expending triradylglycerols on actions such as increasing 20:5- and 22:6-possessing ether glycerophospholipids for downregulating inflammation was additionally observed in the coral host cells. Predominantly increasing membrane lipids, including betaine [such as DGCC(22:6/22:6), DGCC(16:0/28:7), DGCC(20:5/16:0) and DGCC(14:0/22:6)] and galacto- [such as MGDG(18:4/20:5) and DGDG(18:4/20:5)] lipids, that expended storage lipids as well was also observed in the coral symbiotic algae, relating with the increased light sensitivity. DEHP exposure not only induced effects similar to that regulated by peroxisome proliferators activated receptors on coral host cells but also affected the physiological conditions of symbiotic algae and potentially the interaction of symbiosis. Although coral seems unstressed directly by DEHP, some weaknesses, such as hypoimmunity, would result in chronically risk coral health as highlighted by this study.

1.12.P-We095 Multi-Omics in Nanoplastic Research: A Spotlight on Aquatic Life

Mohamed Helal[1], *Min Liu*[2], *Honghong Chen*[3], *Minglian Fang*[4], *Wenhui Qiu*[3], *Frank Kjeldsen*[5], *Knut Erik Tollefsen*[6], *Vengatesen Thiyagarajan*[7], *Henrik Holbech*[8] *and Elvis Genbo Xu*[1], *(1)Biology, University of Southern Denmark, Denmark, (2)School of Civil and Environmental Engineering, Nanyang Technological University, Singapore, (3)School of Environmental Science and Engineering, Southern University of Science and Technology, China, (4)Environmental Science and Engineering, Fudan University, China, (5)Department of Biochemistry and Molecular Biology, University of Southern Denmark, Denmark, (6)Norwegian Institute for Water Research (NIVA), Norway, (7)School of Biological Sciences, University of Hong Kong, China, (8)University of Southern Denmark, Denmark*

Amidst increasing concerns about plastic pollution's impacts on ecology and health, nanoplastics are gaining global recognition as emerging environmental hazards. This potential review aimed to examine the complex molecular consequences and underlying key toxicity mechanisms that were reported from the exposure of diverse aquatic organisms to nanoplastics. Through the comprehensive examination of transcriptomics, proteomics, and metabolomics studies, we explored the intricate toxicodynamics of nanoplastics in aquatic species. The findings raised important questions about the consistency of findings across different omics approaches, the value of combining these omics tools to better understand and predict ecotoxicity, and the potential differences in molecular responses between species. By amalgamating insights from 37 Omics studies (transcriptome 22, proteome 6, and metabolome 9) published from 2013 to 2023, the work uncovered both common and distinct toxic effects and mechanisms in which nanoplastics can affect aquatic life, also a special emphasis on zebrafish response and underlined toxicity mechanisms to nanoplastic is highlighted. Finally, recommendations were provided for advancing omics-based research on nanoplastic pollution. This comprehensive review illuminates the nuanced connections between nanoplastic exposure and aquatic ecosystems, offering crucial insights into the complex mechanisms that may drive toxicity in aquatic environments.

1.12.P-We096 In vivo high throughput screening for mechanism-based toxicity assessment of chemical mixtures from consumer products using Caenorhabditis elegans Transcription Factor RNAi

Elizabeth Dufourcq Sekatcheff, PhD, *Siyeol Ahn, Chaein Chong and Jinhee Choi, School of Environmental Engineering, University of Seoul, Korea, Republic of (South)*

Identifying toxic effects of consumer products is challenging due to undisclosed composition of the products and the assessment of combined effects of ingredients. Indeed, toxic effects of chemical mixtures are often more complex than the simple addition of effects of ingredients. Numerous mathematical models are available to assess synergetic or antagonistic effects of chemical mixtures, but they lack empirical evidence to strongly support risk assessment and decision making. Here, we have developed an in vivo high throughput screening method to assess the toxicity mechanisms of chemical mixtures from consumer products using Caenorhabditis elegans model species. A set of 384 transcription factors which covers 41% of all predicted transcription factors in C. elegans were tested using RNAi method. The RNAi library covers a wide range of biological pathways that can be triggered upon exposure to various types of chemicals. RNAi-fed worms are then tested for various toxicological endpoints including reproduction, locomotion, or development, using automated assays. Then, the biological pathways triggered by the transcription factors significantly leading to either rescued or exacerbated toxicity are analyzed using KEGG and REACTOME databases. Downstream genes involved in these pathways are then functionally validated by measuring their expression in a dose dependent manner. This method was successfully implemented for complex chemical mixtures such as crude oil in which worms were tested for reproductive toxicity. Several transcription factors involved in NER (Nucleotide Excision Repair) pathway led to exacerbated toxicity. Downstream genes were validated in zebrafish and showed the same dose response relationship, confirming the possibility to extrapolate to vertebrates. This approach can be used to infer molecular key events to build Adverse Outcome Pathways (AOPs) and enhance the prediction of toxicological adverse outcomes. In conclusion, this method has great potential as a fast and efficient screening method for mechanism-based toxicity assessment of chemical mixtures in consumer products.

1.12.P-We097 Molecular Response of Chironomus riparius to Antibiotics

Judit Kalman[1]*, Yolanda Valcarcel Rivera*[1] *and Jose-Luis Martinez-Guitarte, PhD*[2]*, (1)Rey Juan Carlos University, Spain, (2)National Distance Education University (UNED), Spain*

Antibiotics are widely used in human and veterinary medicine and can enter the environment by several ways. Although these pharmaceuticals have been released into the environment for many years, they are usually detected at concentrations below than those known to cause acute toxicity to organisms. Indeed, antibiotics have received particular attention, mainly because of the ability of bacteria to develop resistance against them. While these biologically active compounds are designed to interact with microorganisms, the continuous introduction of antibiotics into the environment likely has an impact on non-target organisms living in aquatic systems.

Standard toxicological tests may fail to detect the adverse effects of antibiotics, however, new methods can give an insight into the pathways and physiological responses affected by them. *Chironomus riparius* is a dipteran with aquatic larvae widely used in toxicology tests. This species is abundant in the freshwater ecosystems, acts as an important component of many food chains, moreover it is sensitive to different toxicants. Currently, little is known on the effects of antibiotics on this aquatic insect at the molecular level.

In this study, the gene expression profile of *C. riparius* in response to different groups of antibiotics (aminoglycosides, fluoroquinolones and penicillins) was assessed. Fourth instar larvae were exposed to 0.001, 0.1 and 10 mg/L of each antibiotic for 24 and 72 h. The expression of genes involved in hormonal regulation, detoxification mechanisms, stress response and DNA reparing were analyzed. Results showed that all antibiotics altered the mRNA levels. Three of the four antibiotics (amoxicillin, neomycin and levofloxacin) caused downregulation at 24 h and an increased transcription of genes at 72 h. While genes affected by gentamycin showed an opposite trend.

These findings indicate that the transcriptional activity of endocrine related, cellular stress, detoxification and DNA repair genes was altered by antibiotics in *C. riparius*. Gene expression analysis has been shown as a useful tool to provide information on the underlying mechanisms of toxicity for these pharmaceuticals. Additional research is needed to better understand the impacts of antibiotics on this species.

1.12.P-We098 "Understanding impact of BEMT on larval zebrafish: Thyroid hormone disruption, transcriptome profiling and implications for early life development"

Yujin Park[1]*, Yunchul Ihn*[1]*, Jihye Park*[2]*, Keunsoo Kang*[2] *and Kyungho Choi*[1]*, (1)School of Public Health, Seoul National University, Korea, Republic of (South), (2)Dankook University, Korea, Republic of (South)*

Due to the health risks associated with ultraviolet radiation, the use of sunscreen is commonly recommended. Bis-ethylhexyloxyphenol methoxyphenyl triazine (BEMT) serves as an organic UV filter and UV stabilizer in sunscreens. Its extensive use and frequent detection in sediment and freshwater have raised concerns regarding potential environmental health implications. However, limited information exists regarding its toxicological characteristics, notably its impact on endocrine disruption.

In this study, we conducted a 5-day exposure of embryo-larval zebrafish (Danio rerio) to a range of BEMT concentrations (0.01, 0.1, 1uM). Following the exposure, we evaluated its effects on thyroid hormone disruption and developmental toxicity. Additionally, we performed RNA-seq analysis to identify differentially expressed genes (DEGs) and to elucidate affected genes and pathways.

Our findings revealed a dose-dependent decrease in thyroid hormone levels in larval fish along with down-regulation of genes associated with the hypothalamic-pituitary-thyroid (HPT) axis. Moreover, exposure to higher BEMT concentrations resulted in a notable decrease in swim bladder size in larval zebrafish, indicating potential thyroid hormone disruption. RNA-seq analysis unveiled a significant number of DEGs, notably the downregulation of *ugt1ab* and *hhex* genes. Confirmatory qPCR analysis suggested reduced thyroid hormone metabolism, aligning with the observed decrease in thyroid hormone levels in the fish.

Furthermore, KEGG and GO analyses indicated that upregulated DEGs were primarily involved in neurological pathways, while downregulated DEGs were associated with lipid metabolic pathways. These observations suggest potential disruption in nervous system development and lipid metabolism due to BEMT exposure, in addition to thyroid hormone disruption. However, the correlation between alterations in neurodevelopment and lipid metabolism with thyroid disruption requires further investigation. Given the limited understanding of BEMT's toxicity despite its widespread use, our study underscores the necessity for comprehensive investigations into its endocrine and various other effects, particularly during early stages of life.

This work was supported by Korea Environmental Industry & Technology Institute (KEITI) through "Core Technology Development Project for Environmental Diseases Prevention and Management", funded by Korea Ministry of Environment (MOE) (RS-2022-KE002173).

1.13 The Endocrine Disrupting Properties of Challenging Substances: How to Solve Testing and Interpretation Issues?

1.13.T-01 How to screen UVCBs endocrine activities using OECD guidelines: a case study with essential oils

Barbara ROBIN Duchesne[1], *Benoit Salinier*[2], *Marine Rousseau*[1], *Andrew Tindall*[3] *and Gregory F. Lemkine*[3], *(1)Laboratoire Watchfrog, France, (2)Laboratoire Watchfrog S.A., France, (3)Watchfrog S.A., France*

UVCBs are composed of numerous molecules with different physical and chemical properties influencing their solubility in water, some being easily soluble while some others are practically insoluble.
Assays performed on aquatic eleuthero-embryos of Japanese medaka fish (*Oryzias latipes*) or amphibians (*Xenopus laevis),* require test items to be fully solubilized in aqueous water-based test media. These assays have been developed to identify endocrine active chemicals or mixtures e.g., the XETA assay (OECD TG 248), the RADAR assay (OECD TG 251) and the REACTIV assay (OECD draft TG under review).
We will aim to describe the critical steps of the methodologies to successfully assess UVCBs using in *vivo* models at an *in vitro* scale.
Prior to definitive tests, solubility in test media needs to be determined for each UVCB. If the test item is not fully soluble in the test medium alone, further solubility assays are performed according to the OECD Guidance Document 23 using organic solvent to facilitate solubility. A number of organic solvents including DMSO and ethanol have been shown to be inert on the estrogen, androgen and thyroid axes, as well as steroidogenesis when using the assays listed above.
Subsequently, a critical step is determining of the maximum tolerated concentration (MTC). The MTC is determined by carrying out a range-finding trial performed in the conditions of the definitive test. The highest concentration tested in the range-finding experiment is set by the solubility limit or 100 mg/L, whichever is the lowest, and generally four test concentrations are added following a separation factor ≤ 10.
It is also important prior to testing UVCBs to evaluate the ability of the assay to correctly identify the net effects of several active chemicals in a complex environment, i.e., in the presence of multiple chemicals that are inert in the assay.
Finally, using an endocrine system to assess an endocrine activity is critical. Eleuthero-embryos are sensitive to multiple modes of action, taking into account chemicals acting through nuclear receptors, transporters, hormonal metabolism etc. The specificity of the endocrine response is ensured by reading out expression of a reporter gene under the control of a gene promotor which is directly and specifically regulated by the endocrine axis in question.
Examples of the testing of essential oils and their constituents will be presented to illustrate the importance of these methodological steps.

1.13.T-02 Assessing the endocrine disruptor potential of hydrocarbon UVCBs

Rebecca Jayne Brown[1], *Rhiannon Smith*[1], *Olivia Lin Tran*[1], *Kate Roylance*[1], *Owen Green*[1], *Christopher Prosser*[2,3], *Kat Colvin*[4,5], *Anna Tan Sépot*[3,6], *Nicholas Synhaeve*[3], *Delina Lyon*[3], *Leslie J Saunders*[3] *and Sergio A Villalobos*[7], *(1)wca environment Ltd., United Kingdom, (2)ExxonMobil, (3)Concawe, Belgium, (4)BP I&E Applied Sciences, United Kingdom, (5)Member of Concawe, Belgium, (6)TotalEnergies, (7)BP*

New hazard classes are being introduced under the EU Classification and Labelling (CLP) regulation to cover endocrine disruption (ED). In addition, data requirements for assessing ED are planned as part of updates to the European Union (EU) Registration, Evaluation, Authorisation and Restriction of Chemicals regulation (REACH). ED assessments are complex and data intensive, and multiple mechanisms of action, including effects occurring in the presence of general systemic toxicity, can affect the outcome. Draft CLP guidance for ED does not currently cover UVCBs (substances of unknown or variable composition, complex reaction products or of biological materials), but it is expected that both whole substance data and data for representative constituents will be required to conclude on ED classification.

Here we describe an initial ED data gathering exercise for example UVCBs in a petroleum stream category. Some whole substance *in vivo* data were available for mammals and screening level data based on quantitative structure–activity relationship (QSAR) and *in vitro* ToxCast bioassays was gathered for 25 selected representative constituents covering eight hydrocarbon classes. Many of the constituents were found to be outside the QSAR applicability domains of the methods. Also, despite there being *in vitro* data available for 17 constituents, only data for three were acceptable because analytical data could not adequately confirm the presence of the test item for 14 of the substances, most of which are volatile.

The acceptable *in vitro* data were useful for prioritising constituents for further investigation, with e.g. biphenyl assigned as low priority, and phenanthrene and fluoranthene both assigned high priority. The other screening data were however of limited value, with no scope for ruling out ED activity or considering whether ED activity might differ within or between hydrocarbon classes. Further work is needed to develop more reliable QSAR models and *in vitro* data for hydrocarbons. However, given the difficulties with testing already observed in the available dataset, it is currently unknown whether the battery of proposed *in vitro* tests for ED that are expected to be introduced under REACH will be suitable for testing certain hydrocarbon constituents (e.g., volatiles) or whole petroleum substances.

1.13.T-03 How to Effectively Assess the Endocrine Disruption Potential of Metals Under the EU CLP Regulation?

Chloe Eastabrook[1]*, Louise Pope*[1] *and Stijn Baken, PhD*[2]*, (1)Enviresearch, United Kingdom, (2)European Copper Institute, Belgium*

New hazard classes for endocrine disruption (ED) have been introduced to the EU's Classification Labelling and Packaging Regulation (CLP). Substances may be classified as 'known or presumed to be endocrine disruptors' (Category 1) or 'suspected to be endocrine disruptors' (Category 2) in humans or in the environment, with the differentiation between the categories based on the strength of available evidence. This presents a new challenge for the hazard classification of chemicals that are naturally involved in, or interact with, the endocrine system, particularly where supporting data from regulatory studies is lacking or inadequate.

Metals and inorganic metal compounds have specific properties that complicate their assessment. This is especially the case for essential elements which have a function in a wide variety of endocrine and non-endocrine physiological processes. New guidance is being developed by ECHA on how to assess substances for ED under CLP. A recently published framework describes the three main types of interactions metals can have with the endocrine system: indirect effects, endocrine modulation, and endocrine disruption. This project developed a series of worked examples to demonstrate how this framework can be integrated into and improve the guidance on how to evaluate metals to allow appropriate hazard classification in accordance with CLP Regulation.

Three examples were developed based on realistic and theoretical datasets. These data varied in reliability, included non-standard endpoints and/or non-standard test species. The assessment considers three criteria for endocrine disruption: adverse effects, endocrine activity, and a biological plausible link between the two, and uses a weight of evidence (WoE) approach to conclude the appropriate hazard classification. By giving weight in the evaluation to data depending upon their reliability, the WoE approach helps in identifying the most plausible toxicity pathway that is occurring, and whether this is driven by ED or by an alternative mechanism (e.g., endocrine modulation or indirect effects on the endocrine system). This integration of the metals framework provides a better understanding of the complexity of metal interactions in endocrine systems. This framework, and the examples presented here, can complement ECHA's guidance on CLP, particularly with the WoE approach, to support accurate hazard classification of metals for ED.

1.13.T-04 The Challenges of Distinguishing Non-Endocrine from Suspected Endocrine Responses: The Precautionary Tale of Copper

Douglas J. Fort[1]*, Jeffrey C. Wolf*[2]*, Carol Mackie*[3]*, Kevin Long*[3]*, Craig A. Poland*[3] *and Stijn Baken, PhD*[4]*, (1)Fort Environmental Laboratories, Inc., (2)EPL, Inc., (3)Regulatory Compliance Limited, United Kingdom, (4)European Copper Institute, Belgium*

Experimental design plays a vital role in ecotoxicological endocrine disruption (ED) studies as it helps to distinguish between direct endocrine-related effects and other mechanisms that may involve indirect or compensatory endocrine responses. In both fish and amphibians, non-endocrine factors such as bioenergetics, dietary iodine availability, systemic toxicosis, oxidative stress, and treatment-induced stress must be considered to avoid any misinterpretation. A study was conducted to evaluate whether copper exposure during pre-metamorphic development in *Xenopus laevis* resulted in systemic toxicity that affects early development, growth, and metamorphic processes, independent of the HPT axis. Starting at developmental stage 10, frogs were exposed to copper at test concentrations of 3.0, 9.0, 27.2, 82.5 and 250 µg Cu/L. The primary endpoints included mortality, developmental stage, malformation, hindlimb length, growth (snout-vent length and wet body weight), and histopathology. The study revealed that whilst there was marked developmental delay in frogs exposed at 27.2 and 82.5 µg Cu/L concentrations, this was the result of systemic toxicity that occurred early in development, prior HPT-driven metamorphosis. This delay was not indicative of ED. In order to assess the impact of feeding on the consistency of Cu levels at low treatment concentrations, a 24-hour test was conducted using a simulation of a flow-through diluter system. Results indicated that normal feeding increased total Cu levels by 1 to 8 µg/L total copper reducing the ability to control copper exposures at low concentrations. Finally, a study is currently being conducted to evaluate the potential impact of copper exposure on reproductive performance in adult zebrafish (*Danio rerio*). This study will assess the effect of oxidative stress on the reproductive fecundity over 21-days. Sub-sampling at different timepoints will be done to measure biomarkers of oxidative stress in the gonad and liver. Reproductive endpoints will include fecundity measurements (eggs produced/female/day and fertilization daily), gonado-somatic index, liver-somatic index, plasma vitellogenin, and gonad, liver, and liver histopathology at day 21. This fish reproduction study will assist in understanding the link between non-ED toxicity, such as oxidative stress, and disturbance of the HPG axis by measuring both simultaneously.

1.13.T-05 Population Relevance of Endocrine-Mediated Effects of Pesticide and Biocide Substances – A Way Forward

Charles Hazlerigg[1]*,* ***Alice Tagliati***[1]*, Valery E Forbes*[2]*, André Gergs*[3]*, Nina Hallmark*[4]*, Lorraine Maltby*[5]*, Lennart Weltje, Prof. Dr.*[6] *and James Robert Wheeler*[7]*, (1)Enviresearch Ltd., United Kingdom, (2)Florida Atlantic University (FAU), (3)Bayer AG - Crop Science Division, Germany, (4)Environmental Safety, Bayer AG, Germany, (5)School of Biosciences, University of Sheffield, United Kingdom, (6)Agricultural Solutions - Ecotoxicology, BASF SE, Germany, (7)Corteva Agriscience, Netherlands*

Population modelling, field studies and monitoring approaches have all been proposed for assessing the effects of Endocrine Disrupting Chemicals (EDCs) at the population level for non-target vertebrates, but how these approaches should be used in the regulatory EDC hazard assessment in Europe is unclear and not detailed in the relevant Guidance Document by ECHA &

EFSA (2018). Science-based recommendations from this ECETOC expert group have been developed and presented here with the objective of addressing this shortcoming. Starting from a literature review focused on identifying published approaches assessing the population relevance of effects from EDCs, four guiding principles were developed for assessing the effects of EDCs at the population level, all together forming the 'PIER' framework: 1) Phrase (the regulatory question) - the definition of protection goals and choice of focal species (and models); 2) Implement - the individual level endpoints to be considered, the magnitude of effect to be imposed, for what duration effects should be imposed and whether individuals repairing the damage from exposure should be included; 3) Evaluate - the population-level endpoints to be considered, what threshold to set for defining an adverse effect and whether population recovery should be considered; 4) Report - the requirements for documenting the whole process. Examples for each relevant modelling- and field- case study category from the literature that are generally consistent with the PIER framework were also developed. For the selected case studies, we suggest alterations in the modelling approach and study design which would result in studies that would fulfil the PIER framework requirements and be ready for use in a regulatory context. The PIER framework presented here aims to provide a consistent approach to the population relevance assessment of EDCs based on the criteria set out in Regulations (EU) No 2017/2100 and 2018/605 and may be used to design and evaluate an appropriate modelling, monitoring or field study for any chemical to determine the population relevance of any adverse effects observed in the laboratory. None of the studies identified by the literature review comply entirely with the PIER framework we have developed, thus we suggested alterations in modelling approach and study design which would result in studies that would fulfil the PIER framework. It would be desirable to see examples that fully comply with the approach in the future.

1.13.P The Endocrine Disrupting Properties of Challenging Substances: How to Solve Testing and Interpretation Issues?

1.13.P-Tu035 Endocrine Disruptors – Hazard Classification Under CLP And New Challenges With Aquatic Tests

Adam Jonas[1] *and Lucie Čtveráčková*[2]*, (1)Regartis, Praha 6-Břevnov, Czech Republic, (2)EcoMole*

New EU regulation set classification of Endocrine disruptors (ED) for human health and ED for the environment. These classifications require thoughtful weight of evidence assessment of all relevant data. The draft CLP guidance according to which the chemicals should be assessed is available, and its final version is to be released in the Q2 2024. The draft guidance contains some approaches which were recently discussed in the scientific community and will be globally tested for the first time in the regulatory practice. The new ED REACH requirements and restriction mechanism is expected to be legalised by new Commission after EU election. This is unbalancing an expected regulatory timeframe as the required data sets for the ED evaluation should be defined in REACH whereas the way how to assess without data requirements is formulated in the CLP draft guidance. Due to variability of the REACH chemicals some ED methodologies will be difficult to be tested. Regarding aquatic toxicology, the properties of challenging chemicals and how to address them are described in the OECD 23. This guidance is however not specifically designed for the more robust aquatic ED tests as FSTRA, AMA, XETA, EASZY assay. Regarding assays as XETA and EASZY, that work with genetically modified organisms, additional properties of chemicals interfere with the receiving the correct results which are not defined in OECD 23. First, it is autofluorescence of tested chemicals. Positive endocrine activity in these tests is recognised by decrease or increase of fluorescence. Autofluorecent chemicals bring seemingly dose dependent response indicating ED activity of a chemical. Further, UV activated toxicity of tested chemical can bring almost instant mortality of tested organism. Next to these physicochemical properties, the embryonal model can be sensitive to different toxic mode of action in complex mixture of chemicals than seen in previous testing. These challenges bring more demands into the planning and designing the tests and whole ED testing strategy. Especially since the ED identification of chemical leads to ban of chemical substance in biocidal, plant protection and probably in future REACH Regulation. Any falls positive results or impossibility to perform a planned study within short regulatory timeline is extremely difficult. It is therefore desirable, that difficult substances should be well anticipated and well described in the future REACH requirements or updated CLP guidance.

1.13.P-Tu036 Endocrine Disrupting Assessment for industrial chemicals, biocides and plant protection products in the EU – Summary, challenges and improving points

Yuzhu (Celia) Wei[1]*,* ***Lydia Bouwman***[2] *and Ingrid Sterenborg*[3]*, (1)TRISKELION, Netherlands, (2)Regulatory Services, Triskelion, Netherlands, (3)Triskelion, Netherlands*

The endocrine system is a complex network, making endocrine disrupting assessment challenging. The disparities among relevant (new) regulations for different types of substances/products further complicate the process, especially for people without a scientific background. Moreover, for certain substances (e.g. UVCB), the required testing(s) for the endocrine disruptor endpoint can pose a significant challenge, even for experts in this field. While bridging the science and regulation to improve the endocrine disrupting assessment and testing strategy, especially for "difficult" substances', it is necessary to have an overview of the current frameworks, the challenges in each step of the process and the potential solutions.

Our work provides a comprehensive overview of the current EU regulations concerning endocrine-disrupting properties in industrial chemicals, biocides, and plant protection products. Endocrine disrupting assessment has been a mandatory requirement for the approval of biocides and plant protection products in the EU since 2018. These assessments encompass both active substances and non-active substances, such as co-formulants, safeners, and synergists, though distinct regulations apply to each. In April 2023, the delegated regulation on the Classification, Labelling, and Packaging (CLP) of chemicals came into effect, introducing a new hazard class for endocrine disruptors. Since then, endocrine disrupting assessment has gained significance in the regulation of industrial chemicals under the 'REACH' framework.

This overview not only provides a visual summary of the criteria for evaluating endocrine disrupting endpoints, but also pinpoints areas where enhancements in the assessment process are feasible. For instance, following the available guidance on screening the endocrine-disrupting characteristics of co-formulants can lead to a substantial workload and divergent interpretations among various stakeholders involved in the evaluation process. Furthermore, the environmental endocrine-disrupting properties were not sufficiently covered in the evaluation, which is expected to improve when new (eco)toxicity testing guidelines for ED identification lead to more available data. Our study also delves into the methods and challenges linked to conducting endocrine disrupting assessment for UVCB as a co-formulant in biocidal products and industrial chemical (under REACH regulations), offering a regulatory perspective as a case study.

1.13.P-Tu037 Challenges and Recommendations in Assessing Potential Endocrine Disrupting Properties of Metals in Aquatic Organisms

Kevin V Brix[1,2]*, Stijn Baken, PhD*[3]*, Craig A. Poland*[4]*, Ronny Blust*[5]*, Louise Pope*[6] *and Charles Tyler*[7]*, (1)EcoTox LLC, (2)Marine Biology and Ecology, University of Miami - RSMAES, (3)European Copper Institute, Belgium, (4)Regulatory Compliance Limited, United Kingdom, (5)ECOSPHERE, University of Antwerpen, Belgium, (6)Enviresearch, United Kingdom, (7)University of Exeter, United Kingdom*

New tools and refined frameworks for identifying and regulating endocrine disrupting chemicals (EDCs) are being developed as our scientific understanding of how they work advances. Although focus has largely been on organic chemicals, the potential for some metals to act as EDCs in aquatic systems is receiving increasing attention. Metal interactions with the endocrine system are complicated as some metals are essential to physiological systems, including the endocrine system, and non-essential metals can have similar physio-chemical attributes that allow substitution into or interference with these systems. Consequently, elevated metal exposure could potentially cause endocrine disruption, but can also cause indirect effects on the endocrine system via multiple pathways or elicit physiologically appropriate compensatory endocrine mediated responses (endocrine modulation). These latter two effects can be confused with, but are clearly not, endocrine disruption. In this paper, we provide several case studies that exemplify the challenges encountered in evaluating the endocrine disrupting (ED) potential of metals followed by recommendations on how to meet them. Given metal toxicity can be caused by multiple modes of action (MoAs), we recommend assessments use metal-specific adverse outcome pathway networks to ensure accurate causal links are made between MoAs and effects on the endocrine system. We recommend more focus on establishing molecular initiating events for chronic metal toxicity as these are poorly understood and would reduce uncertainty regarding the potential for metals to be EDCs. Finally, more generalized MoAs such as oxidative stress could be involved in metal interactions with the endocrine system, and we suggest it may be experimentally efficient to evaluate these MoAs when ED is inferred. These experiments, however, must provide explicit linkage to the ED endpoints of interest.

1.13.P-Tu038 Experiences in developing the Amphibian Metamorphosis Assay for regulatory testing – a CRO perspective.

Severine Brigitte Larroze[1]*, Deanna Westfold*[1] *and Richard John Maunder*[2]*, (1)Ecotoxicology, Scymaris Ltd., United Kingdom, (2)Scymaris Ltd., United Kingdom*

With the new EUH-statements and new hazard classes for Endocrine Disrupters (ED) included in the latest version of the CLP Regulation, there is an increasing need for *in vivo* tests capable of identifying ED properties.

To support global chemical risk assessments for our clients, we have established and maintained a *Xenopus laevis* colony and investigated the feasibility of amphibian testing at our laboratory at Scymaris Ltd. Frogs are housed in groups of 6 individuals and spawned every three months on rotation to ensure good egg production and the capacity to start studies monthly.

The Amphibian Metamorphosis Assay (AMA; OECD 231) is a Conceptual Framework level 3 screening assay to identify substances interfering with the hypothalamic-pituitary-thyroid (HPT) axis. Amphibian metamorphosis is modulated via thyroid dependent processes and *X. laevis* is a well-studied and easy to keep under laboratory conditions amphibian model. The observational endpoints for this assay are hind limb length, snout to vent length (SVL), developmental stage, wet weight, thyroid histology and daily observations of mortality.

Sodium perchlorate, which impairs thyroid function by interacting with the sodium iodide symporter (NIS) responsible for iodide uptake in the thyroid gland and thyroxine, the endogenous hormone synthetized by the thyroid gland were used as the two reference substances.

Temperature and feed were adjusted during the pre-exposure phase to ensure tadpoles reached the required developmental stage (NF 51) at test start. Feeding during the exposure phase was decreased to keep the percentage of tadpoles showing developmental stage beyond NF 60 at test end below 20%. Significant treatment effects for developmental stage were determined from the step-down Jonckheere-Terpstra test as well as the multi-quantal Jonckheere test and results compared. Additional test replicates were continued to cover endpoints in the extended AMA test. Different blood sampling methods were also tested and plasma volumes gained were used to investigate the feasibility of measuring plasma T3 and T4 at this timepoint.

Both flow-through studies passed the guideline validity criteria and all performance criteria related to mortality rates and the control group developmental stage (median and distribution) were fulfilled.

1.13.P-Tu039 Lessons learned running a Zebrafish Extended One Generation Reproduction Test as part of a validation exercise

*Becky Burden[1], **Richard John Maunder**[1] and Matthias Teigeler[2], (1)Scymaris Ltd., United Kingdom, (2)Fraunhofer IME, Germany*

An update to the Classification, Labelling and Packaging (CLP) regulation to include new hazard classes including those relating to Endocrine Disruption (ED) aligns this with the existing regulations for biocides and plant protection products whereby substances require assessment for their ED properties as part of their environmental risk assessment.

The OECD provides guidance for ED testing under a conceptual framework with tests being assigned a level based on the comprehensiveness of the testing. The highest level 5 tests include multigeneration testing, such as the Medaka Extended One Generation Reproduction Test (MEOGRT; OECD 240). This test has been reported as difficult to perform, with tests often failing to meet validity criteria, meaning interpretation of results can be difficult. An alternative EOGRT option using zebrafish (*Danio rerio*; ZEOGRT) was proposed in 2015 and is currently at the ring test stage of validation as part of an OECD workplan.

We report on the lessons learned while conducting a ZEOGRT test as part of the validation process. As for other chronic fish studies (OECD 229, 234, 240), the consistency of the test substance analytical chemistry is a proposed validity criterion (±20% of mean measured). Therefore, following initial dosing trials, Prochloraz was selected as the test reference substance over Tamoxifen citrate as it had more reliable dosing and solubility. Triethylene glycol was utilized as a carrier solvent to aid dissolution, and both a dilution water control and solvent control were employed. The test design, adapted from the MEOGRT procedure, began with a filial 0 (F_0) parental adult group in spawning status, followed by a complete F_1 generation derived from the parental eggs and finally a F_2 generation derived from the F_1 eggs, limited to the hatching period. Endpoints include hatch success, post-hatch survival, fecundity, fertility, length, weight, sex ratio, vitellogenin and gonad histopathology. Practical experiences running the test are shared with particular reference to the successful initiation of the F_1 generation, meeting the required hatch and survival validity criteria, maintaining true replication in test vessels, the practicalities of F_1 daily breeding and the timing of evaluation of F_1 egg numbers prior to the initiation of the F_2 generation.

The data obtained in this test will be analysed to investigate the applicability and replicability of the test design and will assist in refining the test method.

1.13.P-Tu040 Control Performance of Medaka Extended One Generation Test Designs

***Natalie Burden**[1], Julie Krzykwa[2], Scott G. Lynn[3], Valentin Mingo[4], Constance Mitchell[5], Edward Salinas[6] and James Robert Wheeler[7], (1)NC3Rs, United Kingdom, (2)HESI Global, (3)U.S. Environmental Protection Agency (US EPA), (4)Corteva Agriscience, Germany, (5)Health and Environmental Sciences Institute (HESI), (6)Bayer AG, Germany, (7)Corteva Agriscience, Netherlands*

Evaluation of endocrine activity in humans and wildlife involves conducting specific assays to evaluate relevant pathways. Multiple *in vivo* test guidelines (TGs) have been validated for mammals, amphibians, and fish, focusing on the estrogen, androgen, thyroid, and steroidogenesis pathways. These assays require the use of a substantial number of laboratory animals, and their outcome can lead to significant regulatory actions. It is therefore critical that the assays are sufficiently reliable and robust.

One such assay, the medaka extended one generation reproduction test (MEOGRT), is designed to provide comprehensive data on adverse effects and endocrine-relevant endpoints for key aspects of the fish life cycle. Potential adverse effects on population-relevant parameters are assessed including survival, growth, development sex ratio (phenotypic vs. genetic) and reproduction. Parameters are also measured which provide mechanistic information and linkage between results from other studies where there is evidence for a chemical having the potential to interact with endocrine pathways.

The current work aims to use historical control data (HCD) to better understand the test performance and endpoint relevance and facilitate understanding of variability within the method as well as data interpretation now that these assays are being more widely conducted. Control data were collated for 25 control groups from 24 independent studies conducted following the MEOGRT TG or providing similar data as in the MEOGRT. The data were assessed across 17 biological validity criteria specified within the TG to determine how often the relevant data were reported and how often control groups meet these criteria. Reliable HCD ranges are being developed for the core study endpoints and the associated validity and performance criteria. Additionally, the HCD is being explored to investigate cross-laboratory and study differences, sources of variability, and the power of the test design.

In summary, this retrospective data analysis will form a knowledge base that could be used to determine what is realistically achievable in terms of the assay performance/validity criteria and inform improvements to the test performance and interpretation of data, which will in turn reduce the instances where these studies may need to be repeated.

This abstract does not necessarily represent US EPA policy.

1.13.P-Tu041 Optimising Concentration Setting for In Vivo Endocrine Screening Assays with Aquatic Vertebrates

Natalie Burden[1]*, Constance Mitchell*[2]*, Thomas Hutchinson*[3]*, Apostolos Koutsaftis*[4]*, Melanie Anderson*[5]*, Julie Krzykwa*[6]*, Samuel K Maynard*[7]*, Lennart Weltje, Prof. Dr.*[8] *and James Robert Wheeler*[9]*, (1)NC3Rs, United Kingdom, (2)Health and Environmental Sciences Institute (HESI), (3)R&D Global Safety Assurance, Reckitt, United Kingdom, (4)ERM Regulatory Services Limited, Netherlands, (5)ERM Regulatory Services Limited, (6)HESI Global, (7)Environmental Protection, Global Sustainability and SHE, Operations, AstraZeneca UK Ltd, United Kingdom, (8)Agricultural Solutions - Ecotoxicology, BASF SE, Germany, (9)Corteva Agriscience, Netherlands*

There is growing regulatory demand for fish and amphibian *in vivo* data to support identification of chemical-induced endocrine activity. To ensure that endocrine-specific effects are detected and aid data interpretation, improvements to concentration setting guidance are needed. Determining the most appropriate highest concentration – or maximum tolerated concentration (MTC) – allows for clear distinction of effects attributable to endocrine-related activity from those of systemic or secondary toxicity that is not directly endocrine mediated. This is challenging because biological effects may depend on the life-stage and species tested. Currently, the MTC is inconsistently defined within the different OECD test guidelines. This work aims to provide a consensus approach to MTC setting for fish and amphibian endocrine studies by developing a strategy for concentration setting using existing data.

A database using results from regulatory fish acute and chronic toxicity studies and corresponding endocrine screening studies (fish short term reproduction and amphibian metamorphosis assays) was established for 32 pesticide active substances. The results of a meta-analysis performed to assess the effectiveness of using data from available acute and chronic studies in setting the MTC for the endocrine screening studies will be presented. This entails examining a) how MTCs derived using different approaches (1/3rd or 1/10th of the fish 96 h acute LC_{50}) relate to effects seen in the acute studies; b) how MTCs derived from results of standard acute and chronic studies relate to the highest concentrations tested in endocrine screening studies; c) how the acute and chronic toxicity outcomes relate to the findings in the endocrine screening assays, *i.e.* whether overt toxicity was observed in the selected test concentrations and if the (remaining) concentrations were sufficient to allow for detection of endocrine activity.

The results will be considered in development of a weight of evidence approach which can be utilised to optimise the setting of the MTC for aquatic vertebrate endocrine tests. Ultimately this work will support the interpretation of data from endocrine screening studies and reduce the instances where studies may need to be repeated, or higher tier *in vivo* tests are triggered unnecessarily. Reducing instances of overt toxicity will also result in the welfare benefit of reducing severity of effects experienced by animals in such assays.

1.13.P-Tu042 Monitoring endocrine disrupting chemicals (EDCs) in wastewater using bioassays: a proof-of-concept from Quebec, Canada

Valerie S Langlois[1]*, Julie Robitaille*[1]*, Mélanie Desrosiers*[2]*, Marianne Métivier*[3] *and Éloïse Veilleux*[4]*, (1)Institut national de la recherche scientifique (INRS), Canada, (2)Direction des expertises et des études, ministère de l'Environnement, de la Lutte contre les changements climatiques, de la Faune et des Parcs, Canada, (3)Ministère de l'Environnement, de la Lutte contre les changements climatiques, Faune et Parcs, Canada, (4)Ministère de l'Environnement et de la Lutte contre les changements climatiques, Canada*

Endocrine disrupting chemicals (EDCs) are compounds which can interact with the hormonal system and generate adverse effects (e.g. reproduction, growth). EDCs have been detected in municipal and industrial wastewater for many years. Despite their impacts, no countries have established maximal endocrine disrupting activity discharge criteria for receiving environments, including in Canada. The aim of this project was to use New Approach Methodologies (NAMs), especially in vitro EDC-based approaches, for resource water management. In vitro bioassays have the advantage of integrating mixture effects which allows lower limits of detection and detect unknown chemicals. The designed bioassay-based approach was constituted of two transactivation assays for the receptors of estrogen (ER) and androgen (AR), testing for estrogenic, anti-estrogenic, androgenic, and anti-androgenic activities. To validate the approach, two subsequent experiments were conducted on a municipal and an industrial effluent. In vitro data were compared to in vivo experimental data ran in parallel. Both experiments showed that fish reproduction was significantly impacted by the municipal and an industrial effluent and this could be linked to detected transactivation assay activations. The purpose of EDC screening in municipal and industrial effluents is to inform the different actors on steps to take to manage and to mitigate the quality of the effluents being released into Canadian ecosystems. For example, these in vitro assays could be helpful to evaluate wastewater treatment efficiency and agricultural run-off. Finally, this project provided basis to a first proof-of-concept for the use of bioassays to monitor EDCs in wastewater in the province of Quebec, Canada.

1.13.P-Tu043 AnthroDrugs-EDC: Personalized Endocrine Disrupting Chemical (EDC) Toxicology through Population Genetics

***Simon Perera del Rosario**[1,2], Laureano E. Carpio[1], Eva Serrano Candelas[1], Jorge García Calleja[2], Laura Vilà Valls[2], Elena Bosch[2], Francesc Calafell[2] and Rafael Gozalbes[3], (1)ProtoQSAR, Spain, (2)Institut de Biologia Evolutiva (UPF-CSIC), Spain, (3)MolDrug AI Systems, Spain*

Endocrine disrupting chemicals are a major concern for human and environmental toxicology because they can cause disruptions in reproductive function, foetal development, thyroid function, and increase the risk of reproductive cancers in men and women. They are also linked to infertility, early puberty, obesity, diabetes, and various cancers" (Mendes 2002, Klanova 2019)

Currently marketed and new drugs can be endocrine disrupting chemicals (EDCs), which is a concern in drug design and development (Soverini 2018).

Personalized medicine is one of the elements of the *P4* medicine of the future, and has already shown its ability to improve patients' lives in an individualized way (e.g. Soverini 2018, Gambardella 2020). However, a series of limitations hinder its widespread implementation in the immediate or short term, which has led to the development of different methods of population stratification (McGuire 2020, O'Hanlon Cohrt 2021, Litman 2019). One of these approaches is stratification based on the biological ancestry of patients, which has seen significant progress in recent years thanks to developments in DNA and ancient DNA analysis.

Stemming from our team's previous work in personalized medicine and drug development (e.g. Font-Porterias 2021, Bhat-Ambure 2023), in this work, we propose to apply "personalized toxicology" for the optimization of drugs with potential EDC by leveraging the human population genetics knowledge about genes related with endocrine disruption. We analyse drug-related genes (DRGs) which are also related to the physiological response caused by endocrine-disrupting chemicals (EDCs), thus allowing for newer, optimized, safer-by-design drugs for all human populations. This contributes to avoiding the current pitfalls of a drug development process specifically focused on people of European descent.

In particular, we analyse a dataset of EDC-DRGs (drug toxicity-related genes) collated from the literature, describing their variability in populations, and searching for potential signatures of natural adaptive selection in specific continental regions (Africa, East Asia, South Asia, Europe, and America). For selected genes, we analyse how the population variability can affect the toxicity experienced by individuals when taking the drugs involved (e.g. affected adverse outcome pathways (AOPs) and molecular initiating events (MIEs) or key events (KEs), and whether drugs can be improved in this respect.

1.13.P-Tu044 The Endocrine Disruption Potential of Isoeugenol and Altrenogest in Daphnia magna

***Madalena Vieira**[1], Maria D Pavlaki[2], Bruna Morim[3] and Susana Loureiro[4], (1)University of Aveiro, Portugal, (2)University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Portugal, (3)Biology, Department of Biology, University of Aveiro, Campus Universitário de Santiago, Portugal, (4)CESAM-Centre for Environmental and Marine Studies and Department of Biology, University of Aveiro, Portugal*

Industrial discharges, intensive agriculture, and improper waste disposal contribute to the presence of harmful chemicals in water bodies. Many substances, such as medicines or industrial chemicals, are created for specific purposes. Still, what happens when these substances enter the environment and affect non-target organisms is often not fully understood. Endocrine-disrupting chemicals (EDCs) are human-made or natural substances capable of affecting the endocrine system in humans and animals, leading to adverse effects, such as alterations in fertility and offspring output and disturbance of the immune system, among others.

This study aims to investigate and understand the potential endocrine-disrupting effects of two compounds, Isoeugenol and Altrenogest, in *Daphnia magna*. Isogeunol is a natural organic compound and is renowned for its aromatic properties. Altrenogest is a synthetic progestin, and its application is in veterinary medicine. As a starting point, the *in vitro* screening assay, YES, was conducted to determine the ability of both compounds to bind to the human estrogen receptor in the *Saccharomyces cerevisiae* yeast. After this confirmation, the two Technical Guidelines from OECD 202 and 210 were used to assess the immobilization and reproduction of *D. magna* exposed to both compounds and the respective ecotoxicity endpoints (NOEC, LOEC, LC50 and EC50) were derived. Generally, altrenogest was shown to be more toxic than isoeugenol (e.g. LC_{50} of 0.793 mg/L vs LC_{50} of 4.39 mg/L, respectively), with reproduction impairment following a similar pattern at very low concentrations. By integrating the results from the YES assay with those from the daphnia reproductive output can highlight the effects of daphnia as an endocrine disruptor. This must be confirmed by future studies, under lower levels of biological organization (e.g. NAMs), to identify mechanisms underlying this process. The present study highlights the importance of addressing the environmental impact of these substances more comprehensively to ensure safety and sustainability in their use.

1.13.P-Tu045 Endocrine Activity of Bisphenol A and Eleven Structural Analogues

***Natalie Reininger** and Jörg Oehlmann, Aquatic Ecotoxicology, Goethe University Frankfurt, Germany*

Bisphenol A (BPA) is currently one of the most used synthetic chemicals in the production of a wide range of plastics. Due to its diverse endocrine disrupting potential alternative bisphenols, also referred to as analogues, were developed. Since the EU identified BPA as a substance of very high concern it is required to be substituted with safer, more sustainable alternatives, increasing the production of the various different bisphenol analogues. While the toxicity of BPA is well studied, (eco)toxicological effects of the bisphenol analogues are largely unknown. However, the similar molecular structure of the analogues suggests comparable toxicological effects. This study evaluates different endocrine endpoints of eleven bisphenol analogues (BPB, BPE, BPF, BPS, BPZ, BPAF, BPAP, BPBP, BADGE, TBBPA, and TCBPA) compared to the reference BPA *in vitro*. The test battery includes five different yeast reporter gene assays (estrogenic, anti-estrogenic, androgenic, anti-androgenic, dioxin-like) to assess the endocrine potential or dioxin-like activity of the substances. Almost all bisphenols demonstrated notable estrogenic and anti-androgenic activity *in vitro* in a comparable range to the reference bisphenol A. Some analogues even exceeded the endocrine potential of BPA. No androgenic or dioxin-like activity was recorded in the tested concentration range for any of the twelve substances. The current work contributes to the insufficient body of literature concerning the risk assessment of bisphenol analogues.

1.13.P-Tu046 Urinary Concentrations of Bisphenols in Young Women from Southeastern Spain: An Exploratory Study.

Isabel Navas DVM,[1], Daniel Carbonell[2], Evdochia Adamnei DM[3], Jonathan Kiwitt-Cárdenas DM[3], Jaime Mendiola PhD[3], Alberto M Torres-Cantero DM,P[3] and ***Antonio Juan Garcia-Fernandez, DVM, PhD**[4]*, *(1)Health Sciences-Faculty of Veterinary-IMIB, Universidad de Murcia-IMIB, Spain, (2)Health Sciences, Universidad de Murcia, Spain, (3)Public Health Sciences, Universidad de Murcia-IMIB, Spain, (4)Toxicology Research Group, Faculty of Veterinary Medicine, Universidad de Murcia-IMIB, Spain*

Bisphenol is a chemical that has been involved in health problems such as diabetes, cardiovascular diseases and especially in reproductive damage. This product is excreted by urine, the sample most widely used for the biomonitoring of bisphenols. The main objective of this study was to evaluate the urinary concentrations of four bisphenols (BPA, BPF, BPE and BPC) in 297 young women from Southeastern Spain, as well as potential socio-demographic and lifestyle factors associated with these bisphenols concentrations. The presence of some endocrine disruptor chemicals, such as bisphenols, has been poorly characterized in young women, particularly bisphenols others than BPA. Total bisphenols (sum of free and glucuronidated forms) present in urine were extracted using a dispersive liquid-liquid micro-extraction procedure and analyzed using an Agilent 6890N gas chromatograph coupled to an Agilent 5973 quadrupole mass selective spectrometer. The column used was an HP-5MS capillary column (30 m length x 0.25 mm internal diameter and 0.25 μm film thickness). A database was assembled with socio-demographic and dietary information and urinary bisphenol concentrations. Socio-demographic and lifestyle data was collected with a questionnaire administered face-to-face by trained field staff. Variables considered as independent variables in this study were: age, body mass index, smoking habit, regular alcohol intake, physical activity, oral contraceptives, recent self-perceived exposure to paint, glue, etc, dietary information included origin of drinking water and frequency of consumption of fish, canned food, dairy products, eggs, meat, vegetables, legumes and fruit. BPA was the bisphenol most frequently detected (95.6%), followed by BPF (45.1%), BPC (20.3%) and BPE (11.5%). Mean concentration (± standard deviation), in ng/ml, obtained were 5.10 (± 6.00) for BPA, 2.23 (± 3.83) for BPF, 0.20 (± 1.26) for BPE, and 1.11 (± 3.28) for BPC. The main hypothesis is that urinary concentrations of bisphenols are associated with several socio-demographic and lifestyle factors in young women from Southeastern Spain. The exposure to bisphenols, well-known endocrine disruptors, is a modifiable risk factor. If urinary bisphenols concentrations are higher compared with other populations and some socio-demographic and lifestyle factors area associated with those levels, potential public health actions could be put in place in order reduce those potential harmful exposures in young women.

1.13.P-Tu047 The endocrine disrupting potential of selective serotonin reuptake inhibitors

Thomas Knigge[1], Tiphaine Monsinjon[2], Cécile Bellanger[3], Cinta Zapater[4], Ana Gómez[4] and ***Patricia IS Pinto**[5]*, *(1)Faculty of Science and Technology, University of Le Havre Normandy, France, (2)Faculty of Sciences and technology, University of Le Havre Normandy, France, (3)UniversitÈ de Caen Normandie, France, (4)Control of Food Intake Group, Aquaculture Institute of Torre de la Sal, Spanish National Research Council (IATS-CSIC), Spain, (5)CCMAR – Centre of Marine Sciences, University of Algarve, Portugal*

The use of selective serotonin reuptake inhibitors (SSRIs) has increased steadily over the last decades and is expected to rise further. Hence, the residues of SSRIs and related antidepressants accumulate to concentrations in the $\mu g \cdot L^{-1}$ range in surface waters. Although not perceived as classical endocrine disrupting chemicals, numerous studies have reported effects of SSRIs on steroidogenesis and steroid hormone signalling in fish. Using a reporter gene assay with the three nuclear oestrogen receptors (Esr1, Esr2a, Esr2b) and the two membrane oestrogen receptors (Gper1 and Gper1-like) from the European seabass, *Dicentrarchus labrax*, fluoxetine (FLX) displayed antiestrogenic activity on Esrs in the presence of 17β-oestradiol (E2) as well as oestrogenic activity on the two Gpers without any interaction with E2. Furthermore, fish scales exposed to FLX had a mineral turnover similar to those exposed to E2 and shared common signalling pathways for E2 and FLX in their proteome. These results confirm the endocrine disrupting potential of antidepressants with respect to sex steroid signalling in vertebrates.

The importance of neuroendocrine signalling renders invertebrate endocrine systems preferential targets for SSRIs. Indeed, FLX stimulated the synthesis and release of crustacean hyperglycaemic hormone and the mobilisation of glucose, leading to increased locomotor and burying activity in the European shore crab *Carcinus maenas*. Furthermore, FLX stimulated the release of moult inhibiting hormone resulting in significantly lowered 20-hydroxyecdysone levels indicative of endocrine disruption of moulting. Exposure of juvenile shore crabs to a mixture of FLX and venlafaxine (VEN) significantly reduced the animal's colour change capacity, putatively by stimulating pigment dispersing hormone, thereby compromising camouflage. In the European cuttlefish, *Sepia officinalis*, mixtures of FLX and VEN negatively affected the maturation of feeding and burying behaviour in newly hatched animals over the first 5 and 30 days, respectively. The changes in predatory behaviour tended to reduce food intake and significantly affected growth after 30 days of exposure to FLX+VEN. On the contrary, matching to uniform backgrounds was improved without affecting disruptive body patterns. The results provide indirect evidence for antidepressant derived modulation of neuronal and neuroendocrine signalling in crustacean and mollusc by altering their neurotransmitter levels.

1.13.P-Tu048 In Silico Profiling of Triclosan and its Metabolites as Reproductive Toxic Agents

Maja Milanović*, Nataša Milošević, Larisa Đurić, Jovana Drljača Lero and Nataša Milić, Department of Pharmacy, University of Novi Sad, Faculty of Medicine, Serbia*

More than thousands of chemicals are associated with endocrine disruption. However, the data about the association between the exposure to an endocrine disrupting chemical and fertility are mostly incomplete. Triclosan is a halogenated biphenyl ether widely used in different cosmetic products, disinfectants, clothing textiles, and other materials. The high production rates and excessive use of triclosan contribute to the long-term exposure via air, surface water, drinking water, and soil. Hence, triclosan ability to impair the reproductive function through multiple nuclear receptors raises concerns. The aim of this study was to evaluate the potential of triclosan and its metabolites to interfere with estrogen receptors using molecular docking approach. The affinity of triclosan, triclocarban, methyl-triclosan and monohydroxy-triclosan derivatives for estrogen receptor alpha (ERalpha; PDB entry code: 6VPF), beta (ERbeta; PDB entry code: 5TOA), and gamma (ERgamma; PDB entry code: 6KNR) was determined using Genetic Optimisation for Ligand Docking (GOLD) version 2020.3.0. Bisphenol A was used as reference ligand. ChemPLP fitness scores were applied for the evaluation of binding affinities of the analysed compounds. Molecular properties were predicted using SwissADME online tool. Based on the obtained results all examined compounds have desirable properties in the terms of physicochemical characteristics expected for optimal oral bioavailability. The affinity scores for ERalpha receptor were from 50.4 to 57.9. The obtained ChemPLP scores of triclosan and its metabolites for ERbeta and ER gamma receptors were in the same range (41.3-56.9 and 53.5-58.4, respectively). Monohydroxy-triclosan metabolites expressed the highest score for ERalpha and ERbeta while methyl-triclosan showed the highest affinity for ERgamma. In compared with bisphenol A as reference compound (ERalpha-64.5, ERbeta-51.9, ERgamma-57.2) triclosan and its metabolites demonstrated the similar affinity to estrogen receptors. Based on the obtained results triclosan and its metabolites might act as agonist or antagonist on estrogen receptors. Therefore, the potential role of triclosan as risk factor for the development of infertility should be further examined.

1.13.P-Tu049 Endocrine Disrupting Potential of Beta-Blockers Exposure - Computational Study

Maja Milanović*, Nataša Milošević, Ivana Bogdanović, Jovana Drljača Lero and Nataša Milić, Department of Pharmacy, University of Novi Sad, Faculty of Medicine, Serbia*

β-blockers are the class of pharmaceuticals frequently prescribed for treatment of cardiovascular disorders. Owning to the high consumption and physiochemical properties, β-blockers undergo wastewater treatment process. Hence, they can migrate through surface water and reach the groundwater and, ultimately, the drinking water. Therefore, the β-blockers effects on the human endocrine system and its function arouses serious concerns among scientists since their negative impact on aquatic organisms has been well documented. The aim of this study was to investigate b-blockers' potential to interrupt the human endocrine system using molecular docking. Propranolol and 16 structurally related compounds were selected using DrugBank base. The interaction between analysed b-blockers and estrogen receptor alpha (ERα; PDB entry code: 7UJ8) and androgen receptor (AR; PDB entry code: 5CJ6) was determined using GOLD molecular docking tool. Docked poses were scored using ChemPLP function. All β-blockers expressed the high affinity to estrogen and androgen receptors. The binding affinities of the analysed compounds for ERα were in the range 51.4-87.3 (co-crystallized 4-Hydroxytamoxifen affinity-96.8). Carvedilol, nebivolol and bisoprolol showed the highest ChemPLP score. Dexpropranolol, nadolol and propranolol demonstrated the higher affinity towards androgen receptor in compared with the co-crystallized ligand (2-Chloro-4-[(2-hydroxy-2-methyl-cyclopentyl)amino]-3-methyl-benzonitrile). The evaluated scores of the analysed compounds for AR were in the range 46.8-77.5 (referent ligand score-68.4). The binding affinity of b-blockers is governed by at least one chiral center and the presence of an aromatic or heteroaromatic ring with an aryloxypropanolamine side chain. Based on the obtained results b-blockers have ability to disrupt endocrine function by binding to both estrogen and androgen receptors. Further studies are needed in order to fill the knowledge gaps about the adverse effects of b-blockers present in the environment on human health.

Acknowledgement: This work was supported by Provincial Secretariat for Higher Education and Scientific Research, AP Vojvodina, Republic of Serbia [Grant number 142-451- 3120/2022-01].

1.14 Unravelling the Complexities of PFAS: From Environment to Human Health and Reproduction

1.14.T-01 Evaluation of PFAS Effects on Nuclear Receptors and Cellular Pathways Using High-throughput Screening Datasets

Menghang Xia*, National Center for Advancing Translational Sciences (NCATS)*

Per- and polyfluoroalkyl substances (PFAS), a group of man-made synthetic organofluorine chemicals containing a carbon-fluorine bond, are widely used in consumer products around the world. PFAS are also called “Forever Chemicals” because their persistence has led to extensive environmental contamination and bioaccumulation. The combination of wide use and poor degradation of PFAS raises large public health concerns. To quickly assess PFAS, especially those not well-studied, for their potential toxicological effects and mechanisms, the Tox21 in vitro assay datasets generated from screening thousands of environmental chemicals against various cellular targets and pathways were extensively analyzed. This presentation will provide an overview of a panel of the in vitro assays used for the Tox21 high-throughput screening, summarize the findings of a group of PFAS for their activities on nuclear receptors and cellular signaling pathways, and compare with the data generated from other in vitro high-throughput screening platform.

1.14.T-02 In silico and in vitro prioritization of emerging PFASs identified by non-targeted analysis for environmental hazard assessment

*Xueqi Fan[1], **You Song, PhD**[2], Maria T. Hultman[2], Li Xie[2], Maria Christou[2], Jan Thomas Rundberget[2] and Jun Huang[3], (1)School of Environment, Tsinghua University, China, (2)Norwegian Institute for Water Research (NIVA), Norway, (3)Tsinghua University, China*

Per- and polyfluoroalkyl substances (PFASs) has raised great environmental concerns due to their persistence, bioaccumulation and toxicity. The restricted use of classical PFASs has led to the development of alternative PFASs. Unauthorized release of “new” PFASs that have not been through hazard assessment can also pose risks to human and environment. Through non-targeted analysis, close to one hundred emerging PFASs were identified in the surface water near an industrial park in China. How to efficiently assess the ecological hazards of the emerging PFASs with strong laboratory animal welfare considerations needs to be quickly resolved. In this study, we have developed a tiered workflow, mainly utilizing *in silico* and *in vivo* new approach methodologies (NAMs), to prioritize key emerging PFASs from a large list of non-targeted sceening for in-depth hazard assessment. According to the concentrations in river and structral differences of emerging PFASs, eight PFASs were selected for QSAR analysis, melocule docking, and in vitro high-throughput screening (zebrafish hepatic cell-line). PFOA was used as a reference compound along with each assay. The results showed that the predicted acute toxicity of HFPO-TA and HFPO-TEA was found to be significantly higher than that of PFOA, warranting follow-up assessment. 6:2 FTCA has the same carbon chain length with PFOA, however, the predicted toxicity of this emerging PFAS is significantly lower compared to PFOA, providing novel insights into future design of alternative. The in vitro results also indicated that neither HFPO-TA nor HFPO-TeA are suitable substitutes for PFOA, emphasizing the importance of assessing their environmental hazards. The workflow developed in this study will not only faciliate cost-efficient assessment of new PFASs, but will also shed light on next generation hazard assessment of other emerging contaminants using non-animal methods.

1.14.T-03 The Relationship Between the Molecular Properties of Per- and Polyfluorinated Substances (PFAS) and Their Ecotoxicity

***Ge Xie**[1], Wanda Puijk[2], Cornelis A.M. van Gestel[1], Arie J. Vonk[2], Thomas L. ter Laak[3], Annemarie van Wezel[4], David Y. Veltman[2] and Michiel Kraak[2], (1)Amsterdam Institute for Life and Environment (A-LIFE), Vrije Universiteit Amsterdam, Netherlands, (2)University of Amsterdam, Institute for Biodiversity and Ecosystem Dynamics, Freshwater and Marine Ecology (FAME), Netherlands, (3)KWR Water Research Institute, Netherlands, (4)University of Amsterdam, Institute for Biodiversity and Ecosystem Dynamics (IBED), Netherlands*

Per- and polyfluorinated substances (PFAS) are a highly diverse group of very persistent and bioaccumulative compounds. Currently, ecotoxicity data are available for only a limited subset of PFAS, such as PFCAs and PFSAs, which poorly represent the plethora of known PFAS molecular structures. Since it is not feasible to test all PFAS for their ecotoxicity, a more viable approach would be to identify potential relationships between ecotoxicity and molecular properties, allowing to predict PFAS ecotoxicity based on molecular structures. Therefore, this study aimed to relate the ecotoxicity of 13 PFAS varying either in the fluorocarbon chain length (7 PFCAs) or in the polar head group (6 PFAS with 4 fluorocarbons), to their membrane-water partition coefficients (K_{MW}), a relevant molecular descriptor. We determined the acute ecotoxicity of the selected PFAS to the daphnid *Daphnia magna*, and the chronic ecotoxicity to the green alga *Raphidocelis subcapitata* and the cyanobacterium *Synechocystis* sp. PC6803. The narcotic LC_{50} calculated using the K_{MW} and the critical body burden very well predicted the ecotoxicity of PFCAs to *R. subcapitata* and *D. magna*, which increased with increasing fluorocarbon chain length. *Synechocystis* displayed a different response pattern, with EC_{50} values increasing as the length of the fluorocarbon chain increased from four to six carbons, followed by a decrease from six to eight carbons. For the 4-fluorocarbon PFAS the polar head group greatly impacted ecotoxicity, with EC_{50} values varying up to three orders of magnitude. Most toxic to all tested organisms was perfluorobutane sulfonamide (FBSA, C_4F_9-SO_2NH_2), with EC_{50} values of 33.9 mg L^{-1} for *D. magna*, 18.5 mg L^{-1} for *R. subcapitata* and 18.5 mg L^{-1} for *Synechocystis*. Perfluoropentanoyl chloride (PFPeCl, C_4F_9-CClO) was the least toxic to all test organisms, with EC_{50} values of 10850 mg L^{-1} for *D. magna*, 819 mg L^{-1} for *R. subcapitata* and 3362 mg L^{-1} for *Synechocystis*. This could be attributed to the differences in charge distribution around the molecules resulting from distinct polar head groups. These differences may affect the affinity of the PFAS to the phospholipid bilayer of cell membranes, subsequently influencing their ability to protrude into the membrane. Our findings indicate that K_{MW} may be a good molecular predictor of PFAS ecotoxicity, and highlight the significance of expanding ecotoxicity studies to a broader range of structurally diverse PFAS.

1.14.T-04 Integrating Experimental and Computational Approaches to Unravel the Toxicity of 33 PFAS Congeners in Human Cell Lines

Periklis Tsiros[1], *Wiebke Alker*[2], *Thorsten Buhrke*[2], *Albert Braeuning*[2], *Emma Arnesdotter*[3], *Tommaso Serchi*[3], *Luisa Nunziangeli*[4], *Greta Immobile Molaro*[4], *Iseult Lynch*[5], *Antreas Afantitis*[6], *Haralambos Sarimveis*[1] *and Francesco Dondero*[7], *(1)National Technical University of Athens, Greece, (2)German Federal Institute for Risk Assessment (BfR), Germany, (3)Luxembourg Institute of Science and Technology (LIST), Luxembourg, (4)Polo Innovazione di Genomica Genetica e Biologia SRL, (5)School of Geography, Earth and Environmental Sciences, University of Birmingham, (6)Department of ChemoInformatics, NovaMechanics Ltd., Cyprus, (7)Department of Science and Technological Innovation, Università del Piemonte Orientale, Italy*

Per- and polyfluoroalkyl substances (PFAS) present complex challenges in toxicology, prompting a multidimensional exploration of their impact. In this study, we employed a holistic approach to investigate the cellular toxicity and nuclear receptor activation of 33 PFAS congeners, spanning legacy and next-generation compounds within the (poly)ether carboxylic or sulphonic groups.

Three human cell lines—HepaRG (liver), HEK293T (kidney), and A549 (lung) and human Peripheral blood mononuclear cells —were subjected to varying exposure concentrations, albumin concentrations, ionic strength of the medium, exposure durations, and assay types. Data from both experimental and computational analyses were seamlessly integrated to model toxicity and nuclear receptor activation. This integrative approach not only provides a quantitative framework for understanding PFAS toxicity but also facilitates predictive modeling for risk assessments. For a comprehensive computational analysis, descriptors were generated using the CDK library. Among these, concentration, VP7 (a measure of a molecule's size), fragC (a measure of complexity based on constituent fragments), MDEC34 (a measure of size and branching), and VPC4 (a measure of size and shape) emerged as the most influential features for cellular toxicity.

Simultaneously, we developed a Quantitative Structure-Activity Relationship (QSAR) model also for predicting PPARα induction. The model utilized dose-response data obtained with HEK293T cells, binding energy estimates from molecular dynamics simulations, and 133 computational descriptors generated through the CDK library for feature selection. The most important features identified for the QSAR model include concentration, Weta3.unity (a measure of structural complexity), binding energy, VP7 (a measure of a molecule's size), and ECCEN (a measure of connectivity and symmetry).

Our study unveils a nuanced perspective on the diverse toxicological profiles of PFAS congeners, considering both experimental intricacies and computational insights. These findings hold promise for advancing risk assessment methodologies and tailoring mitigation strategies to address the complexity of PFAS toxicity.

1.14.T-05 Characterization of Replacement PFAS, Perfluoroethylcyclohexane Sulphonate (PFECHS) and Perfluorobutane Sulphamide (FBSA) in vitro Individually and in Mixture with PFOS

Hannah Mahoney[1], *Francisco da Silva*[1], *Markus Brinkmann*[2] *and John Giesy*[1], *(1)University of Saskatchewan, Canada, (2)Toxicology Centre, University of Saskatchewan, Canada*

The widespread application of poly- and per-fluoroalkyl substances (PFAS) has resulted in some substances being ubiquitous in environmental matrices with associated toxic effects. While certain substances of concern have been phased-out or banned, new substances continue to be produced. Two such substances are perfluoroethylcyclohexane sulphonate (PFECHS) and perfluorobutane sulphamide (FBSA), both of which are developed analogues and replacements of perfluoroctanesulphonic acid (PFOS) which have recently been detected in multiple environmental media around the globe. However, there is little information on the toxic potency of PFECHS and FBSA relative to legacy substances and other known PFAS replacements. As well, although it is more environmentally relevant, there is little data available outlining the effects of PFAS mixtures, particularly when it comes to mixtures of PFAS replacements. Therefore, this research investigated whether binary mixtures of emerging and legacy PFAS have the potential to combine synergistically. The immortalized rainbow trout gill cell line (RTgill-W1) was chosen as the experimental model to investigate two apical endpoints: cytotoxicity and lipid toxicity. RTgill-W1 cells were exposed for 24 hours to each compound from a range of 1 to 1000 mg/L to obtain endpoint and compound specific lethality and effect concentrations (LCx;ECx). These values were then applied to formulate mixture predictions following the Loewes Additivity and Steel and Peckham methods. Four mixture combinations involving five exposure ratios were investigated: PFECHS-PFOS, FSBA-PFOS, FSBA-PFECHS for cytotoxicity, and PFECHS-PFOS for lipid toxicity. Individual compound potency ratios were as followed: PFOS > PFECHS > FSBA for cytotoxicity. PFOS and PFECHS had a nearly identical impact on phospholipidosis, while FSBA did not have any impact. Most mixtures had a synergistic effect on cytotoxicity, but the effect was both dose and ratio dependant. However, PFECHS and FSBA mixtures were synergistic at all combinations. For phospholipidosis, the PFECHS – PFOS mixture was strictly additive at all combinations. These results are suggestive of synergism between emerging PFAS replacements and highlight that independent apical mechanisms of different PFAS could combine to induce unexpected toxicity. Considering that emerging replacements are continuing to increase in concentration in the environment, such mixture scenarios are likely to increase in probability.

1.14.P Unravelling the Complexities of PFAS: From Environment to Human Health and Reproduction

1.14.P-Tu051 Predicting Peroxisome Proliferator-Activated Receptors-γ Cytotoxicity of Small Molecules: A Synergistic Consensus Model and Deep Learning Binding Affinity Approach powered by Enalos Cloud Platform Ma

*Maria Antoniou[1,2,3], Konstantinos D. Papavasileiou[1,2,3], Andreas Tsoumanis[1,2,3], Georgia Melagraki[4], Francesco Dondero[5,6], **Iseult Lynch**[2,7] and Antreas Afantitis[1,2,3], (1)Department of ChemoInformatics, NovaMechanics MIKE, Greece, (2)Entelos Institute, Cyprus, (3)Department of ChemoInformatics, NovaMechanics Ltd., Cyprus, (4)Division of Physical Sciences & Applications, Hellenic Military Academy, (5)Department of Science and Technological Innovation, Università del Piemonte Orientale, Italy, (6)University of Eastern Piedmont, Italy, (7)School of Geography, Earth and Environmental Sciences, University of Birmingham*

The Enalos Cloud Platform, accessible at https://www.enaloscloud.novamechanics.com, hosts a synergistic consensus model for predicting the Peroxisome Proliferator-Activated Receptors (PPAR)-γ cytotoxicity of small molecules. This in silico model was developed using a comprehensive dataset of 6,538 compounds from the Tox21 10K chemical library, sourced from PubChem Bioassay ID 743194 with Enalos tools (https://enalosnodes.novamechanics.com). These compounds were screened against the PPARγ-bla HEK293H cell line and categorized based on cell viability.

Developed with the aid of the Isalos Analytics Platform (http://isalos.novamechanics.com/), the model integrates three distinct modeling methods:

- A Random Forest model, employing an ensemble learning method that combines multiple decision trees to enhance predictive accuracy.
- A k-Nearest Neighbors (k-NN) model, also known as read across, which offers a straightforward yet effective non-parametric technique for managing a wide range of data types.
- A binary class Support Vector Machine (SVM) model, utilizing Stochastic Gradient Descent for hinge loss minimization and producing a robust, margin-based classifier that optimizes class separation.

These methods are integrated with molecular descriptors obtained from the molecules' 2D structures, using the EnalosMold2 node. The model interfaces with a deep learning model via Enalos Application Programming Interfaces (APIs), boosting the prediction of small molecule binding affinity to PPARγ. It leverages the deep learning capabilities of the Enalos Cloud for structure-based information integration. Inputs for the model include SMILES notation, SDF files, or use of a molecular sketcher, and it outputs a classification of 'Active' or 'Inactive' for each compound. The model also assesses prediction reliability based on the Applicability Domain, ensuring predictions stay within the training data's scope. By synergistically blending molecular docking, machine learning, and deep learning techniques with chemoinformatics, the consensus model emerges as an advanced tool for predicting PPARγ cytotoxicity, with a focus on per- and polyfluoroalkyl substances (PFAS). This positions it as an invaluable asset in drug discovery and toxicology. The model is accessible via a user-friendly graphical user interface (GUI) at http://www.enaloscloud.novamechanics.com/scenarios/ppargammaliganddl/, providing a cutting-edge tool for scientific and biomedical research globally.

1.14.P-Tu052 Assessing Apical Toxicity and Sublethal Responses of Earthworms in PFAS-Contaminated Soils: A Comprehensive Study at a Fire Training Site in Sweden

***Davide Gualandris**[1], Davide Rotondo[1], Candida Lorusso[1], Marcello Manfredi[2,3], Antonio Calisi[1] and Francesco Dondero[1], (1)Department of Science and Technological Innovation, Università del Piemonte Orientale, Italy, (2)Department of Translational Medicine, Università del Piemonte Orientale, Italy, (3)Center for Translational Research on Autoimmune and Allergic Diseases, University of Piemonte Orientale, Italy*

Fire training sites and airports are major PFAS contamination sources due to widespread Aqueous Film-Forming Foam (AFFF) use. Recent global policies restrict higher than C8 PFAS congeners, yet PFOS and PFOA legacy persists, impacting ecosystems. Modern AFFF formulations still include short-chain PFAS and their oxidizable fluorolalkylamide precursors. Terrestrial ecosystems, vital for ecosystem services, face threats. Earthworms, essential bioindicators, play a key role in soil processes. This study assesses PFAS-contaminated AFFF impact on earthworms, highlighting ecological consequences and the need for sustainable firefighting policies.

The study investigated apical toxicity and sublethal responses of earthworms across a PFAS contamination gradient from a Trelleborg drill site. PFAS contamination was confirmed, with 22 compounds, mainly PFOS, PFOA, PFNA, and PFHxS, ranging from 960 ppb (B1) to 8.7 ppb (B7). OECD No. 207 (acute toxicity) and No. 222 (reproduction) tests, plus 30-day sublethal assessments, were conducted. Biomarkers included oxidative burst, enzymatic responses, and an escape test. Pristine soil served as an external reference control.

Acute toxicity, seen in B1 and B4, indicated a significant 20% and 12.5% mortality increase (n=4), OECD No. 207. Reproduction tests are ongoing. Immunological responses showed higher reactive oxygen-producing cells in B1 and B4, with lower phenol oxidase in PFAS-impacted sites. Catalase increased in Trelleborg sites, spiking in B6 (22 PFAS 9.6 ppb). Acetylcholinesterase fluctuated, reducing in B4 and linked to impaired behavior as judged in an escape time, showing PFAS sensitivity. Further neurotransmitter investigations are ongoing to unveil potential neurotoxicity.

These findings contribute significantly to the broader understanding of PFAS-contaminated site ecology, aiding in the construction of an environmental database crucial for risk assessment analyses. The call for sustainable firefighting practices is not just a regulatory necessity but a vital step towards preserving terrestrial ecosystems and the invaluable services they provide.

1.14.P-Tu053 Investigating the impact of PFOA, Glyphosate and Cypermethrin on the gut microbiota in vitro
*Vittoria F Borrini[1,2], Denise Marradi[2,3], Virginia Vanella[2,3], Riccardo Nuzzi[2,4], Marco Ghirimoldi[2,3], Beatrice Purghè[2,5], Elia Amede[2,3], Francesco Dondero[6], Andrea Cochis[2,7], Lia Rimondini[2,7], Elettra Barberis[2,8], **Davide Rotondo**[8] and Marcello Manfredi[2,3], (1)Department of Sciences and Technological Innovation, Università del Piemonte Orientale, Italy, (2)Center for Translational Research on Autoimmune and Allergic Diseases, University of Piemonte Orientale, Italy, (3)Department of Translational Medicine, Università del Piemonte Orientale, Italy, (4)Department of Translational Medicine, Università del Piemote Orientale, Italy, (5)Department of Translational Medicine, Università of Piemonte Orientale, Italy, (6)Università del Piemonte Orientale, Italy, (7)Department of Health Sciences, Università del Piemonte Orientale, Italy, (8)Department of Science and Technological Innovation, Università del Piemonte Orientale, Italy*
The human gut microbiota is the totality of the microorganisms that colonizes our gut and many studies have demonstrated its involvement in human health and in the development of many diseases. Humans get in contact with hundreds of chemicals every day, thus the gut microbiota is daily exposed to many factors that could alter its status. The aim of this study was to investigate, using an *in vitro* approach, how three different commonly used chemicals PFOA, a foreever chemical, Glyphosate, a widely used and controversial herbicide and Cypermethrin, a synthetic pyrethroid pesticide higly toxic to fish, bees and aquatic insects,- affect the gut microbiota.

We implemented and validated an *in vitro* method for the culture of gut microbiota that maintains the functional and compositional profiles of *in vivo* gut microbiota. Then, stool samples from healthy donors were employed to test the impact of chemicals on the gut microbiota using metaproteomic and metabolomic analyses. The *in vitro* gut microbiota models were treated separately with PFOA, Glyphosate and Cypermethrin at different concentrations. Control samples grown without chemicals were also prepared and analyzed.

The metaproteomic analyses of the *in vitro* experiments were used to perform both phylogenetic and functional analysis. At the level of phyla only the stimulation with Glyphosate led to statistically significant changes. For the other taxonomic levels investigated -orders, genera and species- all the chemicals led to significant alterations. Almost all modulated taxa were previously studied either to be important for the health and stability of the gut (decreased levels after treatments) or involved in some inflammatory processes (increased levels after treatments). The functional analysis of the samples treated with the higher concentration of Glyphosate showed a clear distinct pattern, at the molecular functions and biological processes levels, in respect with the control group.

Glyphosate, PFOA and Cypermethrin strongly altered the gut microbiota *in vitro*, suggesting a potential direct association with gut microbiota dysbiosis mechanisms, but further studies are needed. The *in vitro* approach coupled with metaproteomic and metabolomic analysis is a valuable tool to investigate the impact of chemicals on the gut microbiota.

1.14.P-Tu054 Unraveling the Proteome Landscape of Perfluorooctane Sulfate Exposure During Pathogen-Associated Molecular Pattern Challenge in Peripheral Blood Mononuclear Cells
***Davide Rotondo**[1], Vittoria F Borrini[2], Luisa Nunziangeli[3], Giuseppe Condorelli[3], Chiara Fabianelli[3], Greta Immobile Molaro[3], Marcello Manfredi[4] and Francesco Dondero[5], (1)Department of Science and Technological Innovation, Università del Piemonte Orientale, Italy, (2)Department of Sciences and Technological Innovation, Università del Piemonte Orientale, Italy, (3)Polo Innovazione di Genomica Genetica e Biologia SRL, (4)Università del Piemonte Orientale, (5)Università del Piemonte Orientale, Italy*
An in increasing body of evidence suggests that per- and polyfluoroalkyl substances (PFAS) may adversely affect the immune system, potentially leading to immune dysregulation, decreased vaccination response and increased susceptibility to infections. In this study, we delve into the intricate molecular changes occurring within peripheral blood mononuclear cells when exposed to perfluorooctane sulfate (PFOS) during a lipopolysaccharide (LPS) challenge, a well-established pathogen-associated molecular pattern. PFOS is a persistent environmental contaminant with known health implications, and its interaction with immune cells remains largely undisclosed. By employing advanced proteomic techniques, we aim to unravel the complex molecular landscape, shedding light on the cellular responses and potential biomarkers associated with PFOS exposure during an inflammatory challenge with LPS as a representative PAMP.

To this end, PBMCs were pre-treated ex vivo with increasing amounts (3-600 microM) of PFOS for 24 hours, followed by LPS challenge after an additional 12 hours. Proteomic analysis was carried out on nano chromatography coupled to high resolution mass spectrometry using a 40-minute gradient with a Data Independent Analysis approach. Data were analyzed using DIA-NN software.

More than 4200 proteins were quantified across all the samples. The results showed that PFOS strongly impacted the PBMC proteome both at low and high concentrations. The main pathways altered by the PFOS treatments were related to inflammatory and immune responses. In particular, the treatment at 3 microM showed a marked increase of proteins associated with innate immune response (IFIH1, IFIT2, DAPK1, MX1, CASP4, ISG20, IN35, etc.), defense immune response (CD48, STAT4, LIRA1, etc.), cytokine-mediated signaling pathway (IL1A, IL1B, LIRB4, among others.), while at 600 microM we found an enrichment of inflammatory response (IL6, IL8, CXCL5, CXCL2, etc.), interleukin 8 and 2 production, and a positive regulation of NF-kB transcription factor (KPCD2, TRI22, TRAF1) proteins. These pathways are essential for inflammatory response mechanisms.

Our findings provide valuable insights into the intricate interplay between PFOS exposure and immune and inflammatory responses, contributing to a deeper understanding of the health implications associated with environmental PFOS exposure.

1.14.P-Tu055 Chronic effects of Perfluorooctane Sulfonic acid (PFOS) on Cloeon dipterum larvae development
Ayesha Siddiqa, *Aquatic Ecology and Water Quality Management, Wageningen University & Research (WUR), Netherlands*
Chronic effects of Perfluorooctane Sulfonic acid (PFOS) on Cloeon dipterum larvae development

Perfluorooctane sulfonic acid (PFOS) is of high concern because of its widespread application in consumer products and its toxic effects on human and animal health. PFOS has been known to be extremely environmentally persistent and has bioaccumulative toxic effects. Previous studies assessed the acute effects of PFOS on the traditional endpoints mortality and immobilizations. However, we evaluated the long-term exposure of PFOS effects on the aquatic *Cloeon dipterum* larvae development, survival, and emergence. Third- and fourth-instar larvae were exposed to five concentrations ranging from 0 to 100 µg/L. The test duration was 31 days. The renewal was done after every two weeks. Animals were fed on commercial snail food every 3 days. During the experiment survival, larvae development, larvae growth, and emergence were evaluated.

Our results show reduced larvae development, greater larvae mortality, and less emergence within the PFOS treatments compared to control. Larvae development was the least sensitive endpoint (NOEC = 10µg/L). Moreover, significant delays in emergence were observed in all the treatments compared to the control. Emergence was relatively less in the highest treatment 100µg/L. The proportion of larvae that survived until emergence did not significantly differ between the control and treatments up to 10 µg/L after 31 days. The present study indicates that aquatic insects appear to vary greatly in their sensitivity to PFOS depending on endpoints. This might be explained by differences in the physiological responses to PFOS and the toxicokinetics of PFOS. Based on these results follow-up experiments for PFOS toxicokinetics and toxicodynamics in insects will be conducted in 2024.

1.14.P-Tu056 Significant Changes Induced By PFOA And GenX Environmental Concentrations In Guppy Testes Transcriptome And Reproductive Traits
Clelia Gasparini[1], Silvia Iori[2], Edoardo Pietropoli[2], Marco Bonato[2], Mery Giantin[2], Andrea Barbarossa[3], Anisa Bardhi[3], Mauro Dacasto[2], Andrea Pilastro[1] and ***Marianna Pauletto****[4], (1)Department of Biology, University of Padua, Italy, (2)Department of Comparative Biomedicine and Food Science, University of Padua, Italy, (3)Department of Veterinary Medical Sciences, University of Bologna, Italy, (4)Comparative Biomedicine and Food Science, University of Padova, Italy*
In humans and rodents, exposure to PFAS has been frequently linked to adverse reproductive health outcomes, but our knowledge of their effects on reproduction remains limited in aquatic organisms. To help filling this gap, we exposed adult males of a freshwater fish (*Poecilia reticulata*) to 1 mg/L of PFOA, a legacy PFAS, or its alternative, GenX, potentially less hazardous.

After 21 days of exposure, we assessed PFAS bioaccumulation in whole-body fish and the expression of the reproductive traits associated with male mating and insemination success, such as body colouration, sexual behaviour (number of sigmoid displays and gonopodial thrusts), ejaculate quality traits (sperm swimming velocity, number, and viability). Then, we performed a transcriptomic analysis (RNA-seq) in testes, a key tissue for the study of the effects on male reproduction.

PFOA exhibited higher bioaccumulation than GenX. Although overall sexual activity was not significantly affected by treatment, GenX (but not PFOA) males performed more courtship displays than controls. As behavioural tests were conducted with unreceptive females, this result can be seen as maladaptation. As to ejaculate traits, both GenX and PFOA reduced sperm swimming velocity compared to controls. This could be attributable to PFAS entering the testes and causing direct detrimental effects on mature sperm, or to PFAS impairing the molecular mechanisms regulating sperm maturation. Accordingly, the transcriptional modulation of some genes contributing to sperm velocity seems to support the observed decrease in sperm velocity, thus linking molecular and phenotypical findings. Overall, compared to controls, we identified a total of 86 and 107 differentially expressed genes in GenX- and PFOA-treated fish, respectively. Modulated genes were involved in immune response, spermatogenesis, antioxidant activity, sperm quality, and lipid metabolism.

In conclusion, we showed that reproductive traits and gene expression were sensitive endpoints highlighting PFAS toxicity at low - environmentally relevant - concentrations in male guppies. The detrimental effects we demonstrated are of great relevance, especially considering that the environmental exposure to alternative PFAS will grow in the future. Our results provide important evidence suggesting that the toxicity potential of GenX may be higher than that of PFOA, despite the fact that GenX is deemed less toxic, at least in the species used here.

1.14.P-Tu057 Assessment of Per and Polyfluorinated Alkyl Substances (PFASs) Residues in Urine samples of children
Arianna Bautista[1], *Marta Llorca-Casamayor*[2], *Joan O. Grimalt*[2] *and Marinella Farre*[1], *(1)Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain, (2)Environmental Chemistry, Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain*
Children are a part of the population that is particularly susceptible to toxicants and, especially, to those that can have a harmful impact on their health. In this context, we wanted to investigate the exposure of early stage population to commonly known per- and polyflruoroalkyl substances as well as any other new PFAS used as a substitute. For this reason, a suspect screening methodology was developed for the study of 40 per- and polyfluoroalkyl substances including the banned PFOA and PFOS, among other 18 legacy PFASs, and the ones considered as new replacement PFASs such as the short TFA, ADONA, and GenX, among others, in urine as a non-invasive matrix. This study includes 185 urine samples from 8-year-old children Inma Asturas cohort.

The samples were analyzed with a liquid chromatography coupled to high resolution mass spectrometer. The separation of legacy PFASs was achieved with a Hypersil Gold PFP column while the short PFASs were separated in an Atlantis Premier BEH C18 AX column.

The main results showed the presence of legacy carboxylic acid PFASs such as PFPeA, PFHpA, PFOA, PFNA, PFUdA and the sulfonates PFHxS, PFOS and PFNS, at concentrations ranging from 4.9 ng/L (PFNS) to 532 ng/L (PFHxS). In addition, some short chain PFASs such as TFA have been detected in some punctual samples. The two most frequently detected compounds have been the short TFA and GenX being present in 51% and 50% of the samples, respectively, at quantifiable concentrations.

The values detected in this work were comparable to the ones reported for children but at much lower concentration compared with the ones reported in the literature for adult people and workers from a PFASs manufacture. However, it is important to remark that this study has been focused on 8-years-old children so their exposure to these toxicants has been basically through the diet and, therefore, these concentrations could increase through the years since their exposure could be chronically

1.14.P-Tu058 Bioaccumulation and Ecotoxicity of Representative PFAS in Model Marine / Estuarine Species
David W. Moore[1], *Guilherme R. Lotufo*[1], *Alan Kennedy*[2], *Ashley N Kimble*[1], *Ed Wirth*[3] *and Peter B. Key*[3], *(1)U.S. Army Engineer Research and Development Center, (2)Environmental Laboratory, U.S. Army Corps of Engineers, (3)National Oceanic and Atmospheric Administration (NOAA)*
In coastal marine/estuarine areas, PFAS concentrations in sediments have typically been reported in the ppb range (i.e., 0.1 to 1o ng/g or ppb), Salinity influences the fate and transport of PFAS (i.e., inverse conc. relationship in seawater with increasing salinity) and sediments appear to serve as a repository (i.e., shorter chain length PFAS primarily associated with sediment porewater while longer chain length PFAS bound to sediment). Currently there is not sufficient data to derive toxicity reference values (TRVs) and/or quantify uptake bioavailability in marine species. This study will quantify the bioavailability and toxicity of 7 PFAS related to legacy aqueous film forming foams (AFFF) in acute and chronic tests with 10 model marine species representing benthic, epibenthic and pelagic species. The 7 PFAS include PFBA, PFHxS, PFHxA, PFOA, PFOS, 6:2 FTS and 8:2FTS. Benthic species will be exposed to spiked sediments while epibenthic and pelagic species will be evaluated in aqueous exposures. In addition to toxicity endpoints (LC50, EC50, NOEC, and LOEC values), bioaccumulation factors (BAFs) and Bioconcentration Factors (BCFs) will be derived for select species (i.e., those with sufficient tissue mass) in sediment and aqueous exposures, respectively. Results of studies for sediment spiking procedures demonstrate complete transference of PFAS sorbed to sand onto sediment particles. A high percentage (>75%) of spiked PFOS, PFNA and 8:2 FTS was associated with sediment particles while PFHxA, PFHxS and PFOA was mostly (>75%) associated with sediment porewater in spiked sediments. Preliminary aqueous acute toxicity results with the silverside minnow (*Menidia berylina*), the sheepshead minnow (*Cyprinidon variegatus*), the grass shrimp (*Palemonetes pugio*), the mysid shrimp (*Americamysis*), the sea urchin (*Arbacia punctulata*) and the copepod (*Acartia*), show PFSAs to be more toxic than PFCAs or the Fluorotelomers evaluated. Of the species evaluated *Acartia* is the most sensitive followed by *Americamysis.* Testing is ongoing and results will be presented as available.

1.14.P-Tu059 Bioaccumulation and Toxicity of Field-collected PFAS-impacted Sediment to Leptocheirus plumulosus and Chironomus dilutus
Guilherme R. Lotufo, *Paige M Krupa, David W. Moore and Ashley N Kimble, U.S. Army Engineer Research and Development Center*
Per- and polyfluoroalkyl substances (PFAS) are currently the focus of much attention due to their ubiquitous occurrence, environmental persistence, and implications to human and ecological health. However, data gaps exist regarding the fate and effects of these substances in aquatic environments, particularly for estuarine and marine systems. Most aquatic toxicity and bioaccumulation studies to date focus on water-column exposures, with less data available for sediment-based exposures. Furthermore, few studies describe effects of sediment-based PFAS at environmentally relevant concentrations. To address this knowledge gap, the current studied collected sediment from 16 estuarine and 10 freshwater sites suspected of having elevated levels of PFAS from various sources. Estuarine sediments were evaluated using 28-d bioaccumulation and 10-d toxicity tests with the amphipod *Leptocheirus plumulosus* while freshwater sediments used 16-d midge (*Chironomus dilutus*) bioaccumulation and toxicity tests. Measured ∑PFAS in sediment ranged from 1 to 120 ng/g ww, with long-chain compounds

accounting for the majority of total PFAS in both estuarine and freshwater sediments. Survival and growth of organisms in the toxicity tests did not appear to be affected by the PFAS-impacted sediment. Preliminary tissue data for *L. plumosus* suggests that biota-sediment accumulation factors (BSAFs) varied between the different PFAS analytes and sites. Additionally, preliminary data did not indicate a clear or consistent trend between bioaccumulation and carbon chain length, percent organic matter, or sand/fine sediment type. As the differential bioaccumulation observed was likely influenced by physical and chemical properties of the sediment, subsequent data analysis will more look into the role of various sediment properties upon bioaccumulation.

1.14.P-Tu060 Biomagnification Or Per/Polyfluoroalkyl Substances Through Mixture Uptake from Soil in a Terrestrial Food-Web

Roman Kuperman[1]*, Linnzi K Wright*[1]*, Michael Simini*[1]*, Andrew East*[2]*, Guilherme R. Lotufo*[3]*, Jennifer Guelfo*[4]*, Zhao Yang*[4] *and Emily Stricklin*[5]*, (1)U.S. Army DEVCOM Chemical Biological Center, (2)U.S. Army Public Health Center, (3)U.S. Army Engineer Research and Development Center, (4)Texas Tech University, (5)Excet, Inc*

We are determining biomagnification of PFAS in a terrestrial food-web from lower trophic level organisms to higher trophic level organisms using environmentally relevant mixtures and concentrations. We quantified the uptake of these PFAS in terrestrial plants from soil and generated bioconcentration factors (BCF). Based on the results of these investigations, we selected PFAS compounds with BCF values of two or greater for the biomagnification study. This study is determining biomagnification calculated as Trophic Transfer Coefficients (TTC) for the chemical transfer of individual PFAS from terrestrial plants grown in PFAS amended soil to mammals (Dutch belted rabbits), exposed to PFAS through their daily diet. Results to date contributed to further refinement of what PFAS, what tissues, what organisms or what trophic paths may be more risk relevant for the variety of sites and scenarios within the interests of PFAS ecotoxicology at large. Ecologically relevant exposure data developed in this research will fill several knowledge gaps regarding biomagnification potential for PFAS compounds released into the terrestrial environment.

1.14.P-Tu061 The Transgenerational Adverse Effects Caused by GenX on Locomotive Behaviors in Caenorhabditis elegans

Wei-Yun Huang and ***Chia-Cheng Wei****, Institute of Food Safety and Health, College of Public Health, National Taiwan University, Taiwan*

Per- and polyfluoroalkyl substances (PFASs), with nearly 15000 variants produced today, exhibit widespread use in industrial and consumer products owing to their amphipathic nature, as well as their chemical and thermal stabilities. Concerns have emerged due to the adverse health effects associated with human exposure to PFASs, prompting the search for substitutes. For instance, perfluorooctanoic acid, one of the most commonly used PFASs, has been linked to adverse effects such as reduced reproduction and impaired locomotion in zebrafish. Moreover, it raises the possibility of transgenerational transmission, which is known as the "transgenerational effect".

To reduce concerns caused by perfluorooctanoic acid, GenX emerged as a substitute with a shorter carbon chain length, anticipated to be less toxic. However, studies have indicated that GenX may still induce toxic effects such as hepatic or reproductive toxicities. As current research primarily focuses on these aspects, there are gaps in comprehending the neurotoxic effects and their underlying mechanisms. Additionally, whether GenX can induce transgenerational effects remains unclear. Under these circumstances, our study aims to investigate the transgenerational neurotoxic effects induced by GenX.

This study focuses on understanding the GenX induced transgenerational neurotoxic effects in the *Caenorhabditis elegans* model, as well as elucidating the potential underlying mechanisms. Our preliminary findings indicate that GenX exposure at various concentrations (0, 0.0003, 1, 10, 100, 1000, 10000, and 30000 μM) results in inhibited growth (10000 & 30000 μM), reproduction (0.0003-10000 μM), and locomotive behaviors including body bend and head thrash (0.0003-10000 μM). Moreover, we found that the phenomenon of the decrease in locomotion can be transmitted from parental generation to their offspring (F1-F3) under 0.0003 μM exposure, suggesting that GenX could cause the transgenerational neurotoxic effects and may not be safer than we thought.

The significance of this research lies in advancing our understanding of the potential transgenerational neurotoxicity associated with GenX exposure and its implications for human health. This study contributes essential insights to the broader discussion on PFAS substitutes and their implications for human health.

1.14.P-Tu062 Insight into the differential toxicity of PFOA and PFBA based on a 3D-cultured MDA-MB-231 cell model

Huan Wang[1]*, Ting Xu*[2] *and Daqiang Yin*[2]*, (1)Tongji University, Shanghai, China, (2)Tongji University, China*

Perfluoroalkyl substances (PFASs) are a category of high-concerned emerging contaminants which are suspected to correlate with various human adverse health outcomes including tumors. It is also a question whether short-chain PFASs are qualified alternatives under the regulation of long-chain PFASs. In this study, a three-dimensional (3D) culture system based on Gelatin methacrylate (GelMA) hydrogel matrix was used to investigate the impacts of 120-h perfluorooctanoic acid (PFOA) and perfluorobutanoic acid (PFBA) exposure of MDA-MB-231 cells. The results showed that PFOA exposure promoted the proliferation, migration, and invasion of MDA-MB-231 cells in an environmentally relevant concentration range (0.1 to 10 μM), exhibiting a clear malignant-promoting risk. In contrast, PFBA only showed a trend to induce non-invasive cell migration. Hippo/YAP signaling pathway was identified as the contributor to the differences between the two PFASs. PFOA but PFBA reduced YAP phosphorylation and increased the nuclear content of YAP, which further facilitated abundant key factors of epithelial-mesenchymal transition (EMT) process. Our results provided a new idea for the carcinogenicity of PFOA using a 3D-based paradigm. Although the effects by PFBA were much milder than PFOA in the current test duration, the cell model suitable for longer exposure is still necessary to better assess the safety of alternative short-chain PFASs.

1.14.P-Tu063 Environmental Modeling Of Trifluoroacetic Acid (TFA) Originating From Hydrofluoro-Olefins
*Kun Zhao[1], Krish Vijayaraghavan[1] and **Geert Boeije**[2], (1)Ramboll, (2)Honeywell, Belgium*
Hydrofluoro-olefin HFO-1234yf (2,3,3,3-tetrafluoropropene), the key mobile air conditioning refrigerant, degrades in the atmospheric environment to trifluoroacetyl fluoride which then hydrolyses to form trifluoroacetic acid (TFA). The high-water solubility of TFA together with its ability to spread rapidly in the environment via the water cycle makes it widespread and ubiquitous in nature. This modelling study assessed the fate and transport of TFA in the freshwater aquatic environment resulting from the emission and atmospheric degradation of HFO-1234yf and subsequent atmospheric deposition along the Rhine River basin.

The Rhine was selected as a case study as it represents a prominent watershed in Western Europe with a large population. Environmental fate and transport modelling of TFA in the freshwater aquatic environment was conducted based on the assumption of constant and ongoing HFO emissions, which through atmospheric degradation in turn leads to a constant deposition of TFA.

Modelling results demonstrate that with constant and ongoing emissions, within a short timeframe (months) the concentration of TFA reaches a steady state, and that the concentration of TFA does not further increase over time. In the case study of the Rhine basin, TFA concentrations below 0.6 μg/L are predicted. The modelled TFA concentrations are well in line with the actual measured TFA concentrations in the Rhine River as reported by UBA considering that the measurements include all sources of TFA, not only those from HFO degradation.

The steady state TFA concentrations are at least 100 times below the German drinking water guidelines (60 μg/L) and are multiple orders of magnitude below the no-effects level of the human health risk assessment (NOAEL = 10 mg TFA/kg bw/day, from a 90-day oral study in rats).

In conclusion, this study invalidates the incorrect assumption made in the REACH PFAS Restriction Proposal that freshwater TFA concentrations would continue to increase until “inevitably” reaching a toxic level.

1.14.PC Unravelling the Complexities of PFAS: From Environment to Human Health and Reproduction

Track 2. Ecotoxicology Becomes Stress Ecology: From Populations to Ecosystems and Landscapes

2.01 Advancing Risk Assessment of Anthropogenic Stressors to Non-Target-Arthropods and Ecosystem Functions in a Changing World

2.01.T-01 Key Steps and Development for the Revision of the Guidance Document on Non-target Arthropods
*Domenica Auteri, **Fernando Alvarez**, Rachel Sharp, Maria Arena, Alessio Ippolito, Alberto Linguadoca and Laura Villamar-Bouza, European Food Safety Authority (EFSA), Italy*
Introduction**:** Regulation (EC) No 1107/2009 requires a specific risk assessment for non-target arthropods (NTAs). Currently, the NTA risk assessment is performed according to the SANCO Guidance Document (GD) on Terrestrial Ecotoxicology. EFSA PPR Panel (2015) indicates numerous limitations with this GD and risk assessors from Member States frequently highlight their concerns with the inadequacy of current methods and a lack of clarity in the level of protection. Arthropods are fundamental entities of food networks and preserving both their biomass and diversity is pivotal to safeguard ecosystem services delivery. Following a prioritisation exercise that was endorsed by the Standing Committee on Plants, Animals, Food and Feed in January 2023, the revision of the SANCO GD was identified as of high priority. In this presentation, EFSA will summarise the key steps and scientific development needed to undertake the revision of the GD.

Proposed procedure and main challenges**:** Pesticides regulation states that plant protection products may be approved only if they pose no unacceptable effects on biodiversity and ecosystems. However, the term 'unacceptable' is not further defined in the regulation, and this constitutes a very generic protection goal. EFSA PPR Panel (2010) and EFSA Scientific Committee (2016) proposed a methodology to define specific protection goals (SPGs). Setting SPGs is a crucial step for the GD revision. It requires a dialogue between risk assessors and risk managers, who make the final decision; agreed SPG will then be used as reference for developing risk assessment methodology. Once the SPGs are agreed, the second step will be the development of a protocol which will help making a transparent planning by identifying the problem formulation to be addressed, the methodology to be followed, the resources required and the estimated timelines. Having a pre-defined protocol will allow for different strategies to be followed for addressing the needs (and for adjusting the scope of the GD in the light of the available data while identifying knowledge gaps and needs for further research activities.

For the uptake of the GD in the regulatory risk assessment, the engagement with experts from Member State authorities and stakeholders across the various steps is considered fundamental. Collection of feedback during the revision process will allow to manage expectations and address the feasibility of the GD.

2.01.T-02 Assessing Non-target Terrestrial Arthropods in European Agriculture: A Comprehensive Study on Pest Control Ecosystem Service
***Grzegorz Sylwester Sowa**[1], Steven Droge[2], Mykola Rasko[3] and Lorraine Maltby[1], (1)School of Biosciences, University of Sheffield, United Kingdom, (2)Environmental Risk Assessment, Wageningen University & Research (WUR), Netherlands, (3)University of Coimbra, Centre for Functional Ecology, Portugal*
Non-target terrestrial arthropods (NTAs) found on soil or plants play a crucial role in biodiversity and ecosystem services (ES) by naturally controlling crop pests through predation or parasitisation. The taxonomic similarity between NTAs and pests makes them vulnerable to insecticides, prompting the need for evaluating the risk assessment. This study aims to identify and compare the distribution of NTAs providing pest control ES in EU agriculture, analysing variations across different crops, EU geographical zones, and within-crop habitats. The study concentrated on six annual crops (wheat, maize, barley, oilseed rape, potato, beet) and three perennial crops (apple, grape, olives) chosen for their significant contribution to EU production and data availability. Arthropod information for arable crops was sourced from an existing arthropod database [1], while a literature review was conducted for perennial crops by using CAB Abstracts platform. The dataset, focusing on EU-based invertebrates on or above the soil, was refined by excluding pest species, and non-metric multidimensional scaling analysis was used to compare NTAs compositions. Representative NTA families were identified based on criteria such as abundance, dominance, diversity, and distribution. Current pesticide testing strategies, which often focus on standard species like mites or parasitic wasps, face limitations in adequately assessing the diverse biodiversity crucial for pest control. The study emphasizes the extensive taxonomic diversity of NTAs in agroecosystems, revealing patterns in their composition across different crops, EU zones and within crop habitat. A comparison revealed similarity within rather than between major crop types, although this grouping was tighter for perennial crops than for arable crops. These groupings persisted when the data were analysed by EU geographic zones or within-crop habitat. Further examination aimed at identifying key NTA families shows that there are some that are either ubiquitous (e.g *Carabidae*), occurred sporadically in both crop categories (e.g *Lycosidae*) or only in one of them (e.g *Gnaphosidae* and *Pteromalidae*). The findings underscore the necessity for a more precise and ecosystem-service-oriented approach in developing risk assessment guidance for pesticide use in agriculture.

2.01.T-03 Off-Crop Non-Target Terrestrial Organism Drift Exposure and Risk for Plant Protection Products: Processes, Procedures and Practical Proposals
***Neil Mackay**[1], Sonja Braaker[2], Andrew C. Chapple[3], Heidi Cunningham[4], Jerome Goulet-Fortin[2], Heike Fremdt[5], Rena Jutta*

Irene Isemer, PhD[6], Thomas G Preuss[5] and Carola Schriever[7], (1)FMC Corporation, United Kingdom, (2)BASF SE, Germany, (3)Bayer AG, (4)Product Safety, Syngenta, United Kingdom, (5)Bayer AG - Crop Science Division, Germany, (6)Crop Science, Bayer AG, Research Triangle Park, United States, (7)BASF SE Agricultural Solutions, Germany
Developing an effective understanding of the potential for plant protection products to impact non-target terrestrial organisms requires consideration of a range of processes that will influence exposure. This includes better understanding of the role of application techniques, the influence of the target and non-target environment characteristics, and how these effect drift as a key route of entry, as well as ecological/behavioural characteristics of the organisms themselves. Key challenges for these assessments include development of a practical framework that addresses process variability and uncertainty within inherently diverse non-target environments and allows for practical implementation at a meaningful ecologically relevant resolution for a range of organisms. Recently, there has been an initiative from EFSA and Wageningen University and Research to support development of plant protection product exposure assessment scenarios for non-target terrestrial organisms. This project is intended to support guidance development for in-field and off-field exposure assessment associated with spray drift where there are currently considered to be deficiencies. This presentation summarises key differences between conventional two-dimensional deposition/sedimentation spray drift considered in current risk assessments and the more complex challenges associated with interactions with three-dimensional vegetation structures. Various research needs are highlighted: these are required to support development of an effective and meaningful exposure and risk assessment. Appropriate resolution of assessment and strategies for addressing variability are deemed key considerations. Primary challenges include mechanistic representation of spray drift, characterisation of vegetation capture of drift and the implications of spatial variation of exposure in field margins (vertically, with depth and laterally along field interfaces). A truly effective and meaningful risk assessment framework also needs to take into account non-target organism distribution, development and life stage vulnerability, and ecological characteristics such as mobility, routes and duration of exposure. This presentation will summarise research efforts underway within CropLife Europe of relevance to these challenges that may offer practical contributions towards development of a coherent, practical and meaningful basis for tiered risk assessment.

2.01.T-04 Integrating Multiple Exposure Routes for Assessing Pesticide Impact on Terrestrial Non-Target Arthropods
***Anna Huang**[1], Jan Baas[1], Dick Belgers[2], Nina Jansen[2] and Ivo Roessink[3], (1)Wageningen Environmental Research (WUR), Netherlands, (2)Environmental Risk Assessment, Wageningen University & Research (WUR), Netherlands, (3)Wageningen University & Research (WUR), Netherlands*
To ensure the protection of terrestrial non-targeted arthropods (NTAs), conducting comprehensive environmental risk assessments (ERAs) for pesticides is crucial. Currently, Tier 1 risk assessment frameworks often rely on standardized test species such as *Aphidius rhopalosiphi* and *Typhlodromus pyri*, evaluated on glass plates focusing on freshly dried residues post-application. However, NTAs encounter pesticides through diverse routes in natural settings—contact with dried and fresh residues on plant surfaces, direct overspray, and oral exposure through contaminated food. Moreover, each test employs distinct units (e.g., chemical per individual, per surface area, and concentration in food items), which hampers a holistic understanding of pesticide risks in the actual environment.

Recent advancements have demonstrated the potential for establishing an integration framework to encompass different exposure routes for bees. This framework used a toxicokinetic-toxicodynamic model (TKTD), i.e., the BeeGUTS framework. This model discerns between kinetic effects (uptake and elimination) and dynamic effects (intrinsic sensitivity), unveiling organism sensitivity irrespective of exposure routes. As a result, such an approach allows for unified interpretation of results from diverse exposure routes. In other words: knowing the actual outcome of a chronic oral test, will allow predictions of the outcome of a future acute contact test.

Our study aims to implement a TKTD approach, akin to BeeGUTS, to explore three distinct exposure routes (acute contact, acute indirect, and chronic oral) involving *Gryllus bimaculatus* toward imidacloprid. Our experimental design involved exposing the organisms to direct chemical exposure, surface exposure, or oral ingestion in three separate experiments. Through the utilization of TKTD models, we interpret data, calibrate, and validate the model for untested exposure routes, leading to the development of a comprehensive model capable of integrating various exposure pathways. Ultimately, our study endeavours to advance the integrated framework for assessing pesticides on NTAs, underscoring the significance and feasibility of incorporating multiple exposure routes when evaluating the pesticide impact on these organisms.

2.01.T-05 Development of Ecotoxicological Testing Methods on Herbivorous Larvae of Locusta Migratoria and Spodoptera littoralis under Laboratory Conditions
***Lena Böhrs**[1], Jörg Leopold[2], Andreas Duffner[3], Charlotte Elston[4], Susanne Oberdörster[5], Heike Fremdt[5] and Stefan Kroder[6], (1)Eurofins Agroscience Services Ecotox GmbH, Germany, (2)ibacon GmbH, Germany, (3)Eurofins Scientific, Germany, (4)Syngenta, United Kingdom, (5)Bayer AG - Crop Science Division, Germany, (6)ADAMA Deutschland GmbH, Germany*
Non-target arthropods (NTA) can be affected by Plant Protection Products (PPP) via different exposure routes. Besides `overspray´ and `contact` there is also the oral exposure route via residues on food. In the current environmental risk assessment of Plant Protection Products (PPP) to non-target arthropods, oral exposure via food ingestion by herbivorous species is not considered and therefore, no standard laboratory test protocols for oral exposure of arthropods other than bees are available. In the EFSA Scientific Opinion of 2015 on NTA's, *Lepidoptera* and *Orthoptera* are two of the suggested taxa to cover this herbivorous oral route of exposure. There are few studies with both taxa, which are representative for NTAs, indicating that a comparison of contact versus both oral and contact is not always possible.

In May 2022 CropLife Europe NTA expert sub-group initiated the development of an ecotoxicological testing method to assess side effects of plant protection products on herbivorous *Lepidoptera* and *Orthoptera* via oral exposure route. For both species a main test was conducted and evaluated in two different GLP laboratories. The main tests comprised the exposure phase of 48 hours (acute mortality) as well as the development period (sublethal effects) and reproduction assessment.

The objective of this presentation is to present the results of these ecotoxicological test methods developed for oral exposure with *Spodoptera littoralis* and *Locusta migratoria* and evaluate criteria to assess suitability and reliability of both test species for an oral exposure test system. The criteria are control mortality, sensitivity, food consumption / oral uptake, handling, test duration, challenges, sex determination and feasibility of reproduction assessments. Acute and chronic endpoint were assessed and statistically evaluated for both species. The ERx values will be presented for *Spodoptera* and *Locusta* in comparison.

2.01.P Advancing Risk Assessment of Anthropogenic Stressors to Non-Target-Arthropods and Ecosystem Functions in a Changing World

2.01.P-Tu064 The Effects of Landscape Structure and Pesticides on the Populations of Non-Target Arthropods in Germany

Urwa Alalouni[1]*, Elżbieta Ziółkowska*[2]*, Christopher Topping*[3]*, Klaus Swarowsky*[1]*, Silvia Pieper*[1]*, Stephan Marahrens*[1]*, Hella Kehlenbeck*[4]*, Susanne Stein*[5]*, Anto Raja*[5]*, Steffen Matezki*[1] *and Jörn Wogram*[1]*, (1)German Environment Agency (UBA), Germany, (2)Jagiellonian University, Institute of Environmental Sciences, Poland, (3)Aarhus University, Denmark, (4)Julius Kühn-Institute Federal Research Centre for Cultivated Plants (JKI), Germany, (5)Julius Kühn-Institut , Institute for Strategies and Technology Assessment, Germany*

The recent decline in the diversity and abundance of insects has been linked to intensified agriculture and simplified landscape structures as well as the intensive use of pesticides. Pesticides, in particular, have been shown to affect the populations of Non-Target Arthropods (NTA) both in-field and off-field, with their impacts influenced by several factors, including landscape structure. To disentangle the links between landscape structure, pesticide use and their effects on NTA populations, land use/cover and agricultural data from two German federal states, Brandenburg and Lower Saxony, were examined. The selected study areas showed significant variation in the composition and configuration of landscape elements (e.g. field size, natural habitats) in the two states. ALMASS (Animal, Landscape and Man Simulation System) modelling framework was utilised to simulate the impact of pesticide on NTA populations (represented by *Bembidion lampros*) and the effectiveness of selected mitigation measures: grassy field boundaries (FB) and unsprayed field margins (UM). Under the baseline scenario (no changes to landscape structure and no pesticides applied), significant variation in *B. lampros* populations was observed across study areas and explained by landscape characteristics. The addition of FB led to an average increase of 9.8% in beetle populations across all study areas. Under the pesticide scenario, beetle populations decreased significantly in all study areas (average 14%), and the effects varied depending on landscape structure. The impacts were higher in homogeneous landscapes with low initial beetle populations, high arable land coverage and low source habitat coverage. The beetles were also affected in exclusive off-field areas where pesticides were not applied or drifted. The simulations showed that both, FB and UM, reduced the effects of pesticides. However, FB were a more effective measure than UM. Our results indicate that pesticide use affects *B. lampros* populations also through source-sink dynamics, resulting in significant off-field effects that persist even with mitigation measures in place. The findings show that the existing risk assessment of NTA has significant shortcomings and that the existing measures for mitigating risks are insufficient. It is recommended that the management of agroecosystem landscapes focuses on establishing, preserving, and safeguarding habitats for insects, particularly in homogeneous agricultural landscapes.

2.01.P-Tu065 An approach to include more realism in the assessment of human impacts on species abundance and diversity

Magnus Wang *and Su Yeong Park, WSC Scientific GmbH, Germany*

Current risk assessment schemes focus on a very defined aspects of the risk posed by chemicals applied by farmers and other human activities, e.g. the risk is considered for one product at a time and the assessment focuses on a very defined calculation of exposure, which does not reflect the full range on conditions in agriculture. Furthermore, also changes of agricultural practice, habitat loss, climate change related impacts and other factors become more and more important. Hence on one side, the relatively narrow view of the risk assessment scheme may not indicate a risk for those substance approved for the market, and on the other side, studies from scientist show an alarmingly rapid loss of biodiversity. And it often remains unclear, which factors drive that loss mostly. In the present study we present a landscape scale approach to evaluate which factors play a main role for the presence of species. Aerial images of the same landscapes from Germany from 2003/2004 and 2018 were used to evaluate changes of landscape structure over time. After automated digitisation of these aerial images using our software ALDiS, arthropod abundance was simulated and the effects related to changes of landscape structure were compared to those resulting from application of hypothetical pesticides. We discuss the use of this relatively simply screening approach to analyse potential reasons of changes in species abundance and diversity.

2.01.P-Tu066 Consideration of Sublethal Effects of Insecticidal Substances in Plant Protection Products or Genetically Modified Plants on Non-target Invertebrates

Udo Hommen[1] *and Mathias Otto*[2]*, (1)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (2)Federal Agency for Nature Conservation, Germany*

Systemic insecticides and insecticidal substances produced by genetically modified crops (GMP) share that non-target invertebrates can be exposed via the diet, either by feeding directly on crop material or by feeding on herbivores which have fed on the crop. Especially dead or less mobile pest organisms can be an easily accessible food resource for invertebrate omnivores and predators. Since insecticidal substances can be produced over the full life-time of such a GMP and systemic insecticides are designed to protect the crop over prolonged time periods, non-target organisms can be chronically exposed, partly in low doses. Hence, this type of exposure may lead to sublethal rather than lethal effects. We evaluated for which invertebrate taxa which sublethal endpoints are addressed in the first tier effect assessment of plant protection products (PPP) in the EU and compared this with current practice in the effect assessment of GMP with insecticidal properties. For PPP, exposure via diet is routinely tested only for the honeybee. In addition to bees and surrogate soil organisms, the lower tier effect assessment for PPP considers only ‘beneficial’ non-target arthropods, a predatory mite and a parasitoid wasp. Testing of a non-target herbivore is actually not required for PPP and the focus of tests is often on short-term exposure via overspray and contact. For GMP environmental risk assessment, no fixed data requirements are defined. Selection of test species and test protocols are often derived from risk assessment but modified to address exposure via diet. Survival is almost always assessed but often also growth and/or development are monitored. Analysis of reproduction is much rarer, but this may be partly explained by the mode of action of most GMP assessed so far. In , we identified a lack of consideration of sublethal effects on non-target invertebrates in case of potential chronic exposure. Thus, we think that the time is ripe for a cooperative action of scientists from both, the PPP and the GMP community, to collect experiences gained in the past with different test protocols and to initiate the preparation of refined or new test guidelines, especially for non-target arthropods.

2.01.P-Tu067 The Interspecies Sensitivity of Non-Target Terrestrial Arthropods (NTAs) for Pesticides: Species Vulnerability and Exposure Route

***Steven Droge**[1], Paul van den Brink[2], Louise Wipfler[1], Grzegorz Sylwester Sowa[3], Lorraine Maltby[3], Leonhard Urs Bürger[4], Andreas Focks[4], Daniel Paredes[5], Mykola Rasko[5], Artur Miguel Paiva Sarmento[5] and José Paulo Sousa[5], (1)Environmental Risk Assessment, Wageningen University & Research (WUR), Netherlands, (2)Wageningen University & Research (WUR), Netherlands, (3)School of Biosciences, University of Sheffield, United Kingdom, (4)Institute of Mathematics, Osnabrück University, Germany, (5)University of Coimbra, Centre for Functional Ecology, Portugal*

The first Tier of the pesticide environmental risk assessment for non-target terrestrial arthropods (NTAs) has a data requirement on effect studies with two standard test species involved in pest control, the predatory mite *Typhlodromus pyri*, and the parasitoid wasp *Aphidius rhopalosiphi*, using contact exposure to dried spray residues on glass plates. Several other NTA species are commonly used if higher Tier assessment is required, applying standardized laboratory experiments using contact exposure-effect studies using dried residues on natural substrates, such as leaves or soil. The EFSA (2015) Scientific Opinion on NTA risk assessment addressed various concerns on the risk assessment framework, e.g., that these generic species and safety margins may not sufficiently cover interspecies sensitivity of vulnerable species that are key drivers for various Ecosystem Services (ES). It was also noted that for bee risk assessment, exposure routes are based on dietary exposure and topical contact, which would also relate to many other (pollinating) NTAs. The ongoing AENEAS project has identified key driver NTA families for various agricultural crops, for ES pest control and pollination. Our literature search indicated that studies on species sensitivity distributions (SSDs) for NTAs are extremely scarce, while toxicity endpoints are abundantly reported in published literature and active substance dossiers for many NTA species. One major issue is that NTA exposure routes and durations vary strongly, hampering strict SSD comparisons. Using CAB Abstracts, Hertfordshire PPDB, and EPA-Ecotox Knowledgebase, surface contact lethal rates (LR50) and topical lethal doses (LD50) were retrieved, in order to compare generic test species endpoints to those for NTA from selected families. Defined LR50 endpoints for the two standard NTA in PPDB showed that for 34% of 131 chemicals, sensitivity differed between 10-18000x. Other NTA species listed in PPDB for 46 pesticides showed endpoints with lower sensitivity than the two generic species for 17%. From the EPA-database, surface contact SSDs were derived for 18 pesticides (>5 species), for comparison to generic NTA species. From a topical LD50 review database, SSDs were derived for 32 pesticides (>5 species), for comparison to honeybee endpoints. Most data-rich pesticides, however, are no longer allowed for use in, e.g., Europe, but do allow for evaluating sensitivity ranking and comparison to different exposure routes.

2.01.P-Tu068 The Impacts of Nitrogen Dioxide Exposure on Insect Fitness

***Rachael Haw**[1], Karl L Evans[1], Stuart A Campbell[1] and Laurence Jones[2], (1)University of Sheffield, United Kingdom, (2)UK Centre for Ecology & Hydrology (UKCEH), United Kingdom*

Tropospheric pollutants generated by anthropogenic activities pose a significant threat to public and environmental health. Previous research has focused on their link to human disease; however, the ecological effects of air pollution remain poorly understood. Insects are a highly diverse group that play a critical role in ecosystem functioning, but are showing patterns of decline, particularly in industrialised countries. The links between pollutant exposure and insect fitness have not yet been thoroughly investigated. This work aims to characterise insect responses to air pollution, focusing on the direct effects on individual fitness. Using fumigation chambers, we will expose aphids, moths, and lacewings to ecologically relevant concentrations of nitrogen dioxide (NO_2), and observe growth, development, fecundity, and survivorship. We hypothesise that NO_2 will have a deleterious impact on the growth, development, and fecundity of moths and lacewings, with mortality rate increasing with pollutant concentration. We predict this will be driven by oxidative stress and cellular damage, and will perform glutathione-S-transferase (GST) assays to confirm the mechanism of toxicity. In contrast, we also hypothesise that aphids could benefit from higher concentrations of NO_2, based on previous research demonstrating population increases under poor air quality. This study will provide vital and novel understanding of the consequences of air pollution on biodiversity and ecosystems and grants scope to further investigate the cascading effects on trophic levels. We hope that by enhancing the existing knowledge base, this research will contribute valuable ecological insights to inform future air pollution policy making and legislation.

2.01.P-Tu069 Episyrphus balteathus Adult Acute Overspray Toxicity Protocol

*Mykola Rasko[1], **Artur Miguel Paiva Sarmento**[1], Steven Droge[2] and José Paulo Sousa[1], (1)University of Coimbra, Centre for Functional Ecology, Portugal, (2)Environmental Risk Assessment, Wageningen University & Research (WUR), Netherlands*

The use of plant protection products (PPPs) is crucial for modern agricultural practices, but when performed in an extensive manner, it can negatively impact important non-target arthropods (NTAs), essential for a functional and healthy ecosystem. Pollinators, foliage and ground dwelling predators, parasitoids and several other ecosystem service providers are exposed to pesticides applied in crops. The lack of studies on exposure of NTAs to PPPs via overspray contact makes it difficult to draw a clear picture of what might be the possible consequences of PPP use. Also, the data retrieved from standard ecotoxicological tests might not be very useful for the development of population models necessary to understand long-term effects. With this study we aim to elaborate a protocol that can be applied to different NTA species and help us to collect data to assess effects of PPPs derived from an overspray application and also to collect extra data that could feed TK/TD models. The developed protocol was tested with Episyrphus balteatus to assess its feasibility and its applicability to different NTAs. Pre-exposures practical aspects like the time needed for adults to hatch (to guarantee sufficient number to perform a valid ecotoxicological test), the number of individuals per replicate, the diet and type of feeders, the time that they need to be exposed to the CO2 to be anesthetized, and the overall time that is needed to complete all the procedures, were tested. After being anesthetized and before exposure, individuals were placed in an spraying cage (10 per cage) weighted and a photograph was taken to know precisely the amount of substance that will come into contact with each specimen. Using a Potter tower, organisms were sprayed allowing a more even distribution of the solution across the pretended area, namely on top of our test organisms, and the cages were weighted again and the individuals were transported to clean arenas. During the exposure period several cages were sampled over different time periods (instead on only one time) to collect data for TK/TD models. Survival was assessed and live organisms were used for residue analysis to assess internal body burdens, linking external exposure dose with internal concentrations. This test allowed us to optimize the protocol for further test species of NTAs from different functional groups.

2.01.P-Tu070 Evaluation of the exposure to triazole fungicides in arthropods

***Paula Bolívar**[1], Rafael Mateo[2] and Manuel Ortiz Santaliestra[3], (1)Castilla La Mancha University (UCLM), Spain, (2)Wildlife Toxicology, Instituto de Investigación en Recursos Cinegéticos (IREC) CSIC-UCLM-JCCM, Spain, (3)Instituto de Investigación en Recursos Cinegéticos (IREC) CSIC-UCLM-JCCM, Spain*

The use of pesticides in agriculture has emerged as a major cause of biodiversity loss in agroecosystems. Triazole fungicides are among the most widely used pesticide groups nowadays. The mechanism of action of these substances consists of impeding the formation of the fungal wall by inhibiting the synthesis of ergosterol, one of the wall's main components. In arthropods, the alteration of the sterol biosynthesis pathway by triazoles may be interfering with the production of ecdysteroids, a type of hormones involved in moulting and reproduction processes. This study evaluated the impact of triazoles on arthropods through two experimental exposures simulating field scenarios: (1) ingestion of treated cereal seeds and (2) ingestion of treated leaves. Two arthropod models, mealworms (*Tenebrio molitor*) and silkworms (*Bombyx mori*), were employed.

For exposure to treated seed, mealworms were exposed to ground barley seeds treated at 100, 50 and 25 % of the Raxil® Plus (tebuconazole and prothioconazole) application rate mixed with untreated barley seed. For exposure to foliar treatments, silkworms were exposed to treated mulberry leaves previously dipped for ten seconds in different concentrations of Folicur® (tebuconazole): 2.5, 1, 0.5, 0.1 ml/L. Food consumption, weight at each stage, development time and reproductive parameters were evaluated in both experiments.

On exposure to treated seeds, mealworms showed aversion to treated seeds, especially in the intermediate treatments, and experienced a decrease in weight. No significant differences in development time were observed and reproductive parameters could not be evaluated. As for foliar exposure, exposed silkworms showed lower leaf consumption, lower weight and delayed pupation compared to controls. In addition, an increased proportion of individuals failed to form cocoons in the higher concentration treatments. No significant differences in egg fertility were found.

These results indicate that experimental exposure to triazoles, at levels similar to field conditions, affects the growth of mealworm larvae and the development of silkworms. It is suggested that steroid-disruption effects related to the use of these pesticides could impact arthropod populations in agricultural environments, emphasizing the need to better understand the implications of triazoles on biodiversity and ecosystem functioning.

2.01.P-Tu071 A test design to assess the oral exposure of the herbivorous lepidopteran larvae Plutella xylostella to pesticides under controlled laboratory conditions – Pros and Cons and further challenges

***Daniela Jans**[1], Sabine Sixt[1], Susanne Oberdörster[1], Maria Teresa Almanza[1], Mark Miles[2] and Heike Fremdt[1], (1)Bayer AG - Crop Science Division, Germany, (2)Bayer AG*

In the EU, the risk assessment for non-target arthropods (NTAs) follows the framework developed by ecotoxicologist in the ESCORT workshops. In 2015 EFSA published a Scientific Opinion (SO) to address the request of the EU commission to review the existing framework. Different ways of exposure to pesticides are one of the aspects that were addressed in the SO asking for an additional test species. In particular, the oral exposure through ingestion of contaminated food was identified as a challenge since the current available endpoints from a tier 1 test design cannot be related to oral toxicity and cannot be used in a risk assessment for this exposure mode. Therefore, the working group of the PPR panel recommended to develop assessment methodologies for focal species such as herbivorous NTAs. Hence, there is the need to develop a reproduceable methodology to enable us to evaluate the oral toxicity of PPP to lepidopteran larvae, for example.

Additional to other initiatives followed by the CLE NTA working group, we started working with one common lepidopteran species to gain first experiences which will guide the further development of methodologies. The project's purpose is to develop a test method to be used under Good Laboratory Practice (GLP) in the laboratory. Criteria for the selection of test species were defined and *Plutella xylostella* (Plutellidae, Lepidoptera) was identified as a suitable test organism. Different exposure matrices and diets were tested during first trials. Key factors related to validity criteria like control mortality, Larval feeding behavior, larval development time, adult hatching rate and egg production in the control were evaluated.

The advantages and disadvantages of *P. xylostella* as an organism for which laboratory-based breeding techniques are well established, also for efficacy trials, will be highlighted.

We will provide first recommendations for the development of a testing protocol and present results to illustrate the technical feasibility and expected challenges in developing assessment methodologies for oral exposure using an herbivorous arthropod like *P. xylostella.*

2.01.P-Tu072 Urban gardens as important small-scale habitats for insect species - in vitro and in vivo methods indicate chemical pollution

***Johanna Bock** and Jörg Oehlmann, Aquatic Ecotoxicology, Goethe University Frankfurt, Germany*

Insects are experiencing a drastic biodiversity and biomass decline, while providing important ecosystem functions. Therefore, it is of great concern to further uncover causes for species loss, with the goal of identifying mechanisms to dampen species loss. The interdisciplinary project “SLInBio” (https://www.insektenvielfalt-frankfurt.org/) is investigating how the perception and valorization of insects can be increased in Frankfurt am Main and what contribution cities can make to the conservation of insect diversity. Garden owners supposedly hold the potential to influence small-scale habitat quality: in urban areas, private gardens display a relevant amount of the total green area distributed among the city, hence gardens pose important habitats for organisms. But individual practices and preferences in aesthetics and the use of pesticides and fertilizers, chemical run-off from building materials, water management or animal keeping can strongly influence the habitat quality and thus insect biodiversity. As an ecotoxicological approach to this subject, sediment and water samples were collected from ponds from 12 gardens, distributed among the city of Frankfurt am Main. The samples were tested in vivo with the non-biting midge *Chironomus riparius* in a sediment-water system. Emergence success varied strongly between the samples and was compared to in vitro assays performed on water and sediment extracts. A significant correlation was found between Microtox data from water samples and emergence success of midges: water samples with higher toxicity showed lower emergence success in their corresponding sediment-water system and vice versa. Other parameters like pH, temperature, ammonium, organic fraction or particle sizes could not explain the different emergence rates in the samples. Furthermore, a non-target was performed on the water samples to identify chemicals that could possibly explain this observation. The results show that toxic substances can affect populations of merolimnic insect species, even in small water bodies maintained by gardeners.

This study aims to help improve habitat quality of small-scale habitats for insect species by hopefully uncovering feasible changes gardeners can make on their private property to support local insect diversity.

SLInBio is funded by the Federal Ministry of Education and Research (BMBF) in the funding measure “BiodiWert" as part of the research initiative for the preservation of biodiversity (FEdA).

2.01.P-Tu073 Ants as Model Organism to Evaluate the Ecological Risk of active plant protection substances? Lethal and Sublethal Effects of the Systemic Neonicotinoid Imidacloprid in Three Ant Species

***Marius Pohl**[1], Udo Hommen[2], Sebastian Eilebrecht[3], Christoph Schaefers[4], Benedikt Ringbeck[5], Bernd Göckener[2], Jürgen Gadau[1] and Mathias Otto[6], (1)University of Münster, Germany, (2)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (3)Ecotoxicogenomics, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (4)Ecotoxicology, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (5)Trace Analysis and Environmental Monitoring, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (6)Federal Agency for Nature Conservation, Germany*

To minimize potential risks to non-target organisms, including ecologically beneficial ants, pesticides have to undergo toxicity risk assessments. However, ants (Hymenoptera: Formicidae) are not included in any type of risk assessment for non-target organisms. Ants are important components of most terrestrial ecosystems and provide crucial ecological services such as pollination, soil improvement and nutrition cycling. They have developed many specialized traits to thrive in various ecological niches and have evolved complex feeding ecologies, e.g. fungus cultivation, seed harvesting, omnivory, or pure predation. These distinct feeding ecologies expose ants to different types of pesticides, especially in agricultural areas where pesticides are applied to manage pest organisms that can compromise crop yield.

In this study, we developed a testing strategy with different levels of complexity and present a method to evaluate the impact of pesticides on three ant species. We used the systemic neonicotinoid imidacloprid to assess both lethal and sublethal effects on three ant species which can be maintained in the laboratory. To do so we orally exposed subsets of 50 minor worker ants to seven different Imidacloprid concentrations dissolved in 10%-honey water. The results revealed that Imidacloprid has an LC_{50} of 8.42 mg/L (4.72 -16.18 mg/L 95% confidence interval) for the model species *Camponotus maculatus* over a 10-day period. Similar LC_{50} concentrations were observed for *Lasius niger* (11.03 mg/L (6.30 – 21.93 mg/L 95% confidence interval)) and *Crematogaster sp.* (3.97 mg/L (3.27 – 4.84 mg/L 95% confidence interval)). Furthermore, analysed internal Imidacloprid concentrations in deceased and survived individuals using UPLC-MS/MS after QuEChERs extraction and calculated LD_{50} values to approximate the lethal body burden and the tolerance range of surviving specimens.

In an identical follow up experiment (extended exposure period of 21 days), we also included larvae (20 per 50 worker subset). While there was lethal effect of imidacloprid on larvae at concentrations which did not affect the workers, we found a disruption of the metamorphosis process during early pupation. In particular, 38% of the surviving larvae failed to create a functional pupal cocoon. Considering our results and the proven feasibility of using ants as study organisms, we see a good potential for including ants in future risk assessment studies.

2.01.P-Tu074 Unveiling the Ecotoxicological Impacts of Realistic and Worst-Case Scenarios of Plant Protection Product Mixtures on the survival of Chironomus riparius

***Ana-Belen Muniz-Gonzalez*[1]**, *Isabel Campos[2], Ana Ré[3], Joana Luisa Pereira[4], Fernando J. M. Gonçalves[2] and Nelson Abrantes[5], (1)Physics, Mathematics and Fluids, UNED, Spain, (2)University of Aveiro, Portugal, (3)Department of Environment and Planning, Department of Environment and Planning & Centre for Environmental and Marine Studies (CESAM), University of Aveiro, Portugal, (4)Department of Biology, University of Aveiro, Portugal, (5)Department of Biology, University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Portugal*

Plant protection products (PPPs) are intensively employed in agriculture to ensure crop yields, with 466 pesticide-active ingredients approved within the European Union (EU). This excessive overuse leads to a substantial part ending up in water systems, compromising their quality. Despite the well-documented adverse effects of PPPs, a predominant focus on individual compounds overlooks the real-world application scenarios, where PPPs are applied as mixtures resulting in the input of approximately 300 billion kilograms of PPPs mixtures into waters. This stands out the need for a comprehensive understanding of the collective impact of PPP mixtures on the environment. This study, conducted within the framework of the H2020 SPRINT project, aimed to assess the impact of realistic and predicted PPP mixtures, on the survival of the aquatic insect *Chironomus riparius*. For this purpose, 11 case study sites (CSSs) were selected, within each, the concentration of PPPs was measured in aquatic systems near agricultural fields. A mixture of 5 PPPs was delineated for each CSS, according to their frequency of occurrence and the risk quotient (RQ). Following the OECD test guideline 235, larvae of *C. riparius* were exposed to each condition: measured environmental concentration (MEC), predicted environmental concentration (PEC) 3*PEC and 5*PEC, for each mixture. Of the total of 11 mixtures, only one (CSS2) provoked significant differences in mortality for all conditions and for PEC, 3PEC and 5PEC in the case of CSS1 and CSS6. Moreover, significant differences were detected after 3PEC and 5PEC for CSS3, CSS4, CSS7, CSS9, and CSS11. By contrast, lower toxicity, only by 5PEC, was observed for the CSS8 and CSS10. The environmentally relevant conditions MEC and PEC, altered mortality on CSS1 and CSS6, spite of having concentrations lower to the LC50 values for each PPP, reinforce the heightened risk of PPP mixtures in aquatic systems. Furthermore, in the worst-case scenario (5PEC), a 100% mortality rate was observed across all CSSs. These findings emphasize the urgency of identifying the co-occurrence of distinct PPPs in real scenarios and studying their effects on non-target aquatic organisms. Additionally, it is imperative to incorporate more realistic approaches, considering PPP mixture with diverse modes of action, given the diverse effects associated with the specific mixture employed. **Funding**: EU Horizon 2020 (grant 862568); UNED (REGAGE21e00018296847: A.B.M.G).

2.02.A Aquatic and Terrestrial Plant Ecology, Ecotoxicology and Risk Assessment

2.02.A.T-01 Chronic multigenerational radionuclide exposure in Lemna minor: from epigenetics to population

***Luca Boldrini*[1]**, *Nele Horemans[2], May van Hees[1], Gustavo Turqueto Duarte[1], Robin Nauts[2], Jean Wannijn[3], Yelltrich Reymen[1], Brix De Rouck[1], Hilde Loots[1], Morten Foldager Pedersen[4] and Henriette Selck[4], (1)SCK CEN, Belgium, (2)Belgian Nuclear Research Centre (SCK CEN), Belgium, (3)SCK CEN, (4)Roskilde University (RUC), Denmark*

It is the purpose of this project to study the long-term effects (over multiple generations) at different levels of biological complexity (from molecular to population level) in a duckweed species (*Lemna minor*) exposed to environmentally relevant concentrations of different genotoxic radionuclides linked to possible nuclear accidental scenarios (137Cs, 90Sr). The organism Lemna minor was chosen for this project as it is a fast vegetative-growing macrophyte, the only freshwater plant for regulatory toxicity testing for chemicals, and a model organism within ecotoxicology.

The Chernobyl nuclear accident in 1986 has given rise to a region characterized by the presence of multiple radionuclides, with 90Sr and 137Cs still persisting nowadays in the Chernobyl Exclusion Zone (CEZ). Therefore, we investigated the long-term effects of these genotoxic radionuclides on the molecular physiology of the aquatic plant Lemna minor.

In our study, we employed a 6-week multigenerational setup and worked with both high activity concentrations (kBq/l) and ecologically relevant ones (Bq/l). Data from qPCR analysis of chromatin remodeling (SRT1), methyltransferases (DRM3, MET1, ROS1), glutathione biosynthesis (GR, GSH1, GSH2.1, GSH2.2), and telomere length regulation (TERT) genes show time-specific gene expression trends differing upon exposure to different radionuclides.

Results indicate that morphological trait analysis (frond area analysis), photosynthetic activity (DUAL pam measurements), pigment and glutathione level measurements, and enzyme activity (GPOD) analyses support the hypothesis of a putative hormetic ionizing radiation response specific to either 90Sr or 137Cs contamination. Lemna minor may differentiate its abiotic stress responses towards either 90Sr or 137Cs by funneling energy respectively into epigenetic regulation or redox balance maintenance.

In conclusion, by employing molecular biology (gene expression analysis) and non-conventional ecotoxicological endpoint testing, this project contributes to expanding current scientific knowledge on Lemna minor's radiation stress biology with the final aim of environmental risk assessment amelioration.

2.02.A.T-02 Amendments Improve Performance of Perennial Native Plants for Revegetation of Acidic Mine Tailings Over Time

*Michael Bollman[1], **David Mark Olszyk**[1], Maliha Nash[1], Marjorie Storm[2], Viola Manning[3], Kristin Trippe[3], Jeffrey Novak[3], Donald Watts[3] and Mark G. Johnson[4], (1)U.S. Environmental Protection Agency (US EPA), (2)CSS Inc., (3)U.S. Department of Agriculture, (4)Center for Public Health and Environmental Assessment, U.S. Environmental Protection Agency (US EPA)*

In the US there are over 20,000 abandoned hardrock mines that may present risks to human health or the environment from long-term exposure to harmful substances. One site is the Formosa mine Superfund site located in Oregon, US. The site lacks plant cover due to phytotoxic tailings with high acidity, possible metal toxicity, insufficient nutrients, and poor soil structure which make it difficult to establish vegetation. We evaluated the effects of amending the tailings on tailing chemistry, and survival and growth of local native herbaceous species: *Anaphalis maragitacea* (ANMA), *Carex inops* (CAIN), *Chamerion Angustifolium* (CHAN), *Elymus glaucus* (ELGL), and *Potentilla gracili* (POGR). The treatments were (1) withholding any amendments, (2) amending with lime, biosolids, and biochar, (3) amending with lime, biosolids, and K fertilizer, and (1), (2) or (3) plus inoculation with locally-sourced microbes (LSM). Amendments increased pH and reduced available heavy metals in the tailings, and improved plant survival and growth. The grass, ELGL, had greater survival and growth than the other species with the amendments. Plant biomass during the fifth year of growth was greater for ELGL with the amendments with the biochar treatment than the amendments with the K treatment. In contrast, the other species had greater biomass with the amendments with the K treatment. There were no LSM effects to date, though evaluation is continuing. Thus, soil amendments can improve soil chemistry and enhance native herbaceous survival and growth on mine tailings.

2.02.A.T-03 Measuring the effect of time variable concentrations on green microalgae: a laboratory comparison study

***Cecilie Rendal**[1], Johannes Witt[2], Thomas G Preuss[2], Ian Sims[1], Roger Baetscher[3], Sibylle Eck[2], Emily Scorgie[4], Roman Ashauer[3] and Eric Bruns[5], (1)Syngenta, United Kingdom, (2)Bayer AG - Crop Science Division, Germany, (3)Syngenta Crop Protection, Switzerland, (4)Global Science Delivery, Syngenta Seeds B.V., Netherlands, (5)Environmental Safety, Bayer AG - Crop Science Division, Germany*

Due to their ubiquitous presence in the environment, green micro-algae play a central role in the risk assessment of Plant Protection Products (PPP). OECD guideline 201 provides a clear protocol for how the response of these organisms to constant exposure scenarios can be routinely tested in a laboratory setting. However, due to the rapid growth patterns that quickly deplete the nutrients in the test medium, it has proven far more challenging to test longer time variable exposure patterns. We present the preliminary results of a laboratory comparison test that evaluates the robustness and reproducibility of two distinct methodologies for generating data for time-variable exposures tested on green microalgae. One method is a semi-static approach that relies on a series of filtration and resuspension steps allowing the testing of time-variable exposures in a test regime that approximates the OECD 201 guideline. The other method is a flowthrough chemostat system that, once steady state has been reached, can be used to test long and complex exposure patterns. Both methodologies can be used to address important risk assessment questions, and can also serve to validate TKTD models, thus expanding the possibilities of refined risk assessment.

2.02.A.T-04 Reproducibility, Reliability and Regulatory Relevance of Terrestrial Plant Visual Injury (PVI) assessments

*Sebastian Fellmann[1], Joshua R. Arnie[2], Patricia Lopez-Mancisidor[3], Gunther Ulric du Hoffmann[2], Gwendolin Kraetzig[4], Ashlee Kirkwood[5], Andreas Duffner[6], Markus Simon[7], Jette Bramby-Gunary[8] and **Rena Jutta Irene Isemer, PhD**[9], (1)Bayer AG - Crop Science Division, Germany, (2)Eurofins Agroscience Services, (3)Corteva Agriscience, (4)ADAMA Deutschland GmbH, Germany, (5)Ecotoxicology, Smithers, (6)Eurofins Scientific, Germany, (7)Ecotoxicology, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (8)AgroChemex, Germany, (9)Crop Science, Bayer AG, Research Triangle Park, United States*

The authorization of plant protection products (PPP) in the EU requires an assessment of potential impacts on non-target terrestrial plants (NTTP) taking into account quantitatively assessed parameters like biomass, survival or emergence. Recently, considering an ER_{50} derived from visually assessed plant injuries (PVI) in the risk assessment has been requested in addition. The PVI Working Group (WG) within the SETAC Plants Interest Group is aiming to support the determination of regulatory endpoints for PVI, and foster harmonization in PVI assessments, ultimately strengthening the environmental impact assessments for PPPs and the protection of NTTP. In a first step, current challenges were determined (e.g., by conducting surveys in laboratories that are assessing PVI regularly). The utilization of a non-harmonized scoring system for the quantification of PVI (e.g., chlorosis, necrosis, wilting etc.) relies on subjective human observations, making results less reliable and objective. In addition, the survey results revealed that there is a lack of guidance concerning how PVI assessments are to be conducted with regards to both scoring methods as well as statistical evaluation, yet both are needed to reliably determine an objective ER50 for PVI. Various PVI scoring methods (e.g., 0-4; 0-5; 0-10 rating groups) exist that encompass both percentage ranges or categorical descriptions, leading to varying interpretations. The method of converting scores into percentage values affects the 50% effect level definition, as does the statistical model (e.g., regression model or Cochran-Armitage test) for ER_{50} determination. Due to the subjectivity of the assessment, the variation in the scores assigned to an individual plant by different assessors can be substantially. Given the diversity of PVI assessment methods, it is often challenging to objectively determine whether the PVI ER_{50} is lower than other endpoints and accordingly should be used to conduct the risk assessment. To address these challenges, the WG is actively pursuing a standardization of PVI data interpretation, acknowledging the various assessment methods. This endeavor includes evaluating data from different methods and comparing outcomes through different statistical tests. In the future, the WG aims to develop new assessment methodologies, standardized PVI scoring systems, and appropriate statistical analyses including ring testing to evaluate the viability of a new approach.

2.02.A.T-05 Simulating ecosystem services of natural plant communities of importance for indirect effects on Endangered Species: the IBC-Grass model as a case study

*Ismael M Rodea-Palomares[1] and **Zhenglei Gao**[2], (1)Bayer AG - Crop Science Division, (2)Data Science, Bayer AG, Germany*

In the USA, Endangered Species Assessments (ESA) are of critical importance to ensure pesticides are used in such a way that ensures protection of non-listed and endangered species. Besides direct effects of pesticides on endangered species, effects on biotic elements on which endangered species rely on for e.g., food and shelter are critically important for a successful ESA. Among those biotic elements, the plant community that provides both food and shelter to the rest of the ecosystem is probably the most evident biotic element that, if affected by pesticide use, can result in detrimental indirect effects on endangered animals (such as terrestrial arthropods, mammals, birds, etc.)[1]. In this work we explore a framework for model plant communities in field margins and some of their ecosystem services through mechanistic plant community modelling. For this, we use an Agent-Based plant community model (the IBC-Grass model)[2] that simulates a grassland plant community though the definition of plant functional types. As the modelling is based on plant functional types rather than specific plant species, it can be considered to represent plant attributes that are generic to any plant species if the species belong to a similar functional type (e.g., small rosette vs tall plants, etc.). The model can represent various plant functional types and their interaction through competition for resources above and below ground, and the effect of agronomic practices (such as annual plowing, mowing, etc.) in the plant interactions. A module to represent effects of pesticides based on standard plant toxicity studies is also incorporated in the model. In the presentation we will explore a framework to use this model in the context of indirect effects on endangered species. We will explore how endpoints for effects on some of the ecosystem services linked to indirect effects on endangered species (such as shelter and food provision) could be derived and used in the context of ESA assessment of pesticides.

2.02.B Aquatic and Terrestrial Plant Ecology, Ecotoxicology and Risk Assessment

2.02.B.T-01 Ecotoxicological Test Protocol for the Assessment of Reproductive Endpoints in Non-Target Terrestrial Plants under Greenhouse Conditions

***Andreas Duffner**[1], David Mark Olszyk[2], Bianca Flickinger[3], Fernando Huerta[4], Holger Teresiak[5], Gwendolin Kraetzig[6], Joanna Davies[7], Lucia Privitera[8] and Christine Mihan[9], (1)Eurofins Scientific, Germany, (2)U.S. Environmental Protection Agency (US EPA), (3)BASF SE, Germany, (4)EUROFINS TRIALCAMP, SLU, Spain, (5)Agro-Check, Germany, (6)ADAMA Deutschland GmbH, Germany, (7)Syngenta, United Kingdom, (8)Greenhouse Team, AgroChemex Environmental, United Kingdom, (9)Bayer AG - Crop Science Division, Germany*

Ecotoxicological testing to assess the effects of plant protection products on non-target terrestrial plants (NTTPs) under greenhouse conditions is conducted according to standard guidelines (e.g. OECD 208 and OECD 227). EFSA’s Scientific Opinion of 2014 on the risk assessment of plant protection products (PPP) for non-target terrestrial plants raised awareness of a potential need to assess effects on plant reproduction. Literature reviews and experimental studies evaluated the feasibility and relevance of plant reproductive endpoints. In summary, it can be concluded that (a) assessment of reproductive endpoints in selected plant species is in principle feasible, (b) there is no clear trend that reproductive endpoints are more sensitive than vegetative ones, and (c) cases may occur where reproductive endpoints appear to be more sensitive depending on, e.g., mode of action of a plant protection product and/or test species. For cases where effects on reproductive endpoints need to be assessed for regulatory purposes, a standard test protocol is required. A working group within the SETAC Plant Interest Group collected and analyzed relevant and available data and experiences to provide an ecotoxicological test protocol for the assessment of reproductive endpoints in Non-Target Terrestrial Plants under greenhouse conditions. This presentation will provide an overview of the protocol and will highlight the challenges and special considerations such as test duration, plant species and endpoint selection as well as statistical evaluation.

2.02.B.T-02 Microalgal Responses to Organic Contaminants and Influence on Contaminants Fate in Aquatic Ecosystems

Giulia Cheloni[1], *Christine Felix*[2], *Emilie Le Floc'h*[3], *David Rosain*[4], *Frederique Courant*[4], *Elena Gomez*[5], *Christophe Leboulanger*[3] *and Éric Fouilland*[3], *(1)MARBEC, Univ. Montpellier, CNRS, Ifremer, IRD, INRAE, France, (2)Universite de Montpellier, (3)UMR MARBEC, Univ. Montpellier, CNRS, IFREMER, IRD, France, (4)HydroSciences Montpellier, IRD, CNRS, University of Montpellier, France, (5)HydroSciences Montpellier, University of Montpellier, CNRS, IRD, France*
Effects of organic contaminants (OCs) on microalgal physiology were extensively studied in the last years. However, a knowledge gap exists regarding the role of microalgae on OCs fate. Such information is required to better assess contaminants persistence and their trophic transfer, to identify biomarkers of contaminants exposure and to improve microalgae-based water remediation strategies. Genome sequencing of model microalgal species revealed the presence of genes encoding for enzymes (e.g. Cytochrome p450) involved in OC biotransformation in other organisms such as bacteria, higher plants, animals. However, knowledge about biotransformation pathways in microalgae lag far behind that of other microorganisms.

In our study the marine diatom *Phaeodactylum tricornutum* was exposed to three OCs, two pharmaceuticals (Diclofenac, Ethynilestradiol) and the herbicide Diuron. OC effects on cellular traits and physiology were studied together with OC removal from the exposure medium (HPLC-UV) and OCs biotransformation (HPLC-MS).

The lowest observed effect concentration (LOEC) varied considerably between pharmaceuticals (0.3-1 mg/L) and the pesticide (3 ug/L) and different modes of toxic action were described for the three contaminants. Diuron inhibited cell growth and photosynthetic activity, Diclofenac effected membrane integrity but not through generation of oxidative stress. Finally, Ethynilestradiol induced oxidative stress and altered cell morphology with lipid droplets formation.*P. tricornutum* cultures were shown to be able to influence pharmaceuticals fate. Significant removal from the exposure medium was observed for Ethyniestradiol (up to 60% for the tested concentrations after 72h exposure) while transformation products were identified for Diclofenac.

Our results confirm that phytoplankton can influence the fate of contaminants in the water column. However, this process depends on the OC and its modes of toxic action. Ongoing analyses on transcriptomic (RNA-seq) data will shed light on the activated pathways possibly involved to respond to OCs exposure through biotransformation and compartmentalization processes.

2.02.B.T-03 Functionalisation and size dependence effect of upconverting lanthanide doped nanoparticles, NaYF4:Yb,Er@NaYF4 on wheat seedlings' growth, germination, cell death and membrane permeability
Anna Ekner-Grzyb, *Department of Cell Biology, Adam Mickiewicz University, Poznan, Poland*
In recent years, nanotechnology has become widely utilized. Nanoparticles (NPs) are applied in various fields, including medical applications, plant fertilizers and cosmetics. One of the rapidly developing materials are inorganic nanocrystals doped with lanthanide ions, which possess distinctive spectroscopic properties, including luminescence capability, resistance to photobleaching and degradation, extended luminescence lifetimes and narrow absorption and emission bands. Moreover, the NPs exhibit efficient anti-Stokes emission (known as up-conversion), converting NIR or IR radiation into visible emission. These properties minimise autofluorescence from biological tissues, and cells and enhance signal detection sensitivity, which is one of the primary challenges in bioimaging. Additionally, eliminates harmful UV radiation exposure to biological materials.

However, these NPs may enter the environment and influence biota. Consequently, there is a need to investigate their influence on living organisms. Therefore, our study focuses on analysing the toxic effects of two core@shell lanthanide-doped upconverting nanoparticles ($NaYF_4$:Yb^{3+},Er^{3+}@$NaYF_4$), with different surface modifications (poly(ethylene glycol)-neridronate, PEG-Ner and poly(acrylic acid), PAA) and sizes (26 nm and 52 nm). We examined the impact of the NPs on germination percentage, germination rate, growth and cell membrane damages and cell death of wheat seedlings (*Triticum aestivum* L.), the species being one of the most extensively cultivated crops.

In summary, the study demonstrated that non-modified NPs, regardless of size, the most effected the wheat seedlings. PAA-modified NPs exhibited toxicity, particularly at smaller sizes, while PEG-Ner-modified UCNPs had no toxic impact. Consequently, PEG-Ner was identified as the safest surface compound among the investigated UCNPs, potentially mitigating the adverse effects of nanoparticles on plants. Moreover, whole plants were imaged using an up-conversion laser scanner, successfully detecting all tested NPs inside.

2.02.B.T-04 Ecotoxicological Effects of Copper and Pendimethalin at Three Different Temperatures on Raphidocelis subcapitata- the Impacts of Climate Changes
Micael Mendes Neves[1], *Fernando J. M. Gonçalves*[1] *and Ana M. M. Gonçalves*[2], *(1)University of Aveiro, Portugal, (2)Department of Life Sciences, University of Coimbra, MARE - Marine and Environmental Sciences Centre / ARNET – Aquatic Research Network, Portugal*
In the last decades, climatic changes have been a great concern among the scientific and political communities. Nowadays, climatic changes effects have been reported associated to extreme climatic events like the raise of temperature, floods and droughts with impacts in several activities (e.g. agriculture) and in the ecosystems. The exponential increase in world population and growth in food consumption are placing unprecedented demands on agriculture and natural resources. Hence,

more research is needed, not only for a more diverse array of pesticides, but also for comercial formulations, applied in the field.

Fitoplanktons (ex: *Raphidocelis subcapitata*) are a key biological group that produce essential nutrients vital for the survival of higher trophic levels, being the main source of food. Copper belongs to the group of transitional essential metals, of vital importance for every organism at low concentrations, becoming toxic at high amounts, being considered the third most toxic metal after cadmium and mercury. Pendimethalin is a worldwide used herbicide part of the dinitroaniline family. It is used to control annual grass and broadleaf weed in various crops and in residential lawns.

Hence, this work aims to determine the combined effect on the growth of Raphidocelis subcapitata of a range of temperatures (15°C, 20°C and 25°C) on the toxicity of two pesticides.

Both compound were tested using OECD 201 growth inihbition test, with some modifications. Total number of cell in each replica was obtained through spectrophotometric absorbance at 440 nm. As expect in the three tested temperatures pendimethalin proved to be more toxic than copper to *Raphidocelis subcapitata.* In the case of copper Kruskal-Wallis's test was used to determine the significance of each parameter. In the case of pendimethalin a Two-way ANOVA followed by Tukey´s test was used to determine the significance of each parameter. In both cases statistical tests pointing to both temperature and concentration and indicating the combination of temperature and concentration are significant.

These studies are of the highest importance in our actual context, since they allow us to predict the potential toxic effects of these two compounds in freshwater primary producers. Further research should focus the mixture of these two compounds since this can provide a more realistic approach of the interactions that occur in the environment.

2.02.B.T-05 Developing a Reference Tier with Quantitative Aquatic Macrophyte Field Data

Gertie Arts Mrs., PhD[1], *Dick Belgers*[1] *and Stephan Hennekens*[2], *(1)Environmental Risk Assessment, Wageningen University & Research (WUR), Netherlands, (2)Wageningen Environmental Research (WUR), Netherlands*

It has been identified that there is a strong need to establish ecological baseline responses as a means to create workable tools for the risk assessment of aquatic macrophytes. This project aimed at collating quantitative field data to characterize the baseline biotic and abiotic parameters in the edge-of-field water bodies. The project collected information from freshwater edge-of-field aquatic ecosystems to identify which macrophyte species grow in edge-of-field water bodies (ponds, streams and ditches) and which species can be considered as characteristic species; which abiotic conditions prevail in edge-of-field ponds, streams and ditches and which can be considered as key conditions and are also relevant for macrophyte models; and which functional traits do these characteristic macrophytes species represent. We followed a stepwise methodology to meet the project aims. First we explored available databases at the European level, openly published datasets and datasets available in The Netherlands and surrounding countries of the central zone to select a group of 30 macrophyte species characteristic for edge-of-field ponds, streams and ditches. Secondly we explored databases and published literature to extract the key conditions under which these macrophytes grow under field conditions, how wide they are distributed over Europe, how often they are used in Species Sensitivity Distributions and microcosm and mesocosm studies and which growth forms and functional traits they represent. The data show that most of the macrophyte species characteristic for ponds, streams and ditches have a wide distribution in Europe. The characteristic species show a large overlap with those tested in potted plant studies in mesocosms. The selected aquatic macrophytes grow in circum-neutral surface water (average pH 7.4). The water is buffered (average alkalinity 2.6), medium to high in nutrient content and medium in salinity and chlorinity. This project results in a database with 30 aquatic macrophytes, their scientific and common names, growth forms, some functional traits, presence in the three selected categories of water types as well as genus, family, order, use in SSDs or micro- and mesocosm studies, and surface water, pore water and sediment quality at the stands of these aquatic macrophytes. The collated database can serve to support a reference tier for aquatic macrophyte risk assessment and to support macrophyte models.

2.02.P Aquatic and Terrestrial Plant Ecology, Ecotoxicology and Risk Assessment

2.02.P-Th083 Uptake and Toxicity of Per- and Polyfluoroalkyl Substances (PFAS) at Environmentally Relevant Water Concentrations by Azolla filiculoides

Gina M Lintern[1], *Alan Scarlett*[2], ***Marthe Monique Gagnon***[1], *Damian Lettoof*[3] *and Kliti Grice*[2], *(1)School of Molecular and Life Sciences, Curtin University, Australia, (2)Curtin University, Australia, (3)CSIRO, Australia*

Environmental contamination of aquatic systems by per- and poly-fluoroalkyl substances (PFAS) have generated significant health concerns. Remediation of contaminated sites such as fire-fighting emergency training grounds that used Aqueous Film Forming Foams are of a high priority and phytoremediation may help play a part in removing PFAS from associated contaminated waters. In this study we investigate the potential of the water fern, *Azolla filiculoides,* to uptake seven common PFAS during a 12-day exposure to environmentally relevant concentrations delivered as equimolar mixtures: low ($\sum$PFAS = 0.0123 ± 1.89 µmol L^{-1}), medium ($\sum$PFAS= 0.123 ± 2.88 µmol L^{-1}) and high ($\sum$PFAS= 1.39 µmol L^{-1}) treatments, equivalent to ~5, 50 and 500 µg L^{-1} total PFAS respectively. Possible phytotoxic effects of PFAS were measured at 3-day intervals using chlorophyll *a* content, photosystem II efficiency (F_v/F_m), performance index and growth rate. PFAS concentrations in plant tissue and water were measured every three days using ultra-high performance liquid chromatography - tandem mass spectrometry. PFAS exposures did not lead to any detectable phytotoxic effects that may negate the use of *A. filiculoides* in phytoremediation. All seven PFAS were detected in plant tissue with most uptake occurring during the first six days of exposure. At three days post treatment, a maximum bioconcentration factor was recorded for PFHxS of 9.9 and minimum of 2.8 for PFBA. Consequently, the application of *Azolla* spp for phytoremediation of PFAS from aquatic environments is limited but does show potential as part of an integrated water treatment system.

2.02.P-Th084 Ecotoxicological Assessment of Four Veterinary Antibiotics (Enrofloxacin, Doxycycline, Tylosin, and Lincomycin) on Terrestrial and Aquatic Indicators

Felix Calvo Sr[1], Guillermo Lorca[1], Natalia Ferrando Lázaro[1], Elisa Langa[2], ***María Rosa Pino Otín[1]*** *and Diego Ballestero[1], (1)Universidad San Jorge, Spain, (2)San Jorge University, Spain*

Antibiotics play a crucial role in treating bacterial infections in both humans and animals. However, their extensive usage has led to their presence and accumulation in the environment, raising concerns about potential adverse effects on aquatic and terrestrial organisms. This study aims to assess the ecotoxicological impact of four prominent antibiotics—enrofloxacin, lincomycin, doxycycline, and tylosin—chosen for evaluation due to their status as among the top ten most consumed antibiotics in Europe. Understanding their environmental impact is particularly vital given their significant role in the livestock industry.

Three organisms were selected as indicators for this study: *Daphnia magna*, *Eisenia foetida*, and *Allium cepa*. These organisms are widely employed in assessing antibiotic ecotoxicology. *D. magna*, a freshwater crustacean, is known for its sensitivity to various environmental contaminants. *E. foetida*, a soil-dwelling worm, is commonly used to evaluate chemical toxicity in soil organisms. *A. cepa*, a plant species, is sensitive to diverse environmental stressors.

In terms of toxicity to *D. magna*, the antibiotics ranked from most to least toxic are enrofloxacin (272.93 ppm), doxycycline (287.44 ppm), tylosin (523.20 ppm), and lincomycin (2564.12 ppm). For *A. cepa*, doxycycline (18.61 ppm) exhibited the highest toxicity, followed by tylosin (21.06 ppm), lincomycin (45.56 ppm), and enrofloxacin (78.88 ppm). All compounds showed an EC_{50} exceeding 1000 ppm in the *E.foetida* test.

Furthermore, the toxicity of the four antibiotics studied closely aligns with that of other antibiotics detected in the environment, such as chlortetracycline, oxytetracycline, and florfenicol. Previous research has shown similar toxicity levels against *D. magna* (200-300 µg/ml), *A. cepa* (94 µg/ml), and *E. foetida* with EC_{50} values exceeding 1000 µg/ml.

These findings suggest that acute toxicity effects of these four antibiotics are unlikely to manifest in these indicator organisms, as the concentrations required to induce toxicity are considerably higher than those observed in the environment (ng/l to µg/l.). Additional ecotoxicity tests spanning multiple trophic levels, including community-level assessments and extended-duration studies, are imperative to comprehensively evaluate potential chronic effects.

2.02.P-Th085 Seasonal Dynamics of Phytoplankton Biodiversity, Abundance and Biomass in the Freshwater Lentic Mesocom System Located in Southern Poland

Anna Maria Arendarczyk*, Zuzanna Kacperek - Karetta, Agnieszka Godziek-Botor, Aneta Gierbuszewska, Paweł Pieczka, Mirosław Śmietana, Anna Wróbel and Małgorzata Górska, Łukasiewicz Research Network-Institute of Industrial Organic Chemistry Branch Pszczyna, Poland*

Static mesocosm systems are used to assess the risk posed by introduction of chemicals into water and soil matrix. The mesocosm system is carried out under field conditions and mimics natural ecosystems, which allows for a comprehensive assessment of the effects of a chemical on selected, closely related aquatic ecosystem parameters. The analysis of phytoplankton populations in mesocosm studies can be crucial when assessing the effects of herbicides.

Due to the field nature of the study, the aim of the presented project was to analyse the seasonal variability of phytoplankton population during one production season in relation to selected physico-chemical parameters. The test was performed in stainless steel tanks, settled in the ground (about 2400 L each tank), situated in Southern Poland. The tanks were supplied with an appropriate amount of sediment and water and inoculated by adding sediment and water from natural reservoirs. Sampling was carried out from April 2022 to September 2022. The project included qualitative and quantitative (biomass) phytoplankton analysis, physico–chemical analysis of water i.e.: temperature, pH, oxygen concentration, conductivity, nitrites (NO_2^-), nitrates (NO_3^-), phosphate (PO_4), ammonium (NH_4^+) and Total Organic Carbon (TOC).

During observations, the number of taxa verified to at least genus level ranged from 53 to 96 depending on the tank. The total abundance of taxa indicated an increase in Euglenozoa and Cynaprocaryota genera from June onwards and the occurance of Cryptophyta only in April, May and September. In addition, there was a peak in the taxa number of Chlorophyta and Bacyllariophyta in the first half of June. Myzozoa were present throughout entire vegetation period but the taxa were mainly limited to *Certium hirundinella*.

Shifted biomass levels, observed during temperature increases, were recorded from the end of July and emerged in relation to the mixed-type blooming by Cyanoprocaryota (*Dolichospermum crassum*) and Myzozoa (*C. hirundinella*). The increase in *D.*

crassum biomass was associated with the increase in turbidity and a decrease in the number of Chlorophyta taxa. Moreover, blooming elevated oxygen, TOC and phosphate concentrations.

These findings improve the interpretation of the risk experiments results, and furthermore they could implicate mesocosm designing processes.

2.02.P-Th086 Further Evaluation of Macrophytes for Species Sensitivity Distribution (SSD) Tests
*Maren Dill[1] and **Guido Gonsior**[2], (1)GG BioTech Design GmbH, Germany, (2)Aquaculture, Ecotox, Marine Science, GG BioTech Design GmbH, Germany*
The OECD guideline 239 assessing the rooted aquatic plant *Myriophyllum spicatum* and the OECD guideline 221 assessing *Lemna* sp. free-floating species are followed to evaluate toxicity in macrophytes. By now it became obvious that the focus on one submerged rooted and one free floating species might under, or overestimate effects based on the mode of action of test items. Therefore, further tests with additional species were setup to refine risk assessment. This leads to the general question: what other species show good growth under lab condition and can be tested based on the available guidelines? Following this question, we performed tests with non-standard species, including monocotyledons and dicotyledons, emergent, submersed, and free-floating species, to refine risk assessment. We present data of non-standard macrophyte test species which based on doubling time and coefficient of variation fulfilled validity criteria according to OECD 239 or OECD 221.

2.02.P-Th087 First Approach to Compare Sensitivity of Macroalgae and Symbiosis-Living Microalgae to Standard Test Species
***Guido Gonsior**[1], Maren Dill[2] and Sara Cuellar[3], (1)Aquaculture, Ecotox, Marine Science, GG BioTech Design GmbH, Germany, (2)GG BioTech Design GmbH, Germany, (3)Algae Research, GG BioTech Design GmbH, Germany*
Macrophytes and microalgae are highly sensitive to pollutants. This highlights the importance of including photosynthetic active organisms in risk assessment. However, there are other photosynthetic organisms that have been less studied, namely, macroalgae and symbiosis-living microalgae, such as microalgae living in corals.

In this work, we present results on their sensitivity to 3,5-dichlorophenol which is used as reference standard for standard test species. Based on the mode of action of the pollutants, we will present evidence that macroalgae species and microalgae living in symbiosis with corals have a high sensitivity. These data could be useful to further evaluate the importance of considering additional photosynthetic organisms for risk assessment.

2.02.P-Th088 Study on the Effects of Particulate Matter on Plants According to Exposure Routes
***Hyun Jung**[1], Min-Hee Jang Sr[2] and Yu Sik Hwang[2], (1)Environmental Exposure & Toxicology Research Center, Korea Institute of Toxicology (KIT), Yuseong-gu, Daejeon, Korea, Republic of, (2)Environmental Exposure & Toxicology Research Center, Korea Institute of Toxicology (KIT), Korea, Republic of (South)*
The research on the impact of particulate matter on the environment and human health continues to expand, with a growing interest, particularly in its effects on plant ecosystems. Particulate matter can settle from the atmosphere onto plant surfaces or accumulate in plants through the soil, potentially causing adverse effects on plants. This study aimed to evaluate the impact of particulate matter on plants, taking into consideration various exposure pathways. Furthermore, to assess the impact of particulate matter on plants based on leaf morphology, we conducted a comparison between cabbage, characterized by fine outgrowths or appendages(trichome) on its leaves, and lettuce, which lacks such features. To assess the impact of particulate matter on plants, we evaluated various factors, including plant growth, photosynthetic efficiency, ROS effects, and leaf stomatal size. This study provides vital information for comprehending the effects of particulate matter pollution on plant ecosystems and for devising measures for environmental conservation and plant protection.

2.02.P-Th089 Using Flow Through Mesocosms to Investigate How Herbicide Exposure Impacts Macrophyte Communities and Long Term Recovery
***Isabel Navarro Law**[1], Colin Brown[1], Rachel Samantha Benstead[2], Isabelle Durance[3] and Michael Fryer[4], (1)University of York, United Kingdom, (2)Food and Environment Research Agency, United Kingdom, (3)Cardiff University, United Kingdom, (4)Ecotoxicology, UK Health Security Agency, United Kingdom*
Small water bodies (SWBs) are commonly located on or near agricultural land, meaning that macrophyte communities can be exposed to herbicides that enter SWBs via spray drift, surface runoff and/or subsurface drainage. Macrophytes provide a number of important ecosystem services, such as positively influencing biogeochemical cycles and functioning as ecosystem engineers.

Currently, most research focuses on the immediate in-season impacts on aquatic macrophytes from exposure to single herbicides, but does not consider longer term recovery, the influence of mixtures or the impact of herbicides on plant communities.

This is the first long-term study to use state-of-the-art flow-through mesocosms situated at FERA Ltd in York, UK. Here, we bring together researchers from different institutions and regulatory bodies to answer the following questions:

- What are the community level effects after exposure to a herbicide dose that exerts a clear effect on individual macrophyte species?
- What is the nature and timescale of recovery for individual species following an impact?
- How does exposure to a mixture of herbicides change the nature of community impacts and/or the timescale of recovery?

Ten mesocosms are being studied over an 18-month period. Eight emergent and one submerged macrophyte species are included within the mesocosms to represent a realistic SWB community. Six mesocosms are dosed with the sulfonylurea herbicide metsulfuron-methyl in successive spring seasons, and three of these mesocosms are also dosed with a mixture of autumn-applied herbicides in the autumn following the first metsulfuron-methyl treatment. Macrophyte recovery is being measured using fortnightly recordings of: chlorophyll fluorescence, number of leaves and flowers, and length of the longest stem. Community composition is being measured using aerial photographs to calculate percent cover with data being analysed using principal response curves.

The results of this study will be used to assess the necessity and feasibility of incorporating recovery potential and community-level impacts into herbicide risk assessment.

2.02.P-Th090 Temperature related sensitivity of the green alga Ankistrodesmus falcatus exposed to Diflufenican
Melanie Grolms-Aal[1]*, Eric Bruns*[2]*, Johannes Witt*[2]*, Tido Strauss*[1] *and Jutta Hager*[2]*, (1)gaiac Research Institute, Germany, (2)Bayer AG - Crop Science Division, Germany*
Ecotoxicological tests with primary producers, such as planktonic algae, contribute to a better understanding of the environmental impact of pesticides (herbicides) and to an informed risk assessment. In general, during the last years, the ERA is increasingly focused on non-standard organisms. Also, more realistic environmental conditions are applied as refinement option to address the effects in the environment more accurately.

This study was based on OECD 201 (2011) and aimed to determine the influence of the herbicide Diflufenican on exponentially growing populations of the unicellular green alga *Ankistrodesmus falcatus* under different temperature and light conditions.

Four experiments were performed at 8°C, 11°C, 17°C and 23°C. Light regimes were adapted to these temperatures to avoid light inhibition at low temperatures and to obtain natural, and therefore physiologically meaningful, light and temperature combinations for the laboratory experiments. This was achieved by combining field data on global radiation and water temperature. All tests were conducted under static exposure over 96 h and increasing Diflufenican concentrations at lower temperatures. Growth was quantified daily by microscopic cell counts and fluorescence measurements.

Diflufenican exposure was stable over time at all temperatures. As expected, growth generally decreased with lowering temperature for both endpoints. When considering the effects of exposure, a more differentiated pattern emerged. Lower sensitivity and delayed growth inhibition to Diflufenican with decreasing temperature were observed in the cell count results. Furthermore, fluorescence levels increased during the first few days of treatment before showing almost the same effects as cell counts.

Rapid detection of growth by biomass is the advantage of fluorescence measurement. Cell counting provides information about cell division. Therefore, both endpoints, cell count and fluorescence measurements were relevant. Exposing algae to lower temperatures requires extending the duration of the test to detect growth inhibition.

This study demonstrates how uncertainties in ERA can be reduced by better understanding the mechanisms leading to the effects of herbicides. Integrating seasonal light and temperature conditions in laboratory experiments allow a more reliable extrapolation to the field.

2.02.P-Th091 Residue assessment of toxic metals in seaweeds for livestock feeds
Jin Seong Kim*, Kang Sang Woo, Oh Kyeong Yeol and Kim Jin Hyo, Agricultural Chemistry, Gyeongsang National University, Korea, Republic of (South)*
Seaweed is known to contain 10-20 times higher minerals than terrestrial plants, and is interested a useful alternatives for feed sources. Furthermore, it has been reported that a few seaweeds can reduce methane emissions from livestock up to 30%, and the value for feed are increased. However, seaweed can be a potential source of heavy metal, thus, the contents of toxic metals (As, Cd, Cr, and Pb) in the commercially availble six species of seaweeds were analyzed by ICP-OES. From the experiments, Cd, Cr, and Pb were not detected in *Ecklonia cava*, *Chrysymenia wrightii*, *Undaria pinnatifida*, *Porphyra tenera*, *Ulva lactuca* while *Codium fragile* was detected Cd, Cr and Pb as total ions at 0.1 mg kg^{-1} 0.74 mg kg^{-1}, and 2.5 mg kg^{-1}, respectively. In addition, As detected in ranging on 6.6 - 87.1 mg kg^{-1} in the all six species of seaweeds.

2.02.P-Th092 Survey of bromoform contents in seaweeds on the Korean coast by GC-μECD
Kang Sang Woo*, Jin Seong Kim, Oh Kyeong Yeol and Kim Jin Hyo, Agricultural Chemistry, Gyeongsang National University,*

Korea, Republic of (South)
Methane exhibits a global warming potential 28 - 34 times higher than CO2, and ruminent is known to a major methane emission source. Reduction of methane emission are currently issued in the livestock industry, and bromoform is known to a potential inhibitor for methanogenesis in rumen. A red algae, *Asparagopsis taxiformis*, was known for the potential methane production inhibition, and bromoform as a trihalomethane (THMs) was found in the seaweed. However, the potential toxicity of bromoform as a feed additive were concerned. In this study, bromoform contents including (chloroform, chlorodibromoform, dichlorobromoform and iodoform) were investigated in six commonly used seaweed species (*Undaria pinnatifida*, *Codium fragile*, *Porphyra tenera*, *Ecklonia cava*, *Ulva lactuca*, and *Chrysymenia wrightii*). Freeze-dried seaweed samples were extracted using methyl tert-butyl ether and the extracts were analyzed by GC-μECD. The results showed that bromoform was not detected in any of the six seaweeds. However, chloroform was detected to 1.5 – 37.0 mg kg_{dw}^{-1} in the six seaweeds. THM contents were not considerably high in the seaweeds.

2.02.P-Th093 Investigation of the residue dissipation and pre-harvest residue limit for sethoxydim and fluazifop-p-butyl as an herbicide in root minor crops.

Kim Jin Hyo*, Jin Seong Kim, Oh Kyeong Yeol and Kang Sang Woo, Agricultural Chemistry, Gyeongsang National University, Korea, Republic of (South)*

Fluazifop-p-butyl and sethoxydim were known as selective herbicides and these were not registered for minor crop application. In South Korea, 17.5% fluazifop-p-butyl as emulsifiable concentrate (EC) and 20% sethoxydim as EC were registered and these were use for the investigation of magnitude of crop residue for critical GAP. In this study, the two pesticides were applied to twice to surface soil in minor root crops, and the residues were investigated in the leaf and root. In the root, both of sethoxydim and fluazifop-p-butyl were not detected trace amount on below 0.01 mg/kg when applied before 20-days of harvest, while trace amounts of the herbicides were detected below 0.01 mg/kg in the leaves. Thus, the MRL establishment were not suggested when the root minor crops cultivation practice were considered. The theoretical maximum daily intakes of the two herbicides in South Korea were calculated to be 4.5-10.8% of ADIs.

2.02.P-Th094 Sewage sludge long-term fertilization: effects on heavy metal accumulation in soil and willows (Salix viminalis L.)

Jurate Zaltauskaite[1]*, Inesa Kniuipyte*[2]*, Milda Plytnikaite*[1]*, Gintare Sujetoviene*[3]*, Jelena Ankuda*[4] *and Eugenija Baksiene*[4]*, (1)Vytautas Magnus University, Lithuania, (2)Lithuanian Energy Institute, Lithuania, (3)Vytautas Magnus University, Kaunas, Lithuania, (4)Lithuanian Research Center for Agriculture and Forestry, Lithuania*

The use of renewable energy resources is one of the high priority areas in the EU policy in order to decrease greenhouse gas emissions and to increase energy independence. Short rotation energy forestry, i.e. the production of fast growing tree species, is one of the alternatives for energy production. Wastewater treatment generates huge amounts of sewage sludge (Ss) and its production in the world is projected to increase in the future. Sustainable sewage sludge management and disposal is a growing problem worldwide. The main risks of using SS are related with heavy metals (HM), persistent organic chemicals and high content of nutrients. This study aimed to evaluate long-term fertilization (15 years) with SS impact on soil quality and heavy metals accumulation in soil and multi-purpose energy plant willow (Salix viminalis L.). Willow plantation was fertilized twice in the period of cultivation: 20 t/ha of SS in 2011 and 100 t/ha in 2016. Plants were harvested in 2011 and in 2020. The following parameters were evaluated of soil samples and willow cuttings made after fifteen years of cultivation (2005-2020): accumulation of heavy metals in soil, shoots and leaves of willows, bioconcentration and translocation factors.

2.02.P-Th095 Phytotoxicity Effects of Tetracyclines and Sulfonamides mixture in presence of copper on Lemna x mediterranea plants

Chiara De Carolis[1]*, Marco Fabriani*[2]*, Giovanna Frugis*[2]*, Fabrizio Pietrini*[3]*, Valentina Iori*[2]*, Maria Letizia Costantini*[4] *and Maria Adelaide Iannelli*[2]*, (1)Sapienza University of Rome, Italy, (2)Institute of Agricultural Biology and Biotechnology, National Research Council (IBBA-CNR), Italy, (3)Italian National Research Council (IRET-CNR), Italy, (4)Dipartiment of Environmental Biology, Sapienza Università di Roma*

Aquatic environments have become one of the main destinations of antibiotics, with significant negative effects on ecosystems. Pharmaceuticals limit the habitable living environment for aquatic organisms and antibiotics, considered as emergent contaminants, contribute to cause severe water bodies pollution. Duckweed (*Lemna x mediterranea 9425a*), a common aquatic plant found worldwide, was grown in a solution polluted with sulfamethoxazole (SMX-sulfonamide group) and chlortetracycline (CTC-tetracycline group) with low copper concentrations (Cu) usually present in moderately polluted environments. Following OECD guideline protocols[1], *L. mediterranea* 9425a plants were tested as monocultures with different concentrations of antibiotics, alone, mixed and in presence of copper sulphate to simulate environmental conditions. The adverse effects on *Lemna* sp. are concentration- and time-dependent for growth inhibition, photosynthetic capacity decrease and induction of oxidative stress response. The inhibitory effects induced by SMX, CTC and Cu on duckweed plants have been evaluated by measuring the number and size of fronds, wet/dry fronds biomass, relative growth rate (RGR), pigment content and chlorophyll fluorescence analysis. Concentration-response relationship were defined to estimate toxic endpoints of Cu, EC_{50}: 7.27 mg/L; SMX, EC_{50}: 173.00 mg/L and CTC, EC_{50}: 6.9988 mg/L since their presence, in aquatic environments, may have significant implications for tested organisms and their ecosystems.

[1]OECD. *Lemna* sp. growth inhibition test. Guideline 221. Organization for Economic Co-operation and Development: Paris, France 2006.

2.02.P-Th096 Challenges in calculating the mean measured concentrations for Algal Growth Inhibition Test According to OECD Test Guideline 201 - And what about the toxicity?

Stefan Josef Hoeger[1]*, Anne Dupont*[1] *and Jana Hoffmann*[2]*, (1)Innovative Environmental Services (IES) Ltd., Switzerland, (2)Symrise AG, Germany*

Green algae, blue-green algae and diatoms (tested following the OECD TG 201) are at least partly important for the risk assessment of plant protection products, human and veterinary pharmaceuticals and industrial chemicals under REACH. Especially chemicals as basic elements for the synthesis of more complex products show a broad variety of characteristics from well water soluble, stable and non-toxic to hardly water soluble, unstable, volatile and very toxic for water organisms. The group of chemicals with one or more of the latter characteristics is therefore a challenge for toxicity tests with aquatic organisms. The OECD GD 23 for difficult substances provides some hints how "standard testing" with such test items should be conducted, but due to numberless combinations of characteristics of these substances, some innovation is required to find the best test design for individual chemicals. Substances that degrade rapidly or are volatile in particular pose a challenge for testing but also for interpreting the results. When testing algae, a semi-static test is difficult to carry out and involves a lot of effort. Therefore, the test is usually carried out statically. In the case of volatile substances, a closed system can be used. However, in experiments with rapidly degradable substances, the recovery can be very low after a test period of 72 hours. For these substances, it is advisable to measure the degradation or loss of the substance every 24 hours, to obtain data at test start, after 24, 48 and 72 hours. In case of very low values measured 24 h intervals (< limit of quantification), the mathematically formula chosen to calculate the mean measured concentrations is very decisive since it will give them more or less weight. Therefore, the challenge is to correctly calculate the mean value from these different values, which is important for risk assessment. To our knowledge, there are still no binding specifications from authorities as to how this should be calculated. Each version of the OECD GD 23 proposes a different type of calculation, but there is no GD summarizing of all possibilities. It should also not be forgotten that the toxicity and thus the growth of algae can be affected by the degradation or offgassing of the substance. This has also not yet been considered in the calculation. Various options for calculating of geometric mean measured concentrations and the determination of EC_{50} values for growth and biomass are explained and discussed.

2.02.P-Th097 Paper-disc Soil Method to Predict Ex-situ Soil Quality Evaluation

Sun-Hwa Nam *and Youn-Joo An, Konkuk University, Korea, Republic of (South)*

Soil algae are potential soil test species due to being representative terrestrial organisms in terms of ecologically important producer, wide distribution, and ease of cultivation. The paper-disc soil method is a soil algal bioassay for assessing soil water transferred from the contaminated soils. In this study, we performed the paper-disc soil method for predicting *ex-situ* soil quality evaluation. Test media were contaminated soils collected from the smelter sites and remediated soils. The test species were *Chlorococcum infusionum* and *Chlamydomonas reinhardtii* and algal photosynthetic fluorescence was measured to indicate biomass. We verified different chlorophyll *a* effects depending on soil properties. This result suggests the application of the paper-disc soil method to *ex-situ* soil quality evaluation. *Acknowledgement-This work was supported by Korea Environment Industry & Technology Institute (KEITI) funded by Korea Ministry of Environment (MOE) 2022002450002 (RS-2022-KE002074).*

2.02.P-Th098 Photosynthetic Effects of Polyvinyl Chloride Microplastics in Paints

Sanghee An, ***Sun-Hwa Nam*** *and Youn-Joo An, Konkuk University, Korea, Republic of (South)*

Polyvinyl chloride (PVC) is an additive for a paint to prevent the attachment of illegal flyers. Paint particles can be naturally or artificially fragmented via deterioration or removal from the surface coating materials. In the end, PVC can be contaminated the areas adjacent or distant to the source after weathering, aerial dispersion, or deposition of paint particles. In this study, we assessed the photosynthetic effects of PVC microplastics as an additive in paint on a plant mung bean. Photosynthetic effects on *Vigna radiata* were conducted by following OECD test guidelines No. 208 and assessed in seven exposure system: 0, 0.01, 0.1, and 1% paint only (paint), and 0.01, 0.1, and 1% paint mixed with PVC microplastics (P + PVC). Significant differences between paint and P + PVC treatments were showed in Fv/Fm, ABS/RC, TRo/RC, ETo/RC, and Dio/RC. This result suggests that PVC microplastics in paints enhance disruption of photosynthetic mechanism in plants. *Acknowledgement- This work was supported by Korea Environment Industry & Technology Institute (KEITI) funded by Korea Ministry of Environment (MOE) 2022002450002 (RS-2022-KE002074).*

2.02.P-Th099 Toxic Effects of Three Detergents on Cladophora Sp. (Chlorophyta)

Eduardo Ruiz Hernandez[1]*, Jose Roberto Villagomez-Ibarra*[2] *and* ***Alma Sobrino-Figueroa***[3]*, (1)Autonomous University of Hidalgo, Mexico, (2)Universidad Autónoma del Estado de Hidalgo, Mexico, (3)Hidrobiology, Metropolitan Autonomous University (UAM) Iztapalapa, Mexico*

Detergents are products that are discharged in large quantities into aquatic systems, causing harmful effects to species. Various toxicological studies have been carried out with microalgae exposed to surfactants and detergents, however, studies with filamentous algae are scarce, for this reason, the objective of this work was to evaluate the effects of three types of detergents: a dishwasher(DW), a laundry detergent (DL) and a multipurpose detergent (DM); in growth, production of pigments, production of macromolecules (proteins, carbohydrates and lipids) and degree of lipoperoxidation in the filamentous algae *Cladophora* sp. to evaluate their sensitivity to these compounds. Static tests of seven days duration were carried out, where the algae were exposed to 5 concentrations of the surfactant sodium dodecyl sulfate (0, 0.01, 0.1, 1, 5, 10, 50 and 100 mg/l) and to 5 concentrations of the three commercial detergents (0, 1, 15, 30, 45 and 60 mg/l). At the end of the exposure period, growth (wet weight), production of pigments and macromolecules and the degree of Lipoperoxidation were evaluated. The EC_{50}

values varied from 0.7 to 18.06 mg/L, the most toxic detergent was the multipurpose detergent. A decrease in the concentration of total chlorophyll was observed in algae exposed to detergents of between 2% and 68%. Exposure to SDS and commercial detergents cause changes in the production of macromolecules and an increase in the production of TBARS of 10%. 300% compared to the control group. The degree of toxicity of the detergents ranged from highly toxic to harmful.

2.02.P-Th100 Reassessing Exposure Design: Exploring Overspray in Toxicity Tests for Herbicides with Unexpectedly Low Toxicity to Macrophytes

Bastian H. Polst, Dick Belgers, Nina Jansen, Laura Buijse and ***Gertie Arts Mrs., PhD****, Environmental Risk Assessment, Wageningen University & Research (WUR), Netherlands*

Herbicides are commonly classified based on their mode of action, which has implications for their toxicity to aquatic macrophytes. While some herbicides, including contact herbicides, exhibit localized toxicity, there are instances where contact herbicides unexpectedly show low toxicity to emergent and floating macrophytes compared to systemic herbicides. This raises concerns about the protectiveness of current exposure designs in toxicity tests. Standard tests for macrophytes typically involve dissolving the herbicide in the test media to ensure even exposure. However, contact herbicides primarily act through direct contact with non-submerged parts of the plants. As a result, the use of overspray exposure, involving spraying or drift, may provide a more appropriate method for assessing the toxicity of contact herbicides specifically to emergent and floating aquatic macrophytes.

Previous research has indicated increased sensitivity differences in overspray or spray drift exposure scenarios for aquatic macrophytes.

This study investigates the potential influence of overspray exposure on the estimation of toxicity for contact herbicides. To accomplish this, we subjected *Lemna mino*r to the contact herbicide Bentazone using two distinct exposure scenarios: overspray and exposure via the growth medium. In accordance with the OECD 221 Lemna Growth Inhibition Test, we conducted a dose-response experiment to evaluate differences in biomass and frond area. We reached approx. 90% of the nominal concentrations for the exposure via the medium. Exposure via spray resulted in an approx. 4.5x higher concentration than via the medium, e.g., for the highest dose. Nevertheless, effects on *Lemna* were only observed when the herbicide was dissolved in the medium. We will discuss potential explanations for these results, e.g. related with the uptake of the test item by the lower or upper part of the *Lemna* fronds.

2.02.P-Th101 Ecotoxicity evaluation of several composts through Lactuca sativa, Daphnia magna and Lemna minor

Mathilde Henrion*, Erika Soto, Lluis Martin-Closas and Ana M Pelacho, Dpt. Agricultural and Forest Science and Engineering, University of Lleida, Spain*

To match the European Green Deal by 2050, the global system must urgently move to contaminant free and zero residues. The agricultural system, through the Farm to Fork strategy, must contribute towards a sustainable food production and to circular economy, particularly shifting from conventional to organic agriculture and limiting mineral fertilization.

Composting the increasing organic residues has arisen as a promising technological option, the resulting bio-products as organic fertilizers available to a huge potential market. Correspondingly, composts are aimed not only to fulfil the standard quality test requirements of their basic chemical composition; they are also to guarantee minimizing their environmental impact. Analyses and routine assays for compost quality are however frequently insufficient to secure absence of effects on the environment.

To assess for the agricultural use suitability of representative composts produced from a diversity of raw materials by composting plants in the North-East area of Spain, a lettuce Petri dish seed germination and early plantlet growth test with two crude compost concentrations, and a standard acute toxicity test of compost leachates on *Daphnia magna* as biosensor to determine the concentration which induced half-maximum effects (CE_{50}) were carried out. For most compost samples, germination rate was unaffected, but some of them decreased plantlet development (shoot and radicle height and weight). The *D. magna* neonates exhibited different sensitivities to increasing concentrations of the compost leachates depending on the nature of the composts, even though their EC_{50} was high and well over that of the compost concentration intended for their use. Conversely, only one of the composts exhibited a parallel effect both on *D. magna* and on lettuce germination and early plantlet growth. Further bioassays with *L. minor*, are still ongoing. The proposed approach of testing compost impacts on plants and on other ecotoxicity test model organisms is needed to ensure the feasibility of compost use to safely producing agricultural goods without compromising soil fertility. Research towards determining the minimal environmental impact of agricultural compost practices is required to contribute to maximize production in a circular economy context.

2.02.P-Th102 Risk Assessment based on Visual Effect Endpoints for Terrestrial Plant (NTTP)

Carmen Schweikert[1]*, Thomas Gräff*[2] *and Vanessa Hörmann*[2]*, (1)IV 1.3-1, German Environment Agency (UBA), Germany, (2)German Environment Agency (UBA), Germany*

The Non-target terrestrial plant (NTTP) risk assessment of chemicals uses ecotoxicological endpoints based on effects on plants (phytotoxicity). Phytotoxicity can be indicated as change in visual appearance of the plants (such as chlorosis, necrosis, wilting, leaf and stem deformation), weight or length. As neither of these parameters alone covers the effects of the other in either assessment cases, authorities ask to determine ER_{50} values for visual effects, emergence, biomass, and shoot length to conduct NTTP risk assessment for plant protection products (PPP).

However, some assessors feel challenged by the use of "visual phytotoxicity" in the risk assessment. We want to respond to two important points. One is that the visual effect value provides an overall picture of the phytotoxic effects by covering the sum of all symptoms appearing in parallel in the plants affected. However, if these effects are treated separately, the overall phytotoxic effect on the plants is not captured, e.g. when chlorosis precedes necrosis in the plant tissue. As herbicides cause different symptoms in the plants which might have a population-relevant effect, we propose to preferentially use the endpoint "visual phytotoxicity" as a sum of effects.

Another issue is that the information to conclude on the effect value depends on the quality of the documentation provided in the studies used to evaluate the PPP risk to NTTPs. However, it is common practice that if no ER_{50}-value could be derived from the data, then a minimum effect value ($ER_{50} > x$) will be used in the risk assessment. Although the guideline recommends to present the effects in percentages (0-100%), the studies often provide an alternative scoring system. To deal with that, besides derivation of a minimum ER_{50} (> x) based on hypothesis testing for binomial data, often the ER_{50} can be derived from the different scores (typically 5, 9 or 10 scores or levels of phytotoxicity). Therefore, firstly each scoring is set to the midpoint of its range. Then effect endpoints (ER_{50}) are calculated for these binomial distributed data using common software tools to derive ER_{50} values from a dose/effect curve (e. g. R-package drc, implemented in OpenRTox).

We want to share these thoughts on the use of the endpoint "visual phytotoxicity" in PPP risk assessment to support the design of such tests for PPP risk assessment.

2.02.P-Th103 Use of Egeria dense as a Pb adsorbent in wastewater treatment

***Cynthia Wong Arguelles, PhD**, Ingenierías, Tecnologico Nacional de Mexico campus Ciudad Valles, Mexico*

Water pollution is a global environmental problem; human activities, through industrial and agricultural processes, have caused the degradation of water quality, which generates problems related to the supply of drinking water and wastewater treatment (Lavado-Meza et al., 2020). Currently, there is great concern worldwide, due to the considerable increase in the contamination rates of industrial effluents by heavy metals such as Cr, Ni, Cd, Pb and Hg (Tejada-Tovar & Garcés-Jaraba, 2015). Adsorption is an efficient technique for purifying water, removing low levels of contaminants, and is often advantageous in terms of simplicity and cost-effectiveness. In recent years, the use of low-cost materials obtained from different biomasses from plants, fruits, algae and agro-industrial waste has been investigated to replace the use of conventional methods in the removal of contaminants, such as heavy metals. Said removal is achieved due to the interaction between metal ions with the functional groups present on the surface of the biomaterial. Egeria dense or elodea as it is also known, is an aquatic plant that is used in aquariums, to oxygenate ponds and aquariums. On the other hand, other properties have been found such as adsorption and its great metal removal capacity (Martinez-Vasquez et al. 2018). The objective of this project is to study the adsorption of biochar obtained from Egeria dense as an alternative process for the removal of contaminants such as Pb. 0.1 g of biochar was used in 25 mL solutions with concentrations from 0 to 300 mg/L of Pb (II). They were brought into contact by stirring for 120 minutes and the retention time of 30 minutes was determined to obtain 72.31% removal and an adsorption capacity of 179.88 mg/L of Pb (II). The results obtained demonstrate that biochar produced from elodea can be useful as an adsorbent for the treatment of water contaminated with Pb (II).

2.02.P-Th104 Duckweed (Lemna minor) Response to Triclosan and its Recovery after Exposure under Elevated Temperature

***Diana Miškelytė** and Jurate Zaltauskaite, Vytautas Magnus University, Lithuania*

Antimicrobials are important for preserving the quality of life and public health. Due to the rising amounts of antimicrobial agents in the environment and the lack of knowledge on their ecotoxicity, there is growing concern regarding their effects on the terrestrial ecosystem. Triclosan (TCS), an antibacterial chemical used extensively in pharmaceutical and personal care products, is also an often-recognized emerging organic pollutant in the environment. Physiological or morphological endpoints are used in most published studies assessing TCS toxicity to aquatic plants. Additional detailed research is needed to understand the underlying toxicity mechanisms of TCS-induced effects at the biochemical plant level. With potentially far-reaching consequences for life on Earth, climate change is an increasingly urgent issue. There is a growing awareness of the importance of anticipating the interactions between natural and chemical stressors, and the way they affect organisms and their performance. There is a lack of knowledge on the impact of climate factors on the ecotoxicity of antimicrobials including TCS. The main objective of this study was to evaluate elevated temperature effect on triclosan toxicity to duckweed (*Lemna minor*) and its recovery potential. *L. minor* were grown in TCS-contaminated growth medium (1–400 $\mu g\ L^{-1}$) under different temperature regimes (23˚C and 27˚C). After 7 days of TCS exposure, *L.minor* fronds were transferred to uncontaminated growth media for 7 days recovery. *L. minor* morphological indicators (dry weight, frond area), relative growth rate, biochemical indicators (enzyme activity and metabolites) as well as oxidative stress damage (lipid peroxidation) were measured.

2.02.P-Th105 Water contaminations by persistent toxic substances and responses of phytoplankton community in the Geum River Estuary, South Korea

Seo Joon Yoon[1]*, Junghyun Lee*[2]*, Seongjin Hong*[3]*, Hyeong-Gi Kim*[4]*, Bong-Oh Kwon*[5] *and Jong Seong Khim*[1]*, (1)School of Earth and Environmental Sciences & Research Institute of Oceanography, Seoul National University, Korea, Republic of (South), (2)Department of Environmental Education, Kongju National University, Korea, Republic of (South), (3)Department of Marine Environmental Science, Chungnam National University, Korea, Republic of (South), (4)Department of Ocean Environmental Science, Chungnam National University, Korea, Republic of (South), (5)Kunsan National University, Korea, Republic of (South)*

A comprehensive understanding of the plankton ecosystem with water pollution has been limited considering changes due to freshwater discharge and the temporary influx of terrestrial substances. This study investigated the response of phytoplankton community to water contamination by persistent toxic substances (PTSs) and nutrients in an estuary affected by an artificial dam over one year. The distribution of PTSs, including 15 polycyclic aromatic hydrocarbons, 6 alkylphenols, and 8 metal(loid)s, along with nutrients, exhibited relatively high concentrations with irregular temporal fluctuations in the inner estuary. However, a few PTSs concentrations in the estuary exceeded the environmental quality guidelines of South Korea and the Canadian Council of Ministers of the Environment. The water quality parameters in the Geum River Estuary exhibit typical patterns seen in mid-latitude estuaries, with phosphorus playing a significant role as a limiting nutrient. During winter and spring, phytoplankton communities showed good ecological quality, with an average of 28 species and a density of 1750 cells L^{-1}. In contrast, during summer, there was a significant increase in the density of freshwater species (max 45,000 cells L^{-1}). These community were categorized into three seasonal groups, featuring dominant taxa like blue-green algae and diatoms. Temperature and nutrient levels were the principal factors influencing phytoplankton community, while PTSs had a minor impact. Overall, phytoplankton community displayed strong seasonal variation, mainly influenced by freshwater input and nutrient availability.

2.02.P-Th106 The Microscopic world: a comparison of different techniques for quantifying plankton

Marie Brown[1]*, Zoe Leanne Parker-Crosse*[1]*, Ellie Welch*[1]*, Nadine S Taylor*[1] *and Valeria Manifredi*[2]*, (1)Cambridge Environmental Assessments (CEA), United Kingdom, (2)University of Nottingham*

Plankton communities are integral to freshwater ecosystems. However, due to their small size, very short life cycles and dynamic ecological and environmental interactions, assessing these organisms on a community level can be very challenging. The presence of a stressor, such as a plant protection product (PPP), within the ecosystem creates an additional layer of complexity. Necessarily large datasets, acquired from samples collected over large temporal scale are required to decipher true direct and indirect effects against the dynamic natural changes to abundance. Traditionally, these communities are generally assessed using taxonomy techniques, however, there are new and emerging techniques for quantifying these microscopic organisms. When designing a study to investigate the impacts of a PPP on plankton, consideration must be given to the ecology and biology of these organisms, to ensure that appropriate methods are used for data collection. Freshwater phytoplankton cells vary in size by several orders of magnitude between species with any taxa recorded as colonies resulting in the biggest variation in size. Biovolume measurements can be used to adjust for this variation in size by calculating the total volume of each taxa and can be useful for assessing the functionality of individual species or groups, for assessing changes in morphology and for collecting data on algae taxa classed as colonies where it is difficult to distinguish individual cells. Abundance counts are able to show more subtle changes in the community structure, and these data are considered to be more standardized and statistically robust. Current standard practice for such measurements requires laborious microscopy techniques and expert taxonomic training, limiting the frequency and number of samples that can be processed. The development of metabarcoding techniques could provide an alternative, more efficient, method. Molecular analyses could be used in conjunction with microscopy identification, or as a complete separate analysis, to show variation in plankton communities as a large number of samples can be analyzed very quickly.

Here we present the benefits of reporting data from microscopy counts in terms of abundance or biovolume, and we introduce a comparison of traditional approaches against molecular data from a metabarcoding technique.

2.02.P-Th107 Incorporating macrophyte health measurements into higher tier risk assessments

Marie Brown*, Zoe Leanne Parker-Crosse, Ellie Welch, Katie Smith, Hanna Samantha Schuster and Nadine S Taylor, Cambridge Environmental Assessments (CEA), United Kingdom*

Current guidelines recommend that at least 8 sensitive/vulnerable taxa, with acceptable minimum detectable difference (MDD) values, should be tested within a mesocosm study, however, there is little guidance on the selection of appropriate endpoints for macrophytes that will provide regulatory acceptable data. In addition, many assessment methods for macrophytes are considered subjective such as visual determination of chlorosis and necrosis. The lack of standardized methods and challenges associated with using this subjective and ordinal data to derive statistically meaningful endpoints can lead to questions over reliability and relevance in the risk assessment of PPPs. Despite this, these measures are useful in supporting the assessment of potential effects on macrophytes and as a weight of evidence approach for the derivation of suitable overall endpoints. The considerations for macrophyte studies should include ecological relevance as well as the practical implications of ensuring good growing conditions and appropriate assessment methods to achieve robust and reliable data. The unique sloped mesocosm employed at CEA allows a wider range of macrophytes to be planted within the mesocosm and methods have been optimised to assess macrophyte growth and health, increasing valid data collection throughout the study. The endpoints have been specifically developed for each species, in order to maximise the quality and quantity of data collected. These include height measurements, number of stems, number of nodes per cm, counts of leaves and flowers as well as visual assessments of aereal coverage (cm^2) and percentage of chlorosis and necrosis. On completion of the test period, measurements of wet and dry weight of each species are determined, however by measuring additional parameters throughout the study, this data can be used to contextualise the wet/dry weight results, assess short term effects and recovery, and determine the overall community effect of the test item.

By sharing our considerations for macrophyte endpoint evaluation in mesocosm studies we aim to highlight the relevance of mesocosm studies, particularly within the future of risk assessment for macrophyte communites. We will also demonstrate the sloped mesocosm design as a reference study in order to consistently derive more reliable and robust population and community level endpoints, using macrophytes as an example.

2.02.P-Th108 Are TKTD Models for Algae and Macrophytes Protective in a Community Context – a Simulation Study
***Udo Hommen**[1], Tido Strauss[2], Eric Bruns[3], Thomas G Preuss[4] and Johannes Witt[4], (1)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (2)Research Institute gaiac, Germany, (3)Environmental Safety, Bayer AG - Crop Science Division, Germany, (4)Bayer AG - Crop Science Division, Germany*
Toxicokinetic-toxicodynamic (TKTD) models are more and more used as a tier 2 tool to address the time-variable exposure of aquatic organisms resulting from entries of plant protection products into edge-of-field surface waters. If successfully validated, the models can be used to predict the effects of many more complex exposure time series, predicted by regulatory exposure models (e.g. FOCUS step 3 or 4 models). However, if used as such and without coupling to a population model, the models still simulate laboratory tests and their outputs are the endpoints addressed in the corresponding tier 1 tests. For animals, these are organism level endpoints like survival, reproduction, development or growth. Under dynamic exposure, recovery of the organisms is possible (damage repair). In contrast to this, for algae and also for the standard test macrophyte *Lemna* sp., the standard tier 1 test assesses the inhibition of the population growth rate. Thus, dynamic exposure allows recovery of the population (ecological recovery). However, according to the EU Aquatic Guidance Document, Ecological Recovery can only be assessed in micro- or mesocosm studies, which means in a community context where species interactions can affect the recovery of a population. Because tier 2 studies provide the same type of endpoints as the related tier 1 test for algae and Lemna already population level endpoints are already used at tier 1, there is a dilemma with the general request that recovery of populations should only be assessed at tier 3. To analyse whether TKTD modelling for algae or Lemna is still protective in a community context, we used 2 different ecosystem models, Stolam and CASM. As worst-case scenario for recovery, we assumed that only one species is affected by a chemical (thus, all competitors are not affected). We simulated dynamic exposure profiles predicted to be regulatory acceptable by a TKTD model. Following current practice (Tier 1 RAC = ErC50 / 10), an acceptable profile was defined as the time series of PECs 10 times below the profile which resulted in 50 % inhibition of the growth rate in the simulated laboratory test. These profiles were compared to control runs and it was checked which effects the predicted acceptable exposure profile had on the different populations in the community. The poster will present first results.

2.02.P-Th109 Aquatic primary producers in the prospective risk assessment for pesticides; some insights into considering the framework and connecting to the reality.
***Sabine Duquesne**[1], Stephan Brendel[1], Marco Konschak[1], Linda Hönemann[1], Magali Solé[1], Oliver Weisner[2], Silvia Pieper[1] and Jörn Wogram[1], (1)German Environment Agency (UBA), Germany, (2)Plant Protection Products, German Environment Agency (UBA), Germany*
The environmental risk assessment (ERA) for pesticides follows a prospective tiered approach, starting with the most conservative and simple step (so-called tier 1). For aquatic primary producers, since 2015, the type of endpoint derived from ecotoxicological tests to use in ERA was changed; it is now the endpoint corresponding to 50% inhibition (EC50) of the growth rate (ErC50). Prior to 2015, it was the lowest EC50 based either on biomass (area under the curve- EbC50), yield (EyC50) or growth rate (ErC50). Our findings show that the use of the ErC50 while maintaining the default assessment factor (AF) of 10 clearly reduces the level of conservatism in the tier 1 RA compared to prior 2015; a minimum adequate level of protection is achieved now only in about 67% of cases versus 88% of cases prior to 2015. To restore the previous level of protection, an extra factor of minimum 2.4 could be used. However, it is questionable if this previous level of protection of 88% should be considered acceptable, since a sufficient protection level should theoretically be ensured for each individual substance. Besides that, the regulatory framework does not consider realistic conditions in agricultural landscapes where e.g. multiple stressors, pesticide mixtures and repeated application within and over the years occur. Ideally the tiered approach for primary producers should be appropriately calibrated towards such a realistic field situation since the population in the field is the actual entity to be protected. Some recent field monitoring studies of pesticides in surface waters have indicated concerns about their concentrations and ecological impacts. It is important to acknowledge these findings as well when questioning the protectiveness of the prospective risk assessment of pesticides.

2.02.P-Th110 Protectiveness check of Tier-1 pesticide risk assessment for aquatic primary producers: learnings and possible next steps
***Sarah Hartmann**[1], Eric Bruns[1], Andreas Solga[2], Gertie Arts Mrs., PhD[3], Ivo Roessink[4] and Steven Droge[3], (1)Environmental Safety, Bayer AG - Crop Science Division, Germany, (2)Bayer AG - Crop Science Division, Germany, (3)Environmental Risk Assessment, Wageningen University & Research (WUR), Netherlands, (4)Wageningen University & Research (WUR), Netherlands*
In the last decade, the protectiveness of European aquatic risk assessment (RA) has been validated for insecticides, fungicides and herbicides by comparing the regulatory acceptable concentrations from Tier-1 (Tier-1 RAC) with those from mesocosm

studies (Tier-3 RAC), the latter representing the reference tier according to the EFSA aquatic guidance document (AGD). This resulted in several publications and conference publications. What makes herbicides and other substances with a herbicidal mode of action different from insecticides and fungicides, is the discussion which sublethal measurement endpoints to use in the risk assessment. The key aspect discussed in the validations of protectiveness performed so far is the impact of changing from biomass/yield related EC_{50} values ($E_{b/y}C_{50}$) to growth rate related values (E_rC_{50}). Although E_rC_{50} values are in general slightly higher than E_bC_{50} values, it should be noted that only growth rate related figures allow a proper comparison of differences in sensitivity between species. By some authors these lower sensitivities are interpreted as a severe decrease of protectiveness within the RA. However, our work from the last two years demonstrated that only in 2 of 17 cases the change from $E_{b/y}C_{50}$ to E_rC_{50} values resulted in a change of protectiveness for the substances involved. When discussing a potential loss of protectiveness in primary producer RAs, it is frequently not mentioned that the Tier-1 data requirements for herbicides regarding primary producers are usually exceeded, and therefore higher tier options are a next step. We have investigated higher-tier options for herbicides further and will present information on some complete primary producer related data sets. The newly presented data comparisons will also include additional data for *Myriophyllum spicatum* and other macrophyte species (e.g. *Glyceria maxima*) in order to study how protectiveness might change when adding data from additional macrophytes to the herbicide risk assessment. In addition for one compound we will add a modelling exercise to the comparison and compare Tier-1 RACs with Tier-3 and Tier-2C RACs.

2.02.P-Th111 The Influence of Abiotic Factors on the Distribution of Macrophytes in Small Water Bodies in Temperate Ecosystems

Isabel Navarro Law[1]*, Colin Brown*[1]*, Rachel Samantha Benstead*[2]*, Isabelle Durance*[3] *and Michael Fryer*[4]*, (1)University of York, United Kingdom, (2)Food and Environment Research Agency, United Kingdom, (3)Cardiff University, United Kingdom, (4)Ecotoxicology, UK Health Security Agency, United Kingdom*

Small water bodies (SWBs) have been shown to support both higher levels of gamma macrophyte richness and greater numbers of rare species than rivers or lakes, but they are facing unprecedented anthropogenic threats from habitat degradation, climate change and exposure to fertiliser and herbicide from nearby agricultural land. Little is known about how abiotic factors influence the distribution of macrophytes in SWBs and this makes it difficult to (i) design representative scientific investigations to understand how anthropogenic threats will impact macrophyte communities in SWBs, and (ii) target actions aimed at conserving and enhancing these ecosystems.

This is the first review to investigate the influence of abiotic factors on macrophyte distribution in SWBs. Thirteen different abiotic factors were studied: SWB type, SWB size, substrate size class, velocity, conductivity, depth, shading, surrounding land use type, hydroperiod, isolation, distance from the source, nutrient concentrations (phosphorus and nitrogen), and pH. Macrophytes were categorised by phylogeny into bryophytes and vascular plants, which were then subdivided by their morphology into emergent, rooted submerged, floating and submerged with floating leaves.

Results suggest that the impact of abiotic factors on macrophytes varies with macrophyte phylogeny and morphology. Both velocity and shading have a negative relationship with macrophyte richness and abundance for vascular plants, however a positive relationship with the richness and abundance of bryophytes, which favour shaded, fast flowing waters. Additionally, the substrate size class influences the distribution of emergent but not free-floating macrophytes, as emergent macrophytes require a fine sediment to anchor their roots. The proportion of land adjacent to the water body that is agricultural has a positive influence on the abundance and richness of vascular macrophytes, potentially because SWBs near agricultural land will have less shading from riparian vegetation and higher nutrient concentrations from fertiliser runoff.

The review provides information on how macrophyte communities vary across different SWBs, thus helping to target efforts from conservationists and policy makers and contextualising assessment of impacts from anthropogenic activities. The results also support the design of a long term mesocosm experiment, investigating the impact of herbicide exposure on macrophyte communities.

2.02.P-Th112 Betula pendula (Roth.) Seedlings Exposed to Polycyclic Aromatic Hydrocarbons: Insights into Plant Defense Mechanisms

Greta Striganavičiūtė *and Vaida Sirgedaitė Šėžienė, Lithuanian Research Center for Agriculture and Forestry, Lithuania*

Polycyclic Aromatic Hydrocarbons (PAHs) represent a pervasive environmental challenge, originating from various anthropogenic activities such as industrial processes and combustion of fossil fuels. These persistent organic pollutants can have detrimental effects on plant physiology, disrupting cellular functions through the generation of reactive oxygen species (ROS). Understanding the impact of PAHs on *Betula pendula*, a keystone species, is essential for assessing the broader consequences of environmental contamination. This study investigates the relationship between PAH exposure and the activation of antioxidant enzymes in *Betula pendula* seedlings, focusing on the variability across different half-sib families (genetic groups). Seedlings from four half-sib families of *Betula pendula* were cultivated in hydroponic conditions using a nutrient medium supplemented with phenanthrene, pyrene, naphthalene, and fluoranthene, at varying concentrations (10, 100, and 200 µg L-1). This growth experiment spanned a period of 4 weeks. Following cultivation, leaves were harvested, and enzyme activities were measured spectrophotometrically. The assessment of antioxidant enzyme activity, including catalase (CAT), peroxidase (POD), ascorbate peroxidase (APX), and glutathione-S-transferase (GST) serves as a molecular lens to explain the plant's defense mechanisms against PAH-induced oxidative stress.

Results showed that CAT enzyme exhibited increased activities in all half-sib families except those affected by phenanthrene, showing no impact or negative effects. POD enzyme displayed increased activity in one half-sib family, while three others experienced slowdown of it's production or no impact. APX enzyme showed increased activity in one half-sib family but significantly decreased activity in three others. GST enzyme results divided half-sib families into two sections, with two showing increased activity and two with decreased activity.

In conclusion, the findings highlight that antioxidant enzyme activities in birch seedlings vary significantly among different half-sib families. Such a response suggests a genetic influence on the antioxidative defense mechanisms. This knowledge can inform the development of resilient plant varieties or the selection of suitable families for ecological restoration efforts in PAH-contaminated environments.

2.02.P-Th113 Multiplexed Algal Cytological Imaging (MACI) - A Novel Image-Based Phenotypic Profiling Assay for Screening Environmental Chemicals in Microalgae

Eric Ostovich *and Rebecca Klaper, University of Wisconsin, Milwaukee*

High-throughput phenotypic profiling assays, which use high-content imaging to characterize changes in single-cell morphological feature data, have become popular in recent years for their ability to predict cellular targets and mechanisms of action (MoAs) for different chemicals and novel drugs. However, this approach has not yet been widly used in ecotoxicology due to the lack of studies and established methods for performing this kind of assay in environmentally relevant species, especially that of plant-type organisms. Here, we developed a novel image-based phenotypic profiling assay for *Raphidocelis subcapitata*, a toxicology and ecological model species, based on subcellular sturctures that are important and unique to unicellular microalgae (eg. chloroplast, nuclei, lipid droplets), which we coined as multiplexed algal cytological imaging (MACI). As a proof of concept, eight different herbicides and antibiotics with unique MoAs were exposed to *R. subcapitata* cells, and MACI was used to characterize their cellular impacts by measuring subtle changes in their morphological features, including metrics of area, shape, quantity, fluorescence intensity, and granularity of individual subcellular components. Based on clustering and neural network analyses, MACI was sensitve to the subtle changes in phenotype and was able to correctly delieated treated samples based on MoA. This study demonstrates that MACI offers a poteineally quick and effective framework for screening environmental chemicals, and for characterizing their complex phenotypic responses, which can be used to determine their MoAs and identify their cellular targets in plant-type organisms.

2.02.P-Th114 Effects of Imidacloprid and Deltamethrin to aquatic macroinvertebrates using a microcosm approach

Marelize Labuschagne[1], Paul van den Brink[2] and ***Victor Wepener***[3]*, (1)North-West University, South Africa, (2)Wageningen University & Research (WUR), Netherlands, (3)Water Research Group, Unit for Environmental Sciences and Management, North-West University, South Africa*

Pesticide contamination in aquatic ecosystems is a growing global concern. Pesticides are widely used to meet the food demands of a growing population, with various types used to control pests depending on the crops grown. Rainfall, overspray, and runoff from agricultural fields can wash these pesticides into water bodies, posing documented risks to the environment. This concern extends beyond regulators and the public to the industries that develop and apply these chemicals. Insecticides, in particular, are extensively applied for pest control, with over 3000 registered in South Africa alone. Pesticides can migrate from their point of application into non-target environments, leading to potentially harmful effects. Limited studies in South Africa have linked pesticide contamination to toxic impacts on aquatic and terrestrial ecosystems, with trace amounts lingering in soil and water. This study examines two widely available insecticides, deltamethrin and imidacloprid, which are moderately hazardous. This study assessed their effects to aquatic macroinvertebrates and zooplankton communities under field-realistic conditions using a microcosm approach. A microcosm is an artificially constructed test system that simulate parts of natural ecosystems. This study consisted of a 16 week exposure period where these pesticides were applied at week 0, 2, 4 and 6 and then left to see if recovery of the systems would occur. Macroinvertebrates were collected from the sediment, pebble baskets, plants and water column at week 0, 2, 4, 8, 12 and 16, while zooplankton were collected every 2 weeks from the water column. The results indicated that at higher concentrations these communities are severely impacted and that some organisms can tolerate these compounds and thrive. Even though these compounds break down rather quickly due to photolysis and cannot be quantified in the water and sediment the effects could still be seen after a long period of time.

2.02.P-Th115 Amoxicillin at Environmentally Relevant Concentrations Affects the Reproduction and Survival of the Littoral Cladoceran Simocephalus Punctatus. A Life Table Study.

Jesús Rodríguez Estrada[1] and ***Fernando Martínez-Jerónimo***[2]*, (1)Instituto Politécnico Nacional-ENCB, Mexico, (2)Escuela Nacional de Ciencias Biologicas, IPN, Mexico*

Amoxicillin (AMX) is classified as an emerging pollutant. This ß-Lactam antibiotic is used to treat and prevent bacterial infections in humans and livestock. This drug is discharged into aquatic systems through treated and untreated wastewater, hospital effluents, and the disposal of expired drugs. Currently, AMX is detected in aquatic environments in concentrations ranging from ng to µg L^{-1} in different regions worldwide; nevertheless, the harmful effects that could produce this drug in aquatic biota are scarce. Cladocerans are used as test organisms to assess the effects of pollutants in aquatic environments. *Simocephalus punctatus* is a daphnid distributed in freshwater bodies in the coastal zone. In this study, in a life table assay, S. punctatus was exposed to amoxicillin (0.1, 1, 10, and 100 µg L-1) for 21 days, starting from neonates. Daily, the released progeny (once reproduction started) and the adults' survival were recorded; the conditions of neonates were also observed. Reproductive responses were used to determine the age of first reproduction, the number of clutches, and the progeny per brood; moreover, the life table parameters GRR, Ro, G, Ex, and r were calculated. Results were analyzed with the Bootstrap method, one-way ANOVA, and *post hoc* Tukey's test. Amoxicillin adversely affected the reproduction and survival of *S. punctatus*; additionally, in the concentration of 100 µg L^{-1}, affected and dead neonates were observed (average of 4.16 and 3.96, respectively). All the life table parameters decreased significantly with the increase of amoxicillin concentration; the values of Ro ranged from 27.4 to 20.4 neonate $female^{-1}$, while the population increase rate r varied from 0.32 to 0.29 neonate $female^{-1}$ day^{-1}. The life expectancy (Ex) also diminishes from 18.3 to 17 days. The drug AMX, at environmentally relevant concentrations, produced detrimental effects on *S. punctatus*, warning about the potential impact of this drug in aquatic organisms, specifically on Cladocerans, which are an essential link in the energy transfer to high trophic levels in aquatic environments.

2.02.P-Th116 Screening of wheat lines for biological nitrification inhibition in hydroponics using a novel high-throughput experimental platform

Clara Aguilar I Vilar*, Kristian Brandt, Jasmeet Kaur Bhambra and Jonathan Sølve, University of Copenhagen, Denmark*

The increasing use of nitrogen fertilizers in modern, intensified agricultural soils has resulted in higher nitrification rates, contributing to the disruption of the nitrogen cycle in soil. Approximately 50-70% of the nitrogen fertilizer used is lost to the environment through nitrate (NO_3^-) leaching and gaseous nitrogen emissions before crop plants can uptake it. In the context of a climate change emergency and growing population, it is essential to find solutions to make agriculture more nitrogen efficient by improving nitrogen use efficiency (NUE) of crop plants. One such mitigation technique is crop plants with the ability to release biological nitrification inhibitor (BNI) compounds. This approach has been proposed to tackle N-emissions and NO_3^- leaks, benefiting both agriculture and the environment.

The aim of this study is to employ a high-throughput bioreporter nitrification inhibition assay on root exudates of various double haploid wheat lines and its parental lines grown in hydroponics, to screen for their ability to inhibit ammonia-oxidizers. The bioreporter is a recombinant strain of the ammonia-oxidizing bacterium *Nitrosomonas europaea*, containing a bacterial luciferase gene (*luxAB*). The four parental lines have been further studied using the bioreporter at different incubation time points with the respective root exudates. Additionally, molecular analysis, nitrite measurements, and cell counting using the same bioreporter will be conducted to complement and gain a better understanding of limitedly studied BNI compounds.

We observe the crossed double haploid lines to exhibit BNI capabilities similar to the parental lines. When assessing the inhibition rates over time across the four parental lines, the results suggest the potential release of different BNI compounds with diverse modes of action. However, notable variability is observed among the biological replicates which needs to be further evaluated. The study further analyses the mode of action of the BNI compounds and reaffirms the efficacy of the proposed whole-cell bioreporter as a valuable screening tool for crop plants with BNI characteristics.

2.02.P-Th117 Challenges With Ecotoxicity Testing of Surfactants: The Impact of Water Hardness on Toxicity to Algae

Sylwia Kosmala-Grzechnik *and Rhiannon Smith, wca environment Ltd., United Kingdom*

Lithium salts of monocarboxylic acids are widely used chemicals, including as lubricants in the automotive industry and hydraulic fluids, and as such, they have the potential to exhibit substantial exposure to surface waters. However, the substances are difficult to test in aquatic toxicity studies. Due to the manufacturing method, many of these substances are considered as Unknown or Variable Composition, Complex Reaction Products or Biological materials (UVCB). Also, the substances have a soap structure, and thus form stable colloidal dispersions in water, and are surfactants with limited water solubility, which consequently limits their bioavailability.

The properties of surfactants pose challenges in ecotoxicity testing when attempting to conform to required regulatory testing approaches. It is recognised that water chemistry such as pH, hardness, or dissolved organic carbon (DOC), influences the availability of surfactants to organisms. In natural surface waters, the hardness typically exceeds levels found in standard algal growth test media. The United States Environmental Protection Agency (US EPA) recommends evaluating the effects of chemicals in both standard and a modified algal growth medium with increased hardness to ensure a relevant assessment of their effects in receiving waters. However, under the EU Registration, Evaluation, Authorisation and Restriction of Chemicals (REACH) regulation non-standard testing approaches, such as changes to water chemistry, are now recommended to be avoided due to concerns that water hardness influences the bioavailability of the substances.

To address the concerns about the influence of water hardness on toxicity to algae, algal growth inhibition studies with two lithium salts of monocarboxylic acids substances were conducted following OECD 201 protocol at both standard (24 mg/L $CaCO_3$) and increased (150 mg/L $CaCO_3$) water hardness levels.

The results revealed no significant differences in toxicity of both tested substances at standard and increased test medium hardness, indicating that the standard testing approaches are sufficiently protective for algae.

These findings provide valuable insights into the impact of water hardness on the toxicity of surfactants, enhancing our understanding of their environmental behaviour and guiding future risk assessments.

Acknowledgement - The authors would like to thank the members of the European REACH Grease Thickeners Consortium for allowing the work to be shared.

2.02.P-Th118 Physiological Effects of Suspended Sediments to Macroalgae Using Pulse-Amplitude Modulation (PAM) Fluorometry

Shin Yeong Park[1]*, Inha Kwon*[1]*, Hyunseo Song*[1]*, Taewoo Kim*[2]*, Junghyun Lee*[3]*, Seo Joon Yoon*[1]*, Changkeun Lee*[4] *and Jong Seong Khim*[1]*, (1)School of Earth and Environmental Sciences & Research Institute of Oceanography, Seoul National University, Korea, Republic of (South), (2)Seoul National University of Science and Technology, Korea, Republic of (South), (3)Department of Environmental Education, Kongju National University, Korea, Republic of (South), (4)School of Earth and Environmental Sciences & Research Institute of Oceanography, Seoul National University of Science and Technology, Korea, Republic of (South)*

Suspended sediments, often found in high concentrations in the water columns due to anthropogenic activities such as aquaculture, dredging, mining, and urban development, have adverse effects on various organisms in marine ecosystems. This study aimed to assess the biological response of suspended sediments on macroalgae and to enhance bioassays using imaging-pulse amplitude modulation (PAM) fluorometry to evaluate photosynthetic performance. Ecological effects on suspended sediments were tested with various species of macroalgae including nori (*Porphyra tenera*), kombu (*Laminaria japonica*), and five-ribbed kelp (*Costaria costata*). Exposure concentrations ranged from control to 10.0 g L^{-1} of suspended sediment. Imaging-PAM fluorometry was employed to measure various endpoints: Fo, Fm, Y(II), Y(NPQ), Y(NO), qL, qN, qP, and ETR. The results revealed that nori and kombu exhibited decreased Fo with increasing suspended sediment concentrations. Notably, nori, with its thin thallus thickness, appeared to be most sensitive to suspended sediments among the species studied. The sensitivity to suspended sediment followed the order: nori > kombu > five-ribbed kelp. This highlights the higher sensitivity of red algae (nori) compared to brown algae (kombu and five-ribbed kelp) towards suspended sediments. This study confirms the impact of suspended sediments on the PSII performance of various macroalgae species. Exposure to suspended sediments in marine environments can potentially disrupt marine ecosystems by reducing food sources for upper trophic levels. These findings provide important insights for estimating suspended sediment criteria in marine ecosystems.

2.03 Assessing and Predicting the Impact of Chemical Pollution on Marine Mammals: Challenges to Be Overcome, Future Prospects, and Conservation Strategies

2.03.T-01 How to detect impact of multiple anthropogenic stressors in Mediterranean cetaceans: the first application of exposomics

Maria Cristina Fossi[1]*, Giacomo Limonta*[1]*, Matteo Baini*[1]*, Jorge Urbán-Ramírez*[2]*, Ioannis Athanassiadis*[3]*, Jonathan W. Martin*[4]*, Stefano Papazian*[5] *and Cristina Panti*[1]*, (1)Department of Physical Sciences, Earth and Environment, University of Siena, Italy, (2)Universidad Autónoma de Baja California Sur, (3)Department of Environmental Science (ACES), Stockholm University, Sweden, (4)Stockholm University, Sweden, (5)Department of Environmental Science, Stockholm University / Science for Life Laboratory (SciLifeLab), Sweden*

Concern is growing regarding hazards to Mediterranean cetaceans that simultaneously face concurrent exposure to multiple stressors, such as marine litter, climate change, as well bioaccumulation of contaminants. The main objective of this study was to apply for the first time a multi-diagnostic approach to demonstrate the use of exposomics combined with gene expression analysis for assessing the susceptibility of multiple stressors in an iconic whale species (*Balaenoptera physalus*) from the largest Specially Protected Areas of Mediterranean Importance: the Pelagos Sanctuary. Skin and blubber biopsies of fin whale were collected from the Mediterrenean Sea (n=17), and from the pristine area of the Sea of Cortez (Mexico; n=11). **Exposome profile of skin biopsies fin whale**: In blubber (GC-HRMS), 58 substances were confirmed with authentic standards (Level 1), and 120 were annotated (Level 2). In total, 41 substances were quantified, including polychlorinated biphenyls (PCBs), organochlorine pesticides, polychlorinated dibenzofurans and polybrominated diphenyl ethers. A multivariate model significantly explained the variation in chemical exposures, with levels of PCBs higher in the samples from the Mediterranean than the Sea of Cortez. Several phthalate plasticizers were also detected by GC, and often higher in Mediterranean samples. A total of 386 compounds detected in skin by LC-HRMS were annotated, of which 113 in ESI+ mode (10 Level 1) and 273 in ESI- mode (25 Level 1). Of these, 39 compounds which belonged to a priority list of emerging contaminants, ranging from industrial chemicals, pharmaceuticals, biocides, plasticizers, bisphenols, PFAS, and UV-filters. The tobacco alkaloid nicotine, and its isomer anabasine, were detected in most of the Mediterranean samples. **Correlation between transcriptomic and exposome data in Mediterranean fin whale**: The correlation of 17 marker genes and exposomic data was investigated through a partial correlation analysis using the Spearman's coefficient. Interestingly, the levels of the plastic additives monoethyl phthalate ($R2=0.73$), monomethyl phthalate ($R2=0.81$) were found positively correlated with PPARα expression; a positive correlation was observed with Aspirin as well ($R2=0.70$). In conclusion, we show a successful first application of chemical exposomics combined with gene expression analysis in cetaceans inhabiting the fragile and highly anthropized ecosystem of the Mediterranean sea in comparison to Sea of Cortez.

2.03.T-02 Associations Between Dietary Fatty Acid Tracers and Blubber PCB Concentrations in Eastern Beaufort Sea Belugas

Laura Zeppetelli-Bédard[1]*, Emily Choy*[2]*, Magali Houde*[3]*, Lisa L. Loseto*[4] *and Jonathan Verreault*[5]*, (1)Department of*

Biological Sciences, University of Quebec in Montreal (UQAM), Canada, (2)McGill University, Canada, (3)Environment and Climate Change Canada, Canada, (4)Arctic Aquatic Research Division, Fisheries and Oceans Canada, Canada, (5)University of Quebec at Montréal, Canada

The Eastern Beaufort Sea (EBS) beluga population, an important traditional food source for Inuvialuit communities in the Northwest Territories, Canada, represents a prominent Arctic odontocete species with strong associations to sea ice and varying habitat preferences based on size, sex, and reproductive status. Arctic ecosystems are undergoing rapid climate-associated change and a potential shift in diet from mainly Arctic Cod to Capelin could affect the body condition of individuals as these prey species are found at different depths and habitats in the Beaufort Sea. However, it is unclear how this climate-induced prey shift may impact the animal's exposure to environmental contaminants. The main goal of this study was to investigate the relationships between EBS beluga diet (estimated through fatty acid (FA) dietary markers) and blubber polychlorinated biphenyl (PCB) concentrations over a 22-year period. EBS beluga blubber samples (n = 166) were collected during traditional Inuvialuit harvests in the Mackenzie Estuary area (Northwest Territories, Canada) between 1995 and 2017. Specific objectives were to assess: 1) the temporal trends of PCBs in EBS beluga blubber, 2) the relationship between specific FA dietary markers (20:1n-7, 20:1n-9, 20:4n-6, 20:5n-3, 22:1n-11 and 22:6n-3) as well as principal components derived from FA signatures and blubber PCB concentrations, and 3) the impact of male size class (small or large) on PCB levels and diet. We found that blubber ∑PCB concentrations in EBS belugas increased slightly between 2003 and 2017 for smaller EBS belugas. Moreover, several monounsaturated FAs (20:1n-7, 20:1n-9, 22:1n-11) were positively correlated with ∑PCB concentrations for both small and large males, whereas certain polyunsaturated FAs (20:4n-6 and 22:6n-3) were negatively correlated with ∑PCB concentrations for both size classes. We also observed that principal components derived from FA signatures were correlated with blubber ∑PCB concentrations. These results suggest that dietary markers may be valuable predictors of PCB exposure in EBS belugas, provided that body condition must also be considered as an important confounding factor. Understanding the ramifications of these dietary changes on EBS beluga exposure to PCBs and other bioaccumulative chemicals underscores the necessity for ongoing monitoring with a focus on the interconnectedness between environmental factors, pollution and marine mammal health in the face of climate change.

2.03.T-03 Fatty Acid Carbon Isotopes as a New Approach to Assess POP and Hg Accumulation among Marine Mammals and through Food Webs in the Arctic

***Adam Pedersen**[1], Aaron Fisk[2], Bailey C. McMeans[3], Rune Dietz[4], Christian Sonne[5], Aqqalu Rosing-Asvid[6], Steven H Ferguson[7] and Melissa A McKinney[1], (1)McGill University, Canada, (2)University of Windsor, Canada, (3)Department of Biology,, University of Toronto, Canada, (4)Aarhus University, Denmark, (5)Bioscience, Aarhus University, Denmark, (6)Greenland Institute of Natural Resources, Greenland, (7)Arctic Aquatic Research Division, Fisheries and Oceans Canada, Canada*

Top predators in the Arctic show among the highest concentrations globally of major contaminants of concern, including persistent organic pollutants (POPs) and Hg. To trace these contaminants among predators and through food webs, researchers have commonly used bulk stable isotopes (SI) of nitrogen and carbon. Yet, bulk isotope approaches have notable drawbacks, mostly from spatial variation in baseline signals and overlapping isotope values of different dietary resources. Here, we instead analyzed fatty acid carbon isotopes (δ^{13}C-FA) and explored their potential to assess 1) interspecific variation in POPs among marine mammals (killer whale [*Orcinus orca*], narwhal [*Monodon monoceros*], long-finned pilot whale [*Globicephala melas]*, and polar bear [*Ursus maritimus*]) in East Greenland and 2) biomagnification of Hg in a Cumberland Sound food web from zooplankton to Greenland sharks (*Somniosus microcephalus*). Several δ^{13}C-FA values varied widely among species, while others were not significantly different. For example, δ^{13}C values of the long-chain polyunsaturated FA 22:6n3 were highest in Greenland shark in Cumberland Sound and lowest in zooplankton, and also higher in East Greenland polar bear and killer whale than pilot whale and narwhal. In contrast, the δ^{13}C values of monounsaturated FAs 20:1 and 22:1 in Cumberland Sound food webs did not differ among species, but were higher in East Greenland pilot whale and killer whale compared to narwhal and polar bear. Thus, these FAs may reflect spatial variation in δ^{13}C-FAs as pilot whale and killer whale that only feed in the Arctic seasonally. Results from generalized linear models testing the influence of δ^{13}C-FA values on contaminants relative to bulk isotopes and FAs will be presented. Preliminary results from the Cumberland Sound food web show that bulk δ^{15}N better explains Hg concentrations than δ^{13}C-22:6n3. However, δ^{13}C-22:6n3 values explain more variation in PCB-153 than bulk δ^{15}N among East Greenland predators. As such, δ^{13}C-FAs may provide unique insights into the flow of dietary lipids and lipophilic contaminants across food webs, although bulk SI approaches may still better explain contaminant accumulation for proteinophilic contaminants, such as Hg. Yet, further testing of δ^{13}C-FAs in other marine food webs system is warranted to confirm these findings.

2.03.T-04 Contaminant associated health effects revealed through a non-invasive metabolomics platform in at-risk killer whales in the Northeastern Pacific

***Tanya Brown**[1,2], Sheila Thornton[1], Xiangjun Liao[1], Lance Barrett-Lennard[3] and Adam Warner[3], (1)Fisheries and Oceans Canada, Canada, (2)Biological Sciences, Simon Fraser University, Canada, (3)Raincoast Conservation Foundation, Canada*

The *Endangered* Southern Resident killer whale (SRKW; *Orcinus orca*) population, consisting of only 73 individuals in the Northeastern Pacific, continues to experience a decline and is failing to recover due to a combination of stressors including reduced prey availability, noise and disturbance, and contaminants. Endocrine-disrupting contaminants including polychlorinated biphenyls (PCBs), polybrominated diphenyl ethers (PBDEs), and organochlorine pesticides (OCPs) are exceptionally high in the tissues of this population, which places them among the most contaminated marine mammals in the world. The ability to characterize contaminant concentrations and trends, as well as assess the health of SKRW, has been constrained by legal and ethical constraints. Here, we measured contaminant concentrations in Resident killer whale fecal samples and applied a non-invasive targeted metabolomics platform to assess the health of SRKW in relation to contaminants. This characterization of contaminants and health in SRKW was strengthened through a comparative approach with Northern Resident killer whales (NRKW), a population that feeds on similar prey and is experiencing growth. Average fecal contaminant concentrations of PCBs, PBDEs, OCPs, HBCDD, APs and Hg were significantly higher (up to 5.5-fold) in SRKWs compared to NRKW. Average percent lipid was lower in SRKW compared to NRKW. SRKW were feeding more coastally and in closer proximity to urban sources compared to NRKWs, which is consistent with their elevated contaminant concentrations. A total of 238 metabolites were quantified in killer whale fecal samples. Compared to the NRKWs, SRKW had 24 metabolites that were upregulated (10% of metabolites quantified) and 21 that were downregulated (8.8%). Several of these altered metabolites correlated with contaminant levels in these individuals. Ongoing metabolomics data analysis will identify the metabolic pathways associated with contaminant exposure and biological variables (e.g. feeding ecology, % lipid) in these at-risk killer whale populations. This noninvasive appraoch using a fecal metabolomic platform serves as an effective tool to assess the effects of contaminants on the health of free-ranging Resident killer whales. Results of this study are providing much needed information on the current levels and trends of priority contaminants in these at risk killer whale populations and the associated impacts on their health.

2.03.T-05 A Framework for Developing Harmonized Environmental Quality Guidelines for Persistent Bioaccumulative Chemicals for the Protection of Marine Mammals and Their Habitat

Brendan Eoin Hickie[1]*, Tanya Brown*[2]*, Peter Ross*[3]*, Kathleen McTavish*[4]*, Angeline Tillmanns*[5]*, Neil Dangerfield*[2] *and Juan Jose Alava*[6]*, (1)Trent University, Canada, (2)Fisheries and Oceans Canada, Canada, (3)Raincoast Conservation Foundation, Canada, (4)Environment and Climate Change Canada, Canada, (5)BC Ministry of Environment and Climate Change Strategy, Canada, (6)Ocean Pollution Research Unit, Institute for the Oceans and Fisheries, University of British Columbia, Canada*

Many jurisdictions have well established protocols to define environmental quality guidelines (EQGs) as contaminant sediment or water concentrations deemed to be protective for fish and benthos and, to a lesser extent, concentrations in prey for the protection of fish-eating birds and mammals. These have often been developed and applied separately, resulting in non-harmonized EQGs and, to the best of our knowledge, do not include consideration of long-lived apex predators, especially marine mammals. Here we outline a flexible EQG framework developed for persistent bioaccumulative (PB) chemicals that includes consideration of the complex life history of marine mammals that enables development of harmonized EQGs for sediment, water and prey to protect members of marine mammal populations deemed to be at greatest risk of adverse health effects. The framework includes two main pathways that can be used to calculate EQGs: A top-down approach starting from a toxicity reference value (TRV) for mammals that uses measured or modeled biomagnification and bioaccumulation factors, and trophic magnification factors to calculate EQGs for diet, water and sediment that align with the TRV; And a bottom-up approach that uses chemical fate and food web biomagnification models to calculate EQGs aligned with the chosen TRV. When available, empirical data are used to validate results. In this presentation we apply the framework to the case of PCBs in Canadian waters using fish-eating killer whales, beluga whales and Arctic ringed seals as representative species to be protected. Resulting EQGs calculated by either pathway yield EQGs for ΣPCBs that are lower than ones defined by the protocols currently used and show that killer whale populations are at greatest risk of adverse health effects from ambient ΣPCB concentrations. The flexibility of the framework enables its broader application to other marine mammals and less data-rich PB chemicals.

2.03.P Assessing and Predicting the Impact of Chemical Pollution on Marine Mammals: Challenges to Be Overcome, Future Prospects, and Conservation Strategies

2.03.P-Mo104 Can Amino Acid Nitrogen Isotope Analysis Provide New Insight into POP Biomagnification in North Atlantic Killer Whales?

Melissa A McKinney[1]*, Anais Remili*[1]*, Chantel Michelson*[2]*, Rune Dietz*[3]*, Christian Sonne*[4]*, Audun Rikardsen*[5] *and Aqqalu Rosing-Asvid*[6]*, (1)McGill University, Canada, (2)Acadia University, Canada, (3)Aarhus University, Denmark, (4)Bioscience, Aarhus University, Denmark, (5)Faculty of Biosciences, Fisheries and Economics, UiT The Arctic University of Norway, Norway, (6)Greenland Institute of Natural Resources, Greenland*

Biomagnification is a key characteristic used to identify persistent organic pollutants (POPs). To evaluate trophic position (TP) for assessing POP biomagnification, nitrogen stable isotopes are measured in whole (bulk) tissues or organisms. Yet, $\delta^{15}N_{Bulk}$ shows variability at the base ('source') of food webs that may confound assessments of TP and biomagnification. Instead, the $\delta^{15}N$ of individual amino acids (AAs) are increasingly used to estimate TP, as taking the ratio of 'trophic' AA(s) relative to 'source' AA(s) may reduce confounding source variation. Yet, the extent of 'trophic' or 'source' AA increases with TP appears more variable among species than first thought, particularly for high TP species. Here, we explore $\delta^{15}N_{AA}$ relative to other tracers to provide insight into TP and POP biomagnification in top predator killer whales in Greenland and Norway. Those in Greenland show higher $\delta^{15}N_{Bulk}$, suggesting that they feed at a higher TP compared to those in Norway. Killer whales in Greenland similarly show higher $\delta^{15}N_{AA}$ of 'trophic' AAs than in Norway, but this pattern is also evident for 'source' AAs. 'Source' AAs may differ due to spatial variation in baseline $\delta^{15}N$, yet non-negligible trophic discrimination of 'source' AAs in high TP organisms may also contribute. Indeed, while the difference in $\delta^{15}N_{Glx}$, an established 'trophic' AA, between Greenland and Norway is ~3.7‰, an attempt to correct for 'source' variation by comparing instead the difference between Glx and the established 'source' AA, Phe, i.e., $\delta^{15}N_{Glu\text{-}Phe}$, gives just ~0.2‰ difference between sites. Either TP differences between these killer whales is not as large as suggested by $\delta^{15}N_{Bulk}$ or typical approaches for $\delta^{15}N_{AA}$ do not suffice for this and possibly other high TP marine species. Concentrations of recalcitrant POPs are 10-fold higher in Greenland than Norway killer whales, consistent with $\delta^{15}N_{Bulk}$ and diet estimates, but not with $\delta^{15}N_{Glx\text{-}Phe}$. As POP correlations with $\delta^{15}N_{Bulk}$ are stronger than with $\delta^{15}N_{Glx\text{-}Phe}$, 'source' correction with Phe may remove not only 'source' but also 'trophic' variation. Thus, killer whale $\delta^{15}N_{AA}$ show qualitatively but not quantitatively similar patterns of 'trophic' and 'source' AAs as found for other species, and typical approaches to estimate TP using $\delta^{15}N_{AA}$ give unreasonable results that do not well explain POP variation. Basic studies on AA discrimination in high TP species and through marine food webs are needed to further evaluate this new approach.

2.03.P-Mo105 Unveiling Contaminant Exposure Patterns in Cetaceans from Madeira Island: Insights into Phthalates and Fatty Acid Markers

Annalisa Sambolino[1,2,3]*, Filipe Alves*[1]*, Marta Rodriguez*[1]*, Mieke Weyn*[1]*, Rita Ferreira*[1]*, Ana Mafalda Correia*[4,5]*, Massimiliano Rosso*[6]*, Manfred Kaufmann*[2,4]*, Nereida Cordeiro*[3,4] *and Ana Dinis*[1]*, (1)MARE - Marine and Environmental Sciences Centre, ARNET - Aquatic Research Network, ARDITI - Regional Agency for the Development of Research, Technology and Innovation, Portugal, (2)Faculty of Life Sciences, University of Madeira, Portugal, (3)Faculty of Exact Sciences and Engineering, University of Madeira, Portugal, (4)CIIMAR-Interdisciplinary Centre of Marine and Environmental Research, Portugal, (5)FCUP-Faculty of Sciences, University of Porto, Portugal, (6)International Center for Environmental Monitoring - CIMA Research Foundation, Italy*

Plastic additives, such as phthalates, are pervasive pollutants in aquatic environments, with concerning impacts on the health of marine life and the integrity of ecological systems. Monitoring key indicator species, such as cetaceans (e.g., dolphins and whales), can provide valuable information on the state and vulnerability of marine ecosystems. To investigate the interconnections among trophic niches (epipelagic vs. mesopelagic), contaminant levels, and individual health conditions, fatty acid profiles and phthalates were studied in blubber samples from two delphinids (short-finned pilot whale – Globicephala macrorhynchus; common bottlenose dolphin – Tursiops truncatus) on a remote island system. A multivariate study of chosen dietary fatty acids indicated niche segregation between the two species. An innovative method was developed and applied to detect and quantify phthalates in fresh cetacean blubber from biopsy samples. Out of the seven phthalates analyzed, the most encountered were di-n-butylphthalate (DBP), diethyl phthalate (DEP), and bis(2-ethylhexyl) phthalate (DEHP), with DEHP having the highest concentration (4697.34 ± 113.45 ng/g) in a bottlenose dolphin. Phthalate concentrations differed between the two species (Mean ∑ PAEs: 947.56 ± 1558.34 ng/g in bottlenose dolphin, 229.98 ± 158.86 ng/g in pilot whale), with bottlenose dolphins mainly affected by higher concentrations of DEHP, and pilot whales by DEP and DBP. Health biomarkers indicated potential physiological challenges in pilot whales, although fatty acid profiles also revealed notable metabolic variations between the two species. No significant differences were observed in phthalate levels across ecological or biological groups, seasons, or years. This pioneering study examines the prevalence of plastic additive contamination in free-ranging cetaceans off Madeira Island, emphasizing the intricate interplay between ecological niches and contaminant exposure. Vigilant monitoring of these chemicals and their potential impacts is crucial to evaluating wild populations' health, guiding conservation efforts, and safeguarding critical species and habitats.

2.03.P-Mo106 Legacy POPs contaminant variation among cetaceans inhabiting the historically contaminated Gulf of St Lawrence, Canada

Anais Remili[1]*, Melissa A McKinney*[2]*, Steve Ferguson*[3]*, Michelle Caputo*[4] *and Jeremy J Kiszka*[4]*, (1)Department of Natural Resource Sciences, McGill University, Canada, (2)McGill University, Canada, (3)Fisheries and Oceans Canada, Canada, (4)Department of Biological Sciences, Florida International University*

Historical contamination in the Gulf of St Lawrence, resulting from industrial discharges in the North American Great Lakes region, has led to the accumulation of persistent organic pollutants (POPs), including polychlorinated biphenyls (PCBs) and organochlorine pesticides (OCs), particularly in marine mammals. However, the accumulation of POPs in cetaceans feeding in the Gulf and adjacent downstream waters remains poorly known, fifty years after their ban. Here, we quantify PCB and OC concentrations in six species (n = 48) of cetaceans in the Gulf of St Lawrence from 2015 to 2022. Knowledge on differential exposures between cetacean species will be useful for more targeted conservation strategies in Eastern Canada. ∑PCB concentrations were highest in killer whales (*Orcinus orca*), at 101.6 ± 32.9 mg/kg lw, followed by other toothed whale species, then baleen whale species, with lowest concentrations in humpback whales (*Megaptera novaeangliae*) at 1.0 ± 0.4 mg/kg lw. For OCs, similar patterns were observed, with killer whales having by far the highest concentrations, followed by toothed whales then baleen whales. Previous diet analyses have estimated that killer whales feed on baleen whales which would explain their elevated levels. While PCB and OC concentrations are lower in humpback whales and dolphins than concentrations measured in the 1990s, these compounds remain extremely high and above thresholds for risks of reproductive failure in killer whales. Contaminant profiles showed that common dolphins (*Delphinus delphis*) and killer whales had a high percentage of highly-chlorinated PCBs, such as CB-138, -180, -183 and -187, compared to baleen whales, for which CB-49, -52, -101 and -110 were the dominant compounds. For OC profiles, common dolphins and killer whales showed the highest percentages of DDE and *trans*-nonachlor, while baleen whales showed higher percentages of hexachlorobenzene and DDT. Elevated DDT proportions in baleen whales could represent a recent exposure to DDTs, as DDT is still being used for pest control in some countries. This represents the first study to quantify PCBs and OCs in such a broad range of cetacean species in the Gulf of St Lawrence. Future efforts will attempt to assess the impact of the species' feeding habits (through correlations with stable isotopes and fatty acids as tracers), to provide a more comprehensive understanding of contaminant accumulation among cetaceans inhabiting this historically contaminated area.

2.03.P-Mo107 Identification of potential impacts of an elevated and long-term exposure to POPs on the endangered beluga (Delphinapterus leucas) population from the St. Lawrence Estuary using transcriptomics

Antoine Etienne Simond, PhD[1], *Véronique Lesage*[2], *Jonathan Verreault*[3], *Lisa L. Loseto*[4], *Magali Houde*[5], *Ashley Elliott*[6], *Marie Noel*[7] *and Tanya Brown*[6], *(1)Simon Fraser University, Canada, (2)Maurice Lamontagne Institute, Fisheries and Oceans Canada, Canada, (3)University of Quebec at Montréal, Canada, (4)Arctic Aquatic Research Division, Fisheries and Oceans Canada, Canada, (5)Environment and Climate Change Canada, Canada, (6)Fisheries and Oceans Canada, Canada, (7)Ocean Wise Conservation Association, Canada*

The St. Lawrence Estuary (SLE) beluga whale (*Delphinapterus leucas*) population in Canada is endangered. It has been postulated that exposure to elevated concentrations of polychlorinated biphenyls (PCBs), chlorinated pesticides, polybrominated diphenyl ethers (PBDEs), and emerging halogenated flame retardants (HFR) might be contributing to the decline of this population. Concentrations of PCBs, chlorinated pesticides and emerging HFRs in SLE male beluga blubber were shown to correlate with skin transcript levels of genes coding for nuclear receptors and proteins involved in the regulation of thyroid and steroid hormones as well as the metabolism of xenobiotics. A growing number of studies investigating contaminant exposure-related effects in cetaceans rely on "*omics*" methods such as transcriptomics, as these approaches require small amounts of tissue and are amenable to multiple analyses, yielding a maximum of biological information. To develop new transcriptomic health assessment tools to evaluate and understand the biological effects of contaminants in the endangered SLE beluga population, we compared transcriptomic skin profiles between adult male SLE belugas and Eastern Beaufort Sea (EBS) belugas (reference population). Being exposed to dramatically different levels of contaminants, the comparison of transcript profiles will allow to shed some light on specific genes and pathways affected by the exposure to organic contaminants. Total RNAs were isolated from skin samples of adult male belugas from the SLE (n = 35) and EBS (n = 29) and PCBs, PBDEs and emerging flame retardants were measured from their blubber. A total of 3,438 genes were upregulated, and 1,005 were downregulated in SLE belugas compared to EBS belugas. Among the metabolic pathways involved, several may be the results of epigenetic changes related to differences of exposure levels to PCBs, PBDEs and hexabromobenzene between these populations (e.g., regulation to reactive oxygen species, structural constituent of chromatin**,** cellular response to chemical and organic substances, immune system). These results represent a major advance in the identification and understanding of the impacts that long-term exposure to high levels of POPs have on the SLE beluga population. However, it remains difficult to know whether these observed effects remain specific to the skin, or whether they are an indication of a deeper disruption affecting the entire organism.

2.03.P-Mo108 Assessment of Polycyclic Aromatic Hydrocarbon (PAH) Exposure, Sources, and Maternal Transfer in Threatened Killer Whales (Orcinus orca) of the Northeastern Pacific Ocean (Canada)

Kiah Lee[1,2], *Stephen Raverty*[3,4], *Paul Cottrell*[5], *Zeinab Zoveidadianpour*[3], *Brendan Cottrell*[6], *Dana Price*[3] *and Juan Jose Alava*[3,7], *(1)University of Oslo (UiO), Norway, (2)Ocean Pollution Research Unit, Institute for the Oceans and Fisheries, University of Oslo (UiO), Norway, (3)Ocean Pollution Research Unit, Institute for the Oceans and Fisheries, University of British Columbia, Canada, (4)Animal Health Centre, British Columbia Ministry of Agriculture, Food, and Fisheries, Canada, (5)Fisheries and Aquaculture Management, Fisheries and Oceans Canada (DFO), Canada, (6)Applied Remote Sensing Lab, Department of Geography, McGill University, Canada, (7)School of Resource and Environmental Management, Simon Fraser University, Canada*

The northeastern Pacific (NEP) Ocean spans the coast of British Columbia, Canada, and is considered impacted by anthropogenic activities including oil pipeline developments, maritime fossil fuel tanker traffic, industrial chemical effluents, urban wastewater discharges, and forest fires. Such events may expose surrounding marine environments to toxic polycyclic aromatic hydrocarbons (PAHs) and impact critical habitats of threatened killer whales (*Orcinus orca*). We analyzed skeletal muscle and liver samples from stranded Bigg's (Transient) killer whales and endangered Southern Resident killer whales (SRKWs) for PAH contamination using low-resolution mass spectrometry (LRMS). C3-phenanthrenes/anthracenes (mean: 632 ng/g lw), C4-dibenzothiophenes (mean: 334 ng/g lw), and C4-phenanthrenes/anthracenes (mean: 248 ng/g lw) presented the highest concentration across all tissue samples. Diagnostic ratios indicated pyrogenic-sourced burdens for Bigg's killer whales and petrogenic-sourced contamination for SRKWs; differences between ecotypes may be attributed to habitat range, prey selection, and metabolism. A SRKW mother-fetus skeletal muscle pair provided evidence of PAH maternal transfer; low molecular weight compounds C3-fluorenes, dibenzothiophene, and naphthalene showed efficient and preferential exposure to the fetus. This indicates *in-utero* exposure of PAH-contamination to the fetus. Our results show that hydrocarbon-related anthropogenic activities are negatively impacting these top predators; preliminary data found here can be used to improve oil spill and other PAH pollution management and regulation efforts, and inform policy to conserve killer whale NEP habitats.

2.03.P-Mo109 Trace element concentrations in dolphins of south-east Australia show elevated mercury concentrations for bottlenose dolphins

Dayanthi Nugegoda and ***Chantel Sarah Foord***, *School of Science, RMIT University, Australia*

Among Cetaceans, trace elements have been linked to serious health issues such as neurological and reproductive disorders, immunosuppression, and in some cases leading to mortality.

In the south-east of Australia, trace element toxicology has traditionally focused on sediments and water, with biological studies centered on fish, mollusks, and penguins. Earlier investigations revealed exceptionally high mercury concentrations in stranded Burrunan dolphins (*Tursiops australis*) sampled between 2004-2008, surpassing those in well-known compromised

waterways like the Mediterranean. This raised questions about whether other dolphins in the region share similar trace element burdens or if this phenomenon is species-specific.

This study presents trace element concentrations in three dolphin species: the Burrunan dolphin, short-beaked common dolphin (*Delphinus delphis*), and the common bottlenose dolphin (*Tursiops truncatus*). Species-specific differences emerged, with both Burrunan and common bottlenose dolphins exhibiting higher hepatic (641 ± 1,405 mg/kg, 730 ± 655 mg/kg, respectively) and renal (56 ± 46 mg/kg, 60 ± 33 mg/kg, respectively) mercury (Hg) levels than short-beaked common dolphins (hepatic; 144 ± 110 mg/kg, renal; 17 ± 14 mg/kg). This was found to be significant for renal tissues ($p<0.05$).

Conversely, short-beaked common dolphins displayed significantly higher concentrations of arsenic (As) in both hepatic (2.2 ± 1.2 mg/kg) and renal tissues (1.5 ± 0.8 mg/kg), as well as renal cadmium (Cd) compared to Burrunan (hepatic As; 0.9 ±0.8 mg/kg, renal As; 0.4 ± 0.3 mg/kg, renal Cd; 25 ± 28 mg/kg) and common bottlenose (hepatic As; 0.92 ± 0.4 mg/kg , renal As; 0.53 ± 0.5 mg/kg, renal Cd; 13 ± 7.5 mg/kg) dolphins.

Burrunan and common bottlenose dolphins in this region exhibit among the highest mercury (Hg) concentrations globally, with only three studies reporting higher hepatic Hg in dolphins. Additionally, mercury-to-selenium (Hg:Se) ratios raise concerns, as almost all adults surpass the 1:1 molar ratio threshold for hepatic toxicity concentrations.

The elevated Hg levels observed across species in the region, combined with the accumulation of Hg and Cd, pose potential concerns. Hg:Se ratios above one for most adults suggest a diminished ability to mitigate the toxic effects of mercury. This study emphasizes the necessity of ongoing monitoring and understanding trace element burdens in marine mammals to preserve both these species and the broader ecosystem.

2.03.P-Mo110 Twenty years of temporal trend assessment for regulatory contaminants in common dolphins (Delphinus delphis) from French Atlantic waters

Paula Mendez[1,2]*, Tiphaine Chouvelon*[3]*, Florence Caurant*[4]*, Matthieu Authier*[4] *and Jérôme Spitz*[2]*, (1)Observatoire Pelagis, France, (2)Observatoire Pelagis Université de La Rochelle/CNRS, France, (3)IFREMER, France, (4)Observatoire Pelagis, La Rochelle Université, France*

Marine mammals may act as sentinel species for monitoring long-term trends in chemical contaminant exposure of the marine environment. Indeed, they are long-lived species that often occupy high trophic positions, making these species integrative and reliable indicators of environmental pollutant pressure, especially for bioaccumulating and biomagnifying contaminants. Here, the temporal trends of regulatory contaminants were analysed in the most abundant and hence representative cetacean species of French Atlantic waters, the common dolphin (Delphinus delphis), over a nearly twenty-years period (2000-2019). Moreover, this species is subject to high rates of bycatch in fishing nets in the area, which adds to the chemical pressure.

The aim of this assessment was to evaluate the temporal variations in contaminant levels in common dolphins in order to set the base for the development of an indicator of chemical pollution in marine predators from French waters. Three toxic trace elements (Hg, Cd and Pb) and seven classes of persistent organic pollutants (POPs: polychlorinated biphenyls, dichlorodiphenyltrichloroethanes, polybrominated diphenyl ethers, hexachlorobenzene, hexachlorocyclohexanes, chlordanes and mirex) were studied using dynamic linear models, for a total of 201 dolphins stranded along the French Atlantic coasts. Temporal trends were estimated taking into account the age, the gender and stable isotope ratios of carbon ($\delta^{13}C$) and nitrogen ($\delta^{15}N$) measured in individuals, as proxies for their feeding ecology. The results showed that Pb concentrations in dolphins decreased over time, probably following the lead petrol regulation after the 2000s. In contrast, increasing concentrations were observed for total Hg and Cd. For POPs, all classes analysed showed decreasing trends, with the exception of hexachlorobenzene. As molecules regulated by the Stockholm Convention, these results are in line with what would be expected and with most of the literature for POPs. The identification of temporal variations in concentrations in these sentinel species validates the use of these trends (i.e. relative values of concentrations) as a contamination indicator of the marine environment.

2.03.P-Mo111 Relationships among Mercury Concentrations, Sea Surface Temperature, and Survival in Steller Sea Lion Pups in the Aleutian Islands, Alaska

Lorrie Rea[1]*, Amanda J. Warlick*[2]*, Stephanie Crawford*[3]*, Brian S. Fadely*[2]*, Tom S. Gelatt*[2]*, Todd O'Hara*[4] *and Kim Raum-Suryan*[5]*, (1)Institute of Northern Engineering, University of Alaska Fairbanks, (2)Marine Mammal Laboratory, NOAA Fisheries, (3)University of Alaska Fairbanks, Institute of Northern Engineering, (4)Texas A&M University, (5)NOAA Fisheries*

Although many Steller sea lion (*Eumetopias jubatus*) metapopulations within the endangered western Distinct Population Segment have stabilized or begun to recover after a dramatic population decline in the 1970–90's, some rookeries in the western and central Aleutian Islands continue to decline. To examine mercury/contaminants as potentially contributing to these divergent trends in abundance, we examined spatio-temporal patterns in mercury concentration and direct effects on survival probabilities. Lanugo (natal fur) samples collected from pups on Agattu Island (western Aleutian Islands) over 8 breeding seasons between 2011-2022 (n=389) showed a broad range of [THg] (2.55–73.74 µg/g dw). We identified a significant doubling in median [THg] in the lanugo of pups over this brief period from 8.0 µg/g in 2011 to 19.7 µg/g in 2022 (Kruskal-Wallis $H=54.56$, $p<0.001$). The proportion of pups sampled on Agattu Island with lanugo [THg] above 20 µg/g THg (threshold of concern) increased more than twofold from 21% in 2011 to 48% in 2022. To elucidate potential correlations between [THg] in lanugo and survival probabilities, we used [THg] from those pups permanently marked at birth and subsequently resighted as an individual-based covariate in a mark-resight framework. During the study period, localized September sea surface temperature fluctuated in the western Aleutian Islands with the lowest average temperatures seen early in the decade between 2010-2012 (8.9 ± 0.2 °C), peak fall temperatures over 11°C found in 2015 and 2018, and mean fall temperatures of 9.8 ± 0.2 °C between 2020-2022. Preliminary results indicate that lanugo [THg] above 10 μg/g was weakly positively correlated with pup and yearling sea lion survival over the study period in some metapopulations, though larger sample sizes are needed to elucidate region- and sex-specific effects with greater certainty. We discuss potential mechanisms for these results and outline ongoing efforts to maximize the utility of available data to examine the potential effects of this and other contaminants on this endangered top predator.

2.03.P-Mo112 True seals as bioindicators of emerging pollution in the Northeast Atlantic Ocean

***Marianna Pinzone**[1], Laurine Marchand[2], Rune Dietz[3], Thierry Jauniaux[2], Paula Mendez[4], Erling Nordøy[5], Heli Routti[6], Ursula Siebert[7] and Krishna Das[2], (1)FOCUS RU, University of Liège, Belgium, (2)University of Liège, Belgium, (3)Department of Ecoscience, Aarhus University, Arctic Research Centre (ARC), Denmark, (4)Observatoire Pelagis, France, (5)The Arctic University of Norway (UiT), Norway, (6)Norwegian Polar Institute, Norway, (7)University of Veterinary Medicine Hannover, Germany*

Amidst the ongoing global energy transition, demand for Critical Raw Materials (CRMs) employed in strategic sectors such as renewable energy and digital technologies is surging. However, knowledge gaps exist regarding the trophic transfer and toxicological effects of CRMs on marine biota. True seals being long-lived and coastal predators that are widely distributed across the Northeast Atlantic, serve as ideal bioindicators for assessing pollution levels within marine food webs.

This study quantifies the concentrations of 21 CRMs in muscle and liver tissues from six seal species: the harp seal *Pagophilus groenlandicus*, hooded seal *Cystophora cristata*, ringed seal *Pusa hispida* and bearded seal *Erignatus barbatus* from European Arctic waters, and the grey seal *Halichoerus grypus* and harbour seal *Phoca vitulina* from the Southern North Sea and the Channel (OSPAR Region II). Using Inductively Coupled Plasma Mass Spectrometry (ICP-MS), we detected CRMs, including REEs, Li, V, Mn, Co, Ni, Cu, Y, Ta, Ga, Sn, Sb, Tl, and U in 103 muscle and 110 liver samples from adult seals. Principal Component Analysis (PCA) and Redundancy Analysis (RDA) were utilized to encapsulate CRM concentration variability and to identify influential factors such as species, sampling area, and tissue type.

Findings reveal the presence of all CRMs across each species and tissue, with concentrations varying from as low as 0.00004 $mg.kg^{-1}$ dw (U in muscle) to 161$mg.kg^{-1}$ dw (Cu in liver). Tissue type emerged as a primary factor influencing CRM variability, with the liver being notably more contaminated, except for Li, which was more concentrated in muscle ($F = 255$, $p < 0.01$). PCA results indicates that REEs primarily contributed to the variability along PC1(39%). Seals from the Greenland Sea exhibited higher concentrations of REEs (Mean ∑REEs: 0.27$mg.kg^{-1}$ dw) compared to their North Sea counterparts (∑REEs: 0.07$mg.kg^{-1}$ dw). Additionally, significant interregional and interspecific variability influenced by sex was observed, with males presenting higher CRM levels ($F= 4.716$, $p = 0.001$).

The study highlights tissue specificity and potential intersex trophic differences as major contributors to CRM variability, laying the groundwork for developing pollution indicators. These insights are pivotal for the initiatives of the Convention for the Protection of the Marine Environment of the North-East Atlantic (OSPAR Convention) to prevent and regulate marine pollution by emergent contaminants.

2.03.P-Mo113 Contaminant Burden of Stranded Sentinels - The Case Studies for Lulu and Spike

***Rebecca von Hellfeld**[1], Christoph Gade[1], Mariel ten Doeschate[2], Nicholas Davison[2], Andrew Brownlow[2], Lenka Mbadugha[1], Astley Hastings[1] and Graeme Paton[1], (1)School of Biological Sciences, University of Aberdeen, United Kingdom, (2)University of Glasgow, United Kingdom*

Although recent years have seen conventions and regulations implemented to protect ecosystems from pollution, the effect of e.g., legacy contaminants remain a threat to wildlife. Heavy metals, such as mercury, continue to be released from both natural and anthropogenic sources and are ubiquitously present in the environment. They bioaccumulate in marine wildlife and biomagnify through the foodweb, with the potential to cause irreversible damage to organism health. Top predators, such as some marine mammal species, are thus at increased risk of contamination. It has been accepted that the prevalence and persistence of pollutants in marine ecosystems can be approximated from pollutant levels in marine mammal tissues, making them ecosystem sentinels. An understanding of the contaminant burden and health status of these animals may provide a more holistic insight into the ocean’s status.

We measured the concentrations of 9 analytes (mercury, methylmercury, arsenic, cadmium, copper, lead, nickel, selenium, and zinc) in tissue samples from 15 marine mammal species that stranded along the Scottish coastline between 2015 and 2022 using ICP-MS and TDA-AAS. The samples were provided by the Scottish Marine Animal Stranding Scheme (SMASS). Our results indicate an organ-dependent trend for some of the analytes, although animals of the same species accumulated vastly different amounts of contaminants. Alongside overall trends, we will showcase two animals, Spike the bottlenose dolphin and Lulu the Orca. Spike’s samples were used to test various high-throughput methods we adapted for mercury speciation assessment. As bottlenose dolphins are under protection, insights into their heavy metal contamination and overall health are vital for their conservation. Lulu's samples were also analysed for e.g., PCBs by other researchers, and can thus be used to highlight the life-time contaminant accumulation.

Our findings have highlighted that while overall trends in contaminant accumulation in trop marine predators can be observed, more focus must be placed on understanding individuals and processes involved. Vulnerability factors must be better quantified in order to guide future protection and conservation measures.

2.04.A Bridging the Gap between Exposure, Ecotoxicology and Ecology – Identifying and Regulating the Impact of Chemical Pollution on Biodiversity

2.04.A.T-01 Indirect Antimicrobial Effects in Aquatic Food Webs – Using Heterotrophic Pathways as a Model

Alexander Feckler[1]*, Frederik Meyer*[2] *and Mirco Bundschuh*[3]*, (1)Rhineland-Palatinate Technical University Kaiserslautern-Landau (RPTU), Germany, (2)University of Kaiserslautern-Landau (RPTU), Germany, (3)Institute for Environmental Sciences, RPTU Kaiserslautern-Landau, Germany*

Many registered chemicals enter freshwater ecosystems, potentially affecting ecosystem functions. One crucial function is the decomposition of leaf litter, contributing substantially to the energy supply in aquatic food webs. This function is achieved by microbial decomposers and macroinvertebrate detritivores. Antimicrobially active chemicals can affect leaf-associated decomposers, specifically bacteria and fungi, leading to indirect effects on higher trophic levels by altering litter quality for detritivores. These indirect effects are currently not considered in environmental risk assessment, although potentially propagating along the food web and beyond the borders of aquatic ecosystems. Changes in the leaf-associated microbial community composition have been associated with alterations in leaf consumption across major detritivore taxa. For instance, amphipods and caddisfly larvae avoided fungicide-exposed leaf material when control leaves were provided as alternatives. This avoidance behavior resulted from the dominance of unpalatable fungal species within the leaf-associated microbial community. Contrary effects have been observed with substances having an antibiotic mode of action. In this case, *G. fossarum* preferred leaf litter exposed to antibiotics over control leaf litter, likely due to the competitive release of fungi resulting from antibiotic effects on bacteria, leading to higher fungal growth and diversity. Persistent consumption of low-quality leaf litter can have lasting effects on detritivore physiology. Consequently, these effects may lead to further consequences along the food chain, including alterations in fine particulate organic matter production and reduced secondary production, which has been observed in multiple studies. Furthermore, fungicides and antibiotics can induce indirect effects on detritivore physiology by altering the gut microflora, reducing efficiency in nutrient and energy assimilation. This reduced efficiency could impact detritivore growth and reproduction, potentially having long-term adverse effects on leaf litter decomposition. Finally, the effects of fungicides taken up by trees on leaf litter quality and microbial interactions have not been extensively studied, but initial findings suggest indirect effects on detritivores through altered leaf quality. Considering these indirect effects during chemical testing will help safeguard ecological integrity within aquatic ecosystems and beyond their boundaries.

2.04.A.T-02 The mesocosm HeMHAS: A novel non-forced system to integrate the ecosystems' structural and functional changes due to contaminants in a multispecies scenario

Mohammed Ariful Islam[1,2]*, David Salvatierra*[1]*, Andrea Cordero-de-Castro*[1]*, María del Pilar Gonzalez Muñoz*[1]*, Rajaa Kholssi*[1]*, Ilaria Cecconi*[1]*, Ignacio Moreno-Garrido*[1]*, María Úbeda-Manzanaro Crespo*[1]*, Julian Blasco*[1] *and Cristiano Araújo*[1]*, (1)Institute of Marine Sciences of Andalusia, Spanish National Research Council (ICMAN-CSIC), Spain, (2)Sylhet Agricultural University, Bangladesh*

Although the forced exposure system has shown its usefulness for establishing the relationship between exposure and effects, it lacks ecological relevance for motile organisms (as many organisms can move out from contamination) and when contamination is not homogeneously distributed. To address these limitations, Mesocosm HeMHAS (Heterogeneous Multi-Habitat Assay System), a novel system, was constructed to assess the structural and functional changes in a community resulting from exposure to contaminants, while considering the complex ecological scenarios of heterogeneous landscapes. Copper concentrations (0, 1, 10, 100, and 250 µg/L) were chosen as a case study due to their reported presence in estuarine and marine ecosystems. Species belonging to different trophic levels: fish (*Sparus aurata*), shrimps (*Palaemon varians*) and three different classes of marine microalgae (*Isochrysis galbana*, *Nannochloropsis gaditana* and *Tetraselmis chuii*) were used as test organisms. Motile fish and shrimp were used to assess contamination-driven habitat selection, while sessile microalgae represented toxic effects on non-mobile species. Other species as *Artemia* sp., macroalgae and macrophytes were also introduced into the system as environmental enrichment. All species were distributed across five interconnected mesocosm compartments for 24 h, with three replications. Results revealed that fish and shrimps selected habitats where copper concentrations were not higher than 1 µg/L (24 h-AC_{50}: 4.88 µg/L) and 50 µg/L (24 h-AC_{50}: 136.58 µg/L), respectively. The lower avoidance of shrimp was linked to a balance between predation risk and exposure to contaminants. The study suggested that species' habitat selection against contaminants may vary based on interspecies interactions, potentially jeopardizing population persistence. Among the non-mobile organisms, the growth of *I. galbana* was more sensitive (growth reduction of 50%). The nutrient uptake was only rapid for ammonium. The mesocosm HeMHAS should be considered as a complementary tool in ecological risk assessment studies as it provides complex scenarios of interconnected disturbed habitats for higher ecological relevance and a broader assessment of stressor effects. From a Stress Ecology perspective, mesocosm HeMHAS

identifies how contaminants, besides their continuous toxicity, stress organisms and disturb habitat selection, affecting the spatial distribution of biodiversity.

2.04.A.T-03 Progress in the Application of Non-Invasive Targeted Environmental DNA (eDNA) Methods for Enhanced Confidence in Risk Assessments and Evaluation of Mitigation and Remediation Effectiveness

***Caren C. Helbing**[1], Michael Allison[2], Mark Louie Lopez[2], Jacob Imbery[2], Julie Couillard[3], Matthew Bonderud[2], Neha Acharya-Patel[2], Anna H. Dema[2], Lauren Coombe[4], Cecilia L. Yang[4], Tuan Anh To[3], Rene L. Warren[4], Inanc Birol[4,5] and Valerie S Langlois[3], (1)Department of Biochemistry and Microbiology, University of Victoria, Canada, (2)University of Victoria, Canada, (3)Institut national de la recherche scientifique (INRS), Canada, (4)Michael Smith Genome Sciences Center, Canada, (5)Pathology & Laboratory Medicine, University of British Columbia, Canada*

Environmental DNA (eDNA), genetic material released by organisms into the environment, can provide rapid, non-destructive, accurate population distribution and biodiversity information. Within the context of ecotoxicology, eDNA methods can provide critical field data related to complex mixture and chronic, sublethal exposure impacts. Moreover, mitigation and remediation effectiveness can be readily assessed without disturbing at-risk species or their habitats. However, poorly performing tools hinder broad adoption of eDNA-based detection methods, due in part to their associated high false negatives and false positives that can impair effective management decision-making. We therefore addressed workflow issues associated with targeted eDNA assay design to help improve user confidence in the approach. We focused on targeted quantitative real time polymerase chain reaction (qPCR)-based eDNA assays as a highly accessible and mature technology. Yet, several challenges remain to analyze environmental samples for eDNA. These include effective identification of unique regions of target taxon mitochondrial DNA conducive to high quality assay design. This is best accomplished with full mitogenome sequences of target and relevant non-target taxa. However, there is a significant gap in publicly available resources, including mitogenome sequences, especially from multiple voucher specimens living in each environment. It is often extremely difficult to obtain these specimens, let alone obtain high quality DNA from them. To address this, we created a protocol for amplifying small amounts of DNA suitable for whole genome shotgun sequencing. The resulting sequencing reads can then be assembled using *mtGrasp*, a utility we developed for reference-grade mitogenome sequence assembly. The full mitogenome sequences from target and non-target taxa are processed by *unikseq*, a utility we developed for the identification of unique DNA sequence regions for specific qPCR primer and probe design within a target taxon compared to non-target taxa. Primers and probes are empirically validated to ensure they meet or exceed the qPCR-based assay performance criteria as established by the recently released CSA W219:23 national Canadian standard. Through use-case examples, we demonstrate the efficacy of this approach for application of eDNA methods in environmental surveys. *mtGrasp* and *unikseq* are freely available as software repositories at https://github.com/bcgsc.

2.04.A.T-04 Micro-pollutant Biotransformation in Field-collected Fish: Implications for Species-specific Sensitivity to Chemical Pollution

***Marco Enrique Franco**[1], Juliane Hollender[2] and Kristin Schirmer[1], (1)Environmental Toxicology, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (2)Environmental Chemistry, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland*

Among the multiple biological processes that are triggered in response to chemical exposure, biotransformation pathways are key in supporting detoxification and the elimination of xenobiotics. However, while biotransformation-related genes are often conserved among species, their inducibility and translation to enzymatic activity in relation to species sensitivity to pollution remains understudied. Environmental and anthropogenic factors such as pollution level may also alter biotransformation activity and the ability of species to cope with chemical exposure. Thus, in the present study, fish species that are representatives of Swiss biodiversity assemblages were collected in watercourses with different levels of pollution and surrounded by different land use. Liver S9 enzymatic fractions were isolated and comparative assessments were conducted to assess enzymatic activity and biotransformation rates of different pharmaceuticals and pesticides. Among species, brown trout (*Salmo trutta*) displayed the highest activity for the enzymes CYP1A and Glutathione-S-transferase, particularly in sites with high levels of anthropogenic influence. However, the invasive species pumpkinseed (*Lepomis gibbosus*) presented significant activity of other biotransformation enzymes, like CYP3A4, and the highest intrinsic clearance and biotransformation product formation of most of the micro-pollutants tested. On the other hand, bottom-dwelling species, like the European bullhead (*Cottus gobio*) and the common barbel (*Barbus barbus*), displayed the lowest enzymatic activity and micro-pollutant biotransformation. These observations underline biotransformation processes as major indicators of species sensitivity, making them an important consideration when evaluating the role of chemical pollution in altering the biodiversity of aquatic ecosystems.

2.04.B Bridging the Gap between Exposure, Ecotoxicology and Ecology – Identifying and Regulating the Impact of Chemical Pollution on Biodiversity

2.04.B.T-01 Synthetic Chemicals as a Cause of Biodiversity Loss

***Iris Pit**[1], Annemarie van Wezel[2] and Anna Sobek[3], (1)Stockholm University, Sweden, (2)University of Amsterdam, Institute for Biodiversity and Ecosystem Dynamics (IBED), Netherlands, (3)Environmental Science, Stockholm University, Sweden*

Industrial and agricultural discharges cause European rivers to be exposed to mixtures of synthetic chemicals. It is unclear to what extent biodiversity is being affected by the cocktail effect of chemicals. The current mandatory Water Framework Directive’s (WFD) monitoring schemes fail to accurately quantify if pollution results in insufficient ecological status, where

biological parameters for assessing ecological status are not related to chemical exposure. Although knowledge is lacking, the EU Biodiversity Strategy for 2030 acknowledges pollution as a key driver of biodiversity loss. In this project, the limited knowledge of how biodiversity is affected by chemicals will be addressed through an eco-epidemiology study in which ecology and ecotoxicology are integrated. Modelled mixture toxicity pressure from 1760 synthetic compounds will be linked to available macro-invertebrate field data present in European rivers. The results will reveal to what degree and which synthetic chemicals are responsible for biodiversity loss, which will be used to help improve the implementation of WFD. The ambition is to strengthen the bridge between scientific evidence and water management policies to help create a toxic-free environment.

2.04.B.T-02 From Ecotoxicology to Ecology: Changes in Macroinvertebrate Communities Along a Toxicity Gradient

Sebastian Heß[1,2]*, Delia Lara Hof*[3]*, Matthias Oetken*[3] *and Andrea Sundermann*[2,4]*, (1)Department of River Ecology and Conservation, Senckenberg Research Institute and Natural History Museum Frankfurt, Germany, (2)Institute of Ecology, Evolution and Diversity, Goethe University Frankfurt, Germany, (3)Aquatic Ecotoxicology, Goethe University Frankfurt, Germany, (4)River Ecology and Conservation, Senckenberg Research Institute and Natural History Museum Frankfurt, Germany*

Water pollution is one of the major stressors to freshwater ecosystems with significant inputs of nutrients and micropollutants such as trace metals, industrial chemicals, pesticides and pharmaceuticals. Considering the large number of chemicals in the environment, current standard chemical monitoring methods are limited for technical and economic reasons. In addition, complex mixtures with interactive effects impede the environmental risk assessment. Ecotoxicological tests with water and sediment samples could overcome these limitations by assessing the overall toxicity of a sample and providing further indications through specific mode-of-action testing. Thus, so-called effect-based methods are increasingly used in water and sediment quality monitoring. However, the ecological relevance of ecotoxicological effects observed in these methods is rarely evaluated. To address this gap, we used data from the DECIDE project, which aims to develop an ecotoxicological assessment system for rivers and streams complementary to the current monitoring practices of the European Water Framework Directive. At 30 sites in central Germany, a comprehensive set of *in vivo* and *in vitro* methods was tested for their informative value and practicality. These ecotoxicological investigations were complemented by an assessment of the benthic macroinvertebrates, local river habitat structure and supporting physicochemical quality components. By linking ecotoxicological and ecological data, we investigated the changes in the benthic macroinvertebrate community along toxicity gradients. More specifically, we aimed to evaluate the ecological relevance of toxicities derived by effect-based methods and the potential of macroinvertebrate communities as pollutant-specific indicators.

We like to thank the German Federal Environmental Foundation for funding the DECIDE project (AZ 35663/01).

2.04.B.T-03 Pesticide Fate in Understudied Freshwater Vertebrates: the Case of a Threatened Terrapin (Emys orbicularis) in Several Wetland Regions of France

Leslie-Anne Merleau[1]*, Mickaël Charriot*[2]*, Olivier Lourdais*[3]*, Anthony Olivier*[4]*, Marion Vittecoq*[4]*, Yvann Foucault*[2]*, Louisiane Burkart*[5]*, Emmanuelle Migne*[6]*, Hélène Blanchoud*[7]*, Fabrice Alliot*[8] *and Aurelie Goutte*[7]*, (1)Practical School of Advanced Studies (EPHE), France, (2)UMR METIS 7619 - EPHE, France, (3)Centre d'Etudes Biologiques de Chizé, (4)Tour du Valat, (5)INRAE Bordeaux, UMR1065 SAVE, France, (6)Réserve Naturelle Nationale de Camargue - Société Nationale de Protection de la Nature, (7)EPHE, PSL Research University, (8)METIS - UMR 7619, France*

Pollution is one of the major threats to freshwater ecosystems and remains understudied in wetlands, especially agricultural pollution. Chronic exposure to water pollution from increasing plant protection product applications is expected to play a role in biodiversity decline in these ecosystems, but little is known about the fate and effects of pesticides in wild populations, notably reptiles. Freshwater turtles, especially, are longlived species with high spatial fidelity and suffer from local contamination. We worked on the European pond turtle (*Emys orbicularis*) a species with high potential for pesticide exposure. From 2018 to 2023, we conducted longitudinal and transversal studies and sampled 15 populations of *E. orbicularis* in three regions of France. We obtained 719 blood samples from 568 individuals and we assessed the levels of 40 pesticides in LC-MS/MS after a single step of purification-extraction by acetonitrile. We also evaluated the contamination pathways by taking water and soil samples, passive samplers, and sampling crayfish, one of the main prey of *E. orbicularis*. During the three-year longitudinal study on two populations in the Camargue, we detected 24 pesticides among 29, on 408 blood samples. We showed that the site of capture and its hydrology was one of the main factors explaining pesticide occurrences and levels, alongside the day of capture, with an increase of both of these variables across the season of capture. However, the frequency of detection was low except for bentazone, an herbicide widely used. Thanks to the longitudinal monitoring, we recaptured 116 individuals over two or three years, and we showed that bentazone levels varied at the intra-individual level. Regarding the transversal study, we have already analyzed 102 blood samples from 5 populations of the Camargue. We confirmed the effect of the site of capture as the main explicative factor. We showed that the frequency of bentazone detection was related to its concentration in the water. The samples from the 10 other populations will be processed at the time of the congress. Analyses are currently underway to measure the effects of pesticide exposure on various biological parameters that we hypothesize to be disrupted in populations living in the most contaminated sites. Together, our results suggest a rapid response of this species to environmental pesticide contamination and call for attention to bentazone, a widely and heavily used herbicide worldwide

2.04.B.T-04 Effect of Pesticides on Soil Microbial Networks of Variable Trophic Diversity

Marta Eugenia Pérez-Villanueva[1,2]*, Cédric Malandain PhD*[2]*, Stephanie Jurburg PhD*[3,4] *and Antonis Chatzinotas Prof*[3,4,5]*, (1)Department of Environmental Microbiology, University of Leipzig, Germany, (2)HYDREKA, France, (3)Department of*

Environmental Microbiology, Helmholtz Centre for Environmental Research (UFZ), Germany, (4)German Centre for Integrative Biodiversity Research (iDiv) Halle-Jena-Leipzig, Germany, (5)Institute of Biology, Leipzig University, Germany
The toxicity of pesticides to natural ecosystems is an ongoing concern, yet little is known about the ecotoxicological effects of these compounds on soil microorganisms and microbial food webs. Since microbial predator-prey interactions play an essential role in the soil ecosystem by modulating microbial diversity and nutrient distribution at various trophic levels, we aimed to assess the effect of two pesticides at the recommended application dose on microbial communities using a food-web approach. Microbial communities with increasing diversity of predators were assembled in gamma-sterilized soils: i. bacteria only (extracted from soil), ii. bacteria + selected bacterivorous protists and iii. bacteria + selected protists with different feeding modes and prey preferences. Systems were prepared in quintuplicate and sampled on days 0, 7, and 21 after pesticide addition. Functional aspects were addressed by substrate-induced respiration (SIR), microbial biomass, total N and C, NH^{4+}, NO^{3-}, NO^{2-}, and PO_4^{3-} analyses. The effects on microbial community composition and abundances of functional groups were assessed by Illumina 16S rRNA gene sequencing and qPCR of nitrogen-cycling bacteria, respectively.

Our results show a higher sensitivity of archaeal nitrifiers (as measured by *amoA* gene abundance) to pesticides compared to bacterial nitrifiers. However, at the recommended application dose, the effect was only observed in microcosms with higher trophic diversity. A consistent decrease in 16S rRNA gene abundance was observed in line with the increase in trophic diversity, while no direct effect due to pesticide exposition was observed. Nevertheless, indirect effects of pesticides on the microbial community composition were observed depending on the level of trophic diversity. These results provide insight into the soil microbial response to pesticide exposure and confirm the need for food-web assessments to avoid an underestimation of pesticide effects on soil microbial communities at recommended application doses.

2.04.C Bridging the Gap between Exposure, Ecotoxicology and Ecology – Identifying and Regulating the Impact of Chemical Pollution on Biodiversity

2.04.C.T-01 Impacts of antimicrobial stressors on bottom-up regulation in aquatic macroinvertebrate food webs

***Frederik Meyer**[1], Alexander Feckler[2], Eric Bollinger[1], Mirco Bundschuh[3] and Ralf Schulz[4], (1)University of Kaiserslautern-Landau (RPTU), Germany, (2)Rhineland-Palatinate Technical University Kaiserslautern-Landau (RPTU), Germany, (3)Institute for Environmental Sciences, RPTU Kaiserslautern-Landau, ., Germany, (4)iES Landau, Institute for Environmental Sciences, Rhineland-Palatinate Technical University Kaiserslautern-Landau (RPTU), Germany*
In heterotrophic streams a substantial proportion of the energy budget is represented by organic matter of terrestrial origin, particularly leaves. Nutrients and energy bound in leaf litter is made accessible to the wider aquatic food web by microbial decomposers (bacterial communities and fungi) and shredding macroinvertebrates. Microorganisms can improve the nutritious quality of leaves for shredders by reducing leaf toughness and by concentrating essential elements (i.e., conditioning). Antimicrobial substances, which are released into streams via wastewater or runoff have the potential to modify the conditioning processes leading to bottom-up directed effects on shredding macroinvertebrates. However, consequences for species interactions translating to changes in the aquatic food web are unclear. Therefore, the main objective of this study was to investigate bottom-up directed effects by antimicrobial stressors in aquatic macroinvertebrate food webs. For this purpose, leaves were conditioned two weeks under exposure to 8 concentrations of an antibiotic (Ciprofloxacin) and a fungicide (Azoxystrobin), respectively, leading to alterations in the leaf-associated microbial community. After modification of the conditioning process, these leaves were provided to an extended macroinvertebrate food web in model stream ecosystems (16 x 3.6 m long flow through stream microcosm). The macroinvertebrate communities were only slightly indirectly affected by Ciprofloxacin while Azoxystrobin resulted in significant indirect impact on the composition of the macroinvertebrate communities with increasing concentrations. Analyses of stable isotopes and fatty acids are ongoing. Additional experiments possibly explain changes in heterotrophic food webs, such as respiration and feeding plasticity tests. It is expected that the combined results will provide new insights into the magnitude and mechanisms of these effects in heterotrophic food webs in terms of changes in feeding preferences, affected physiological fitness translating to altered trophic interactions and community structure. These insights could generate fundamental knowledge for an area that has received little or no attention in the past.

2.04.C.T-02 Beyond the Crop: Assessing Insecticide Deposition and Ecological Risks for Non-target Arthropods in Flower Strips

***Michael Peter Meissle**, Research Division Agroecology and Environment, Agroscope, Switzerland*
While Plant Protection Products (PPPs) play a crucial role in modern agriculture, concerns about biodiversity loss exist, especially for non-target arthropods (NTAs). In Swiss agriculture, temporary flower strips are one government-promoted element to provide additional habitat and food supply for valued NTAs. When crops need to be sprayed with insecticides and other pesticides, however, arthropods in flower strips and other off-crop habitats may potentially be affected by PPP inputs through spray drift. The current off-crop risk assessment relies on models, assumptions, safety factors, and methods extrapolated from the in-crop situation, thus high uncertainties regarding actual exposure, effects on communities, and recovery of NTAs in off-crop habitats remain. The presented project aims at addressing those challenges for the habitat of flower strips. Specifically, we study drift deposition in the flower strip structure; we investigate toxic effects on NTAs in the field by simulating realistic drift scenarios; and we establish a vulnerability index for NTAs using existing toxicity databases combined with trait-based databases.

Field studies were conducted in Tänikon, Switzerland from 2021 to 2024 involving flower strips arranged in a plot design. The plant-dwelling NTA community within the flower strips was monitored using a suction sampler before and after application of acetamiprid insecticide. Preliminary data will be presented. The outcome of this multidisciplinary research, combining exposure measurements, effects data, and ecology in a realistic field setting, will inform risk assessment regulation and policy regarding promotion of flower strips and other non-crop habitats near field that may be subject to PPP applications.

2.04.C.T-03 Indirect Effects of Pesticide Use on Farmland Birds: Lessons from 50 Years of Monitoring, with a Way Forward.

Julie Ann Ewald*, Stephen J Moreby and Nicholas J Aebischer, Game & Wildlife Conservation Trust*

The Game & Wildlife Conservation Trust has monitored, through the Sussex Study, farmland biodiversity and pesticide applications on an area of the South Downs in southern England for over 50 years. The study was designed to monitor changes in grey partridge (*Perdix perdix*) numbers across a core 32 km^2 of mixed farmland. Monitoring includes not only grey partridge abundance and productivity, but also arable flora and invertebrates in the cereal crops, which provide food for grey partridges and other farmland birds (both as adults and at the chick stage). Pesticide use, on a field-by-field basis, has been monitored over the same time-frame. Over the 50 years, analysis of changes in food availability and pesticide use indicates a significant negative effect of insecticide use on the abundance of important groups of chick-food invertebrates, from an 8% to 35% decline when insecticides were used, controlling for cereal type, year, herbicides and fungicides. In the last 20 years, one farm on the study area was determined to recover grey partridges after breeding density declined from eight pairs per 100 ha to one pair per 100 ha from 1970 to 2003. Its efforts have been successful, resulting in an average density of 14 pairs per 100 ha over the past 15 years. We explore what the farm has accomplished, how farm management changed to achieve recovery, how pesticide use was restricted as part of this management, and the effects on both arable flora and invertebrates. The other farms on the study area have undertaken some conservation activities but at a lower level, allowing a comparison with a more “business as usual” approach. We compared pesticide use on the Sussex Study to national statistics from similar crops, to put the Sussex Study into perspective. On average across the Sussex Study herbicide and fungicide use was less intensive than nationally, while insecticide use was similar to use across the UK. This talk updates previous work on the long-term monitoring ongoing on the Sussex Study area and illustrates a way forward to help mitigate the indirect effects of pesticide use in a cereal-based ecosystem.

2.04.C.T-04 Assessing In-Field Pesticide Effects Under European Regulation and Implications for Biodiversity

Stephan Brendel*, Magali Solé, Steffen Matezki, Jeremias Martin Becker, Klaus Swarowsky, Sabine Duquesne, Silvia Pieper and Jörn Wogram, German Environment Agency (UBA), Germany*

The use of pesticides plays a major role in the biodiversity loss in agroecosystems and it was shown that the negative effects exerted by pesticides are persistent. Despite legal requirements that pesticides should not have unacceptable environmental effects, there is a lack of an adequate assessment regarding their impact on on-target terrestrial plants (NTTPs) and arthropods (NTAs) in agricultural fields. Such in-field areas are important, as they constitute a substantial proportion of the total area in typical agricultural landscapes. NTTP and NTA are the basic components of terrestrial food webs and play an integral role in terrestrial biodiversity. Thus, their decline can have cascading effects on consumer species, including farmland birds and mammals; these potential indirect effects via alteration of food webs are also largely ignored in the current environmental risk assessment.

Shortcomings lie within the guidance documents that do not adequately implement the requirements of the current legal framework. An in-field assessment for NTTP is missing and the implemented in-field assessment for NTA is inadequate. To overcome these shortcomings, we developed a readily applicable assessment scheme that allows to assess these risks; it is based on the currently available data required in regulations.

In order to bridge science and regulation, a workshop was held in July, 2023 at UBA in Dessau, Germany. The workshop's experts agreed on the necessity of adequately considering effects of in-field exposure of pesticides in risk assessments. While the proposed scheme was considered appropriate, it was acknowledged that more profound changes beyond pesticide regulation are needed for sustainable agriculture.

In conclusion, to protect biodiversity and to satisfy legal protection requirements, the risk assessment of NTTP and NTA must include an appropriate assessment of in-field effects and indirect effects via alteration of the food webs. In our contribution we highlight current gaps and present a simple assessment scheme to broadly consider the outlined deficiencies in risk assessment.

2.04.C.T-05 Consideration of Environmental Risk Assessment for the protection of biodiversity under the EU Pesticides Regulation (EC) No. 1107/2009

Rachel Sharp*, Domenica Auteri, Csaba Szentes, Alessio Ippolito and Fernando Alvarez, European Food Safety Authority (EFSA), Italy*

In the context of the EU regulation of pesticide plant protection products (EC No. 1107/2009) the potential impact of the active substance on biodiversity, and the ecosystem, including potential indirect effects via alteration of the food web (i.e., indirect effects), should be considered. Whilst a definition for biodiversity is given in Regulation EC No. 1107/2009, its operational definition in the context of a regulatory assessment of pesticides is ambiguous. Although various proposals have been made to integrate indirect effects into the Environmental Risk Assessment (ERA) performed for pesticides currently, no harmonised and widely accepted approach is available. Nevertheless, the protection of biodiversity, via the assessment of indirect effects, have been highlighted to be a key area for improvement for the EU regulatory framework of pesticides. This presentation will use the case of the biodiversity assessment performed for the EU renewal of glyphosate to highlight key issues and make proposals for how this area of ERA may be further advanced. An update will also be given to what current, and near-future, EFSA activities will feed into such development.

2.04.P Bridging the Gap between Exposure, Ecotoxicology and Ecology – Identifying and Regulating the Impact of Chemical Pollution on Biodiversity

2.04.P-Tu075 MeMo – Mesocosm Modelling – Building a bridge from higher tier data to ecosystem modeling

***Lukas Kruckenfellner**[1,2], Ann-Kathrin Loerracher[3], Andre Patrick Heinrich[1], Rolf-Alexander Düring[1] and Klaus Peter Ebke[3], (1)Justus Liebig University Giessen, Germany, (2)MESOCOSM GmbH, Institut fuer Gewaesserschutz, Germany, (3)MESOCOSM GmbH, Institut für Gewässerschutz, Germany*

Owing to the complex interplay of the growing number of stressors affecting aquatic communities, it is becoming increasingly important to predict the potential effects as accurately as possible. Outdoor aquatic mesocosms have already been used in risk assessment for over two decades to investigate effects of stressors under more realistic conditions. In order to be able to utilize this comprehensive higher tier data even better and more efficiently in the future, this data might be complemented and extended via modeling e.g. by simulating multiple or time variable exposure scenarios by application of mechanistic effect models. Therefore, providing a solid data basis is essential. For this reason, the MeMo Environmental Database Plus (MeMo Umweltdatenbank^{PLUS}) project was launched. The project, which is funded by the Hessen Agentur GmbH, focuses both on making historical data sets from mesocosm experiments usable for modeling and on generating new data sets meeting modeling requirements.

Within the project, a mesocosm study was performed in which classical sampling methodologies were characterized with regard to their representativeness and effectiveness. This was achieved, e.g., by fully sampling of macroinvertebrates in individual mesocosms following application of classical sampling methodologies. With this method, extrapolation factors can be determined from the classical trapping technique and the absolute numbers of organisms in the entire mesocosm. By applying the determined extrapolation factors, total abundance, which is needed for modeling purposes, can be calculated retrospectively from historical count data.

In a second phase, a follow-up mesocosm experiment assessing potential harmful effects on aquatic freshwater organisms of the veterinary pharmaceutical eprinomectin was carried out with extended chemical analysis. In addition to the classical abundance data, the community structure (frequencies of size classes of species) of macroinvertebrates was determined. In this way, it is possible to determine a potential influence on the biomass of individual taxa. This allows to document effects on the population in much greater detail. In future, these extensive ecosystem data sets allow a better understanding of effects at population and ecosystem level and can beused as a basis for various modeling approaches.

2.04.P-Tu076 Predicting Bacterial Functional Responses From Water, Biofilm, and Sediments to Land Use-Derived Chemical Pollution at River Basin Level

***Pedro A. Inostroza**[1,2], Gerdhard L. Jessen[3], Xiaowei Zhang[4], Werner Brack[5,6] and Thomas Backhaus[1,7], (1)Biological and Environmental Sciences, University of Gothenburg, Sweden, (2)Institute for Environmental Research, RWTH Aachen University, Germany, (3)Universidad Austral de Chile, Chile, (4)Nanjing University, China, (5)Department of Effect-Directed Analysis, Helmholtz Centre for Environmental Research (UFZ), Germany, (6)Evolutionary Ecology & Environmental Toxicology, Goethe University Frankfurt, Germany, (7)Institute for Environmental Research, RWTH-Aachen University, Germany*

Microbial organisms, especially bacterial communities, are key players in biochemical processes that sustain ecosystems. Furthermore, they are also responsible for degrading toxic chemicals and developing resistance against antimicrobial drugs, ultimately impacting human health. In the field of microbial ecotoxicology, there is not standard approach for assessing the effect of trace organic chemicals derived from human activities, such as pesticides, pharmaceuticals and personal care products, and industrial chemicals on bacterial communities. Therefore, the use of DNA- and RNA-sequencing-based methods is called upon to play a role defining new assessment frameworks. In the last decades, most studies have focused on assessing structural microbial responses to chemical pollution, including shifts in biodiversity, increase or decrease dissimilarities, and correlations to chemicals. Consequently, functional microbial assessment, such us the degradation of toxic chemicals and nutrient recycling processes, critical microbial functions, is often overlooked. In this study, environmental DNA (eDNA) was analysed from water, biofilm, and sediment samples collected in the River Aconcagua Basin (Central Chile) to evaluate: i) whether bacterial functions changed depending on the type of land uses, ii) identify potential bacterial functions affected or linked by chemical pollution, and iii) determine whether these changes are compartment-specific or affect the entire bacterial community. Our results suggest negative impacts on the degradation potential of organic chemicals in bacterial communities inhabiting stream and rivers affected by nutrients and antibiotics compared to reference conditions. Specifically, significant reductions in the degradation of hydrocarbons and aromatic compounds were determined in water, biofilm, and sediment samples. We predict changes in processes related to the nitrogen cycling, such as potential reduction of nitrogen fixation in bacterial in water and biofilms in stream running through agricultural streams compared to reference conditions at a river basin level.

2.04.P-Tu077 Multiple contaminants in complex communities: evaluating non-additive effects of multiple simultaneous stressors on biomass flux and ecosystem functioning

Hana B Mayall[1]*, Lorraine Maltby*[1]*, Dylan Z Childs*[1]*, Claudia Rivetti*[2]*, Andrea Gredelj*[3] *and Andrew Beckerman*[1]*, (1)School of Biosciences, University of Sheffield, United Kingdom, (2)Unilever - Safety and Environmental Assurance Centre (SEAC), United Kingdom, (3)Norwegian Geotechnical Institute (NGI), Norway*

Biodiversity has declined as a result of numerous stressors, including chemicals. Conventional environmental risk assessment approaches tend to evaluate single stressors individually, with effects assessed at the individual and population scales. This overlooks the fact that multiple stressors impact multiple species interacting in complex communities, with indirect effects emerging at a community level. Understanding how multiple sublethal stressor effects combine is crucial to be able to predict and mitigate their impacts on biodiversity. By combining food web theory of interacting species with ecotoxicological theory of contaminant effects, we performed in-silico modelling experiments to assess how biomass and stability of a tri-trophic food chain respond to herbicide-like and pesticide-like contaminants. We applied these contaminant effects simultaneously across stressor intensity gradients, varying the trait rates and trophic levels targeted by the pesticide-like contaminant. We measured community biomass as an indicator of productivity and ecosystem functioning, investigated the distribution of biomass across the community (i.e. trophic level biomass), and calculated stability metrics. Using recent methods to distinguish between additive and multiple non-additive antagonistic and synergistic effects, we found responses in biomass and stability to be dominated by additive and antagonistic effects and no synergistic effects. We found that patterns of non-additivity in community and trophic level biomass varied depending on the trait and trophic level targeted by the pesticide-like contaminant. This study reveals how simple community structure and the modification of direct and indirect effects in a community by contaminants leads to diverse outcomes of multiple stressors on biomass and stability. This demonstrates the value of leveraging ecological community modelling techniques to evaluate the long-term indirect effects of multiple sublethal contaminants acting on multiple species on ecological functioning.

2.04.P-Tu078 Evaluation of toxicological effects of fungicides used in vineyards agroecosystem using Apis mellifera as a model species

Tommaso Campani[1]*, Ilaria Caliani*[1]*, Agata Di Noi*[2]*, Laura Giovanetti*[1]*,* ***Isabella Calattini***[3]*, Ginevra Manieri*[4] *and Silvia Casini*[1]*, (1)University of Siena, Italy, (2)Department of Life Sciences, University of Siena, Italy, (3)University of Siena, Siena, Italy, (4)Department of Physical, Earth and Environmental Sciences, University of Siena, Italy*

Agroecosystems provide habitats, food and water, for many species, but are areas where pesticides and fertilizers are widely used. Pesticides are the most important threat to pollinator insects that live in agroecosystems, especially due to their intensive use in agriculture. Many European regions are famous for wine production, with land covered by vineyards where the biodiversity is absent and to preserve wine production many pesticides are used. The European Directive 128/2009/CE and No 540/2011 regulate the use of pesticides in agroecosystems. Although many active principles have been banned, some substances such as those used in viticulture are already permitted. Breed bees and wild bees come in contact with the pesticide used in vineyards collecting the morning dew from vine leaves and using sugar from the grapes, especially during increasing periods of drought. Our study aimed to investigate the toxicological effects on honeybees, used as model species, of the commercial formulation of two fungicides: 1)Folpet-based and cymoxanil+copper-based, alone and in combination and the toxicological effects of 2)copper. Laboratory experiments with fungicides and copper and a 2 years beehive survey in two vineyards with different types of management (conventional and organic) during the use of this type of fungicide were carried out. A multi-biomarker approach was applied to test the neurotoxic effect (AChE, CaE), metabolic alterations (ALP), detoxification system (GST), efficiency of the immune system (LYS, proPO, PO and hemocyte count and genotoxicity (NA assay). The results of the laboratory experiment with Folpet-based, and cymoxanil+copper-based showed induction of GST activity in all treatments except the mixture at the lowest concentrations and a decrease in the ALP activity. LYS activity increased in the groups exposed to the Folpet-based fungicide, to the lower concentration of cymoxanil-copper-based and the mixtures. The pesticide interaction model showed that the mixture of the two fungicides had subadditive effects. The beehive monitoring showed no esterase inhibition during and after the treatment of the vineyards compared to the organic vineyard and metabolic alterations and effects on the immune system were found in bees sampled during the vineyard treatments. This study confirms the need to deeply investigate the sublethal effects of commercial pesticides, in particular those used in vineyards, to protect wild and farmed pollinators.

2.04.P-Tu079 Differential Gene Expression of Freshwater Macroinvertebrates Exposed to Micropollutant Mixtures across the River Holtemme (Germany)

Camilo Escobar Sierra[1]*, Sameer Hassan*[2]*, Kathrin Lampert*[1]*, Thomas Backhaus*[3,4] *and Pedro A. Inostroza*[3,5]*, (1)Zoology Institute, University of Cologne, Germany, (2)University of Gothenburg, Sweden, (3)Biological and Environmental Sciences, University of Gothenburg, Sweden, (4)Institute for Environmental Research, RWTH-Aachen University, Germany, (5)Institute for Environmental Research, RWTH Aachen University, Germany*

Chemical pollution is recognised as one of the major drivers influencing the ecological status of aquatic ecosystems. Micropollutants are organic chemicals occurring at trace environmental contractions, including pesticides, pharmaceuticals, personal care products, and industrial chemicals among other, which have raised concern due to their negative impact on aquatic organisms. Some of these chemicals have known mode and mechanism of action (e.g., neonicotinoid insecticides

altering nicotinic acetylcholine receptors). Nevertheless, for many chemicals their mode of action is unknown. Besides, we still have a poor understanding of the combine effects when these chemicals co-occur in the aquatic environment. Aquatic benthic invertebrate fauna represents one of the Biological Quality Elements, which is used to determine the Ecological status of surface water bodies according to the EU Water Framework Directive. They are therefore extensively used as biological indicators to assess water quality. Nevertheless, a thorough understanding of the adverse biological consequences of micropollutant mixtures at the pathway level under real exposure conditions is still absent. There is not a standard approach defined to unveil such effects and most of the evidence available is based on single gene assessment. This study employs an RNA-based-sequencing (transcriptomic) approach on *Gammarus pulex* populations, shredder invertebrates, across a gradient of stations with increasing chemical pollution in the River Holtemme to address this gap. Non-targeted gene assessment reveals alterations in gene expression, with an increasing number of differentially expressed genes (DEGs) downstream of chemical pollutant influences. Notably, a station downstream of a wastewater plant exhibits up to 6014 DEGs compared to the reference site. Our findings indicate a significant upregulation of invertebrate DEGs downstream of wastewater treatment plants. Furthermore, a pathway enrichment analysis identifies over-represented gene classes in categories such as nervous system development, carcinogenesis, and stress response across all stations under micropollutant stress. Thus, our results link observed biological responses to specific chemical groups, shedding light on the intricate interplay of micropollutants and their impact on freshwater macroinvertebrates in freshwater ecosystems.

2.04.P-Tu080 Investigating the relationship between contamination and coral reef condition in the Red Sea: An integrated assessment from bacteria to fish

Susana Carvalho[1]*, Gloria Gil Ramos*[1]*, Micaela Sofia dos Santos Justo*[2]*, Margarida Branco*[3]*, Karla Gonzalez*[1]*, Mariana Elizabeth Rodrigues*[4]*, Joao Curdia*[3]*, Darren Coker*[3]*, Rodrigo Villalobos*[3]*, Fernanda Tavares*[4]*, Geert-Jan Witkamp*[4]*, Eva Aylagas*[1]*, Andreia Sofia Filipe Farinha*[1] *and Diego Lozano-Cortes*[5]*, (1)King Abdullah University of Science and Technology, Saudi Arabia, (2)Red Sea Reasearch Science, King Abdullah University of Science and Technology, Saudi Arabia, (3)Red Sea Research Center, King Abdullah University of Science and Technology, Saudi Arabia, (4)Water Desalination and Reuse Center, King Abdullah University of Science and Technology, Saudi Arabia, (5)Environmental Protection Department, Saudi Aramco, Saudi Arabia*

Coral reefs are the most diverse marine ecosystems, harboring over one quarter of known marine life. They provide habitats and resources for numerous sedentary and mobile organisms, from small invertebrates to large fish. They also play a critical role in biogeochemical cycling and coastal protection, being essential drivers of economic activities. Coral reefs are, however, undergoing rapid changes due to the synergy of global and local stressors. One of the most detrimental threats resulting from anthropogenic activities is pollution, caused by the release of contaminants from different sources, such as treated or untreated municipal, industrial and agricultural wastes. Marine pollution can severely affect the biodiversity and the functioning of coral reef systems. However, comprehensive studies integrating contamination and biological information across multiple components of the reef biodiversity are scarce. Here, we present the preliminary findings of an inter-disciplinary project conducted in the Red Sea spanning three regions of contrasting anthropogenic pressure and including biodiversity (bacteria, corals, and fish), bioaccumulation patterns in fish, and environmental data, including inorganic and organic contaminants. Our dataset includes *in situ* data of reef benthic structure and fish density and biomass, molecular-based assessments of the metazoan and prokaryotic communities (18S and 16S, respectively) in reef sediments, bioaccumulation patterns in fish, and concentration of trace metals and metalloids, as well as targeted emerging contaminants (Personal Care Products; e.g., medicines, caffeine), used as indicators of human pressure. We predict that the concentration of contaminants mirrors the anthropogenic gradient and that the condition of the coral reefs (measured as hard coral cover, fish biomass, diversity, and composition of metazoan and prokaryotic communities) is affected by the increasing human pressure, i.e., the concentration of contaminants in the reef abiotic matrices (sediments and waters). This study is one of the few integrating multiple angles of the coral reef ecosystem following an inter-disciplinary approach and will contribute to elucidating the existing ranges of contaminants in Red Sea coral reefs and guide dedicated ecotoxicological studies and future regulations. The results of this project can also help managers implementing mitigation strategies to alleviate the effects of marine pollution in Red Sea coral reefs.

2.04.P-Tu081 A complementary approach based on contaminant analysis, biomarker responses and behavioural performances to investigate the toxicological status of Parus major from Veneto region

Laura Giovanetti[1]*, Silvia Casini*[1]*, Sara Valsecchi*[2]*, Marianna Rusconi*[2]*, Maria Teresa Palumbo*[2]*, Michele Mazzetti*[3]*, Tommaso Campani*[1]*, Stefania Ancora*[4]*, Flavio Monti*[4]*, Matteo Schiavinato*[5]*, Matteo Beccardi*[5]*,* ***Isabella Calattini***[6] *and Ilaria Caliani*[1]*, (1)University of Siena, Italy, (2)Water Research Institute - Italian National Research Council (IRSA-CNR), Italy, (3)Environmental Protection Agency of Tuscany Region, Italy, (4)Department of Physical, Earth and Environmental Sciences, University of Siena, Italy, (5)University of Padova, Italy, (6)University of Siena, Siena, Italy*

Pesticides and other classes of anthropogenic contaminants can cause reversible alterations or permanent damage to avian species. Great tit (Parus majoj) is an important model species for environmental studies. Its aptitude for nesting in artificial boxes and territoriality can provide precise toxicological information on a given territory. In the last six years, several nest boxes for great tit were installed in different areas of Veneto region, characterised by different anthropogenic impacts. This study aimed to investigate the effects of environmental contaminants on great tit populations by a non-lethal approach integrating chemical analysis, biochemical/cellular responses, breeding and behavioural traits. In 2021 and 2022, biological materials such as blood, feathers, excreta and unhatched or abandoned eggs were collected from nestlings living in nest boxes installed in different areas of Veneto region. The study areas, subjected to different anthropogenic pressures, were wooded, agricultural and urban environments. Per- and polyfluoroalkyl substances (PFAS) and heavy metal levels were determined on eggs and feathers, respectively and porphyrin concentrations were evaluated on excreta. A set of non-lethal biomarkers capable of providing different toxicological responses was performed on blood. Behavioural traits such as reactivity performances and fitness were also assessed. PFOS was the most abundant compound, and the long-chain perfluorinated carboxylic acids levels were agricultural<urban<wood. Cu was the most abundant metal in all areas and Hg had higher values in the urban area. Nestlings from urban and agricultural areas had higher genotoxic effects than this from wood. The H/L ratio was more severe in urban birds, which showed a physiological stress condition. Complement system activity was higher in nestlings from an agricultural area suggesting that these birds might be exposed to substances that act on innate immune system. The applied approach was proved to be a valuable tool for the ecotoxicological monitoring of great tit. It is fundamental to obtain a complete picture of the health status of this species and to investigate the environmental quality in which the studied species lives.

2.04.P-Tu082 Assessment of multiple stressors of aquatic ecosystems using invasive Corbicula clams in Argentina

Florencia Liquin[1], Verónica Lozano[2], Priscila Stephanie Beraldo Pissinis[3], Tatiana Noya Abad[4], Camila Muñoz[2], Henrique Knack de Almeida[4], Henner Hollert[5], Sebastián E. Sabatini[4], Esteban M. Paolucci[3] and ***Francisco Sylvester***[6]*, (1)Facultad de Ciencias Naturales, IEBI, Universidad Nacional de Salta, Argentina, (2)Cátedra de Biología y Diversidad de Protistas Autótrofos y Fungi, Universidad Nacional de Salta, Argentina, (3)Museo Argentino de Ciencias Naturales "Bernardino Rivadavia", CONICET, Argentina, (4)Laboratorio de Enzimología, Estrés Oxidativo y Metabolismo (LEEM), Departamento de Química Biológica, IQUIBICEN-CONICET, Facultad de Ciencias Exactas y Naturales, Universidad de Buenos Aires, Argentina, (5)Evolutionary ecology and environmental toxicology, Goethe University Frankfurt, Germany, (6)Faculty of Biological Sciences, Goethe University Frankfurt, Germany*

Multiple stressors shape populations, communities, and ecosystems. In freshwater ecosystems, chemical pollution, temperature changes, and parasites are common stressors, yet few studies have investigated them simultaneously. Invasive clams of the genus *Corbicula* are widespread in Argentina and can be used to assess their impacts. In 2021-2023, we collected *Corbicula largillierti* clams to assess chemical pollution by pesticides in an irrigation channel in the northern part of the country (Salta) and *Corbicula fluminea* congeners to assess urban pollution in the Río de la Plata Estuary (Buenos Aires). In Salta, we conducted 48-h exposure experiments to two concentrations of glyphosate (0.3 and 3 mg L^{-1}), imidacloprid (20 and 200 µg L^{-1}) and their mixture, and one control (total N=35). In Buenos Aires, we assessed 120 clams from two populations exposed to contrasting pollution conditions: Parque de los Niños strongly impacted by urban pollution and Punta Lara away from this influence. In all populations, we measured the effects of pollution on standard metabolic rate and several parameters of oxidative stress: concentrations of proteins, glycogen, reduced glutathione (GSH), thiobarbituric acid-reactive substances (TBARS), and glutathione S-Transferase (GST) activity. Additionally, in Buenos Aires, we studied the influence of temperature (12ºC and 21ºC) and *Chaetogaster limnaei* gill parasites (estimated prevalence and intensity following clam dissection) on the metabolic and cellular endpoints measured. The degree of exposure to urban effluents was assessed using detailed physicochemical datasets of each site from monitoring programs of the Argentine Ministry of Environment and Sustainable Development in both sites in Buenos Aires. This was complemented with direct assessment of metals (cadmium, copper, chromium, iron, nickel, lead, and zinc) in the gills, digestive gland, and mantle of the clams. We found that imidacloprid had a more pronounced effect compared to glyphosate on the respiration rates of *C. largillierti* clams in Salta, although additive effects on oxidative stress parameters were clear when both pesticides were present. Our analysis of Buenos Aires populations shows differential effects of environmental stressors on metabolism and oxidative stress that suggests a dependence of context. These findings highlight the use of *Corbicula* spp. clams and multiple biomarkers to enhance biomonitoring sensitivity of multiple stressors in aquatic ecosystems.

2.04.P-Tu083 Using effect-based methods to assess chemical stress in old river restorations

Sarah Hörchner[1]*, Ariane Moulinec[2], Andrea Sundermann[3], Klaus Peter Ebke[4], Thomas Bing[4], Jörg Oehlmann[1] and Matthias Oetken[1], (1)Aquatic Ecotoxicology, Goethe University Frankfurt, Germany, (2)Section River Ecosystem Managment, Senckenberg Society for Nature Research, Germany, (3)River Ecology and Conservation, Senckenberg Research Institute and Natural History Museum Frankfurt, Germany, (4)MESOCOSM GmbH - Institute for Water Protection, Germany*

Aquatic ecosystems are often altered by multiple stressors, including hydrologic and morphological degradation, high nutrient loading, and chemical pollution. More than 90% of German surface waters do not meet the objective of at least good ecological status of the Water Framework Directive. To improve freshwater habitats and thus the ecological status of water bodies, hydromorphological restoration has been increasingly implemented. However, follow-up assessments often show little to no improvement in ecological status even years after restoration measures have been implemented. The failure of many restoration projects can be attributed to the fact that not all relevant stressors were considered. These stressors include water pollution and inadequate sediment quality, which often receive too little attention compared to non-chemical stress. For this purpose, effect-based methods (EBMs) are recommended to gain a better insight into the impacts of pollutants and their underlying mechanisms. In this study, the impact of chemical stress on five restored streams, each with a restored and a nearby located non-restored section, was investigated using EBMs. All streams do not achieve good ecological status according to the EU-WFD. We aimed to determine whether there is a difference in the toxicity and chemical composition of water and sediment samples between restored and non-restored river sections, and if water pollution is a factor that causes the failure to achieve good ecological status.

In this study, we used a bioassay battery to evaluate the effects of water and sediment samples on organisms of different trophic levels. In addition, water samples were analyzed by liquid chromatography coupled with tandem mass spectrometry (LC−MS/MS). To simplify the existing data set from the effect-based assessment and chemical monitoring, a principal component analysis (PCA) was used.

Using EBMs, high activity levels in water and sediment samples of restored streams were found. Differences in toxicity between restored and non-restored sections did not show a consistent trend, depending on the individual test. However, concerning chemical monitoring of water samples, non-restored and restored sections of the same stream were similar in their chemical composition. Accordingly, the present findings suggest that chemical pollution appears to be a non-negligible factor limiting restoration success and improvement of the ecological status of rivers.

2.04.P-Tu084 Moving towards a better protection of terrestrial biodiversity – identify, compare, redefine

*Gabriele Treu[1], **Oliver Machate**[1], Romana Hornek-Gausterer[2], Maria Uhl[2], Paola Movalli[3], Peter Fantke[4], K. Bismejier[3], Susan Oginah[5], Martina G. Vijver[6], Laura Scherer[6], S. Henrik Barmentlo[6], Nikolaos S. Thomaidis[7], Maria-Christina Nika[7], Georgios Gkotsis[8], Marissa B Kosnik[9], Guy Duke[10], Nikiforos Alygizakis[10], Natalia Glowacka[10] and Jaroslav Slobodnik[10], (1)German Environment Agency (UBA), Germany, (2)Environment Agency Austria (EAA), Austria, (3)Naturalis Biodiversity Center, Netherlands, (4)Quantitative Sustainability Assessment, Department of Environmental and Resource Engineering, Technical University of Denmark, Denmark, (5)Technical University of Denmark (DTU), Denmark, (6)Institute of Environmental Sciences (CML), Leiden University, Netherlands, (7)National and Kapodistrian University of Athens, Greece, (8)Chemistry, National and Kapodistrian University of Athens, Greece, (9)Department of Environmental Toxicology, Eawag: Swiss Federal Institute of Aquatic Science and Technology, Switzerland, (10)Environmental Institute, Slovakia*

Chemical pollution is a planetary boundary threat and an important driver of biodiversity decline, which stands in contrast to the European vision to establish a non-toxic environment and put biodiversity on a path to recovery. Despite of this goal, the assessment and evaluation of biodiversity as such is not sufficiently covered in chemical legislation (e.g. REACH). Regulators require sound data to understand and quantify chemical pollution's impact on biodiversity at several scales and to be able to develop means to effectively protect it – something that is currently not available. Furthermore, todays chemical risk assessments are often very generic and only a small fraction of the marketed chemicals have been evaluated sufficiently regarding their (eco)toxicological properties or exposure scenarios. The HORIZON project TerraChem (Nov 2023 – Oct 2026) strives to provide novel and urgently needed monitoring data on the extent of chemical contamination in terrestrial food chains and the adverse effects of single contaminants and their mixtures at an organism level, as well as to develop new methodologies to assess their impact at an ecosystem level. This poster will display how these data can be used to improve the efficacy of current risk assessment practices and trigger further regulatory action by identifying priority substances, while also inspiring change within the political and regulatory frameworks.

2.04.P-Tu085 Developing Environmental Scenarios for The Risk Assessment of Non-Target Organisms

*Alessio Ippolito, **Domenica Auteri**, Rachel Sharp, Fernando Alvarez, Gabriella Fait and Giuseppe Triacchini, European Food Safety Authority (EFSA), Italy*

One of the key aspects of the Environmental Risk Assessment (ERA) performed within the plant protection product authorisation process is that such assessments should be able to predict risks over large geographical areas (e.g., over an entire country, regulatory zone, or even over the entire EU). However, the nature and the magnitude of environmental risks are very much influenced by several biotic and abiotic factors, which are variable in space and time. Therefore, accounting for context-dependent factors is pivotal in developing future methods for ERA.

The concept of environmental scenarios is considered a pragmatic way for condensing the variability of environmental characteristics most likely to have an impact on environmental risks.

This poster will lay down the specific objectives of forthcoming work which will trace the pathway to define the environmental scenarios.

At first, an analysis of the European agricultural landscape will be carried out to identify clusters with similar characteristics. Later, high resolution mapping, gathering georeferenced information particularly on non-cropped landscape elements, such as field margins and other semi-natural areas, will be used to refine the initially defined clusters.

In a subsequent work, habitat and biological assemblages representative of the identified clusters in agro-ecosystem will be fully characterised via systematic literature reviews and field monitoring. Later, the vulnerability of such assemblages to plant protection products will be investigated once again via systematic literature reviews and via targeted experimental studies. The vulnerability assessment will then constitute a further layer in the clustering exercise before the definition of the final scenarios. Developing scenarios should serve for multiple purposes:

- Aligning the conditions used for the exposure assessment and the risk characterisation, incorporating spatial, temporal, and ecological aspects that have not been routinely considered so far.
- Defining baseline conditions which in turn can be used for specific assessments as well as input for the derivation of Specific Protection Goals.
- Providing context for running simulations with population/community models.

- Defining an objective basis for the evaluation of representativeness of higher-tier studies (e.g., field studies) and the extrapolation of findings from such experiments.

2.04.P-Tu086 Metabolic-Based Identification of the Effects of Chemicals Using Arabidopsis Taliana
DONG Geun Song *and Sang Don Kim, School of Earth Science and Environmental Engineering, Gwangju Institute of Science and Technology (GIST), Korea, Republic of (South)*
When chemical exposure occurs in the ecosystem, it carries the potential for profound environmental repercussions, particularly impacting terrestrial ecosystems. Notably, immobile plant species become particularly vulnerable in these scenarios, often serving as valuable indicators for assessing the extent of damage wrought by these chemical incidents. However, diagnosing and evaluating such damage currently lacks robust scientific methodologies, relying heavily on subjective visual assessment. In this context, the science of metabolomics emerges as a promising tool, enabling us to delve deeply into the physiological state of organisms in an environment marred by chemical exposure. Therefore, the focus of this study is to develop a methodology for assessing the implications of substances utilized in chemical accident preparedness. This is achieved by scrutinizing changes in the metabolites of plants exposed to chemical-laden environments through the lens of metabolomics, shedding light on the intricate repercussions of chemical accidents on the natural world. This study presented a methodological approach for understanding the effects of chemicals on plants through the application of metabolomics. For this research, the model plant, *Arabidopsis thaliana*, was used. Arabidopsis is a commonly used model plant in various metabolomics studies. Target chemical exposed to Arabidopsis at selected concentrations and general phenotypic differences like biomass in Arabidopsis were confirmed. Metabolites extraction process was performed from the exposed Arabidopsis, and non-targeted analysis was performed using Liquid and Gas Chromatography Ultra high resolution Quadrupole Time of Flight Mass Spectrometer System (LC-QTOF-MS). Then, statistical analysis was performed to distinguish the difference between the group that was not exposed to the chemical and the group that was exposed to the chemical. This study can help determine the effects of chemicals in plants using metabolomics.

2.04.P-Tu087 How Does Biotransformation Vary Within and Across Species?
Dave T. F. Kuo*, National Taiwan University, Taiwan*
Biotransformation is important for accurate ecotoxicological assessment of chemicals as it influences bioaccumulation potential, toxicity, and persistence of chemicals in natural environments. Understanding how biotransformation differs across biological species or taxonomic grouping can thus provide important insights into interspecies difference and sensitivity of key ecotoxicological traits. This study aims at comparing and understanding how biotransformation rate constant, k_M, varies within and across different biological species, and how it may be affected by exposure conditions, environmental factors, and ecological traits. Using the early-time approximation developed earlier, a total of 241 tissue-specific unique experimental k_M's were obtained for 61 unique species. Intraspecies uncertainty in k_M was typically within ±0.5 log unit with additional variability explained by k_M's dependence on exposure conditions and environmental parameters. k_M generally declined with higher exposure concentration regardless of exposure medium; the influence of temperature, inhibitor, and bioavailability modifiers were more ambiguous and of less important. Significant cross-species k_M differences have been observed among species within the larger biological groups of fish, bivalves, worms, and algae. Further analysis seems to suggest that omnivores may have the highest k_M than species in other feeding guilds. This dependence broadly agreed with the hypothesis that generalists with broad dietary choices may have evolved more mechanisms and diverse gut microflora to detoxify toxic moieties. This work demonstrates the possible integration of toxicokinetics into interspecies assessment framework and tools (e.g., species-sensitivity distribution) as well as the need for more comprehensive biological and ecological descriptors for building large-scale understanding of ecotoxicological data from through the lens of biology and ecology.

2.04.P-Tu088 Changes in Pesticide Contamination With Age in Chicks of a Bird of Prey
Elva Fuentes[1]*, Jérôme Moreau*[2,3]*, Vincent Bretagnolle*[2,4]*, Maurice Millet*[5] *and Karine Monceau*[6]*, (1)University of La Rochelle, France, (2)CEBC UMR CNRS 7372, France, (3)Université de Bourgogne, Biogéosciences, UMR 6282, (4)LTSER France "Zone Atelier Plaine & Val de Sèvre", (5)UMR CNRS ICPEES 7515, University of Strasbourg, France, (6)Université de La Rochelle, CEBC UMR CNRS 7372*
The massive use of synthetic inputs due to agricultural intensification is considered as a main responsible for farmland birds decline across Europe. While experimental studies investigated the toxicokinetics of some pesticides in model species, these do not reflect realistic rates in case of multiple pesticide contamination. Still, wild birds are exposed to pesticide cocktails and no study to our knowledge investigated the variation over time of their pesticide contamination *in natura*. We aimed at filling this gap using Montagu's harrier (*Circus pygargus*), a specialist (feeding on voles) bird of prey living in agroecosystems and nesting on the ground of cereal crop plots. Chicks are thus particularly interesting to study pesticide seasonal changes as they are born and raised in contact with the treated culture and fed with potentially contaminated prey. Consequently, their exposure to pesticides lasts all their growing period (four weeks) and may have important issues on their development. We used blood samples of Montagu's harrier chicks collected at the second and fourth nest visit, when they were ca. 15 days old and ca. 26 days old to investigate the changes in pesticides detected and their concentrations in-between. The detection and quantification of 104 molecules was realized on samples collected in 2018 (35 chicks) and 2019 (32 chicks). We detected in total 18 molecules in 2018 and 8 molecules in 2019. While no temporal pattern arises in 2019, in 2018 chicks sampled had on average two molecules less at the fourth visit than at the second visit. Similarly, the sum of pesticide concentrations was lower in older chicks. However, when regarding molecules' concentrations separately, only one individual had a significant reduction of concentrations between the two sampling dates. Overall, our results suggest that some molecules were metabolized and

detoxified notably through feather growth or stocked in the growing tissues, and/or that a natural depletion of pesticides in the environment occurred over time. These results question pesticides' exposure and detoxification routes in chicks. More investigations are thus needed to better understand the factors influencing pesticide's deposition and excretion within farmland birds. Nonetheless, our study gives insights on the temporal changes in pesticide contamination in blood matrices and highlights the complexity of comparison among birds sampled at different life-stages.

2.04.P-Tu089 A Laboratory-Based Chronic Toxicity Model is Predictive of Nickel Effects on Benthic Invertebrates in the Field

Adrian de Bruyn[1]*, Jordana Van Geest*[2]*, Jennifer Arens*[2] *and Mariah Arnold*[3]*, (1)ADEPT Environmental Sciences Ltd., Canada, (2)WSP Golder, Canada, (3)Teck Resources Ltd., Canada*

Predicting effects of metals on stream invertebrate communities can be hindered by spatial and temporal variation in toxicity-modifying factors, a paucity of toxicity information for stream taxa (mainly insects), and variation in benthic invertebrate community structure related to habitat and factors other than the stressor of interest. We tackled these challenges by combining laboratory-based chronic toxicity data with field-based biological monitoring data to build a lab-to-field stressor-response relationship. A site-specific toxicity model for *Ceriodaphnia dubia* was used to translate nickel concentrations into predicted toxicity, and a quantile regression of field data from a wide range of sites was then used to describe the limiting effect of nickel toxicity on benthic invertebrate community metrics. The most sensitive metric was percent Ephemeroptera, with an EC_{10} occurring at 22% effect to *C. dubia* reproduction. These findings support previous estimates of 20% as a critical effect size in laboratory test organisms that could translate into discernible effects on sensitive invertebrates in the field.

2.04.P-Tu090 Ecotoxicological risk assessment for fish populations - Application to the early life stages of endangered migratory fish living in the Garonne catchment.

Benjamin Bellier[1]*, Sarah Bancel*[2]*, Éric Rochard*[2]*, Jérôme Cachot*[3]*, Oliver Geffard*[4] *and Bertrand Villeneuve*[2]*, (1)University of La Rochelle, France, (2)EABX, Institut national de recherche pour l'agriculture, l'alimentation et l'environnement (INRAE), France, (3)EPOC CNRS, University of Bordeaux, France, (4)RiverLy, Institut national de recherche pour l'agriculture, l'alimentation et l'environnement (INRAE), France*

In the Garonne catchment (South West France), anadromous fish populations have severely decreased over the last decades. Among the potential causes of this decline, questions about water contamination have received limited attention. One of the existing methods to quantify potential toxic risk is called "Potentially Affected Fraction of species" (PAF). This approach consists of estimating the percentage of potentially affected species by comparing environmental contamination data and toxicity data. In our study, PAF approach was applied to quantify the potential toxic risk associated with chemical contamination of water for (1) fish in the Garonne and Dordogne rivers (main river scale) and (2) the development of early life stages in the spawning grounds (SG) of two emblematic species: allis shad and European sturgeon (SG scale). Environmental contamination data were provided for 21 sites from 2007 to 2022, and toxicity data were obtained specifically from freshwater toxicity tests on fish species. Then, for each year and site, the potential toxic risk associated with a single substance (ssPAF) and a mixture of substances (msPAF) was calculated and categorized as: high (> 5%), moderate (> 1% and < 5%) or low (< 1%). At both scales (main river scale and SG scale) and rivers (Garonne and Dordogne), the potential toxic pressure appeared to decrease over the period at most sites, with higher potential toxic risks between 2007 and 2012, although by 2022 few sites showed a low potential toxic risk. Moderate potential toxic risks (1% < msPAF < 5%) were more often observed, and high potential toxic risks (msPAF > 5%) were encountered more or almost as often as low potential toxic risks (msPAF < 1%). Lead (metals), copper (metals), zinc (metals), estrone (hygiene and care products), bisphenol A (other industrial pollutants) and iron (metals) were the higher contributors (ssPAF > 5%). Substances belonging to agrochemicals contributed at most moderately (1% < ssPAF < 5%). Acetochlor (agrochemicals) and 4-tert octylphenol (other industrial pollutants) generated moderate potential toxic risks (1% < ssPAF < 5%), specifically for the development of early life stages of fish in allis shad and European sturgeon SG. In conclusion, this study highlights the potential influence of water contamination on the decline, fate and restoration of anadromous fish populations in the Garonne catchment, focusing notably on the toxic effects on early life stages.

2.04.P-Tu091 Exploring Embryonic Responses of a Migratory Fish to Spawning Grounds Water Quality in a Population Decline Context.

Sarah Bancel[1]*, Jérôme Cachot*[2]*, Olivier Geffard Pr*[3] *and Éric Rochard*[1]*, (1)EABX, Institut national de recherche pour l'agriculture, l'alimentation et l'environnement (INRAE), France, (2)EPOC CNRS, University of Bordeaux, France, (3)UR RiverLy, Institut national de recherche pour l'agriculture, l'alimentation et l'environnement (INRAE), France*

The allis shad (*Alosa alosa*) is an amphihaline migratory fish species, whose population numbers have drastically declined since the early 2000s and remain at a very low level in the Gironde catchment (France). Water quality at the spawning grounds, and its possible toxicity to the species embryos and larvae, is one hypothesis that has not yet been investigated, requiring continuous exposure of the embryos to a natural environment.

Early life stages of fish are sensitive to environmental conditions, notably water contamination, making them relevant for environmental monitoring applications, but also to water parameters. The *ex-situ* method allows a direct continuous exposure of organisms to river water, while controlling physico-chemical parameters (temperature, oxygen, photoperiod), known as confounding factors and to impact the results interpretation. Experiments were carried out on a spawning ground of allis shad in the Garonne river using *ex-situ* exposure method, in spring 2022 and 2023. Allis shad embryos were exposed to the

Garonne river water throughout their development from fertilization up to 2 days after hatching. Temperature was maintained at 20°C ± 1°C and oxygen saturation values were higher than 80%, which is the ideal range for development.

Results showed a high mortality induced by the water of spawning grounds on both experimental years, and on three distinct batches of embryos. Specifically, embryonic mortality was significantly higher in individuals exposed to Garonne water compared to the control, with the probability of survival being less than 25% in the former, while survival in the control ranged between 50% and 90% depending on the batch. The most of embryonic mortality occurred after 30 hpf, or 24 hours of exposure which corresponds to organogenesis for this species.

Survival in controls demonstrates the interest of the *ex-situ* approach and water parameters regulation, allowing the exposure of early life stages in the natural environment. These results also show that the quality of the water has a significant impact on embryonic development, raising questions about the impact of water quality on allis shad population recruitment in the Garonne river.

2.04.P-Tu092 Unravelling The Impact Of Climate Change On Aquatic Ecosystems: Insights From Historically Contaminated Soils In Estarreja, Portugal

Ana Rita R. Silva[1], Rita Soares[1], José Nereu Pinto[1], Fábio Yu Chen[2], Patricia V. Silva[3], Marija Prodana[1], Diogo N. Cardoso[1], M. Nazaret Gonzalez-Alcaraz[4] and ***Susana Loureiro***[5]*, (1)CESAM & Department of Biology, University of Aveiro, Portugal, (2)CESAM - Centre for Environmental and Marine Studies and Department of Biology, University of Aveiro, Portugal, (3)CICECO - Aveiro Institute of Materials & Department of Materials and Ceramic Engineering, University of Aveiro, Portugal, (4)Agronomic Engineering, Technical University of Cartagena, Spain, (5)CESAM - Centre for Environmental and Marine Studies & Department of Biology, University of Aveiro, Portugal*

The global efforts for the mitigation of climate change are formalized within the Paris Agreement. Multistakeholder engagement and local dimension are among the crucial elements for urgent climate adaptation. Our research project TERRA - Climate change impacTs in EstaRRejA region focuses on local problems of Estarreja municipality, categorized as the most polluted municipality in Portugal, according to the World Health Organization. Human activities are leading to negative effects worldwide, not only in relation to the increasing amount of CO_2 released into the atmosphere but also to soil/water contamination, namely in the proximity to industrial chemical complexes (ICC), as the ICC in Estarreja, northern Portugal. Alterations in climate conditions may directly affect organisms by changing their behaviour, physiological state, *etc*. In addition, increased temperature and atmospheric carbon dioxide (CO_2) levels may influence soil and water properties, affecting chemical bioavailability and, consequently, their toxicity to animals and humans.

The present study aimed to assess the effects of climate change on a polluted aquatic ecosystem using the historically contaminated area in Estarreja as a case study. For that, soil was collected from an agricultural area near the Estarreja ICC. Ecotoxicological bioassays with aqueous soil extracts, simulating run-off to surface waters, were conducted with aquatic species from different trophic levels: *Lemna minor*, *Daphnia magna* and *Danio rerio*. Tests were performed under two different climate scenarios: 1) a climate condition based on the IPCC predictions for 2100, with increased temperature and atmospheric CO_2 level (20-30°C ramp + 800 ppm atm. CO_2); 2) and a standard climate condition recommended by OECD 221, 202 and 236 guidelines for each species. Results showed that *D. magna* survival decreased in Estarreja soil extract and was more pronounced in the increased temperature and CO_2 climate conditions compared to the control. The hatching success of *D. rerio* embryos and the growth rate of *L. minor* were negatively affected in exposures to the Estarreja soil extract in the increased temperature and CO_2 climate conditions (compared to the control medium). Within the scope of TERRA project, the present findings will be disseminated among the Estarreja population to increase awareness about soil and water contamination and the environmental impacts of climate change.

2.04.P-Tu093 Development of an Ecotoxicological Bioassay Battery for the Integrated Assessment of Groundwater Systems

Carolin Bertold[1]*, Christian Forberg[2], Sarah Wohlmann[1], Sven Berkhoff[3], Hans-Jürgen Hahn[3], Heide Stein[3], Klaus Schwenk[4], Wolfram Seitz[5], Thomas Riedel[6], Gerhard Schertzinger[6], Sabrina Schiwy[7] and Henner Hollert[1,8], (1)Department Evolutionary Ecology & Environmental Toxicology, Goethe University Frankfurt, Germany, (2)Goethe University Frankfurt, Germany, (3)Institute for Groundwater Ecology IGÖ GMBH, Germany, (4)iES - Institute for Environmental Sciences, Rhineland-Palatinate Technical University Kaiserslautern-Landau (RPTU), Germany, (5)Zweckverband Landeswasserversorgung, Langenau, Germany, (6)IWW Water Centre, Germany, (7)Evolutionary ecology and environmental toxicology, Goethe University Frankfurt, Germany, (8)Environmental Media Related Ecotoxicology, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany*

Germany obtains 70% of its drinking water from groundwater. Thus, Groundwaters of a very high overall quality status are of high importance for the consumers as much as for the ecosystem. Groundwater ecosystems are characterized by unique biodiversity with many rare, endemic and fossil species and are therefore, particularly worthy of protection. However, at many groundwater sites, there is a complex pollution situation due to the input of nitrates, pesticides, pharmaceuticals, and other industrial chemicals. A comprehensive assessment of the impact of this pollutant input on aquatic fauna and the ecosystem cannot be made with the common and in some cases mandatory chemical analysis of groundwater. Also, the ecotoxicological effects should be evaluated in addition to the chemical analysis of anthropogenic pollution and the status of the groundwater fauna. The recording of this triad approach allows a comprehensive assessment of the anthropogenic impact on the groundwater body. It thus creates the basic knowledge required to protect groundwater ecosystems in the long term.

Such triad-based approaches have already been used very successfully for the holistic assessment of sediments and surface water. In the gwTriade project, a triad approach is to be developed for the first time, specifically for groundwater. Based on the gwTriade project, a broadly diversified ecotoxicological bioassay battery will be adapted to the particular physico-chemical challenges of groundwater (high sulphur, nitrate content) in order to investigate the ecotoxicological status. In addition, the stygophilic species *Eucyclops serrulatus* will be integrated into the bioassay battery. The aim here is to comparatively investigate how the simultaneous contamination of *Eucyclops serrulatus* and *Daphnia magna* (Crustacea) with groundwater contaminants and other stressors, such as heat and nitrate pollution, affect the sensitivity of the organisms. For this matter the development of *Eucyclops serrulatus* is systematically studied in order to design an ecotoxicological test method.

The project is funded by the BMBF ("Sustainable Groundwater Management" (LURCH)). A grant from the Stiftung Polytechnische Gesellschaft Frankfurt supports CB.

2.04.P-Tu094 Effects of Copper, Food Quality and Exposure History on Chironomus riparius Emergence: Insights From a Multigeneration Study

Sebastian Pietz[1], *Sara Kolbenschlag*[1], *Nina Röder*[1] *and Mirco Bundschuh*[2], *(1)University of Kaiserslautern-Landau (RPTU), Germany, (2)iES Landau, University of Kaiserslautern-Landau (RPTU), Germany*

Emerging aquatic insects are important vectors for dietary nutrients such as long-chain polyunsaturated fatty acids (LC-PUFA) for riparian consumers. Aquatic contaminants may affect the transport of these nutrients by impairing development and emergence of aquatic insects. However, repeated or continuous contaminant exposure has hardly been studied against the background of aquatic-terrestrial linkages, but may facilitate the understanding of chronic effects on the quantitative and qualitative subsidy of terrestrial ecosystems. Therefore, we assessed the emergence success and timing of populations of the aquatic insect *Chironomus riparius* (Diptera: Chironomidae) when exposed to the essential metal copper (Cu), both before and after about six months of chronic exposure towards this stressor. The nutritional quality of emergent *C. riparius* were determined based on their FA profile. The quality of the basal food source provided to the larvae (Spirulina – low quality or TetraMin – high quality) was assessed as an additional factor triggering differences in emergence quantity and quality. Copper sediment contents predominately shaped the emergence success of *C. riparius* with reductions of about 30%, 60% and 90% at high Cu sediment contents (200-400 mg/kg dw). Furthermore, emergence was more strongly reduced when larvae were fed Spirulina compared to TetraMin (difference in effect size of 35% at 200 mg/kg dw). At 300 mg/kg dw, the number of emergent adults varied based on the exposure history of *C. riparius* (50% and 70% reduction in pre-exposed and control populations, respectively). Both high Cu sediment levels (≥200 mg/kg dw) and lower basal food quality (i.e., Spirulina) delayed the median time until 50% emergence. The FA analysis is ongoing and will provide insights into the effects of chronic contaminant exposure on the transport of FA by emerging aquatic insects. Since LC-PUFA are mostly synthesized in the aquatic environment but are required for many physiological processes, riparian consumers appear to be particularly vulnerable to such changes.

2.04.P-Tu095 Multi-generational exposure of Daphnia magna to pharmaceuticals: Effects on habitat selection behaviour and reproduction

María del Pilar Gonzalez Muñoz[1], *Ilaria Cecconi*[1,2], *David Salvatierra*[1], *María Úbeda-Manzanaro Crespo*[1] *and Cristiano Araújo*[1], *(1)Institute of Marine Sciences of Andalusia, Spanish National Research Council (ICMAN-CSIC), Spain, (2)University of Trieste, Italy*

Pharmaceutical products are a group of emerging environmental contaminants, whose presence in the aquatic environment poses a risk to organisms. In particular, these products are related to effects on lethality, reproduction, stress induction, neurotoxicity, development, as well as changes in the habitat selection processes by organisms. Although most studies focus on short exposures, these substances are increasingly present and are becoming part of aquatic ecosystems; therefore, it was aimed to assess how the multigenerational exposure of *Daphnia magna* to caffeine, ibuprofen, and fluoxetine could affect the reproductive capacity of organisms and their habitat selection behaviour. For this purpose, the crustacean *D. magna* was exposed to 10 µg/L of each pharmaceutical over three consecutive generations (F3). During this culture period, a daily neonates count was performed to determine the multigenerational effect of these contaminants on reproduction. In addition, habitat selection tests were performed in the HeMHAS (Heterogeneous Multi-Habitat Assay System) version #1, where organisms from F3 were provided to select areas with different contaminants and clean areas, under two scenarios: with and without food. As results, the presence of ibuprofen caused a delay of one week for the first brood, and a considerable reduction in the number of neonates per organism. On the contrary, *D. magna* populations cultured in caffeine showed a shorter time between generations and a greater number of neonates. In habitat selection tests, it was observed that most of the organisms that had been cultivated in clean water were in the compartment with caffeine, highlighting their higher attraction effect with respect to the clean water compartment. In the non-food experiments, all the populations pre-exposed to pharmaceuticals were distributed homogeneously in the system, with any particular preference. We showed that the presence of environmentally relevant concentrations of some pharmaceuticals could cause alterations on the habitat selection pattern and, therefore, on distribution patterns of this specie, as well as a significant effect on reproduction. As a consequence, at long-term, populations can be diminished at the local scale. These conclusions underline the importance of the study of pharmaceutical contamination not only by understanding the short-term effects on biodiversity, but also long-term exposure, as well as the combination of multiple products.

2.04.P-Tu096 Effects of antidepressants on Daphnia magna's behavioural response

María del Pilar Gonzalez Muñoz, *David Salvatierra, María Úbeda-Manzanaro Crespo and Cristiano Araújo, Institute of Marine Sciences of Andalusia, Spanish National Research Council (ICMAN-CSIC), Spain*

Selective serotonin reuptake inhibitors (SSRIs) are commonly used as antidepressant to threat mental disorders like depression. Specifically, its mode of action is to block serotonin reuptake and thus keep high serotonin levels. Currently the consumption of these pharmaceuticals is increasing and because of this, they are being detected in aquatic systems; however, there is not enough information on their effects on exposed organisms. The present study assessed the impact of two antidepressants, sertraline and citalopram, on the behavior of the Cladocera *Daphnia magna*. For this goal, the avoidance and colonization capacity of *D. magna* was studied at 24 h and 48 h, respectively, in the HeMHAS (Heterogeneous Multi-Habitat Assay System) version #3. Exposure was at environmentally relevant concentrations: 0, 0.1, 0.5 and 1 µg/L. We observed that there was no avoidance in *D. magna* to these pharmaceuticals. The response to sertraline was concentration-dependent ($F_{3,12}$: 6.139; $p < 0.05$), with a significantly higher percentage of organisms in the compartments of 1 µg/L, compared with control. Citalopram caused also a concentration-dependent attraction ($F_{3,12}$: 4.396; $p < 0.05$), although the distribution of organisms was more homogeneous between compartments. As for the colonization tests, organisms lasted shorter time to reach the highest sertraline concentration. The organisms only needed 90 min to reach the last compartment, instead of 210 min as in the case of control. This response was not so marked in presence of citalopram, as organisms needed more time to reach the compartment with 1 µg/L of contaminant. However, after 24 h the percentage of organisms in that compartment was two-fold of organisms found in the highest concentration of sertraline. These results suggest the influence of this type of pharmaceuticals on the free distribution of organisms, causing a possible attraction, which can pose a risk in the case of causing an imbalance in the way to detect other contaminants and other environmental stressors.

2.04.P-Tu097 Can E-wastes Modify Behavioural Responses of the Crustacean Atyaephyra demarestii?

Mohammed Ariful Islam[1], *María del Pilar Gonzalez Muñoz*[2], *David Salvatierra*[2], *Carmen Michan*[3], *Jose Alhama*[4], *Cristiano Araújo*[2] *and Julian Blasco*[2], *(1)Department of Aquatic Resource Management, Faculty of Fisheries, Sylhet Agricultural University, Bangladesh, (2)Institute of Marine Sciences of Andalusia, Spanish National Research Council (ICMAN-CSIC), Spain, (3)University of Córdoba, Spain, (4)Biochemistry and Molecular Biology, University of Cordoba, Spain*

Electrical and electronic products are part of our daily lives. This situation has experienced a remarkable growth in the last two decades with the increasing digitalization of society. The generation of waste from technological products, known as e-waste, represents a global environmental problem of great concern, as many of these products contain metallic elements that are potentially toxic and can pose a health problem to ecosystems and humans. Electrical and electronic devices generally have a printed circuit board on which a number of circuits are printed with metals. Some of them are rare earth elements such as erbium (Er), cerium (Ce) and neodymium (Nd). However, the case of lithium (Li) deserves a special mention, as its use has increased considerably for its application in batteries of electric and hybrid vehicles. Understanding how the release of these elements can affect aquatic species and ecosystem biodiversity is a challenge. In this work, we have analyzed how the occurrence of these elements in individual form and as binary mixtures can trigger the avoidance behavior of the crustacean *Atyaephyra demarestii*. The experimental setup has been carried out using the HeMHAS (Heterogeneous Multi-Habitat Assay System) for 24 and 48 h, which has allowed it to calculate the relationship between a gradient of exposure and avoidance behavior for individual and mixture elements**.** In this study, it is shown how E-wastes affect the habitat selection behaviour of shrimps and their ability to interact with the surrounding environment.

2.04.P-Tu098 Contamination and habitat fragmentation as drivers of population distribution of stressed landscapes

David Salvatierra[1], *Marcos Krull*[2], *María del Pilar Gonzalez Muñoz*[1], *María Úbeda-Manzanaro Crespo*[1], *Mohammed Ariful Islam*[3], *Cristiano Araújo*[1] *and Julián Blasco Moreno*[1], *(1)Institute of Marine Sciences of Andalusia, Spanish National Research Council (ICMAN-CSIC), Spain, (2)Department of Enthomology, Senckenberg Research Institute, Germany, (3)Department of Aquatic Resource Management, Faculty of Fisheries, Sylhet Agricultural University, Bangladesh*

Changes in the connectivity configuration of landscapes (i.e., habitat fragmentation) and contamination may have long lasting effects on biodiversity, such as the local extinction of species and habitat use. The aim of this study was to evaluate the interaction effects of habitat fragmentation and contamination on the habitat selection by zebrafish (*Danio rerio*), and their ability to explore landscapes with different connectivity configurations and a heterogeneous spatial arrangement of contamination. It was hypothesized that both contamination and habitat fragmentation reduce the probability of organisms finding resources (i.e., food) by increasing the time spent foraging in fragmented landscapes and by avoiding contaminated areas. For this purpose, the organisms were exposed to three scenarios of contamination (0, 0.5 and 25 µg/L of copper) and physical fragmentation (zero, low and high), using the Heterogeneous Multi-Habitat Assay System (HeMHAS). Fish were stimulated to forage by adding food in the last compartment at the end of the system. All experimental trials were videotaped, and the time spent to find food and within each specific compartment were recorded. Generalized Bayesian linear models were used to analyze the data and evidence ratios (ER) were used to test the hypotheses. Strong evidence suggests that the spatial distribution of organisms was hindered as consequence of both high levels of fragmentation and contamination (ER > 1000 and ER = 122 respectively). However, no significant effects were observed in the probability of organisms finding food and the time spent in the low fragmented and contaminated scenarios (ER = 1.56 and ER = 0.76 respectively). Overall, organisms avoided highly contaminated areas by spending less time in compartments with high concentrations of copper and more time in fragmented compartments. These results indicates that the probability of finding resources was reduced by the effect of contamination, and the time spent in the system foraging and within each compartment was linked to the combination of the contamination and fragmentation. As conclusion, the contamination and fragmentation had a noteworthy synergistically effect over the spatial distribution of fish, affecting the probability of reaching food and the time spent to achieve it. Also, the HeMHAS demonstrated its suitability to assess the role of the contamination and fragmentation stressors in the spatial distribution and habitat selection response.

2.04.P-Tu099 Shy vs. bold: Testing if personality traits influence zebrafish propensity to colonize polluted environments

*Natalia Ivone Sandoval Herrera[1], **David Salvatierra**[2], María Úbeda-Manzanaro Crespo[2], María del Pilar Gonzalez Muñoz[3], Erin McCallum[4] and Cristiano Araújo[2], (1)Department of Wildlife, Fish, and Environmental Studies, Swedish University of Agricultural Sciences (SLU), Sweden, (2)Institute of Marine Sciences of Andalusia, Spanish National Research Council (ICMAN-CSIC), Spain, (3)Instituto de Ciencias Marinas de Andalucía, Spain, (4)Swedish University of Agricultural Sciences (SLU), Sweden*

Individual differences in fish behavior, also known as personality traits, contribute to animal fitness by influencing social interactions, foraging success, and predator avoidance. Personality could also affect decision making in unpredictable environments, such as polluted habitats. Bolder fish, for example, tend to colonize new environments faster, potentially increasing their risk of exposure to contaminants. Although research has begun to test how exposure to contaminants affects fish behavior and personality, to what extent personality itself influences the exposure of fish to contaminants via their propensity to enter and stay in contaminated habitats is still unclear. Here, we assessed how fish personality traits (shy and bold) affected their habitat colonization and habitat choice in a gradient of pollution using zebrafish as a model species. We used two standard tests for boldness in fish: novel environment and refuge seeking. We profiled each individual as bold or shy, based on their swimming behavior and positions in the tank. We then tested habitat choice using the Heterogeneous Multi-Habitat Assay System (HeMHAS), a multicompartment arena where the organisms can move freely along a chemical gradient. We tested each fish along a linear gradient of two chemicals: fluoxetine and copper (0.1-100 µg/L), as well as a clean water control. We selected fluoxetine as it is a contaminant of emerging concern that is known to attract fish. Copper was used as a positive control, for its known aversion effects on zebrafish. The personality test we used successfully discriminated between the two phenotypes (bold-shy). For habitat choice, we expect that both bold and shy fish show an avoidance towards copper and attraction towards fluoxetine as has been reported previously for this species. However, we expect to see differences between phenotypes in the colonization time to polluted compartments, and residence time in each compartment. We predict that bolder fish will colonize the compartments with higher concentrations of fluoxetine faster than shy fish, and only bold fish will colonize compartments with high concentrations of copper. As concerns regarding emerging pollutants like pharmaceuticals grow, understanding how personality can shape the exposure of animals to environmental stressors becomes crucial. Our study contributes to this evolving field looking at the intersection of animal personality and environmental pollution.

2.04.P-Tu100 Ecotoxicological Bioessay of Commercial Sunscreens on Phaeodactylum Tricornutum

*Rajaa Kholssi[1], Araceli Rodríguez-Romero[2], María Úbeda-Manzanaro Crespo[1] and **Ignacio Moreno-Garrido**[1], (1)Institute of Marine Sciences of Andalusia, Spanish National Research Council (ICMAN-CSIC), Spain, (2)Department of Analytical Chemistry, Faculty of Marine and Environmental Sciences, Marine Research Institute (INMAR), University of Cadiz, Spain*

The European coast receives millions of tourists each year and significant amounts of commercial sunscreen (SSn) compounds is being released into aquatic environment. Until now there is a significant gap in the information concerning the toxicity of SSn on marine microalgae. Thus, the effect of SSn at different concentrations (0, 5, 10, 25, 50, 100 and 200 $mg.L^{-1}$) were assayed on the growth of the most common species of marine microalagae used in ecotoxicology: *Phaeodactylum Tricornutum.* Culture were exposed under controlled conditions in a climatic chamber with continuous agitation at 20 °C, and salinity of 36 PSU in a 96 h study using flow cytometry analysis (FCM). Reactive oxygen species (ROS) production were monitored by 2′7′-dichlorofluorescein (DCFH) using FCM. Chlorophyll was measured by auto-fluorescence. The Results indicated that *P. Tricornutum* sp. was significantly more sensitive at the highest concentration 200 $mg.L^{-1}$ of SSn used compared to control. As well as, algal growth revealed that in the absence of sunscreens, *P. Tricornutum* grown similarly to two lowest concentrations (5, 10 $mg.L^{-1}$). Chlorophyll *a* fluorescence showed a significant decrease ($p < 0.05$) in *P. Tricornutum* under three highest concentrations (50, 100 and 200 $mg.L^{-1}$). ROS levels were triggered under 100 and 200 $mg.L^{-1}$, by 66 and 63% respectively; which was higher than all the others treatments. Our study resulted in data concerning the potential impacts caused by possible future drastic effect of commercial Ssn in aquatic habitats.

2.04.P-Tu101 Effects of microalgae based biostimulants on water and soil condition and species

***Mishal Antony**, Department of Biology, Campus Groenenborger, GU531, University of Antwerp, Belgium*

The growing global population and rising food consumption have inevitably raised the demand for agricultural food products. In addition, growing environmental awareness prompts questions about agricultural practices and how they affect biodiversity and ecosystem function. The effects of these production processes on environmental quality and climate change are of critical importance. It is important to achieve a balance between efficient food production and sustainable agricultural methods. Developing such a scenario requires a multifaceted approach which includes optimized nutrient input and an increased crop tolerance to environmental stress. To this end, innovative technologies based on bioresources include the use of microalgal biostimulants to improve crop yield while lowering the environmental footprint of agriculture. Today, there is a lack of scientific data on microalgae used as biostimulants and its environmental impact, which hinders the advancement and

establishment of this technology. Specifically, there is a lack of knowledge regarding the underlying mechanism of action and the effectiveness of microalgal biostimulants in improving agronomic efficiency. In this study we examine the potential ecotoxicological impact of microalgal biostimulants on non-target aquatic and terrestrial organisms. We performed toxicity tests to document and understand the potential ecotoxicological impact of microalgal biostimulants (*Spirulina platensis, Chlorella vulgaris*, *Nannochloropsis gaditana* and *Dunaliella salina)* on a range of representative organisms for both terrestrial and aquatic ecosystems. The tests were performed at concentrations of 1g/L, 0.5g/L, 0.25g/L, 0.1g/L, 0.05g/L, 0.01 g/L with model organisms *Daphnia magna* (water flea) 48 hours mortality/immobilization test and 21 days reproduction test, *Eisenia fetida*/*andrei* (earthworm) 21 days mortality test, *Branchionus calyciflorus* (rotifer) 24, 48 hours mortality/ immobilization test- and *Spirodela polyrhiza* (duckweed) 72 hours toxicity test. At the highest concentrations (1g/L and 0.5g/L) of *Spirulina platensis* and *Chlorella vulgaris* there was high mortality in *Daphnia magna* 48 hours test which is indicative of an ecotoxicological impact on the environment. So far optimal biostimulant concentrations seem to be reached at concentrations < 0.1 g/l and chronic assessments are being conducted at this and lower concentrations.

2.04.P-Tu102 Evaluations of aqueous toxicity and cytotoxicity of Ziram

***Nile E. Kemble**, Gavin Saari, Blake Sauey, Danielle Cleveland and Jeffery Steevens, U.S. Geological Survey (USGS)*

The grass carp, is one of four invasive carp species established in North America. The other invasive carp are bighead carp, black carp, and silver carp. Grass Carp have been recorded in 45 states in the United States, with spawning populations in the Great Lakes and the Missouri and Mississippi Rivers. Therefore, fisheries managers are interested in identifying new chemicals that can be used for the selective control of invasive carp. These new chemicals should show some species-specificity, be palatable to target species, demonstrate low persistence in aquatic systems, and have minimal adverse effects on non-target species. One such chemical is Ziram, a dimethyl-dithiocarbamate containing zinc (log K_{ow}:1.23) is currently registered as an agricultural fungicide that may have promise to control undesirable fish, like the Grass Carp. Few studies have measured the toxicity of Ziram to fish or freshwater invertebrates, and many of these studies were based on nominal concentrations. The objectives of this study were to evaluate the potential acute toxicity of Ziram in an aqueous solution to a suite of non-target aquatic fish and invertebrates and determine the *in vitro* cytotoxicity (OECD 249) of Ziram in Grass Carp, Lake Sturgeon, and Rainbow Trout gill cell lines. A total of six species, three fish and three invertebrates, were exposed to a series of aqueous Ziram concentrations for 96 hours and experimental concentrations were analytically verified in exposure media for total Zn concentrations. In the invertebrate bioassays, 96-h LC_{50} values (nominal concentrations) ranged from 0.14 mg/L to greater than 2.0 mg/L, with amphipods being the most sensitive species. In the fish studies, 96-h LC_{50} (nominal concentrations) values ranged from 5.4 µg/L to 354 µg/L, with Lake Sturgeon being the most sensitive species. Similarly, 24-h fish gill cytotoxicity results indicated Lake Sturgeon were the most sensitive species to Ziram. We compared cytotoxicity EC_{50} values to toxicity values from *in vivo* exposures. Preliminary results indicate relative agreement between cytotoxicity and in vivo toxicity values for Rainbow Trout and Grass Carp, and the ratio of *in vitro*: *in vivo* 24-hour toxicity values is less than 2-fold. Toxicity data will be used to determine whether Ziram toxicity is species-specific and sufficient to develop a prospective Ziram formulation for effective invasive carp control.

2.04.P-Tu103 Feeding activity of gammarids as ecotoxicological endpoint for acute fungicide stress in freshwater mesocosms

***Silvia Mohr, PhD**[1], Steffen Carl[1], Ronny Schmiediche[1], Ulrike Scholz[1], Valeska Contardo Jara[1] and Marco Konschak[2], (1)IV 2.5, Umweltbundesamt (UBA), Germany, (2)Umweltbundesamt (UBA), Germany*

Biodiversity as well as ecosystem functioning of aquatic fungi (AF) can be significantly influenced by fungicides. Furthermore, shredders feeding on contaminated leaves may also be affected directly by fungicide exposure (i.e. *via* water phase or fungicides adsorbed onto leaves) or indirectly *via* changes in food quality due to effects on the leaf-associated microbial community. As part of a comprehensive mesocosm study investigating effects of the fungicide Tebuconazole (TBZ; product Folicur®) on fungal biodiversity and functioning in freshwater mesocosms, an *in-situ* experiment using *Gammarus roeseli* feeding on alder leaves was performed. The aim of the *in-situ* experiment was to investigate if the feeding activity of *G. roeseli* can be used as sublethal endpoint in mesocosm studies to evaluate pesticide stress. Eight near-naturally established freshwater mesocosms were dosed once with six different concentrations of TBZ (5-5000 µg/L). The feeding activity of *G. roeseli* was measured after two and six days of TBZ exposure in the contaminated mesocosms under different water temperatures, using leaves previously colonized in control water for three weeks (experiment 1). In experiment 2, leaves were conditioned for 3 weeks in mesocosm water treated with TBZ concentrations and were then used for the feeding experiment with exposure of *G. roeseli* in control and treatment mesocosms (test durations also two and six days). Each experiment consisted of four cages per mesocosm, each containing three *G. roeseli* and ten leaf disks. After the experiment, the remaining leaf disks were photo-documented and weighed to measure leaf loss. The feeding activity of *G. roeseli* was clearly inhibited with TBZ exposure using uncontaminated leaves and showed a clear concentration response relationship. Lowest EC_{50} was 264 µg/L TBZ (2d, 19°C, experiment 1). In experiment 2, feeding activity of *G. roeseli* was reduced by ± 20 %, in which gammarids fed contaminated leaves for two days in control water. However, inhibition of feeding activity of gammarids was negligible in the same experiment when exposed for six days except for the highest concentration. Possibly, hunger effects as well leaching of TBZ from leaves into the uncontaminated medium (analytically measured) may have led to a recovery effect. Inclusion of *in-situ* feeding experiments in mesocosm studies seems to be a promising tool to investigate short-term acute sublethal effects on gammarids.

2.04.P-Tu104 Using Individual Biomarkers to Characterize the Effects of Pesticide Mixture in Gammarus fossarum Under Mesocosm Conditions

Alexandre Michel[1]*, Aliénor Jeliazkov*[2]*, Cedric Chaumont*[3]*, Julien Tournebize*[4]*, Virginie Archaimbault*[2] *and Jérémie D. Lebrun*[2]*, (1)Paris-Saclay University, (2)INRAE, UR HYCAR, CS 10030, France, (3)UR HYCAR, INRAE, University of Paris Saclay, France, (4)Institut national de recherche pour l'agriculture, l'alimentation et l'environnement (INRAE), France*

Pesticide contamination of continental freshwater bodies is now widespread. In agricultural landscapes, constructed wetlands (CW) are set up to intercept and trap pesticides. Pesticides then undergo purification processes linked to physical (sorption) and biological (degradation) processes through interaction with plants and the activity of microorganisms. However, these pesticide-trapping wetlands could act as ecological traps, i.e., habitats that are potentially attractive to species but reduce the fitness of organisms. In addition, little is known about pesticide cocktail effects in general, and in these environments in particular. The aim is to identify the potential effects of a pesticide cocktail in a CW with a model species at the individual scale. Our study site is a French CW of 3,500 m² treating contaminated water from a 355 ha agricultural watershed planted with cereal, representative of intensive agriculture. The model species is the crustacean amphipod *Gammarus fossarum*. In six "in situ" 300L mesocosms (2m × 0.5m × 0.3m), located in the center of the CW, but isolated from the surrounding water, four cages containing 20 gammarids and alder leaves (*Alnus spp.*) were immersed for one week, and the experiment was repeated four times with different groups of gammarids each time (i.e. 4 weeks of independent exposure × 6 mesocosms × 4 cages × 20 gammarids). We used a cocktail of nine molecules, herbicides and fungicides, representative of the main pesticides found in the watershed and in the CW in the last ten years. This cocktail was injected once, in four of the six mesocosms, at the beginning of the four consecutive weeks of exposure from March 25 to April 22, 2021. We monitored four individual biomarkers: survival rate, locomotion rate, amplexus rate (reproduction) and feeding rate. The main results are: (i) survival rate is not significantly different between pesticide-exposed gammarids and unexposed gammarids, (ii) increasing pesticide exposure increases locomotion rate. The latter result may reflect pesticide avoidance behavior in exposed gammarids. Pesticide avoidance by certain invertebrates could have implications for the structure and ecological functioning of CWs under agricultural chemical pressure.

2.04.P-Tu105 Unravelling the Molecular Mechanisms of Fish Salinity Adaptation in the Face of Severe Osmotic Stress: A Comparative Multi-Tissue Transcriptomic Study in the Llobregat River, Barcelona, Spain

Camilo Escobar Sierra[1]*, Miguel Canedo-Arguelles*[2]*, Dolors Vinyoles*[3] *and Kathrin Lampert*[1]*, (1)Zoology Institute, University of Cologne, Germany, (2)Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain, (3)Departament de Biologia Evolutiva, Ecologia i Ciències Ambientals, Facultat de Biologia, Institut de Recerca de la Biodiversitat (IRBio), Universitat de Barcelona, Spain*

Freshwater salinization, driven by activities such as potash mining, is a global environmental concern threatening freshwater biodiversity, particularly fish populations. This study focuses on the intricate molecular mechanisms guiding fish adaptation to rising salinity levels in the urbanized Llobregat River, Barcelona. Employing high-throughput mRNA sequencing, we explored tissue-specific responses in the brain, gills, and liver of the invasive minnow (*Phoxinus septimaniae* x *P. dragarum*) at two distinct stations—a heavily impacted salt-polluted station near the "Potasses del Llobregat" potash mine and a reference station. Salinization significantly influenced global gene expression profiles, with the brain displaying the highest number of differentially expressed genes, highlighting its unique sensitivity to salinity fluctuations. Pathway analyses revealed enrichment of ion transport and osmoregulation pathways across all tissues, alongside tissue-specific pathways related to stress, reproduction, growth, immune responses, methylation, and neurological development in the context of salinization. Rigorous validation of RNA-seq data through quantitative PCR (qPCR) underscored the robustness and consistency of our findings. This investigation unveils intricate molecular mechanisms steering salinity adaptation in non-native minnows facing diverse environmental stressors. Our study provides crucial insights into the adaptive strategies of aquatic organisms grappling with freshwater salinization. Prioritizing efforts to mitigate potash mining pollution is recommended to counteract the physiological adaptive advantage conferred to invasive species over their native counterparts. This comprehensive analysis sheds light on the underlying genetic and physiological mechanisms governing fish adaptation in salinity-stressed environments, offering essential knowledge for the conservation and management of freshwater ecosystems facing escalating salinization pressures.

2.04.P-Tu106 Weight-of-evidence approach for watershed-scale ecological risk assessment near a zinc smelter in the Nakdong River and Andong Lake, Korea

Dae-sik Hwang*, Jiwoong Chung and Jong-Hyeon Lee, EH Research & Consulting Co. Ltd., Korea, Republic of (South)*

The upstream of Nakdong River and Andong Lake is contaminated by heavy metals such as Cd, Zn, As, and Pb. Although the origin of the contamination is unequivocal, it is suspected that the heavy metals have been leached from zinc smelter. Traditional ecosystem assessment, focusing on specific chemicals, faces doubts regarding its effectiveness in translating laboratory findings to real ecological impacts using lab ecotoxicity studies and field measurements for risk evaluation. In this study, we conducted a weight-of-evidence (WoE) approach to better understand the ecological impacts of heavy metal contamination in the upstream of Nakdong River and Andong Lake. The WoE analysis integrated evidence from a variety of sources, including field monitoring of metal concentrations in sediments, sediment elutriate and surface water, toxicity tests on sediments and sediment elutriate, and surveys of the biota.

Analysis of heavy metal concentrations in sediments and surface water revealed elevated hazard quotients(HQ) for As and Cd in sediments and Zn and Cd in surface water. The concentrations of Zn and Cd were notably elevated in the surface water downstream of the smelter, and the hazard decreased after 70 km. Toxicity tests using *H. azteca* on sediment site samples showed that 57% of the samples were toxic. Logistic regression analysis of the sediment toxicity and mean Probable Effect Levels quotients(mPELq) showed a significant correlation, and Cd and As were identified as the primary contributors to the observed toxicity. In contrast, sediment elutriate toxicity tests showed that 18% of the samples were toxic to *D. magna*, and Zn was identified as the primary contributor to the observed toxicity. Benthic macroinvertebrate surveys were used to assess Benthic Macroinvertebrate Index(BMI) and Species At Risk(SPEAR) of metals at 12 sampling sites in the upstream of Nakdong River. Bioavailability toxic unit(TU) derived using the Biotic Ligand Model(BLM) and Hardness correction showed a significant correlation with $SPEAR_{metal}$. Cd and Zn were identified as the primary contributors to the observed toxicity.

These findings suggest that the Zn and Cd contamination is having a significant impact on the ecological health of the upstream of the Nakdong River and Andong Lake. The results of this study provide important information for environmental management and remediation efforts in the area.

2.04.P-Tu107 Watershed-Level Characterization of Chloride Exposure and Associated Risks: A Case Study in One of the World's Largest Watersheds

Braedon W. Humeniuk[1], *Jose Luis Rodriguez Gil*[2,3] *and Mark L. Hanson*[1], *(1)University of Manitoba, Canada, (2)Experimental Lakes Area (IISD-ELA), Canada, (3)International Institute for Sustainable Development (IISD), Canada*

The concentrations of salts in freshwater systems have been increasing globally, resulting in concern of adverse and sustained ecological impacts. With numerous potential pathways for dissolved salts to enter surface waters (e.g., road de-icing, agriculture, wastewater effluents, and resource extraction), there is a need for high quality exposure data to inform risk assessors when making regulatory decisions for freshwater protection. To assess the ecological risk associated with freshwater salinization in Canadian surface waters, we used the Lake Winnipeg watershed as a case study. This is among the largest watersheds in the world, with an area of ~1 million km^2. We were interested in characterizing the current state of salinity and salinization, as evaluated through the lens of a community-based monitoring (CBM) program. CBM volunteers gathered samples over three field seasons (2020-2022), from a total of 119 sites across Manitoba, with approximately 20 samples per site collected per year. The collected water samples were analyzed for chloride ion concentrations and each sampling site was categorized by their dominant land-use (e.g., urban, rural municipality, agriculture, pasture, lake outlet, and forest) to determine the driving sources, as well as temporal trends of salinization in the watershed. During the three field seasons, multiple sites across differing dominant land-uses exceeded the Long-Term Canadian Water Quality Guideline (CWQG) for the Chloride Ion (120 mg Cl^-/L) based on time-weighted averages for each site, with 12.3%, 17.3%, and 3.6% exceedance rates in 2020, 2021, and 2022, respectively. There was a low acute risk of exceedance across sites; however, two urban sites exceeded the Short-Term CWQG (640 mg Cl^-/L) multiple times in 2020 and 2021. The sites that experienced the greatest salinity levels were in rural municipalities within the Red River Valley and near the city of Winnipeg, Manitoba, suggesting that anthropogenic factors are likely driving exposure in these regions. Overall, this project will provide data to inform risk assessment, as well as identify a possible driver of ecological change in freshwater systems, while also enhancing public participation in their protection.

2.04.P-Tu108 A Critical Review of Sodium Chloride Freshwater Toxicity Data for Generating Species Sensitivity Distributions

Braedon W. Humeniuk[1], *Jose Luis Rodriguez Gil*[2] *and Mark L. Hanson*[1], *(1)University of Manitoba, Canada, (2)Experimental Lakes Area (IISD-ELA), Canada*

Rising ion concentrations from salts could pose a direct and indirect risk to freshwater organisms and irreversible impairment on the structure and function of food webs. Additionally, concerns about data quality, reporting and fit of toxicity data for use in risk assessment have been raised, which may lead to ecological impacts if used to generate insufficiently protective guidelines. Thus, high quality toxicity data are needed to inform risk assessors when making regulatory decisions regarding freshwater protection for chloride. To address the concerns surrounding the reliability and relevance of ecotoxicological literature, we conducted a critical review with the overall objective to assess the current state of laboratory toxicological data as it relates to chloride ions associated with freshwater salinization. Specifically, we sought to 1) evaluate the strength of methods of aquatic toxicity studies for sodium chloride on freshwater organisms, as well as their utility for ecological risk assessment via objective scoring rubrics; 2) use studies deemed suitable for risk assessment to create Species Sensitivity Distributions (SSDs), where it is possible to estimate water quality protection thresholds; and 3) identify major knowledge gaps and make recommendations to address current and future toxicity data needs related to freshwater salinization. A total of 313 papers were reviewed. Of these, 98 papers (with 358 data points from unique bioassays) met the inclusion criteria (as of November 2023) and were scored based on their utility for risk assessment. In general, studies described the test substance and test organism well, but there was room for improvement when reporting response results and test conditions. SSDs were created using the strongest chloride toxicity data to contrast with existing water quality guidelines and criteria. The hazardous concentration estimate for the 5th percentile of the distribution (HC_5) values were determined to be 380 mgCl^-/L from 56 species and 40 mgCl^-/L from 52 species for the acute and chronic SSDs, respectively. In contrast, the Short-Term and Long-Term Canadian Water Quality Guidelines for the Chloride Ion are 640 mgCl^-/L and 120 mgCl^-/L, respectively. Therefore, this research provides data that is useful for ecological risk assessment and freshwater protection, as well as guiding future research by identifying specific species and exposure scenarios that might be lacking reliable and ecologically relevant data.

2.04.P-Tu109 Exploring Trait-Based Vulnerability in Korean Freshwater Systems to Enhance Understanding of Heavy Metal Impact on Biodiversity

Jinhee Park[1] *and Sang Don Kim*[2]*, (1)International Environmental Research Institute, Gwangju Institute of Science and Technology (GIST), Korea, Republic of (South), (2)School of Earth Science and Environmental Engineering, Gwangju Institute of Science and Technology (GIST), Korea, Republic of (South)*

Recently, efforts have been made to integrate the distinct practices of biomonitoring and chemical monitoring, traditionally conducted separately, in assessing environmental status. Some researchers used the trait-based approach with biological and ecological information to examine how organisms respond to chemicals. For example, ecological vulnerability, encompassing exposure, recovery potential, and sensitivity to chemicals, relies on multiple trait indicators, enabling the prediction and assessment of organisms' overall states. Understanding the intricate interplay between organisms and chemicals in their environment is promising, especially in the context of preserving biodiversity. This study delved into trait-based vulnerability regarding four heavy metals (Cu, Cd, Pb, and Zn) in Korean freshwater systems. Traits encompassing various modalities served as vulnerability indicators grouped into exposure, recovery, and sensitivity categories. In addition, toxicity indicators for the heavy metals were incorporated to derive the vulnerability scores for target organisms. As a result, the vulnerability scores among different taxonomic groups showed significant differences. Fish displayed lower vulnerability to Cd and Cu than other groups, while Crustaceans, gastropods, and bivalves shifted in their vulnerability rankings due to toxicity indicators. Including the toxicity category markedly altered vulnerability scores for bivalves, especially for Pb and Zn. Such findings offer valuable insight into biodiversity preservation policies. Understanding how different species respond to specific chemicals emphasizes the necessity for customized conservation plans. Policymakers can implement focused actions, like stricter regulations or protective measures, for vulnerable species to chemical pollution. Incorporating these scientific insights into environmental policies will support safeguarding at-risk species, contributing to diverse ecosystem preservation.

2.04.P-Tu110 Is Agricultural Pesticide Pressure of Prime Relevance for the Composition of Macroinvertebrate Communities in Small Agricultural Streams?

Udo Hommen[1]*, Silke Claßen*[2]*, Richard Ottermanns*[3]*, Oliver Körner*[4] *and Carola Schriever*[5]*, (1)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (2)Research Institute gaiac, Germany, (3)Environmental Biology and Chemodynamics, RWTH Aachen University, Germany, (4)ADAMA Deutschland GmbH, Germany, (5)BASF SE Agricultural Solutions, Germany*

The German Federal Environment Agency commissioned a surface water monitoring campaign (2018-2019) to assess the chemical and biological condition of small agricultural watercourses and verify the effectiveness of risk assessment and management in the pesticide approval process. For more than 100 stream sites, water samples were analysed for pesticide active substances, pharmaceuticals and other urban contaminants, and aquatic macroinvertebrates were sampled to determine the community composition. The campaign provides a large monitoring dataset and can help to understand the chemical and ecological situation of small agricultural streams. The final campaign report concluded that the detected concentrations of pesticide active substances are the dominant stressor for vulnerable insects and the macroinvertebrate community. This conclusion is based on a strong correlation between toxic pressure attributed to pesticide active substances and SPEARpesticides, a biological index based on the proportion of the abundance of macroinvertebrate species classified as vulnerable to pesticide pressure. It is the nature of any biological index to correlate with the stressor it was optimized for and the report shows this e.g. for the saprobic index, explained primarily by deficient oxygen conditions and the EPT index explained by habitat factors hydro-morphology, streambed structure and flow. The present study questions whether the relevance of individual stressors can be assessed by means of specific biological indices and aims to shed light on the influence of abiotic factors on the composition of macroinvertebrate communities. The publicly available raw data from the campaign were analysed using ordination methods that, unlike indices, do not require pre-weighting species in terms of their assumed vulnerability to a specific stressor. Instead, species occurrence and abundance are used to group the stream sites and to relate them to various environmental factors. The results showed that that environmental factors such as water quality and quality of habitat structure were more relevant than pesticide pressure. In conclusion, SPEARpesticides can indicate the ecological status of small streams but does not necessarily clarify the multiple environmental factors impacting the status. Without this clarification, the role of pesticide pressure resulting from agriculture cannot be understood well enough to conclude on the pesticide approval process.

2.04.P-Tu111 Regulatory and practical considerations on the implementation of a Mixture Allocation Factor in REACH

Gabriele Treu[1]*,* ***Jona Schulze***[1]*, Wiebke Galert*[2] *and Enken Hassold*[2]*, (1)German Environment Agency (UBA), Germany, (2)Chemicals, German Environment Agency (UBA), Germany*

The exposure to various chemicals originating from diverse anthropogenic sources and through different pathways poses potential combined risks that current European chemical legislations do not adequately address. In its Chemical Strategy for Sustainability, the European Commission (EC) proposed introducing a mixture allocation factor (MAF) into REACH Annex I. This is to address risks from unintentional mixtures by introducing a “new” ceiling for the accepted risk during the chemical safety assessment of single chemicals. Focusing on environmental risk assessments, we critically discuss the MAF as most pragmatic and immediately implementable regulatory measure to account for risks arising from unintentional mixtures. We provide a 12-point action plan with practical recommendations and aspects to be considered for the introduction of a MAF in REACH. To enhance compliance and acceptance, we emphasize the importance of clarity and transparency with respect to the rationale, scope and selection of methods and data basis to define an appropriate magnitude for the MAF. Although it was announced by the EC, a public disclosure on details of the proposal and an analysis of socioeconomic impacts, the effectivity and benefits of introducing a MAF and a comparison to more specific regulatory measures are pending. We argue for the

application of the MAF as a generic risk management tool applicable to all REACH chemicals, without derogations and irrespective of tonnage, use, or environmental compartment. The MAF size should be based on the available different lines of evidence and set at a sufficiently high value to address uncertainties. The effectiveness of the MAF hinges on the implementation, application and enforcement of the MAF and the corresponding risk mitigation measures in order to effectively reduce environmental exposure levels of particularly those chemicals contributing to unacceptable risks for the environment. Still, assessing unintentional chemical mixtures must extend across various relevant chemical regulations in order to approach the real-life exposure situation and ensure harmonization. This is crucial not only for achieving the European Zero Pollution Ambition outlined in the European Green Deal but also for aligning with the global Sustainable Development Goals.

2.04.P-Tu112 Variability of responses to multiple chemical stressors in invasive mosquitofish
Nicolas Martin[1]*, Elena Gomez*[2]*, Geoffroy Duporte*[2]*, Lisa Jacquin*[3]*, Simon Blanchet*[4]*, Etienne Lemaire*[5] *and Emilie Farcy*[6]*, (1)Edb, Laboratoire EDB, Université Toulouse III Paul Sabatier, France, (2)HydroSciences Montpellier, University of Montpellier, CNRS, IRD, France, (3)Laboratoire EDB, Université Toulouse 3 Paul Sabatier; Institut Universitaire de France IUF, France, (4)SETE CNRS, France, (5)HydroSciences Montpellier, IRD, CNRS, University of Montpellier, France, (6)MARBEC, Univ. Montpellier, CNRS, Ifremer, IRD, INRAE, France*
Rapid adaptation to pollution in wildlife is still debated. For instance, recent studies document fish adaptation to dioxin like pollutants, but a limited number of empirical studies in realistic environmental conditions are available so far. In addition, chemical pollution in anthropized freshwater streams is frequently characterized by a cocktail of chemicals including several historical and emerging compounds at sub-lethal concentrations, which could complicate the evolutionary outcome of pollution exposure in the wild. In this study, we evaluated the phenotypic divergence of wild populations of invasive mosquitofish (*Gambusia holbrooki*) exposed to gradients of multiple chemical stressors in French rivers. In addition, we tested the inter-populational divergence in tolerance to an experimental exposure to a cocktail of non-persistent pollutants to test for potential local adaptation to pollution. We hypothesized that increased tolerance to pollutants in fish living in polluted streams would be associated with: (i) no or moderate detrimental effects of chemical stressors on fish health, due to increased detoxication metabolism and/or higher non-enzymatic antioxidant defenses and (ii) a higher tolerance to an experimental exposure to a realistic cocktail of pollutants. First, we performed an extensive field study in 12 populations and compared the phenotype of F0 fish living along gradients of chronic pollution. Second, we experimentally tested the survival of their F1 offspring to an experimental cocktail of non-persistent pollutants (pesticides-pharmaceutics). Results show that F0 fish from highly polluted sites had an increase biotransformation activity and a decrease non-enzymatic antioxidant capacity associated with limited oxidative damages. In addition, their F1 offspring had a higher survival when experimentally exposed to a realistic cocktail of pollutants, revealing a higher tolerance of juveniles coming from the most exposed populations. Further studies are now necessary to investigate the underlying genetic and epigenetic mechanisms explaining this phenotypic divergence.

2.04.PC Bridging the Gap between Exposure, Ecotoxicology and Ecology – Identifying and Regulating the Impact of Chemical Pollution on Biodiversity

2.05.A Marine Ecotoxicology: Impacts and Possible Solutions, From Coastal to Deep-Sea Ecosystems

2.05.A.T-01 The Impact of 17α-Ethynylestradiol (EE2) on Behaviour and Morphology in an Australian Marine Fish
Shiho Ozeki[1]*, Rhiannon Eastment*[2]*, Raiko Rafeeq*[1]*, Jack Lewis Manera*[2]*, Jake Mitchell Martin*[3]*, Anne Peters*[2] *and Bob Wong*[2]*, (1)School of Biological Sciences, Monash University, Melbourne, Australia, (2)School of Biological Sciences, Monash University, Australia, (3)Swedish University of Agricultural Sciences (SLU), Sweden*
Due to the growing use of medication globally, the number of pharmaceutical pollutants in the environment has risen sharply. One pharmaceutical of particular concern is 17α-ethynylestradiol (EE2), a synthetic estrogen used as the primary ingredient in the human contraceptive pill. In the environment, EE2 can alter morphology and physiology of exposed wildlife and increase mortality. However, the majority of EE2 studies have focused on freshwater species, despite the fact that EE2 is prevalent in marine systems. Accordingly, this study aimed to examine the impact of a range of environmentally relevant concentrations of EE2 on the behaviour and morphology of an Australian native marine fish—the crested weedfish (*Cristiceps australis*). Weedfish were exposed to one of three treatment groups using a static renewal system—an unexposed control (marine water; 0 ng/L), low-dose EE2 (measured concentration: 33 ng/L), or high-dose EE2 (measured concentration: 70 ng/L)—for 14 days. Following the exposure period, individuals were subject to a refuge-use assay to investigate the impact of EE2 on boldness and anxiety. Using IDtrackerAI, an automated AI tool for quantitative analysis of animal behaviour, specific behaviours including latency to enter the refuge, time spent out of refuge and overall activity were scored. Moreover, the influence of exposure treatment on morphological characteristics, such as body condition, length and weight, were also analysed as they are closely correlated with boldness and anxiety. Preliminary analyses show that EE2 has an impact on both behaviour and morphology in weedfish, in which fish exposed to the high treatment of EE2 had an increased body condition relative to the low treatment. We also revealed that fish in the high EE2 treatment were less bold and slower to enter the refuge than unexposed fish. Our findings will have repercussions for understanding consequences for population and species persistence in a polluted world.

2.05.A.T-02 Bioplastics as Modulators of the Marine Bacterial Community in a Mesocosm Experiment
Clara Serrano Lorigados[1]*, Katerina Savva*[2]*, Marinella Farre*[2]*, Maria Vila-Costa*[2] *and Marta Llorca*[2]*, (1)Polytechnic University of Catalonia, Spain, (2)Institute for Environmental Assessment and Water Research, Spanish Research Council*

(IDAEA-CSIC), Spain
Biodegradable bio-based plastics (bioplastics) are promising materials in the substitution of non-degradable fuel-based plastics, but they are not exempt from the incorporation of additives that can leachate into seawater. Due to the recent transition to biomaterials, their effects on the marine environment and ecosystems are not fully understood. A closer look into their influence on marine microbial communities, base of the marine food web and essential regulators of marine biogeochemical cycles, provides firsts insights into bioplastics' effects in the oceans. In this work we studied the bacterial communities inhabiting coastal surface seawater after 2 months of exposure to different bioplastic materials in their raw and commercial format, in a mesocosm experiment simulating natural conditions. Each mesocosm presented one bioplastic format to the bacteria, being non-aged biobased polylactic acid (PLA) pellets, PLA-Knife, poly-hydroxybutyrate (PHB) pellet, and PHB-Bag. The study differentiated 3 fractions in the bacterial communities: those free-living in the matrix, those living particle-attached to seawater particles and bioplastic-attached bacteria.

The taxonomical structure of the bacterial community was not conditioned by the bioplastic material, neither the format, but is specific for each of the fractions studied. Bioplastic-attached bacteria are dominated by *Pseudomonadales* and *Phycisphaerales*, as bioplastic-attached specialists, and *Caulobacterales, Planctomycetales, Flavobacteriales* and *Burkholderiales* as generalists, that also predominate in free-living and particle-attached populations across mesocosms. Commercial format increases abundance of bioplastic-attached bacteria, but it decreases bacterial production and abundance in free-living populations. Our work suggests a negative effect of commercial formats in free-living marine bacteria, leading to a very inactive and scarce population of taxa that are adapted. The taxa contributing the most to the differentiation between fractions will be identified in further analyses. This study will describe the specialization of bacterial populations due to exposure to bioplastics and leaching compounds in coastal surface seawater communities. Further research includes clarifying the chemical compounds responsible of the bacterial community structure after exposure, revealing their role as toxic or energy source compund in the marine environment.

2.05.A.T-03 Bubbly behaviours: physiological and behavioral responses of the sea urchin Arbacia lixula from a volcanic CO2 vent

Ilaria D'Aniello[1], *Simonetta Fraschetti*[2], *Alberto Colletti*[3], *Antonino Miccio*[4], *Valerio Matozzo*[5], *Maria Gabriella Marin*[5], *Isabella Moro*[6], *Camilla Della Torre*[7], *Silvia Giorgia Signorini*[7], *Lara Nigro*[7] *and Marco Munari*[1], *(1)Integrated Marine Ecology, University of Padova, Padova, Italy, (2)University of Naples Federico II, Italy, (3)University of Naples, Federico II, Department of Biology, Italy, (4)Marine Protected Area 'Regno di Nettuno', Italy, (5)Department of Biology, University of Padova, Italy, (6)University of Padova, Italy, (7)Biosciences, University of Milan, Italy*
A substantial amount of carbon dioxide released into the atmosphere from human activities is absorbed by oceans and seas, leading to a gradual reduction in ocean pH—a phenomenon known as ocean acidification (OA). OA has been recognized for its influence on the biology of various marine species, particularly those with calcifying properties. However, many studies examining the effects of OA on the physiology and behavior of marine organisms have been limited to aquarium settings, lacking the complexity of ecological processes that interact with changing environmental variables.

In this context, carbon dioxide vents serve as natural laboratories for studying the long-term effects of OA on marine species. This study focused on investigating the physiological and behavioral impacts of chronic OA exposure on the sea urchin *Arbacia lixula*, inhabiting the vents of Ischia, Italy. Adult sea urchins were collected from two vent sites: S1 (pH 8.1; representing ambient pH conditions) and S2 (pH 7.7; representing acidified pH conditions). The experimental design involved reciprocal exposures of adults from both S1 and S2 sites to seawater collected on-site, under both ambient and acidified conditions. Physiological rates (respiration and excretion) and behavioral traits (righting and sheltering time in response to external stimuli) were measured.

The results uncovered a persistent impact of the vent area on the respiration rate of mature sea urchins, particularly notable during the second and third sampling periods. The excretion rate was influenced by pH conditions only in October. Both pH and vent area factors influenced behavioral aspects consistently across all temporal replicates, with a significant interaction effect on righting time. These findings underscore the necessity for long-term observations and field experiments to unravel the intricate processes influencing the physiology and behavior of marine organisms in a changing climate.

2.05.A.T-04 Effects of Ocean Acidification on two calcifying species from the CO2 vent systems of Ischia Island: Mytilus galloprovincialis vs Patella caerulea

Silvia Giorgia Signorini[1,2], *Marco Munari*[3], *Lara Nigro*[1], *Fabio Crocetta*[2], *Lorenzo Federico*[4], *Ilaria D'Aniello*[3] *and Camilla Della Torre*[1,2], *(1)Biosciences, University of Milan, Italy, (2)Integrative Marine Ecology, Stazione Zoologica Anton Dohrn, Italy, (3)Integrated Marine Ecology, University of Padova, Padova, Italy, (4)Applied Science And Technology (DISAT), Department of Applied Science And Technology (DISAT), Italy*
CO_2 vent systems, which are naturally acidified sites by the volcanic CO_2 emitted from the seafloor, represent natural laboratory where it is possible to study the effects of Ocean Acidification (OA). Although several studies already demonstrated the adverse effects of OA on marine biota, there are some species that are able to survive and thrive under low pH conditions. This is well exemplified at the Castello Aragonese CO_2 vent systems (Ischia Island), where few calcifiers are present, showing the ability to survive even in the most acidified areas (pH< 7.4). However, the mechanisms underlying the ability of these species to cope with OA are still poorly investigated.

Therefore, in this study we collected specimens of *Mytilus galloprovincialis* (early recruited) and *Patella caerulea* (long-term resident) along the pH gradient of the Castello Aragonese vent (8.1 – 7.7 – <7.4) and from a nearby control site, named San Pietro (ambient pH: 8.1), in order to investigate the biochemical, molecular, and physiological mechanisms that allow survival and that may be involved in acclimation/adaptation. To do so, (i) morphometric and shell decalcification characteristics were measured; (ii) biomarkers related to oxidative stress, energy metabolism and neurotoxicity, and physiological traits were assessed; and (iii) untargeted metabolomics analysis was performed.

Both species displayed heavy shell corrosion as a function of pH level, whereas only organisms of *P. caerulea* exhibited significant variation of their dimension, with an increase of both shell length and soft-body weight in low pH sites. Furthermore, *M. galloprovincialis* exhibited a significant downregulation of aminoacids, nucleosides, lipids, sugars and several osmolites and a significant decrease of glycogen content in organisms from the extreme acidified site compared to those from ambient pH. Conversely, *P. caerulea* mainly showed an upregulation of metabolites, with a significant increase of carnitine and its metabolites, suggesting a potential induction of β-oxidation to sustain the cellular energetic request in response to OA. Finally, both species displayed slight oxidative stress conditions.

Our findings highlighted quite different effects of OA on the two calcifying species, with more detrimental consequences on *M. galloprovincialis* than *P. caerulea*, which could be locally adapted, but further studies are necessary to broaden the current knowledge on the mechanisms that promote tolerance to OA.

2.05.A.T-05 Effects of Long Exposure to Different Heatwaves in 2 Reef-forming Species through a Comparison of a Multi-biomarker Approach

Verdiana Vellani[1,2], *Marco Munari*[3], *Alessia Cuccaro*[4], *Silvia Giorgia Signorini*[5], *Ilaria D'Aniello*[3], *Matteo Nannini*[6], *Laura Tamburello*[6,7], *Camilla Della Torre*[5], *Saba Diletta Bacchini*[5], *Matteo Oliva*[8], *Carlo Pretti*[8,9], *Luigi Musco*[7,10] *and Monia Renzi*[1,2], *(1)Life Sciences Department, University of Trieste, Italy, (2)CoNISMa - Consorzio Interuniversitario per le Scienze del Mare, Italy, (3)Integrated Marine Ecology, University of Padova, Padova, Italy, (4)Department of Biology & CESAM, University of Aveiro, Portugal, (5)Biosciences, University of Milan, Italy, (6)Integrated Marine Ecology, Stazione Zoologica Anton Dohrn (SZN), Italy, (7)National Biodiversity Future Centre, Italy, (8)CIBM, Italy, (9)University of Pisa, Italy, (10)Dipartimento di Scienze e Tecnologie Biologiche ed Ambientali, Università del Salento, Italy*

Anthropogenic stressors negatively affect marine organisms, with sessile benthic species being particularly vulnerable, posing significant risks to marine ecosystems. One of the most widespread threats to reef-forming species is rising temperatures. Heatwaves (HWs), characterized by regional warming anomalies, are rising globally, with the Mediterranean Sea experiencing a rapid increase in frequency, magnitude, and severity. This study presents a comparative analysis of the prolonged impacts of HWs on two key reef-forming species: Astroides calycularis, the Mediterranean orange coral, and Ficopomatus enigmaticus, an alien and invasive tubeworm. A long-term exposure of 28 days with two distinct HWs ramps was established.

Using as models organisms sessile benthic bioconstructor species known to suffer from HWs-related mass mortality events, and a multi-biomarker approach, the aim is to highlight shared patterns in the biochemical response of habitat forming exposed to different forms of HWs. Parameters assessed included cell membrane damage, cellular reserves, metabolic activity, oxidative status, and biotransformation.

The results demonstrated a negative influence of increased temperatures on the biochemical health of both species studied, with a particular lowering of the protein quantity. Despite differences in shape in the two HWs ramps and the two different species investigated, the biomarker results revealed shared patterns in the response of biobuilders to thermal stress. These commonalities in response to climate anomalies, regardless of organisms or HWs characteristics, suggest a wide-ranging impact of increased temperature. Considering the expected increase in marine temperatures in the near future, further investigations are essential to clarify the effects of this stressor on marine organisms, particularly on benthic sessile reef-formers, which are crucial for maintaining biodiversity in their habitats.

2.05.B Marine Ecotoxicology: Impacts and Possible Solutions, From Coastal to Deep-Sea Ecosystems

2.05.B.T-01 Structural effects of the protein corona formed on various nanoparticles using the coelomic fluid of the sea urchin Paracentrotus lividus

Patrizia Romano[1], *Serena Leone Dr*[2], *Arianna Bellingeri*[1], *Julian Gortz*[3], *Iole Venditti*[4], *Delia Picone*[3], *Ilaria Corsi, PhD*[1], *Rosanna Lucignano*[3] *and Andrea Carpentieri*[3], *(1)University of Siena, Italy, (2)Stazione Zoologica of Naples, (3)Department of Chemical Sciences, University of Naples "Federico II", (4)Roma Tre University, Italy*

Engineered nanomaterials and nanoparticles (NPs), with one or more dimensions in the range of 1-100 nm, have become widely present in everyday products, raising concerns about their potential nanotoxicity on the environment and human health. Upon dispersal in the environment, NPs tend to interact with biomolecules, particularly proteins. The NP-protein interaction results in the formation of the so-called protein corona, which plays a key role in mitigating or stimulating ecotoxicological responses. In this regard, the study of protein corona and the study of their structural changes are crucial steps to clarify the environmental safety of NPs and facilitate regulatory measures governing their use. To date, studies have mainly focused on the effects of NPs and the related protein corona on humans, neglecting their effects on aquatic species including marine ones.

In our study, we explored how different NPs, varying in size and core compositions such as titanium dioxide ($nTiO_2$), functionalized polystyrene ($PS-NH_2$; PS-COOH), and silver (AgNPcitLcys), undergo distinct changes in protein corona composition when incubated with the coelomic fluid (CF) of the Mediterranean sea urchin *Paracentrotus lividus*. DLS parameters such as hydrodynamic diameter, polydispersity index and Z-potential, revealing significant alterations in NP surface charges and size during incubation in both CF and NSW. The protein corona composition of different NPs was assessed through SDS-PAGE and LC-MS. Furthermore, Circular Dichroism spectroscopy was employed to evaluate modifications in the secondary structure of the most abundant protein in the CF, the toposome. Preliminary findings suggest that protein corona characterization revealed distinct protein compositions in the various NPs analyzed, several of the most abundant proteins being involved in the sea urchin immune system. Initial results from Circular Dichroism spectroscopy indicate significant alterations in the distribution of secondary structure elements after 12h of NP exposure in the CF of the sea urchin under all analyzed conditions. This study aims to bridge the knowledge gap in the literature regarding the characterization and changes experienced by protein corona when in contact with NPs. Additionally, it lays the groundwork for a future assessment of the ecotoxicological implications these NPs may pose to *P. lividus* and the surrounding environment.

2.05.B.T-02 Emerging Stressors in Deep-Sea Environments: from Microplastics to Deep-Sea Mining
Bárbara Marlene Pinheiro[1,2], *Renata Amaral*[1,2], *Rithielli Marassi*[2], *Clara Lopes*[1,2,3], *Joana Raimundo*[2,3], *Miguel Caetano*[2,3], *Teresa Neuparth*[2] *and Miguel M. Santos*[1,2], *(1)Biology Department, Faculty of Sciences of the University of Porto, Portugal, (2)CIIMAR - Interdisciplinary Centre of Marine and Environmental Research, University of Porto, Portugal, (3)Portuguese Institute for Sea and Atmosphere (IPMA), Portugal*
The deep-sea is the largest ecosystem on Earth that, despite its remoteness, is also under anthropogenic stressors. Among them, deep-sea mining and microplastics (MPs) are rising as emerging threats. MPs are pervasive in aquatic ecosystems being found in rivers, coastlines, oceans and deep-sea environments. MPs are small plastic particles (<5 mm) that can be ingested by invertebrates, turtles, fish, birds, and marine mammals and eventually by humans through the food web. Deep-sea mining refers to the extraction of mineral resources from the seabed that could, among other effects, release large plumes of sediments across the water column and affect vast areas of the ocean at all levels of the water column. As deep-sea mining-related plumes can also potentially resuspend MPs settled on the seabed, the present work aimed at assessing the effects of suspended sediments and MPs on several benthic species (*Mytilus galloprovincialis, Spisula solida* and *Adreus fascicularis*) under hyperbaric conditions through the screening of functional, biochemical and molecular endpoints to better understand how suspended sediments and MPs impact exposed species and the marine environment. Sediments and MPs were used in three different sizes and concentrations to better represent a realistic scenario of resuspension as a mining byproduct. Experiments lasted for 96h at different pressures (up to 50 Bar) in a hyperbaric chamber. After each exposure experiment, several endpoints were analyzed for each species (i.e. respiratory and filtration rates, oxidative stress biomarkers and transcriptomic profiles). Overall, suspended sediments and MPs caused significant detrimental effects in all three species, varying from a filtration/respiratory capacity decrease to changes in oxidative stress response (catalase, lipid peroxidation and glutathione s-transferase) and gene expression profiles. The results of this study show that suspended particles, i.e., sediments and MPs, caused adverse effects on exposed organisms. These findings emphasize the need to establish guidelines and regulations before deep-sea mining starts to mitigate potential negative effects, especially for benthic communities.

Acknowledgments: Marlene Pinheiro acknowledges the Portuguese Foundation for Science and Technology under the PhD Grant SFRH/BD/147834/2019. The DEEPRISK project (PTDC/CTA-AMB/7948/2020) is also acknowledged.

2.05.B.T-03 Oxidative Damage Induced by Aquatic Contaminants in the Critically Endangered Brazilian Guitarfish: Comparison at Different Life Stages
Mariana da Fontoura Martins, *Patrícia Costa and Adalto Bianchini, Universidade Federal do Rio Grande (FURG), Brazil*
Maternal transfer is a process that exposes elasmobranch embryos to a variety of aquatic contaminants during critical life stages. The extent of the consequences of prenatal exposure, especially compared to adults, is unidentified. Hence, this information is crucial for accurate assessment of the contaminant effects in elasmobranchs. Therefore, we aimed to compare the biochemical alterations related to oxidative damage in whole embryos and liver of mature females of the Brazilian guitarfish *Pseudobatos horkelii* facing exposure to metal(loid)s and organic contaminants. Polycyclic aromatic hydrocarbons (PAHs) and polybrominated diphenyl ethers (PBDEs) were assessed through gas chromatography coupled to mass spectrometry, whereas metal(loid)s were quantified using atomic absorption spectrometry with graphite furnace. Lipid peroxidation (LPO) and protein carbonyl group (PCO) levels were also quantified and used as biomarkers. The relationships between embryos and females were assessed using the Principal Component Analysis (PCA). Generalized Linear Models (GLMs) were applied to investigate effects of contaminants on biochemical parameters. In addition, a Permutation Multivariate Analysis of Variance (PERMANOVA) was carried out to evaluate the effect of contaminants and life stage on overall oxidative damage. The PCA results characterized embryo and female samples according to their contaminant levels and biomarkers. Females showed higher concentrations of contaminants whereas embryos were majorly contaminated with PBDEs (BDE-47 in particular). Biomarkers also characterized these two groups, with LPO influencing the female cluster, and associated with Fe concentration. In embryos, PCO was correlated to BDE-47. The GLM failed to detect effect of contaminants on biomarkers. However, when both LPO and PCO were considered together, PAHs, PBDEs, Cd, Cr, Cu, and Fe concentrations significantly influenced oxidative damage in embryos and adult females. The relationship between oxidative damage and contaminant load was not significantly different between these two groups, suggesting that contaminants effects on biomarkers analyzed are similar in embryos and adults. This is of particular concern as early life stages are generally

accepted as being more sensitive to contaminants. Therefore, we conclude that impacts of prenatal exposure to contaminants are comparable to those found in adult guitarfishes.

2.05.B.T-04 BIOACCUMULATION AND DIETARY BIOACCESSIBILITY OF MICROPLASTICS AND COCONTAMINANTS IN MEDITERRANEAN MUSSELS

Marinella Farre[1]*, Albert Vega-Herrera*[1]*, Katerina Savva*[1]*, Pol Lacoma*[1]*, Isa Marmelo*[2]*, Lúcia Santos*[3]*, António Marques*[4] *and Marta Llorca-Casamayor*[5]*, (1)Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain, (2)IPMA, I.P., Portugal, (3)Catalan Institute for Water Research (ICRA), Spain, (4)Portuguese Institute for Sea and Atmosphere (IPMA), Portugal, (5)Environmental Chemistry, Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain*

Microplastics (MPLs) are contaminants of emerging concern (CECs) ubiquitous in aquatic environments, where they can bioaccumulate entering the food chain.

In this study, the accumulation of polyethylene (PE), polystyrene (PS), and polyethylene terephthalate (PET) microplastics (MPLs) of sizes inferior to 100 µm was assessed in Mediterranean mussels (*Mytilus galloprovincialis* spp). Moreover, the potential of mussels to bioaccumulate other organic contaminants, such as triclosan (TCS) and polyfluoroalkyl substances (PFASs), was evaluated with and without the presence of MPLs. Finally, the potential human bioavailability of co-contaminants in the presence and absence of MPLs was evaluated by an in-vitro experiment that simulated human digestion. Exposure experiments were carried out in 15 L marine microcosms through the diet. The bioaccumulation of PE, PS, PET, and co-contaminants was assessed by liquid chromatography coupled to high-resolution mass spectrometry (LC(SEC)-HRMS), and the results showed how PFASs were more available when those are adsorbed on plastic surface.

2.05.B.T-05 Beyond the Surface: Investigating UV-Filter Presence and Biomagnification in Three NE Atlantic Pelagic Species

Eva Iñiguez Santamaría[1,2]*, Sarah Montesdeoca-Esponda*[3]*, Manfred Kaufmann*[4]*, João Dias*[5]*, Nereida Cordeiro*[6]*, Ana Dinis*[2] *and Maria Zoraida Sosa*[7]*, (1)University of Madeira, Portugal, (2)MARE - Marine and Environmental Sciences Centre, ARNET - Aquatic Research Network, ARDITI - Regional Agency for the Development of Research, Technology and Innovation, Portugal, (3)Chemistry department, Universidad Las Palmas de Gran Canaria, Spain, (4)Faculty of Life Sciences, University of Madeira, Portugal, (5)University of Lisbon, Portugal, (6)Faculty of Exact Sciences and Engineering, University of Madeira, Portugal, (7)Chemistry Department, Universidad Las Palmas de Gran Canaria, Spain*

The increasing concern about protection against sunrays by health institutions together with the increase in tourism, resulted in the release of vast amounts of sunscreen into the marine environment in the last years. These products contain organic UV filters responsible for protecting against sun rays. Their effect on biota as endocrine disruptors (EDs) have been described in some kinds of species [1], [2], [3] and due to their physical-chemical properties, they are persistent in the ecosystem and tend to be bioaccumulated and biomagnified in organisms throughout the trophic chain being considered Emergent Contaminants [4]. This work aims to evaluate and compare the presence of 11 oUV-F (Table 1.) in shallow and deeper waters, using two epipelagic species, *S.colias*, *T.picturatus* and one bathypelagic specie, *A. carbo,* as a bioindicator. Furthermore, check their potential to be biomagnified through the trophic chain. The extraction process was carried out by optimized Microwave-Assisted Extraction method for 10 minutes at 60ºC for the posterior analysis by HPLC-MS/MS. For more information, check [5].

Out of the 11 UV filters analyzed, 6 (4MBC (20.95±11.38), HMS (8.84±2.94), OC (2.90±1.46), UV360 (10.55±7.38), OD-PABA(0.49±0.18)) were detected and identified for *A.carbo*; 3 (HMS (12.23±4.79) UV360 (1.47±0.78), EHS (6.32±2.41)) for *Trachurus picturatus*, and 2 (UV360 (1.14±0.37) and EHS (3.78±0)) for *Scomber colias* (Figure 1.). Higher values are for *Aphanopus carbo*, which is the species that occupies a higher trophic level and is strictly carnivorous. The other two species are zooplanktivorous. The values obtained for the Biomagnification factor (BMFs) indicated that they are potentially biomagnified through the food chain (Figure 1.). The exception was with HMS, which is more abundant in *Trachurus picturatus* than in *Aphanopus carbo* and was non-detected for *Scomber colias*, possibly due to the distribution of this chemical through the water column.

As conclusions, the first results of organic UV-filter concentration in pelagic NE Atlantic species with commercial interest, *T.picturatus* and *A.carbo*, were described in this work.
The biomagnification of this kind of compound is a concern for human consumption, with the higher positions of the trophic chain accumulating more contaminants than those in the lower levels.
The first evidence of the presence of these contaminants in bathypelagic zones using *A. carbo* as a bioindicator.

2.05.P Marine Ecotoxicology: Impacts and Possible Solutions, From Coastal to Deep-Sea Ecosystems

2.05.P-Tu113 Won't Somebody Please Think of the Lobsters? A Methodological Framework for Toxicity Testing of Pesticides Across American Lobster Life Stages.

Davide Asnicar *and Benjamin Patrick de Jourdan, Huntsman Marine Science Center, Canada*

Infestations by the parasitic sea lice are a challenge to most Atlantic salmon farming regions of the world, including Atlantic

Canada. Annually, approximately 75% of the active marine finfish aquaculture sites in Canada use at least one drug or pesticide to mitigate effects on production performance.

Administration of anti-sea lice products are commonly done through water-bath or in-feed treatments. The former type of treatment involves the usage of chemicals such as azamethiphos (AZA) and hydrogen peroxide (H_2O_2), among others. Examples of in-feed anti-sea lice products include emamectin benzoate (EMB) and ivermectin (IVM).

Properties of the chemicals influence their fate once released in the environment. Water-bath treatment products remain in the water column affecting planktonic organisms, whereas the in-feed products accumulate in the sediment becoming available to benthic organisms.

In this presentation, we discuss the framework of methods applied to the American lobster (*Homarus americanus*) to understand the potential impacts of bath and in-feed treatments across its entire life cycle.

We performed a series of toxicity tests to produce hazard concentrations of the 4 compounds using various life stages based on different exposure scenarios. Acute exposures to AZA and H_2O_2 were performed with the planktonic Stage I. Stage IV (first benthic stage) was used in chronic exposure to sediment and feed pellet spiked with EMB or IVM in 10 to 28-day trials. For both Stage I and Stage IV, immobilization and mortality were assessed daily.

Further investigations on the effects of EMB were carried out on: i) the behaviour of Stage IV+ lobsters after 10 days of exposure; ii) intra and transgenerational impacts after 10 days of exposure of adult ovigerous females.

The American lobster proved to be a sensitive and valid model organism for laboratory testing of pesticides.

AZA and H_2O_2 caused mortality at concentrations well below the application rate but greater than the proposed EQS for these compounds. However, results must be considered carefully, due to dilution effects and degradation of the compounds.

EMB and IVM LC50 values are various orders of magnitude higher than the highest value measured in the environment. Similarly, in both the behavioural assay and ovigerous adult trials, EMB concentrations tested were up to 28 times higher than in the environment and did not cause significant adverse effects.

2.05.P-Tu114 Toxicity of the Scrubber Washwater on Marine Organisms: a Focus on the pH Reduction
*Leonardo Romero-Martinez Dr.[1], Lucía Ruiz-Salas[2], **Javier Moreno-Andrés**[3] and Enrique Nebot Sanz Dr.[1], (1)Environmental Technologies, University of Cádiz. Marine Research Institute (INMAR), Spain, (2)University of Cádiz, Spain, (3)Environmental Technologies, University of Cadiz, Spain*
The emissions of sulphur dioxides (SO_X) from the maritime transport is a concern for the ecosystems and human health. For this reason, the International Maritime Organization (IMO) establishes limits for the sulphur content in the fuel used by ships. An alternative to the use of more expensive low sulphur fuel is the installation of exhaust gas cleaning systems (EGCSs), known as scrubbers. Scrubbers use water to absorb the SO_X from the exhaust gas and then this washwater released into the marine environment. Due to the absorption of the SO_X, the washwater has low pH of approximately 3.8. In this regard, the discharge of scrubber washwater may pose a threat for the aquatic organisms.

In this study, the toxicity of acid washwater was evaluated using three marine organisms as indicators: the bacteria *Vibrio alginolyticus*, the diatom *Phaeodactylum tricornutum* and the crustacean *Artemia franciscana*. The organisms the exposed to mixtures of seawater with simulated scrubber in different ratios, and the lethal or growth inhibitory effect was determined.

The results obtained reported EC50 values of the 37.7% for *V. alginolyticus*, 86.4% for *P. tricornutum* and 95.8% for *A. franciscana*. These results show that the different marine organisms have different sensitivity to the low pH and the dilution level is a major factor in the determination of the toxic potential of the discharged washwater.

The toxic effects by the discharged washwater in the marine organisms imply that, although the use of scrubbers for removing SO_X from the exhaust gases may help to reduce the impacts of the atmospheric emissions, it poses a challenge for the protection of the marine environment.

2.05.P-Tu115 MicroTox Bioluminescence Assay Sensitivity to Metals Toxicity in Full Strength Marine Water: Implications for Monitoring Anthropogenic Impacts in the Marine Environment
***Katharine Walsh Kinter**[1], Fiona Quin Zabel[1], Dana Sackett[2] and Lance T Yonkos[1], (1)Environmental Science & Technology, University of Maryland, (2)Environmental Science and Technology, University of Maryland College Park, Baltimore, United States*
MicroTox in vitro bioluminescence assay with *Aliivibrio fischeri* has been proposed for near real-time monitoring of toxicity in marine waters receiving deep ocean metal mining effluent. However, testing of background marine water samples (35 ppt)

against the 2% NaCl diluent provided for the MicroTox assay consistently yields a 20 – 40% increase in microbial metabolic activity and thus light emission relative to the control. This increase in bioluminescence, likely associated with the change in osmotic pressure, serves to mute detection of subtle toxic effects. As a result, 35 ppt pH 7.5 synthetic seawater (SSW) proved more appropriate for use with marine samples. The SSW diluent consistently yielded 10 – 20% increases in light emission following the 15-min exposure period, matching those of field-sourced marine samples whereas 2% NaCl diluent yielded approximately 20% reductions in light emission after the incubation period, explaining the cumulative observed difference of 30 – 40%. Metals toxicity (CuSO4 and ZnSO4) was investigated by testing dilution series produced in each diluent. Resulting dose response curves and calculated EC50s indicate near identical sensitivity of the MicroTox assay to CuSO4 at the two salinities, but significantly reduced sensitivity to ZnSO4 at the higher marine salinity. These toxicity measures were then compared with *Rotifera* toxicity via Marine RotoTox kits and traditional inland silverside (*Menidia beryllina*) 7-d larval toxicity tests. The RotoTox test was performed in SSW and 2% NaCl diluent to determine salinity effects on metals sensitivity for comparison with MicroTox results. MicroTox proved more sensitive to zinc suggesting it would be protective of marine biota but was significantly less sensitive to copper suggesting that marine biota may still be at risk. In mining effluents we found similar toxicity results across Menidia, Rotifer, and MicroTox tests suggesting that MicroTox can give a comparable result for test organisms of interest, though individual metal contaminant constituents should still be considered.

2.05.P-Tu116 Adverse Impacts of Biofilm-Colonized Microplastics on Marine Copepods, Tigriopus japonicus
Ying Wang[1]*, Shuo Cao*[1,2]*, Yu Shen*[1,3] *and Juying Wang*[1]*, (1)National Marine Environmental Monitoring Center, China, (2)Shanghai Ocean University, (3)Dalian Ocean University, China*
Microplastics (MPs), as typical emerging contaminants, have caused global environmental concerns with the increase in plastic production. Different types of MPs, can be ingested by zooplankton and cause several adverse impacts, including altered feeding behavior, developmental and reproductive toxicity. The ecological risks that MPs pose to marine organisms have been widely reported, yet there are still knowledge gaps regarding the adverse impacts of environmentally relevant MPs especially caused by colonized biofilm. The aims of this study were twofold: (i) to examine alterations on the physical, chemical, and biological characteristics of 10 μm polystyrene microspheres (PS-MPs) caused by covered biofilm; (ii) to investigate the long-term impacts of biofilm-covered PS-MPs at two environmentally relevant concentrations (100 and 1000 particles/mL) on marine copepods, *Tigriopus japonicus* over a 21-d exposure. Results showed that aggregation occurred for colonized PS-MPs. The oxygen-containing functional groups of PS-MPs increased after colonization with the occurrence of C-OH and C=O functional groups identified by infrared spectroscopy. Colonized PS-MPs selectively enriched Proteobacteria and Bacteroidota in natural seawater, accounting for 78.1% and 16.6% respectively. The biofilm formation significantly increased the uptake of PS-MPs by copepods, and the bioaccumulation of colonized PS-MPs was significantly higher than that of pristine PS-MPs, leading to an increase in bioavailability and chronic toxicity on development and reproduction. This project would provide scientific basis to ecological risk assessment of microplastics in the real marine environments. Further studies on the influence factors of their bioavailability and toxic effects at tissue and cellular levels should be explored for MPs under environmentally realistic multi-stressors.

2.05.P-Tu117 Developmental Effects of Legacy and Novel Type 2 Diabetes Therapeutics to Embryo-Larval Red Drum (Sciaenops ocellatus).
Kristin Nielsen*, Kerri Lynn Ackerly, Kathleen Roark, Tamara Margarita Rivera and Mona Birgisson, Marine Science Institute, University of Texas at Austin*
Current global land-use trends show increasing rates of urbanization in coastal areas, leaving estuaries and other coastal ecosystems particularly vulnerable to the impacts of municipal contaminants. Pharmaceuticals and their by-products are among these constituents of greatest potential concern, due to a global increase in their production and use, in combination with their low effect concentrations. Compounds that target highly conserved pathways are of particular concern to non-target aquatic wildlife, particularly vertebrates. Type 2 Diabetes and obesity are on the rise globally, as are the environmental presence of therapeutics used to treat these disorders. Because metformin has historically been used as the first line therapeutic for Type 2 diabetes, it is routinely measured in surface waters and is one of the highest drugs by weight detected in aquatic environment, along with its metabolically-active degradation product, guanylurea. Both metformin and guanylurea are known to adversely affect the growth and development of several species of freshwater fish; however, far less is known about the potential risk these compounds pose to marine fish. Recently, multiple Glucagon-like Peptide 1 Agonists, including semaglutide (Ozempic) and Tirzepatide (Mounjaro), received FDA approval for the treatment of Type 2 diabetes. However, off-label applications (e.g., weight loss) for these compounds have rapidly gained popularity, as has the use of compounded salt derivatives. The environmental presence and fate of these emerging compounds remains largely unknown, as do potential ecotoxicological risks to non-target aquatic biota in near shore systems. To investigate the relative potency and effects of both legacy and novel therapeutics used in the treatment of Type 2 diabetes, we exposed embryo-larval red drum (*Sciaenops ocellatus*), an economically and ecologically valuable fish species found in the Gulf of Mexico, to equal concentrations of metformin, guanylurea, semaglutide, and tirzepatide. Developmental effects, including changes in morphological endpoints were subsequently evaluated for each of these compounds, to determine whether effects are conserved in marine species.

2.05.P-Tu118 Validation of a miniaturized multiresidue method for the determination of pharmaceutical products in Zebrafish embryos
Jorge Lejo-Santiago[1]*, E Concha-Graña*[2]*, P López-Mahía*[2] *and S Muniategui-Lorenzo*[2]*, (1)University Institute of Research in Environmental Studies (IUMA), University of a Coruña, Spain, (2)Universidade da Coruna, Spain*

Pharmaceuticals and their metabolites are being found in the environment because of the wastes from laboratories, hospitals and agriculture but also because of their excretion after being consumed. These compounds are considered to be contaminants of emerging concern (CEC) due to their potential toxicity. Toxicity studies are necessary to evaluate the potential risk for the marine biota caused by the presence of these compounds. Zebrafish (*Danio rerio*) embryos are frequently used as model organisms in ecotoxicological studies, and therefore the development of an analytical method for the analysis of pharmaceuticals in this matrix is necessary. The aim of this work is to develop a rapid and sensitive multi-residue method for the determination of pharmaceuticals in zebrafish embryos. The developed method consists of a solid-liquid microextraction (300 µL of solvent) assisted by sonication, followed by centrifugation. This method is adequate for the small sample size (10 embryos). Determination was performed by injection of 100 µL of extract in the liquid chromatograph coupled to triple quadrupole mass spectrometer (LC-MS/MS (QqQ)). The proposed method allows the determination of 52 pharmaceutical compounds including antibiotics, NSAIDs, cardiovascular drugs and psychiatric drugs among others obtaining good accuracy and precision for samples above about 10 pg/embryo in a short period of time, making this method suitable for routine analysis.

Acknowledgment: This work is part of the project “Presence, behaviour and risk assessment of pharmaceuticals in marine ecosystems” (PHARMASEA) (ref. PCI2021-121987) supported by MCIN/AEI/10.13039/501100011033 and the European Union “NextGenerationEU/PRTR”. The Program ‘Consolidación e Estructuración de Unidades de Investigación Competitivas’ of the Galician Government (Xunta de Galicia) is also acknowledged (Grant ED431C 2021/56). Thanks to the University of Heildelberg for providing the *Danio rerio* samples for the development of this method.

2.05.P-Tu119 An integrated approach to determine the food-chain transfer and ecotoxicological effects of UV filters on marine organisms
***Anneliese Ananya Hodge**[1], Frances Hopkins[2], Awadhesh Jha[3] and Mahasweta Saha[2], (1)University of Plymouth, United Kingdom, (2)Plymouth Marine Laboratory, United Kingdom, (3)Plymouth University, United Kingdom*
UV filters are considered emerging pollutants due to their widespread use and application; they are used extensively in personal care products such as sunscreens and cosmetics to protect against photoaging and photocarinogenesis. However, despite their ubiquitousness, very little research has focussed on the ecotoxicological consequences of these compounds, particularly on marine organisms.

Adopting a multidisciplinary approach and incorporating innovative technologies and methods, the research will evaluate the ecotoxicological effects of organic and inorganic UV filters on marine organisms at different levels of organisations (i.e. molecular, cellular and individual levels). The study will adopt marine food-chain analysis and will elucidate the mechanisms of food-chain transfer. The potential biological impact of the pollutants both alone and in combination with UVA radiation will be assessed.

Determination of toxicity potential of UV filters in marine algae (e.g. cellular viability, chlorophyll fluorescence, growth inhibition), potential sub-lethal biological responses in mussels and copepods will be determined (e.g. DNA damage, expression of key genes involved in DNA repair process, histopathological changes), determination of the influence of UV filters on concentrations of organic sulphur compounds (e.g. DMS/DMSP) in the algae will be carried out using purge and trap and GC/MS methodologies. Feeding experiments will be conducted to study the effect of trophic level transfer of UV filters. The bioaccumulation pattern in algae and mussels will be determined using analytical techniques (e.g., GC-MS/ICP/MS).

It is hypothesised that the organic and inorganic UV filters assessed bioaccumulate at different trophic levels in the marine food chain and will result in toxicological effects on the organisms.

This research will highlight the effects UV filters pose to aquatic life, aiding in the awareness of UV-filters as pollutants. UV-filters are emerging chemicals of concern and have already been deemed highly persistent by EU REACH Directives. This research will assist in developing our understanding of the interaction these chemicals have with the marine environment. Overall, the research will fill important knowledge gaps that can be communicated and shared with academic and stakeholder communities. This research is still ongoing, thus, the current results will be discussed and the expected outcomes of ongoing experiments will be highlighted.

2.05.P-Tu120 Seasonal concentrations of organic contaminants of legacy and emerging concern on plastic polymers deployed in the Galician coast
***María del Mar García Pimentel**[1], Fernando Sánchez-Córcoles[1], V Fernández-González[2], C Moscoso-Pérez[2], J Frias[3], M.L Pedrotti[4], V Lenoble[5], S Muniategui-Lorenzo[2], R Casotti[6] and Victor M. León[1], (1)Institute of Oceanography, Spanish National Research Council (IEO-CSIC), Spain, (2)Universidade da Coruna, Spain, (3)Atlantic Technological University (ATU),*

(4)Observatoire Océanologique de Villefranche Sur Mer, (5)Université de Toulon, (6)Stazione Zoologica Anton Dohrn
Plastics act as passive samplers of organic and inorganic contaminants from the surrounding environment (air, water, soil, sediment, etc) and they can be used as an integrative matrix for these contaminants in the marine environment. Additionally, plastics can act as a dispersal vector for their constituents (plastic additives) which can be desorbed and leached to the surrounding environment during physical disintegration processes. Therefore, the analysis of the contaminants sorbed on them can offer an integrated view of chemical pollution particularly for chemicals with medium/high hydrophobicity, more representative than spot seawater analysis. Previous studies have confirmed the concentration of organic contaminants in beached and floating plastics without any information about the exposure period and conditions for the different samples analysed.

In this study supported by ‘PLAS-MED’ (CICYT, CTM2017-89701-C3) and ´MICROPLASTIX´ (JPI OceansProgram, MCIN PCI2020-112145) projects, the seasonal occurrence and distribution of current-use pesticides (triazines, organophosphates and others), personal-care products (fragrances, UV-filters,,..), pharmaceuticals, plastic additives, polycyclic aromatic hydrocarbons (PAHs) and organochlorinated contaminants were characterized in deployed plastics in Ares Ria (A Coruña, Spain). Ten different polymers were used (including polyethylene, polypropylene, polystyrene, tyre and others). The sorption dynamism of different pollutant groups was studied sampling at 30, 60 and 90 days of deployed in the surface water of Ares Ria in spring, summer, autumn and winter.

PAHs, UV-filters, synthetic musks and plastic additives were the most frequently detected contaminants, but other personal care products and current use pesticides were also found. It was also observed the potential contribution of plastic additives and other contaminants from polymer formulation to the environment (i.e.: such as PAHs in tyres samples). The individual contaminants found at the highest concentration were octocrylene, hexylcinnamal, and tris-2-chloropropyl phosphate (UV filters and plastic additives). Along the considered period concentrations varied depending on the variations in the predominant pollution sources, mainly urban discharges influenced by tourist, agricultural, livestock, industrial and maritime activities.

2.05.P-Tu121 Looking for Biological Monitoring Tools: Using Anemonia sulcata as Bioindicator Species to Assess Sunscreen and Ultraviolet Filter in Temperate Seas

***Judit González Delgado**[1], Araceli Rodríguez-Romero[2], Bárbara Úbeda[3] and M. Laura Martín-Díaz[4], (1)University of Cádiz, Spain, (2)Department of Analytical Chemistry, Faculty of Marine and Environmental Sciences, Marine Research Institute (INMAR), University of Cadiz, Spain, (3)University Institute of Marine Research (INMAR), University of Cádiz, Spain, (4)Chemical Physics Department, Faculty of Marine and Environmental Sciences, Marine Research Institute (INMAR), University of Cadiz, Spain*
Sunscreens contain organic and/or inorganic UV filters (UVF) that absorb, reflect or scatter UV light, inactive ingredients such as antimicrobial preservatives, moisturisers and anti-oxidants. Their use contributes to the release into coastal waters of UVF. Benzofenona-3 (BP3) has been identified as the main organic UVF of concern. It has been reported to induce acute, developmental and reproductive toxicities to different organisms. Some studies have shown that sunscreen ingredients promote viral infections in bacteria and zooxanthellae, causing coral bleaching. Nevertheless, most of these studies are performed using no realistic environmental concentrations of sunscreens and UVF. Different cnidarians, coral species, have resulted to be potential bioindicator species for warm sea ecosystems. In the present study, temperate sea abundant cnidarian species is tested as a potential bioindicator species for the assessment of the exposure and effect of environmental concentrations of sunscreen and BP3.

We aim to determine the suitability of the sea anemone, *Anemonia sulcata,* as bioindicator species using a battery of exposure and effect biochemical biomarkers: oxidative stress, genotoxicity, and bleaching. To achieve this, two independent 7 days-exposure experiments under laboratory conditions were conducted. In the first exposure assay (BP3 assay), individuals of *A. sulcata* were exposed to different concentrations of BP3 (0 to 5000 µg/L). Simultaneously, in the second toxicity assay (sunscreen assay), individuals were exposed to different dilutions (0 to 100%) of a commercial sunscreen containing BP3.

The preliminary results showed a clear and significant bleaching effect with increasing BP3 exposure concentration and sunscreen content ($p<0,05$) together with zooxanthellae photosynthetic pigments and membrane integrity lose. Although biochemical responses in anemones´tissues showed significant activation of defence mechanisms against oxidative stress after exposure to BP3 compared with control treatment ($p<0,05$), no significant differences with control treatment were observed after exposure to different dilutions of sunscreen.

This work provides relevant information on the potential use of the cnidarian *A. sulcata* as bioindicator species to exposure to UVFs and sunscreen in temperate seas.

2.05.P-Tu122 The impact of the newly approved anti-sea lice drug, imidacloprid, on the polychaete Capitella sp

***Rosa Helena Escobar Lux**[1], Jinghui Fang[2], Aoife Parsons[3], Rita Hannisdal[4], Ann-Lisbeth Agnalt[1] and Ole Bent Samuelsen[1], (1)Havforskningsinstituttet/Institute of Marine Research, Norway, (2)Yellow Sea Fisheries Research Institute, China, (3)Institute of Marine Research (IMR), Norway, (4)Institute of Marine Research, Norway*
The expansion of Atlantic salmon aquaculture in Norway has raised concerns about its impact on the marine environment,

including negative effects on wild salmonid populations, the release of nutrients and chemical pollutants, as well as the spread of parasites such as the sea lice. To control the sea lice infestations in the salmonid farms, strict regulations have been put in place. In order to comply with these regulations, the industry has relied on veterinary medical products (VMP). One such VMP used to combat sea lice infestations is Ectosan Vet, which has as active ingredient the neonicotinoid imidacloprid (IMI). IMI is known to be a neurotoxin that can disrupt the central nervous system of insects and has been linked to the decline of pollinators. While outdoor use of IMI has been banned in the EU, restrictions in other regions, and recognition as an emerging contaminant of concern, there are concerns about its impact on marine biodiversity even at permitted concentrations. The accidental release of untreated IMI into the marine environment has raised further alarm. Wild non-target populations, living in the vicinity of aquaculture facilities are especially at risk of being exposed. However, there are significant knowledge gaps regarding the effects of IMI on the Norwegian marine environment, as studies have predominantly focused on terrestrial and freshwater species. The current study exposed the polychaete *Capitella* sp, a relevant species for the Norwegian marine ecosystems, to Ectosan Vet.

This study examines both lethal and sublethal endpoints in polychaetes collected from the wild. The organisms were exposed to concentrations ranging from 20 mg/L to 0.2 µg/L of IMI, mirroring treatment and release concentrations in salmon aquaculture. The exposure period lasted for 96 hours, followed by a 24-hour recovery period in clean seawater. Throughout the experiment, mortality and immobilization were recorded. Additionally, oxygen consumption rates (OCR) and burrowing behavior were documented as sublethal endpoints for all treatment concentrations. Given that IMI has been shown to induce paralysis and alter mobility behavior in other invertebrates, our hypothesis suggests that the burrowing behavior of polychaetes is negatively impacted. OCR serves as a direct measure of metabolic activities within the organisms, and it is anticipated in this study that increasing concentrations of IMI will result in lower oxygen consumption in the study animals.

2.05.P-Tu123 IMPORTANCE OF THE INFLUENCE OF POPULATION HABITAT ON THE ECOTOXICOLOGY ASSESSMENT OF SUNSCREEN PRODUCTS: AN ANALYSIS USING SEA URCHIN (P. LIVIDUS) FERTILISATION AND LARVAL DEVELOPMENT BIOASSAYS

Vanessa Aranda Quirós[1], *M. Laura Martín-Díaz*[2], *Esther Bautista-Chamizo*[3] *and Araceli Rodríguez-Romero*[4], *(1)Toxicology Laboratory, University of Cadiz, Spain, (2)Chemical Physics Department, Faculty of Marine and Environmental Sciences, Marine Research Institute (INMAR), University of Cadiz, Spain, (3)Department of Biology, Faculty of Marine and Environmental Sciences, Marine Research Institute (INMAR), University of Cadiz, Spain, (4)Department of Analytical Chemistry, Faculty of Marine and Environmental Sciences, Marine Research Institute (INMAR), University of Cadiz, Spain*

Susceptibility of species to different stress agents could be influenced by their habitats. In this sense, phenotypic plasticity could be crucial for marine biota to cope with pollution and, therefore, decisive in environmental risk assessment of contaminants, especially those of emerging concern such as sunscreens. In this study, we investigate the effects of three commercial sunscreens on the fertilization and larval development of two distant populations of the sea urchin *Paracentrorus lividus* located in anthropogenic impacted and pristine coastal areas, respectively. For that, three commercial sunscreens, with different chemical formulas were selected: sunscreen A with “conventional” UV filters (e.g. zinc oxide-nano, octinoxate, and octocrylene), and sunscreens B and C, labelled by the brand as “ocean respect”, with “new generation” UV filters (e.g. ethylhexyl triazone, bis-ethylhexyloxyphenol methoxyphenyl triazine). A range of 10 different concentrations (0 to 500 mg L^{-1}) were tested. For the three selected sunscreens, no significant differences were observed in fertilization rate between populations. However, significant differences in larval development were observed regarding the origin of the population. Higher and significant malformations on larval development ($p<0.05$) were recorded in the population located at the anthropogenic impacted coast compared with the population from pristine area (sunscreen A: EC_{50}= 75.1×10^{-2} mg L^{-1} and EC_{50}= 8.91 mg L^{-1}, sunscreen B: EC_{50}= 23.9×10^{-2} mg L^{-1} and EC_{50}= 5.95 mg L^{-1} and sunscreen C: EC_{50}= 7.64×10^{-3} mg L^{-1} and EC_{50}= 9.12 mg L^{-1} for the populations from the anthropogenic impacted and pristine coastal areas respectively). In general, “new generation" sunscreens showed higher toxicity, indicating that more research should be performed in assessing the risk of these products before to be labelled as ecofriendly. Other parameters, such as the application format (e.g. cream, oil or sun milk) of these products may affect their toxicity.

Besides, this study highlights the importance of population habitat as an essential factor to be considered in ecotoxicity studies.

2.05.P-Tu124 Assessment of Chemicals Chronic Toxicity on Corals, by Combining Measurement of Growth Inhibition and Photochemical Response, With the Scleractinian Coral Model Stylophora Pistillata

Jean Pierre Fel[1], *Christine Ferrier Pages*[2], *Marc Georges Leonard*[3] *and* ***Noémie de Crozé***[3], *(1)L'Oreal Research & Innovation, France, (2)Centre Scientifique de Monaco, Monaco, (3)L'Oréal, France*

Increasing ocean temperature and acidification, overfishing, coastal development, and pollution are well known stressors on coral reefs. They may induce coral bleaching, a process by which corals lose their symbiotic microalgae (zooxanthellae). Weakened corals, more susceptible to infectious diseases, show poor resilience from episodic bleaching events. Ultimately, corals may die when these stressful environmental conditions last too long.

Concern about the environmental impact of UV filters on coral reef have been raised, leading to the ban of certain UV filters in sunscreens such as Oxybenzone and Octinoxate (e.g., Hawaii ; Palau islands). To assess this potential impact, we developed a predictive test protocol based on the inhibition of chlorophyll photosynthetic efficiency of the symbiotic micro-algae in the coral species *Stylophora pistillata* (Fel *et al.* Coral Reefs 2019). One criticism of the methodology was that direct impacts that chemicals may have on the animal part of the holobionte, may be underestimated if the test endpoint was limited to photosynthesis inhibition only. Therefore, we implemented the methodology by measuring the coral nubbins weight in the sea water [as described by Jokiel et al (1978)], to estimate the impact on growth and mineralization under a chemical stress.

To assess the method feasibility, we exposed nubbins of the scleractinian coral *Stylophora pistillata* for 35 days, using to 2 reference compounds (Diuron and TBT), 2 UV filters and 2 preservatives. Exposure regime was semi static with weekly solution renewal. Both photosynthetic efficiency of the zooxanthellae and the weight gain were monitored weekly. The methodology and the results obtained will be presented.

2.05.P-Tu125 Environmental realistic concentrations of octocrylene and benzophenone affect fertilization and embryo development of pacific oyster Magallana gigas

Ana Carvalhais[1]*, Romina Lippa*[2]*, Isabel Benta Oliveira*[3]*, Gaetano di Lorenzo*[4]*, Mário Pacheco*[1] *and Cláudia Mieiro*[5]*, (1)University of Aveiro, Portugal, (2)Department of Biology, Department of Biology, University of Perugia, Italy, (3)CIIMAR - Interdisciplinary Centre of Marine and Environmental Research, University of Porto, Portugal, (4)Department of Biology, University of Naples Federico II, Italy, (5)CESAM - Centre for Environmental and Marine Studies and Department of Biology, University of Aveiro, Portugal*

Early life stages of bivalves are more sensitive to environmental changes than adults and demonstrate a high sensitivity to various toxic substances. Ultraviolet (UV) filters are among the most commonly detected compounds in water, sediments and biota. They are bioactive, persistent and have a high bioaccumulation potential due to their high stability, lipophilicity, and low biotic degradation. Several studies point to the UV filters harmful effects on marine biota, though information regarding marine bivalves' early-life stages and fertilization is still scarce. Thus, the present study aims to evaluate the effects of two UV filters, octocrylene (OC) and benzophenone (BP), at environmentally relevant concentrations (1, 10 and 100 $\mu g.L^{-1}$) in pacific oyster (*Magallana gigas*) early life stages through a multiparameter approach by evaluating fertilization rate and D-shape larvae development, swimming activity and DNA integrity. The fertilization assays followed 3 approaches: exposure of oocytes, exposure of spermatozoa, and exposure of both gametes. The exposure duration was 30 minutes, and then fertilization rate was calculated by counting unfertilized oocytes among 100 oocytes. Oyster embryo-larval assay followed ICES (*International Council for the Exploration of the Sea*) guidelines, and then the swimming activity was recorded for each replicate. DNA integrity was assessed in oyster larvae cells through the comet assay. The fertilization rate decreased after oocyte exposure to 10 and 100 $\mu g.L^{-1}$ of OC and BP and after spermatozoa exposure to 100 $\mu g.L^{-1}$ of BP. When both gametes were exposed, the fertilization rate decreased in 1 and 100 $\mu g.L^{-1}$ of OC and 100 $\mu g.L^{-1}$ of BP. All concentrations of OC and BP caused developmental abnormalities in D-shaped larvae (24h). The swimming velocity of larvae exposed to 1 $\mu g.L^{-1}$ of OC and to 10 $\mu g.L^{-1}$ of BP decreased. No larvae DNA damage was found. OC and BP induced a reduction of the fertilization rate, embryotoxicity and a decrease in swimming velocity at environmentally relevant concentrations. These sub-lethal effects may have significant consequences for the survival of oysters' larvae, delaying settlement and increasing the risk of predation, which might lead to a reduction of oyster recruitment.

2.05.P-Tu126 Vulnerability of the Sea Urchin (Paracentrotus lividus) to Various Scrubber-waters: Implications for Fertilization and Larval Development

Ana Ré[1]*, Alexandra Monteiro*[1] *and* ***Nelson Abrantes***[2]*, (1)Department of Environment and Planning, Department of Environment and Planning & Centre for Environmental and Marine Studies (CESAM), University of Aveiro, Portugal, (2)Department of Biology, Department of Biology & Centre for Environmental and Marine Studies (CESAM), University of Aveiro, Portugal*

In response to sulphur regulation rules approved and adopted by the International Maritime Organization, many shipping companies have invested in scrubber-water systems instead using lower sulphur fuels. This decision was taken without any risk assessment of the effects of scrubber-water on marine and coastal ecosystems. This way, the exhaust gases containing SOx, NOx, COx, Polycyclic Aromatic Hydrocarbons (PAHs), alkylated PAHs, metals and particles were sprayed with seawater to remove the atmospheric pollutants and transferred them to the seawater. An extremely acidic toxic effluent was created containing potentially persistent compounds with carcinogenic and mutagenic effects. This scrubber-water is continuous and directly discharged into the surrounding surface water.

The present work aims to investigate the ecotoxicological effects of scrubber-waters on the most sensitive stages of development in marine invertebrate organisms, specially focusing on fertility and larval development of the the sea urchin *Paracentrotus lividus*. Given that sea urchin releases the gametes directly into the water, the seawater quality impacts embryonic development.

Three types of scrubber-water produced with Atlantic seawater were used: scrubber-water A (SWA) artificially produced, and Scrubber-water B and C (SWB, SWC) produced on board two different ships. A range of scrubber water concentrations (0.001 to 100% v/v sea water) were tested either with or without pH correction. The scrubber-waters were analysed, revealing notably low pH values and an enrichment of PAHs and alkylated-PAHs, as well as trace metals. The exposure of *P. lividus* spermatozoids and embryos to scrubber-waters evidenced concentration-dependent effects on fertilization success and on the larval development, with the latter proving to be a more sensitive bioassay. The assays performed with pH correction, exhibit lower toxicity, which can be explained by the decrease in metal's bioavailability. The current results indicate that scrubber-waters are highly toxic to this invertebrate species, posing a threat to the more sensitive larval stages crucial for species

recruitment and the sustainability of the entire marine food webs. These bioassays have proven to be effective in assessing the risks posed by scrubber-waters to marine aquatic ecosystems.

2.05.P-Tu127 Biomarker Responses of Clams (Ruditapes philippinarum) Fed on Bisphenol A Analogs-Contaminated Food

Jacopo Fabrello[1], *Michela Dalla Fontana*[2], *Maria Ciscato*[2] *and Valerio Matozzo*[3], *(1)Biology, University of Padua, Italy, (2)University of Padua, Italy, (3)Department of Biology, University of Padova, Italy*

Bisphenol A (BPA) analogs are currently used in manufacturing and as plasticizers as a substitute for BPA. This replacement is taking place because BPA is recognized to be an endocrine disruptor chemical (EDC) that can also cause oxidative stress and genotoxic effects. BPA analogs are speculatively considered safer compounds than BPA and their usage is increasing with a consequent increasing environmental release. In this study, we fed specimens of the clam *Ruditapes philippinarum* for 7 and 14 days with microalgae previously exposed to an environmentally relevant concentration of 300 ng/L of the three main BPA analogs: BPAF, BPF, BPS and their mixture (MIX) to allow their bioaccumulation into the microalgae. Effects on several biomarkers indicative of cytotoxicity and oxidative stress and damage were evaluated in target tissues, such as haemocytes, gills and digestive gland. Results showed that the ingestion of microalgae growth in a BPA analogs-contaminated environment can cause alterations of total haemocyte number and their proliferation. In addition, the activity of phosphatases was significantly altered in consequence of the contaminated microalgae ingestion. Regarding the oxidative stress, we observed an alteration of both antioxidants responses in both gills and digestive gland. Similarly, we observed an increased oxidative damage on lipids and proteins. These results suggest that BPA analogs can be harmful compounds for clams even through a dietary intake and more effort should be performed to assess the effects of these compounds in marine food chains.

2.05.P-Tu128 Combined effect of polystyrene microplastics and bisphenol A on the embryo development of the sea urchin Arbacia lixula

Maria Concetta Eliso[1], *Barbara Billè*[2], *Mariachiara Galati*[2], *Mery Terranova*[2], *Maria Maisano*[2] *and* ***Tiziana Cappello***[2], *(1)Department of Chemical, Biological, Pharmaceutical and Environmental Sciences, University of Siena, Italy, (2)Department of Chemical, Biological, Pharmaceutical and Environmental Sciences, University of Messina, Italy*

Microplastics (MPs, <5 mm) can act as environmental vectors or sinks for hydrophobic organic pollutants, such as polychlorinated biphenyls, polycyclic aromatic hydrocarbons, pharmaceuticals, and perfluorinated surfactants. Until now, the toxic mechanisms of contaminant mixtures are not well understood in marine organisms. In this context, the toxic effects of polystyrene MPs (PS MPs, 1 and 5 µm; 10 µg/mL) and bisphenol A (BPA; 5 and 25 µM), alone and in combination, were herein evaluated on the embryo development of the sea urchin *Arbacia lixula*. Treatment with the two concentrations of BPA significantly reduced the normal larval development, showing skeletogenic alterations at 5 µM and blocked development at 25 µM. On the contrary, both sizes of PS MPs did not significantly reduce the normal embryo development of sea urchins, while the morphological changes observed following co-exposure of the two sizes of PS MPs and the two concentrations of BPA, resemble those obtained following treatment with BPA alone. The impact on nervous system (serotoninergic, cholinergic, GABAergic), stress response, energy metabolism and biomineralization process was therefore investigated through immunohistochemical, molecular and metabolomic analysis to understand the mechanism of action of PS MPs, BPA, and their combination. Overall, these studies provide useful information about the toxicodynamic of complex mixtures of contaminant such as PS MPs and BPA during the embryogenesis of *A. lixula*, which is confirmed to be a sensitive model system for emerging stressors. Furthermore, these findings could contribute on the understanding of the impact of combined PS MPs and BPA on the health of marine organisms living in heavily polluted coastal areas.

2.05.P-Tu129 Risk Characterization of the Antifouling Biocide Tralopyril and Two Natural Compounds Produced by Cyanobacteria: Fertilization and Embryotoxicity Tests using Magallana gigas

Isabel Benta Oliveira[1], ***Ana Carvalhais***[2], *Joana Reis Almeida*[1], *Isabel Cunha*[1], *Vitor Vasconcelos*[1], *Mário Pacheco*[2] *and Cláudia Mieiro*[3], *(1)CIIMAR - Interdisciplinary Centre of Marine and Environmental Research, University of Porto, Portugal, (2)University of Aveiro, Portugal, (3)CESAM - Centre for Environmental and Marine Studies and Department of Biology, University of Aveiro, Portugal*

In the past decades, several biocides have been restricted in the European Union under the framework of the Biocidal Products Regulation (EU Regulation No. 528/2012). Antifouling (AF) biocides are not exception and thus, there is a plea for environmentally acceptable alternatives. Natural compounds with AF activity have been identified as possible alternatives to AF systems. Nevertheless, their natural origin alone is not guarantee of environmental safety. In this sense, this study aims to expand the information available on the toxicity of two natural substances produced by cyanobacteria, with AF potential, namely portoamides and nucuolin A (NocA), and compare their results with those of tralopyril, an AF biocide accepted by the BPR. Therefore, in this work we investigated the toxicity of tralopyril, portoamides and NocA against fertilization and larvae development of the oyster *Magallanas gigas*. Furthermore, the comet assay was also used to assess the genotoxic potential of these three substances on *M. gigas* D-larvae. Preliminary results point towards a higher toxicity of the commercial AF biocide tralopyril when compared to portoamides. On the other hand, NocA seems to have a similar toxicity regarding larvae development but much lesser effect regarding fertilization. Additional data will be assessed and discussed in order to evaluate the genotoxic potential of the assessed substances.

2.05.P-Tu130 Development of green coating solutions for the problems of maritime corrosion and biofouling

Marina Maritati[1], *Natalie Panasiak*[1], *Julia Urbano*[1], *Adrian Love*[1], *Gunhild Hageskal*[2], *Knut Thorshaug*[3], *Ingemar Nardal*[4], *Havard Wilson[4] and Juan Yang[3], (1)AquaBioTech Group, Malta, (2)SINTEF AS, (3)SINTEF, ., Norway, (4)SINTEF Industry, Norway*

Marine biofouling and corrosion are two substantial challenges for shipping, offshore and aquaculture infrastructures, and maritime technologies exposed to sea water. Expensive corrosion resistant materials are often needed to ensure long term equipment functioning while antifouling solutions are required as surfaces and ship niche areas are typical hot spots for the accumulation of biofouling organisms. For these reasons, environmentally friendly and more cost-effective solutions to protect these niche areas offering a combination of corrosion and biofouling protection of metal surfaces are needed.

Effective, environmentally safe corrosion and biofouling protection can be potentially achieved through the investigation and use of high-tech nanomaterial-based formulations, and the development of a thin coating with functional antifouling and anti-rust additives in a green and eco-friendly final product that can be tested in a newly developed innovative testing unit. A novel dual purpose anticorrosion and antirust coating solution under development by the PRONICARE project aims to achieve these goals by:

-investigating a wide range of copper-free green coating formulations with functional additives, through ecotoxicological testing on species of different trophic levels: bacteria, microalgae, microcrustaceans, and fish, and also on two invasive marine biofouling organisms

-developing a new mobile test unit and methodology to validate the effectiveness of the coating mimicking real world environmental conditions and maritime niche areas.

-conducting environmental impact and life cycle analysis of the coating.

2.05.P-Tu131 Assessing the Impact of New Emerging Nanomaterials in the Mussel Mytilus edulis

***Tania Gomes**[1], Maria Elisabetta Michelangeli[2], Sebastian Kuehr[2], Ana Catarina Almeida[2], Steven Brooks[2], Samantha Eslava Martins, PhD[1], Maria T. Hultman[2], Patricia Carvalho[3], Sukdeb Pal[4], Pravin Naoghare[4], Ailbhe Macken[2] and Anastasia Georgantzopoulou[2], (1)Norwegian Institute for Water Research (NIVA), Oslo, Norway, (2)Norwegian Institute for Water Research (NIVA), Norway, (3)SINTEF, Norway, (4)National Environmental Engineering Research Institute (CSIR), India*

The fast expansion and use of nanotechnology in science and industry has continuously led to the development of new emerging nanomaterials (NMs) with unique properties and diverse applications but unknown impacts in the environment. Layered nanostructures, for example, have shown significant promise for use in environmental technology and remediation due to their specific physicochemical properties. This is the case of defect-rich molybdenum disulfide (MoS_2 NMs) and layered double hydroxides nanosheets (LDH NMs), that have been explored for effective removal of contaminants from water samples. However, the impact of these new emerging NMs on aquatic ecosystems are still poorly understood, as well as their potential toxic effects in organisms. Mussels *Mytilus sp.* are widely acknowledged organisms to assess the toxicity and environmental risk of NMs. Thus, the present study aimed to assess and compare the toxicity of MoS_2 and Mg-Al-LDH NMs towards the mussel *Mytilus edulis*. Mussels were exposed to both NMs at 0.1 and 1 mg/L for 14 days, followed by 7 days of depuration. A wide range of biomarkers were determined in mussels at different time points (0, 7, 14 and 21 days), as well as bioaccumulation in tissues. These included condition index, lysosomal membrane stability (LMS), micronuclei formation, DNA damage, acetylcholinesterase activity, antioxidant enzymes activity, lipid peroxidation, cellular energy allocation and metallothionein levels. MoS_2 and Mg-Al-LDH NMs behaviour in exposure media was also evaluated using Transmission Electron Microscopy and Dynamic Light Scattering. Analyses are underway, but preliminary results seem to point to a significant effect in exposed mussels that is concentration and time dependent, with Mg-Al-LDH NMs presenting a clearer toxic response than MoS_2 NMs. This is evidenced by the results obtained on the LMS, where a lower retention time was observed in mussels after 7 and 14 days of exposure to 1 mg/L Mg-Al-LDH NMs and after 14 days for 0.1 mg/L. For mussels exposed to MoS_2 NMs, a significant decrease was only detected for 1 mg/L after 14 days of exposure. Lysosomal retention time returned to values similar to the control after the 7 days of depuration for all exposed mussels. Overall, this study provides valuable information on how new emerging NMs could become a potential risk for the aquatic environment and organisms. This work was supported by the SCANNER Project (#299261) funded by the Research Council of Norway.

2.05.P-Tu132 Approaches to Standardized Methods for Identifying the Negative Influence on the Biodiversity of Coral Ecosystems.

***Guido Gonsior**[1], Sara Cuellar[2] and Maren Dill[3], (1)Aquaculture, Ecotox, Marine Science, GG BioTech Design GmbH, Germany, (2)Algae Research, GG BioTech Design GmbH, Germany, (3)GG BioTech Design GmbH, Germany*

It is very apparent that climate change significantly affects most ecosystems resulting in potentially dramatic changes of food webs. Further chemical pollutants affect ecosystems in a significant way. One of the most endangered ecosystems are coral reefs. Up to now, special focus has been given to the effect of skincare chemicals on corals. But there is still a knowledge deficit in identifying and quantifying other risks. Increasing run-off of pesticides from agriculture and industrial wastewater are origins for contaminants in the costal water. Ecotoxicological research is useful for assessing potential risks and simulating impacts under laboratory conditions. Building new test systems that can quantify potential risks to the environment is an important tool for avoiding biological breakdown in a multicomplex system. We are currently working on new test methods to evaluate ecotoxicological risk for coral reefs. We present test approaches for the generation of reliable and comparable toxicity endpoints.

2.05.P-Tu133 The impact of chemical stressors on biodiversity - An integration of environmental forensic techniques and biological effect markers in the blue mussel Mytilus edulis

Sunna Hrund Sverrisdóttir[1]*, Elina Kvist*[2] *and Joachim Sturve*[3]*, (1)Marine science, University of Gothenburg, Sweden, (2)University of Gothenburg, Sweden, (3)Biological and Environmental Sciences, University of Gothenburg, Sweden*

Anthropogenic activities, including habitat fragmentation, overfishing, freight transportation facilitating invasive species, and pollution events, pose a significant threat to biodiversity. Human population growth contributes to resource overexploitation and chemical pollution. Diverse ecosystems exhibit higher resilience, making them better equipped to withstand environmental stressors. While traditional monitoring methods focus on population and biological effects, there's a lack of integration with the effects of pollutants on biodiversity. Monitoring biodiversity changes due to chemical pollution in the marine environment is challenging with traditional methods, that require high working effort. However, eDNA metabarcoding emerges as a sensitive, non-invasive and cost-efficient tool for detecting a broad taxonomic range. This study integrates eDNA , chemical profiling, genetic and biochemical studies and compares them with traditional monitoring methods. The goal was to establish a simple integrated monitoring strategy applicable in yearly campaigns. The focus is on correlating biodiversity results from eDNA with biological effect monitoring using the mussel species *Mytilus edulis*.

Sediment and mussel samples were collected from two polluted sites on the Swedish Baltic Coast and one reference site. RNA extraction and cDNA synthesis were conducted on six individuals from each site. Quantitative PCR was performed using primers for genes encoding glutathione S-transferase (GST), multidrug resistance-related protein (Mrp2), and antimicrobial peptides mytilin and myticin. Target gene expression was normalised to the reference gene 18S rRNA. Preliminary findings indicate higher antimicrobial peptide gene expression in one polluted site (Ronneby harbour) compared to the reference site Torhamn. Notably, mussels from the second polluted site Karlskrona, a busy marine traffic area with a naval base, exhibit the lowest expression of all target genes. Ongoing analysis includes eDNA, chemical and metal assessments with integration of these results planned for early 2024.

The impact of chemical pollution on biodiversity has the potential to bring about profound and lasting changes in crucial marine ecosystems. This initiative is a dedicated step towards minimising such events, contributing to the advancement of biomonitoring strategies. The focus is on optimising and streamlining monitoring procedures, aiming to reduce costs and efforts, while enhancing efficiency.

2.05.P-Tu134 Testing Marine Heat Waves: physiological and behavioural tolerance in a population of the seaurchin Paracentrotus lividus

Marco Munari[1]*,* ***Ilaria D'Aniello***[1]*, Gil Guastoni Rosenthal*[2]*, Isabella Moro*[3]*, Marco Bonato*[4]*, Chiara Margherita Campaci*[3]*, Marta Formentin*[3]*, Hassan Almetwaly*[3]*, Alejandro Arechavaleta Faría*[3]*, Claudia Gattolin*[3]*, Claudio Bortot*[3]*, Francesco Vairo*[3]*, Irene Fortuna*[3]*, Lara Costantini*[3]*, Lauren Polimeno*[3]*, Lisa Kolodziejczyk*[3]*, Marco Volpato*[3]*, Marco Pagnin*[3]*, Marianna Merci*[3]*, Marta Paganin*[3]*, Moma Maheswari Mishra*[3]*, Neža Leban*[3]*, Noemi Gaiani*[3]*, Orsolya Stipsicz*[3]*, Riccardo Bernardi Malagugini*[3]*, Riccardo Trapasso*[3]*, Samuele Fanna*[3]*, Shaghayegh Kholdihaghighi*[3]*, Shyanne Thompson*[3]*, Tommaso Vian*[3]*, Valentina Ceballos*[3]*, Maria Gabriella Marin*[5] *and Valerio Matozzo*[5]*, (1)Integrated Marine Ecology, University of Padova, Padova, Italy, (2)University of Padova, Department of Biology, Italy, (3)University of Padova, Italy, (4)Department of Comparative Biomedicine and Food Science, University of Padua, Italy, (5)Department of Biology, University of Padova, Italy*

The warming of seawater and the occurrence of marine heatwaves (MHWs) pose a treat to marine organisms, playing a significant role in the fragmentation and loss of coastal marine habitats. It is crucial to comprehend the resilience and potential adaptation of species to ocean warming to better predict future changes and enhancing current conservation strategies. This study conducts a thermo-tolerance experiment to explore the physiological and behavioural effects of short MHWs on the seaurchin *Paracentrotus lividus*, an ecologically and economically relevant species in different area of the Mediterranean Sea and Atlantic Ocean. Adult individuals, collected from the Lagoon of Venice (Italy) in early October 2023, were initially separated by gender through the examination of genital papillae. The separation was conducted using a stereomicroscope. Subsequently, five females and five males were placed in each of six independent tanks, each with a volume of approximately 50 liters. The tanks were filled with natural seawater and maintained under a water flow of 200 ml/min, exposed to natural light conditions. To simulate the HW temperature was progressively increased from 20 °C in the first 3 days until the temperature of 28 °C was reached. This temperature level was then kept for 3 days and then restored to ambient level. Hence, the entire exposure lasted for 9 days. After that, behavioral responses of sea urchins were evaluated. Each individual was tested in terms of: 1) "covering time", i.e. the ability to cover itself with *Ulva* sp. blades; 2) "sheltering time", i.e. the speed with which it escapes from artificial light to shade itself; 3) "righting time", i.e. ability to rotate from "upside-down" to "upside-up" position. Ultimately, the respiration rate of each individual was assessed utilizing optic fiber technology. No significant alterations were observed in any of the tested responses following short-term exposure to heat-wave conditions. These results highlight the behavioral and physiological plasticity of this *P. lividus* population from the Lagoon of Venice, a higly variable enviromnet, to heat-waves' events. This experiment took place at the facility of the Hydrobiological Station Umberto D'Ancona at the University of Padova with the involvment of students from the Marine Ecotoxicology course witihn the Master Degree in Marine Biology of the University of Padova (italy), that are listed among the authors.

2.05.P-Tu135 Investigating primary producers buffer effect against mercury pollution in the seaurchin Paracentrotus lividus

Marco Munari[1], *Jacopo Fabrello*[2], *Ilaria D'Aniello*[1], *Chiara Margherita Campaci*[3], *Marta Formentin*[3], *Isabella Moro*[3], *Maria Gabriella Marin*[4], *Alejandro Arechavaleta Faría*[3], *Claudia Gattolin*[3], *Francesco Vairo*[3], *Hassan Almetwaly*[3], *Irene Fortuna*[3], *Lara Costantini*[3], *Lauren Polimeno*[3], *Lisa Kolodziejczyk*[3], *Marco Volpato*[3], *Marco Pagnin*[3], *Marianna Merci*[3], *Marta Paganin*[3], *Moma Maheswari Mishra*[3], *Neža Leban*[3], *Noemi Gaiani*[3], *Orsolya Stipsicz*[3], *Riccardo Bernardi Malagugini*[3], *Riccardo Trapasso*[3], *Samuele Fanna*[3], *Shaghayegh Kholdihaghighi*[3], *Shyanne Thompson*[3], *Tommaso Vian*[3], *Valentina Ceballos*[3] *and Valerio Matozzo*[4], *(1)Integrated Marine Ecology, University of Padova, Padova, Italy, (2)Biology, University of Padua, Italy, (3)University of Padova, Italy, (4)Department of Biology, University of Padova, Italy*

Over the past few decades, human activities have significantly altered and deteriorated marine environments by releasing various contaminants. The oxygen release by coastal photosynthetic organisms holds promise for alleviating environmental perturbations, enhancing marine animals' aerobic performance in challenging conditions, as observed fo ocean warming and acidification. However, our knowledge of potential buffering effects in response to pollution is still scarce. This understanding becomes pivotal for predicting future changes and enhancing current conservation and restoration strategies of primary producers-based habitats. This study investigates the potential buffering effect against mercury pollution by examining increased oxygen concentration, simulating primary productivity. The sea urchin *Paracentrotus lividus*, an ecologically relevant species in the Mediterranean Sea and the Atlantic Ocean, serves as the model organism. Adult *P. lividus*, collected from the Venice Lagoon, were exposed to the combination of 2 level of oxygen saturation (90% as control and 160% representing daily supersaturation) and 2 concentration of mercury (0 and 1 mg/L) for 7 days. At the end of the exposure, coelomocytes related biomarkers, individual respiration rate and behavioural traits were measured in exposed seaurchins. Results show that righting time was significantly influenced by the interaction of the 2 tested factors with seaurchins exposed to the presence of mercury in a hyperoxigenated condition faster than those from the other 3 conditions. Furthermore respiration rate was singificantly influenced by hyperoxigenation with an increased methabolism of exposed seaurchins. This experiment took place at the facility of the Hydrobiological Station Umberto D'Ancona at the University of Padova with the involvment of students from the Marine Ecotoxicology course witihn the Master Degree in Marine Biology of the University of Padova (italy), that are listed among the authors. The study was conducted as part of the RETURN Extended Partnership, funded by the European Union Next-Generation EU (National Recovery and Resilience Plan – NRRP, Mission 4, Component 2, Investment 1.3 – D.D. 1243 2/8/2022, PE0000005).

2.05.P-Tu136 Investigating primary producers buffer effect against mercury pollution in the clam Ruditapes philippinarum

Marco Munari[1], *Jacopo Fabrello*[2], *Ilaria D'Aniello*[1], *Isabella Moro*[3], *Chiara Margherita Campaci*[3], *Marta Formentin*[3], *Maria Gabriella Marin*[4], *Alejandro Arechavaleta Faría*[3], *Claudia Gattolin*[3], *Claudio Bortot*[3], *Francesco Vairo*[3], *Hassan Almetwaly*[3], *Irene Fortuna*[3], *Lara Costantini*[3], *Lauren Polimeno*[3], *Lisa Kolodziejczyk*[3], *Marco Volpato*[3], *Marco Pagnin*[3], *Marianna Merci*[3], *Marta Paganin*[3], *Moma Maheswari Mishra*[3], *Neža Leban*[3], *Noemi Gaiani*[3], *Orsolya Stipsicz*[3], *Riccardo Bernardi Malagugini*[3], *Riccardo Trapasso*[3], *Samuele Fanna*[3], *Shaghayegh Kholdihaghighi*[3], *Shyanne Thompson*[3], *Tommaso Vian*[3], *Valentina Ceballos*[3] *and Valerio Matozzo*[4], *(1)Integrated Marine Ecology, University of Padova, Padova, Italy, (2)Biology, University of Padua, Italy, (3)University of Padova, Italy, (4)Department of Biology, University of Padova, Italy*

Marine coastal areas are strongly affected by global change and environmental restoration activities with the reintroduction of primary producers are commonly carried out. However, the presence of contaminants in seawaters, like heavy metals, even in restored areas, poses some questions. Indeed, some studies highlighted that a higher presence of primary producers with a consequently increased oxygen concentration in seawaters can have a buffer effect on the toxicity of contaminants, leading to a reduction of physiological and biochemical alterations in animals. For this reason, we investigated if the presence of primary producers can have a buffer effect on the toxicity of mercury or, on the contrary, if there is enhanced toxicity of this heavy metal on clam specimens. In detail, we mimicked the presence of primary producers by exposing the animals to hyperoxia condition (160% of oxygen saturation) with respect to the specimens maintained in normoxia condition (90 % of oxygen saturation), while the mercury was added at an environmentally realistic concentration of 1 µg/L. The exposure lasted 7 days and there were four different conditions: normoxia/no Hg; hyperoxia/no Hg; normoxia + Hg and hyperoxia + Hg. After the week of exposure, we measured the total haemocyte count and the mean diameter and volume of haemocytes. In addition, we investigated the presence of cytotoxic effects between the tested conditions. The results showed that the total haemocyte count was not altered by both mercury presence and oxygen concentration. In the opposite way, we observed that both the mean diameter and volume of haemocytes were significantly reduced by 1 µg/L of mercury. However, the presence of a higher oxygen concentration was not able to restore the initial haemocyte size. Interestingly, we did not record an increased cytotoxicity in any of the treatment conditions. In conclusion, we did not observe a buffer effect on mercury toxicity caused by the simulation of a higher presence of primary producers (hyperoxia condition) which means that the reduction of pollutant concentrations in seawaters still appears as the main way to reduce their hazard. This experiment took place at the facility of the Hydrobiological Station Umberto D'Ancona at the University of Padova with the involvment of students from the Marine Ecotoxicology course witihn the Master Degree in Marine Biology of the University of Padova (italy), that are listed among the authors. The study was conducted as part of the RETURN Extended Partnership, funded by the European Union Next-Generation EU (National Recovery and Resilience Plan – NRRP, Mission 4, Component 2, Investment 1.3 – D.D. 1243 2/8/2022, PE0000005).

2.05.P-Tu137 Does it pass? And what does it do? Maternal transfer and consequences of pollutants' accumulation in sharks

Licia Finotto[1], Guia Consales[2], Letizia Marsili[2], Carlotta Mazzoldi[3], ***Marco Munari[4]*** *and Valerio Matozzo[3], (1)University of Padova, Italy, (2)University of Siena, Italy, (3)Department of Biology, University of Padova, Italy, (4)Integrated Marine Ecology, University of Padova, Padova, Italy*

Sharks are among the most threatened groups of vertebrates. Due to their longevity and high tropic level, these species accumulate high pollutant levels, yet the threat represented by pollution is still highly overlooked. The few information available focus on risks for humans that consume shark meat, rather than on the negative consequences for the animals. Similarly, virtually no data exist on maternal transfer for most of the species; nevertheless, embryonic and early life stage exposure to pollutants might represent a severe risk for health, growth, and survival. This research aims at investigating pollution levels and maternal transfer in three common viviparous shark species inhabiting the northern Adriatic Sea (Mediterranean Sea), *Squalus acanthias*, *Mustelus mustelus* and *M. punctulatus*, and correlating these levels with potential health and physiological consequences. Samples of muscle, liver, blood, placenta, gonads, and embryos have been collected soon after capture from males and females, mature and immature individuals, and pregnant females found among the landings of commercial vessels. Heavy metals, persistent organic pollutants (POPs), and emergent contaminants, such as pharmaceuticals and personal care products (PPCPs), will be quantified in all tissues. Biomarkers associated with pollutant exposure and potential negative effects for the animals will be investigated, including biomarkers of oxidative stress, cytotoxicity, metal exposure, reproductive impairments (i.e., egg quality), alterations to immune function, and general health/energetic status. Maternal transfer will be confirmed and quantified comparing maternal and embryonic pollutant levels. Potential negative effects of pollutants' accumulation will be investigated analysing the correlation between biomarker levels and pollutant concentrations. Multivariate analysis will highlight whether different pollutants act synergistically in causing homeostasis/health impairments. The observed results will be fundamental to better understand the vulnerability towards pollution of these already threatened species, highlighting the potential need for the introduction of effective conservation measures.

2.05.P-Tu138 Scope for Growth in the Blue Mussel Mytilus edulis: Effect of Paint Leachates from Offshore Wind Farm

Moses Ndugwa*, Biology, University of Antwerp, Belgium*

Moses Ndugwa[1], Katharina Alter[2], Bavo DeWitte[3], Lieven Bervoets[1] and Gudrun De Boeck[1]

Wind energy is part of the clean energy systems promoted to minimize the environmental impacts of fossil fuel combustion for power generation. Offshore wind farms have recently gained popularity for several reasons, such as sufficient wind speed and less spatial competition compared to on-land wind farms. Additionally, offshore wind farms present great opportunities for co-location of aquaculture farms alongside electricity generation. However, biofouling coupled with corrosive properties of seawater calls for proactive solutions to minimize the deterioration of offshore wind farm installations, instigating the use of paints mainly composed of epoxy resins and polyurethanes. Despite their application, little is known about the ecotoxicological effect of paints on marine life. Paints used in offshore wind farms installations may leach potentially toxic chemical compounds such as, derivatives of bisphenols, tributyltins, benzophenones and per- and polyfluorinated substances, which may negatively affect marine biota. In laboratory experiments, we are investigating the scope for growth of the blue mussel following exposure to paint leachates from offshore wind farms. Thereby, the mussels will be positioned either directly on the paint coupon (direct exposure) or in close proximity to the paint coupon (indirect exposure). Oxygen consumption rate, maximum clearance rate, and ammonia excretion will be assessed after 1, 3, 7, 14, and 21 days of exposure. Our current preliminary results after 3 days exposure showed an indication of some effects of the paint used in offshore wind farms on the scope for growth in *M. edulis*. Overall these results underscore the importance of understanding the ecological impact associated with the use of such paints in offshore wind farms. This knowledge sheds light on the potential environmental risks posed by rapid global expansion of offshore wind farms.

2.05.P-Tu139 Improving the Survival of Copepods in Ecotoxicology Trials

Adrian Love and ***Marina Maritati****, AquaBioTech Group, Malta*

Ecotoxicity Studies in Copepods: Copepods are ideal candidates for ecotoxicity studies due to their ecological relevance, distribution across a range of environmental conditions, culture within small systems, and sensitivity to pollutants. This has encouraged their wide use within marine ecotoxicology studies, their proposal as a marine model species for OECD assays, and their establishment within ISO assays for both acute and early life stage toxicity. However, all stages of the life cycle after hatching are prone to physical damage which can lead to mortalities occurring days after the initial injury, thereby jeopardizing assays following ISO methods which stipulate the transfer of animals into test solutions. In this study, novel techniques were used to avoid transferring of live animals which resulted in increased welfare and improved data. These steps can be easily integrated into wider ecotoxicological applications in the genera.

2.05.P-Tu140 Electromagnetic fields from subsea power cables: A risk driver for biodiversity changes of offshore wind?

Bjørn Henrik Hansen[1]*, Julia Farkas[2], Bjarne Kvæstad[1], Stefania Piarulli[2], Raymond Nepstad[2] and Tor Nordam Sr[3], (1)SINTEF, Norway, (2)SINTEF Ocean, Norway, (3)Climate and Environment, SINTEF Ocean, Norway*

Offshore wind farms (OWF) utilize subsea power cables for intra-array and export purposes, generating electromagnetic fields (EMF), comprising electric (E-fields) and magnetic fields (B-fields). Electroreceptive marine species, like certain sharks and rays, with specialized organs, may be affected by E-fields, impacting their ability to locate prey. B-fields are likely to disrupt geomagnetic cues and navigation in species relying on such cues, altering natural behaviour and navigation patterns. The impact on marine organisms depends on field strength, species sensitivity and cable proximity to sensitive habitats. Cable insulation and burial can mitigate environmental impact, with burial being more effective. EMF strength varies with cable voltage and current, where B-fields are current dependent, and E-fields are voltage dependant. HVDC cables, responsible for transmitting electricity to the onshore grid, are high voltage, cover longer distances, and are seabed-buried. Benthic and epi-benthic communities, critical for maintaining the ecosystem functionality, are thus at risk of EMF exposure. Some benthic invertebrates, like lobsters and crabs, are sensitive to B-fields, which causes behavioural alterations. The overall impact on organisms, communities and ecosystems remains poorly understood and studied. SINTEF Ocean developed an experimental system for controlled exposure of marine organisms to B-fields. The system, featuring an exposure arena, allows observation of small marine organisms while subjecting them to realistic magnetic fields from submarine cables. The primary research focus is assessing behavioural effects on various marine species, aiming to establish EMF effect thresholds. This research contributes to evaluating EMF as a potential environmental risk factor for offshore wind installations.

2.05.P-Tu141 Strategic Investigative Drivers and Impacts Affecting Marine Environmental Developments

Marina Maritati[1]*, Adrian Love*[1] *and Kirit Wadhia*[2]*, (1)AquaBioTech Group, Malta, (2)Environmental, NOV Inc, United Kingdom*

Aquaculture: The importance of aquaculture is only too evident in light of unsustainable harvests from capture fisheries. A sustainable need for the sector is apparent in order to meet future projected demands for aquaculture production to fulfil global food production demands exacerbated by rapidly growing human population and climate change issues. Aspects of pertinence impacting aquaculture sector production and sustainability include:

global temperature rise; ocean acidification; disease & harmful algal blooms; change in precipitation (rainfall) patterns; sea level rise; uncertainty of external input supplies; changes in sea surface salinity and severe climatic events.

The multi-faceted and site-specific nature of the environmental impacts of aquaculture mean that the primary route for managing these impacts is through the assessment, including through modelling, of individual projects or plans taking into account relevant regulatory systems.

Aquatic Ecotoxicology: Ecotoxicology research and developments are important for the assessment of well-known and emerging environmental contaminants. The conservation of ecosystems and human health is based on a sound assessment of the risks associated with the presence of contaminants in the aquatic environment. In reference to the use and issues of ecotoxicologically relevant species key criterion is the extrapolation of studied species to the whole ecosystem. Important facors for consideration are: (1) the genetic diversity of organisms used in bioassays and their extrapolation to wild populations; (2) criteria to be taken into account for biomonitoring - this is pertinent to the structure and functioning of the whole ecosystem; (3) the variability of responses through taxonomic levels and (4) the variability of responses as a result of confounding factors.

In context of aquatic environment a natural process of significant concern for many industries is biofouling. Biofouling is undesirable biological accumulation of organisms (micro- & macro- organisms) and other constituents on surfaces exposed to natural waters. This biogrowth causes operational inefficiency imposing substantial cost for the maritime and aquaculture industries. Perspective to tackle & address these important aspects will be conveyed.

2.05.P-Tu142 "Unveiling the Long-Term Effects: Exploring Multigenerational Impacts of Commercial Sunscreens on the Marine Microalgae Phaeodactylum Tricornutum"

Esther Bautista-Chamizo[1]*, Bárbara Úbeda*[2]*, Ignacio Moreno-Garrido*[3] *and* ***Araceli Rodríguez-Romero***[4]*, (1)Department of Biology, Faculty of Marine and Environmental Sciences, Marine Research Institute (INMAR), University of Cadiz, Spain, (2)University Institute of Marine Research (INMAR), University of Cádiz, Spain, (3)Institute of Marine Sciences of Andalusia, Spanish National Research Council (ICMAN-CSIC), Spain, (4)Department of Analytical Chemistry, Faculty of Marine and Environmental Sciences, Marine Research Institute (INMAR), University of Cadiz, Spain*

The expanding knowledge about the danger of sunburn, in relation to photoaging and skin cancer, has led to a notorious increase in the use of sunscreens around the world. However, these cosmetics are considered pollutants of emerging concern, especially in marine ecosystems. Sunscreens are composed of an extent range of chemical compounds, making them complex matrices to assess from an environmental point of view. Despite of the number of studies evaluating the detrimental effects caused by the ingredients released from sunscreens on marine environment, they have been focused on the short-term responses of a given species, ignoring how marine biota will respond to this new anthropogenic invader when taking into account trans-generational plasticity

The main objective of this study is to evaluate the effects of commercial sunscreens in the marine microalgae *Phaeodactylum tricornutum* through consecutive generations. The working hypothesis is that sunscreens may not represent a danger for the development of microalgae at short but across generations. To achieve this goal, experiments with *P. tricornutum* were carried out in triplicate. Exponentially-growing populations of microalgae were exposed to five different concentrations of a mixture of five commercial sunscreens (15, 30, 60 and 90 mg L^{-1}) and a control (natural seawater) under laboratory conditions. The experiments were performed during seven consecutive generations with an established initial cell density of 10^4 cells m L^{-1}. Cell density, metabolic activity and chlorophyll-*a* content were measured every 96 hours (at the end of each generation). Preliminary results showed at first a positive relationship between all the selected responses and the concentration of sunscreens, but this tendency changed after the third generation, when the cultures started to show cells damage.

The conclusions obtained from this work proportionate valuable knowledge about the trans-generational effects that sunscreen products may cause on microalgae species. This study highlights the need of conduct multigenerational studies to accurately predict how marine biodiversity will respond to the presence of this new contaminant and avoid over or under estimate its effects at long term.

2.05.P-Tu143 Ecotoxicological Impacts and Recovery Potential in Deep-sea Anemones Exposed to a Sediment Plume Generated by a Deep-sea Mining Vehicle

***Leandro Teixeira Marinho*[1]**, *Juliano Marcelo Vilke*[2], *Carmen S. V. Sousa*[1], *Joana Raimundo*[3,4], *Miguel Caetano*[3,4], *Pedro Aboim de Brito Dr*[4] *and Nélia C. Mestre*[1], *(1)Centre for Marine and Environmental Research (CIMA), University of Algarve, Portugal, (2)Centre for Marine and Environmental Research – CIMA/ARNET – Infrastructure Network in Aquatic Research, University of Algarve, Portugal, (3)CIIMAR - Interdisciplinary Centre of Marine and Environmental Research, University of Porto, Portugal, (4)Portuguese Institute for Sea and Atmosphere (IPMA), Portugal*

The deep sea represents 90% of the world oceans and is mostly unknown due to its magnitude and inaccessibility. Recently, humankind started to look to the deep sea as a potential hotspot of mineral resources that will be essential for the expected green energy transition. One of the major challenges, that has barely been assessed, is the potential ecotoxicological impacts from the exploitation of such resources. This study will provide the 1st ecotoxicological results from deep-sea anemones exposed *in situ* (4500m depth) to a plume of sediments in the Clarion-Clipperton-Zone (CCZ), Pacific. The 1st trial of the prototype Patania 2 robot for deep-seabed mining of polymetallic nodules was closely monitored by the Mangan21 expedition in May 2021, that collected *Actiniaria spp.* specimens from control and exposure areas. After 18 months from the trial, further anemone specimens were collected. Metal concentrations (As, Cd, Co, Cr, Cu, Mn, Ni, Pb, V, and Zn) were determined by ICP-MS and biomarkers of oxidative stress (SOD: Superoxide Dismutase, CAT: Catalase, and GST: Glutathione S-Transferase) and damage (LPO: Lipid Peroxidation) as well as Metallothioneins (MTs), were determined with spectrophotometry, both in whole tissues. All metals, except Zinc and Arsenic, were found in higher concentrations on the individual exposed to the plume when compared to the controls. SOD activity seems to be induced in the exposed anemone, similar to LPO, although less pronounced. Results from metal accumulation and biomarkers after 18 months from the impact trial will also be presented to enable an estimation of the recovery potential in this species. Preliminary results indicate that the single deep-sea anemone exposed *in situ* to the sediment plume, accumulated several metals in its tissues, and that may have caused oxidative stress and damage, when compared to control locations. This shows that sediments from the seafloor of the CCZ might have the potential to cause ecotoxicological harm to the deep-sea fauna. This is essential information for the determination of future thresholds to be incorporated in regulations by policy makers to minimize the environmental damage of this activity.

This work was funded by Fundação para a Ciência e a Tecnologia (FCT) through the BiDiRisk (PTDC/CTA-AMB/2894/2021) and DEEP-REST projects (DivRestore/0009/2020), and the grants CEECIND005262017, CIMA UI/MAR/00350/2020, and LA/P/0069/2020.

2.05.P-Tu144 Identifying the Best Biomarkers for Risk Assessment in the Deep Sea

***Nélia C. Mestre*[1,2]**, *Jin Sun*[3], *Jozée Sarrazin*[4], *Leandro Teixeira Marinho*[2,5], *Daphne Cuvelier*[6,7], *Ana Colaço*[6,7], *Joana Raimundo*[8,9], *Miguel Caetano*[8,9], *Xing He*[3], *Pei-Yuan Qian*[10,11] *and Carmen S. V. Sousa*[1,2], *(1)Centre for Marine and Environmental Research (CIMA), University of Algarve, Portugal, (2)ARNET – Infrastructure Network in Aquatic Research, University of Algarve, Portugal, (3)Institute of Evolution & Marine Biodiversity, Ocean University of China, China, (4)Univ Brest, CNRS, Ifremer, UMR6197 BEEP, France, (5)University of Algarve, Portugal, (6)Okeanos, OKEANOS–Institute of Marine Sciences, University of the Azores, Portugal, (7)IMAR-Instituto do Mar, Departamento de Oceanografia e Pescas, University of the Azores, Portugal, (8)CIIMAR - Interdisciplinary Centre of Marine and Environmental Research, University of Porto, Portugal, (9)Portuguese Institute for Sea and Atmosphere (IPMA), Portugal, (10)Department of Ocean Science, Hong Kong University of Science and Technology, China, (11)Southern Marine Science and Engineering Guangdong Laboratory (Guangzhou), China*

Deep-sea mineral resources are seen as economically valid and technologically possible to exploit. However, the cost-benefit of deep-sea mining (DSM) need to accurately account for the scale of environmental impact, the ecosystem services that might be compromised and the potential mitigation measures that can be implemented. DSM will remove the habitat locally where the mining operations will take place. In addition, localized plumes created by mining collectors at the seafloor and dewatering ore slurry produced by the mining support vessel may introduce complex mixtures of potentially toxic elements in the water column. While species resilience to impact will be conditioned by their capacity to resist exposure to toxic elements at present it is not possible to predict, in advance of DSM operations, the absolute toxicity thresholds. It is thus important to develop novel methodologies and indicators for ecotoxicological evaluation of risks of metal exposure for deep-sea organisms. This study aims to assess the ecotoxicological impacts using transcriptomics and proteomics approaches and to identify potentially new biomarkers. *In situ* sulfides/sediments exposure experiments with local fauna from deep-sea hydrothermal vents and cold seeps were performed. Mussel samples (*Bathymodiolus azoricus* and *Gigantidas platifrons*) were collected from the Lucky Strike hydrothermal vent field (1700m depth) Mid-Atlantic Ridge and from the Haima seep (1385m depth) in the South China Sea, respectively. In the present study, we suggest potential biomarkers that are representative of different biological systems (immune system, metabolism and oxidative stress) that were modified under those exposure scenarios. Twenty-four biomarker candidates based on high-throughput methodologies results were selected and tested. The validation of candidate biomarkers

will help to identify which are the most reliable. Results will help to define future threshold values for plume / metal concentrations, information seen as essential to be incorporated in regulations by policy makers to minimize the environmental impact of DSM activities. This work was funded by Fundação para a Ciência e a Tecnologia (FCT) through the BiDiRisk (PTDC/CTA-AMB/2894/2021) and DEEP-REST projects (DivRestore/0009/2020), and the grants CEECIND005262017, CIMA UI/MAR/00350/2020, and LA/P/0069/2020 and Fundamental Research Funds for the Central Universities, China (202172002 and 202241002).

2.05.P-Tu145 Simulating the deep-sea mining plume exposure on a shallow-water mussel: an ecotoxicological assessment

Juliano Marcelo Vilke[1], *Leandro Teixeira Marinho*[2], *Pedro Aboim de Brito Dr*[3], *Santiago Correia Sr*[1], *Joana Raimundo*[4], *Miguel Caetano*[4], *Katja Schmidt Dr.*[5], *Sophie A. L. Paul Dr*[6] *and Nélia C. Mestre*[2], *(1)Centre for Marine and Environmental Research – CIMA/ARNET – Infrastructure Network in Aquatic Research, University of Algarve, Portugal, (2)Centre for Marine and Environmental Research (CIMA), University of Algarve, Portugal, (3)Portuguese Institute for Sea and Atmosphere (IPMA), Portugal, (4)CIIMAR - Interdisciplinary Centre of Marine and Environmental Research, University of Porto, Portugal, (5)Bundesanstalt für Geowissenschaften und Rohstoffe – BGR, Germany, (6)Helmholtz Centre for Ocean Research Kiel – GEOMAR – Wischhofstrasse, Germany, Germany*

Due to the high metal demand worldwide, the interest in deep-sea mining is increasingly pronounced, mainly for extracting polymetallic nodules, of high comercial value due to their high concentration and purity in metal contents. The Clarion-Clipperton Zone (CCZ) is one of the prominent locations targeted for mining these polymetallic nodules due to its high abundance. During mining on the seafloor, the generation of sediment plumes may release metals in concentrations that can induce ecotoxicological harm. This was investigated on the shallow-water mussel, *Mytillus galloprovincialis*, frequently used as a bioindicator organism. Mussels were exposed for 14 days to concentrations of deep-sea sediment (10 mg/L (C10) and 50 mg/L (C50)) collected from the Belgian contract area of the CCZ. The biochemical biomarkers were evaluated, including those involved in the antioxidant defense system: superoxide dismutase (SOD), catalase (CAT), glutathione peroxidases (GPx), xenobiotic biotransformation system: glutathione *S*-transferase (GST), oxidative damage: levels of lipid peroxidation (LPO), neurotoxicity: acetylcholinesterase (AChE), genotoxicity (comet assay). Elemental screening was performed to detect metals and REE in the mussel's tissues and experiment waters. Results from the exposed waters showed a significantly higher metal (Co, Cu, and Mn) and REE (Ga, Eu, Yb, Dy, Y, Ho, Er, and Lu) content in the C50 treatment, compared to the control waters ($p < 0.05$). Similarly, higher Cr and Mn accumulation was found in the gills of the mussels after 14 days of exposure, whereas in the digestive glands, Mn, Ni, and Co were significantly higher after 14 days of exposure ($p < 0.05$). Regarding biomarker responses, pronounced antioxidants and biotransformation responses were found, namely elicited SOD, GPx, and GST activities, culminating in an absence of oxidative damage (LPO levels) in both tissues after sediment exposure ($p > 0.05$). Signals of genotoxicity and neurotoxicity were also found in mussels exposed to the sediments. Overall, the results of the present study provide evidence of negative ecotoxicological impacts caused by deep-sea sediments on the shallow-water mussel *Mytilus galloprovincialis*.

2.05.P-Tu146 Potential Biomarkers to Assess Metal Toxicity in Deep-sea Invertebrates under Deep-sea Mining Scenario

Carmen S. V. Sousa[1], *Nélia C. Mestre*[1] *and Jin Sun*[2], *(1)Centre for Marine and Environmental Research (CIMA), University of Algarve, Portugal, (2)Institute of Evolution & Marine Biodiversity, Ocean University of China, China*

Deep-sea mining (DSM) activities will remove extensive accumulations of minerals from the deep ocean and are expected to release potentially toxic metal mixtures through the generation of sediment plumes near the seafloor or from the dewatering ore slurry after the ore process. These plumes may spread and impact larger areas and may disrupt the normal functioning of biological mechanisms (e.g. immune system, metabolism and oxidative stress), adversely affecting deep-sea organisms. The crosstalk between the ecotoxicological effects and specific biomarkers across different deep-sea invertebrates has been less explored using omics promising tools. This review summarizes the existing studies and methodologies in deep-sea marine invertebrates that applied genetic techniques and bioinformatic tools, with emphasis on the high-throughput profiling, to assess environmental impacts at the transcript, protein, and metabolome levels. In the present study, we suggest several potential biomarkers that are representative of different biological systems that were modified under increased metal concentrations in deep-sea invertebrates adapted to very harsh environmental conditions (e.g. high pressure, low temperature and absence of sunlight). Our findings highlight several biomarker candidates that could be screened in priority in future ecotoxicological studies related to DSM. However, those potential biomarker candidates need validation with further experiments simulating DSM plume exposure disturbances with deep-sea organisms. Once validated, these can work as early warning signals for environmental disturbance, especially for the exposure to the toxic metals entrained in DSM plumes. Moreover, the definition of potential threshold values for the best candidate biomarkers may allow future biomonitoring actions during DSM activities.

2.06.P New Developments in Sediment Ecotoxicology and Risk Assessment

2.06.P-We099 Estuarine Sediments as "Traps" for Trace Metals, PAHs and Hormones: An Example from Southampton Water, UK

Jana-Sophie Appelt[1], *Andrew Cundy*[2], *Sargent Bray*[2] *and Jessica Whiteside*[2], *(1)University of Southampton, Southampton,*

United Kingdom, (2)Ocean and Earth Science, University of Southampton, United Kingdom
Understanding the fate and behaviour of contaminants across different environmental matrices is crucial for effective risk assessment and management. Estuarine sediments are recognized as "traps" for a range of contaminants, playing an important role in moderating their input from rivers into coastal and marine ecosystems. However, degradation pathways for contaminants in sediments depend on the physicochemical properties of the sediments, such as sediment composition, particle size, organic matter content, the chemical structure and speciation of the contaminants and the environmental conditions. Given the vast amount of different chemicals, and varying environmental parameters, for many contaminants the fate in sediments is still uncertain.

This study focuses on the fate of hormones, PAHs and trace metals in estuarine sediments. Analysis of surface sediment samples and sediment cores from Southampton Water, a heavily industrialized and urbanized estuary in Southern England, allow for a spatial distribution, as well as a historic record of different contaminants in this area. Focusing on three different contaminant groups provides the opportunity to compare the behavior dependent on different chemical properties and moreover, gives a more comprehensive overview of the condition of the estuary. So far, trace metal analysis using XRF analysis indicates increasing concentrations close to point sources such as the port (e.g. Hg with up to 2.4 mg/L), whereas with gamma-spectroscopy dated sediment cores document contamination linked to historical waste discharges into the estuary. Statistical analysis, such as Principal Component Analysis, demonstrates associations between trace metals and the sulfides in the sediments, but no general trends of correlation. Ongoing work includes organic analysis using GC-MSMS. Furthermore, adsorption batch experiments are conducted to gain further understanding of how different chemical structures, as well as varying types of organic matter influence the adsorption and degradation of certain contaminants in estuarine sediments. These results will help to further explain the observations from the environmental sample analysis and contribute to a more comprehensive understanding of contaminant dynamics in estuarine systems.

2.06.P-We100 Paleo-ecotoxicology: Dioxin-like activity in lake sediment core as an indicator of historical anthropogenic environmental pollution
Polina Kanj[1]*, Florian Gigl*[2]*, Matthias Hinderer*[3]*, Kristin Haas*[4]*, Werner Brack*[5]*, Martin Krauss*[5]*, Thomas Schiedek*[6] *and Henner Hollert*[7]*, (1)Goethe University Frankfurt, Germany, (2)Evolutionary Ecology & Environmental toxicology, Goethe University Frankfurt, Germany, (3)Technical University Darmstadt, Germany, (4)Geosciences, Technical University Darmstadt, Germany, (5)Department of Effect-Directed Analysis, Helmholtz Centre for Environmental Research (UFZ), Germany, (6)Hydrogeology, Technical University Darmstadt, Germany, (7)Evolutionary ecology and environmental toxicology, Goethe University Frankfurt, Germany*
The hydrophobic nature of dioxin-like organic substances (PAHs, PCBs, PCDD, and PCDF) leads to the sorption onto organic matter of sediments in aquatic ecosystems, where they can remain stable over extended periods. Sediment cores from lakes play a significant role as a natural archive of pollutant inputs over time. This allows insights into the concentration, composition, origin of the pollutants and the change of those parameters over time.

This study is part of a interdisciplinary historical project that explores the rich history of the town Bad Waldsee in Germany. It focuses on the analysis of ecotoxicological and chemical properties using sediment cores from the Stadtsee lake. The collaboration with historians, geoscientists and botanists within the project, enables to attribute the ecotoxic effects to specific historical events as well as to the ecological data of the lake. The extracted sediment cores display clear lamination, which allows the dating of the core to a (partially) annual resolution over the last 700 years. The aim of this research was on investigating biomarker CYP1A for dioxin-like activity in sediment, cross multiple subsamples of sediment core dated from 2021 AD to 600 BC to record the presence of ecotoxicological pollutants over time. The approach is based on 7-ethoxyresorufin-O-deethylase (EROD) induction in the H4IIE rat hepatoma cell line, with the determination of a Biological Toxicity Equivalent (Bio-TEQ) to TCDD for each sediment subsample. First findings indicate significant variations in the ability of sediment core subsamples to induce EROD activity, with an exceptionally high values detectable during the early modern age (1500 AD - 1800 AD), reaching up to 1000 pg TCDD/g sediment. EROD activity induction in some samples was attributed to specific historical events such as city fires and military conflicts. Data of concentrations of 21 PAHs explained 4.8% to 57.5% of the observed EROD activity in the sediments subsamples. However, EROD activity has been documented since the Middle Ages and steadily increases over the years, suggesting long-term exposure to various dioxin-like compounds. To comprehensively capture components of organic pollutant exposure, specific time subsamples will be further investigated using a non-target analysis. These findings contribute to a deeper understanding of historical environmental pollution and provide valuable insights into development of anthropogenic stressors before industrialization.

2.06.P-We101 When and How to Conduct Ecotoxicological Tests Using Natural Field Collected Sediment
Sara Nicoline Grønlund[1,2]*, Wing Sze Chan*[2]*, Elettra D'Amico*[3]*, Mette Flodgaard*[2]*, Gry Lyngsie*[2]*, Erin McCallum*[1]*, Annemette Palmqvist*[4]*, Monica Hamann Sandgaard*[5]*, Martina Santobuono*[2]*, Amalie Thit Bruus Jensen*[6] *and* ***Henriette Selck***[2]*, (1)Swedish University of Agricultural Sciences (SLU), Sweden, (2)Roskilde University (RUC), Denmark, (3)INM, Roskilde University (RUC), Denmark, (4)Dept. of Science and Environment, Roskilde University (RUC), Denmark, (5)Department of Science and Environment, Roskilde University (RUC), Denmark, (6)DHI group, Denmark*
In recent years, the sediment compartment has gained more attention when performing toxicity tests with the growing emphasis on gaining more ecological relevance in testing. Though many standard guidelines recommend using artificially formulated sediment, most sediment studies are performed using natural sediment collected in the field. The use of natural

field collected sediment contributes to more environmentally realistic exposure scenarios and higher well-being for sediment-dwelling organisms. This underscores the need for comprehensive guidelines on conducting sediment toxicity testing with natural sediment.

In this method paper, we outline six key steps in conducting ecotoxicity assays with natural field collected sediment: collecting sediment in the field, preparing the sediment, characterizing the sediment, altering the sediment, spiking the sediment, and finally using the sediment in an experimental setup. Drawing from decades-long expertise in sediment testing we propose the following recommendations: 1) natural sediment should be collected at a site, that has been well-studied both historically and by laboratory analyses; 2) to collect and store larger quantities of sediment prior to the initiation of an experiment to ensure a uniform sediment base; 3) any sediment used in ecotoxicological testing should be characterized, at the very least, for its water- and organic matter content, pH, and particle size distribution; 4) to select a spiking method, equilibration time, and experimental setup based on the properties of the contaminant and the research question; 5) to include control-, treated similarly to the spiked sediment, and solvent control sediment when appropriate; and, 6) to quantify experimental exposure concentrations in the overlying water, porewater, and bulk sediment at the beginning and the end of an experiment.

It is important to point out that any handling of intact natural sediment will change its physical and chemical properties. Here, we propose a stepwise method that provides control and consistency while maintaining sediment properties in as natural of a state as possible. This method solely applies to instances where a uniform sediment is preferred *e.g.,* when rearing cultures or performing ecotoxicological investigations where you control or add contaminants. Overall, we hope that by making these steps clear and accessible, we can increase the comparability and reproducibility of studies conducted with natural sediments.

2.06.P-We102 A Comprehensive Examination of Fluoxetine Exposure in Lumbriculus variegatus: Insights from Biomarkers to Behaviour

***Jacqueline Hilgendorf*[1]*, Diogo N. Cardoso[1], Diana Campos[1], Jesper Givskov Sørensen[2] and Susana Loureiro[1], (1)CESAM - Centre for Environmental and Marine Studies & Department of Biology, University of Aveiro, Portugal, (2)Department of Biology, Aarhus University, Denmark*

Sediments play a vital role in freshwater ecosystems, providing habitat for organisms like decomposers and bioturbators, which are essential for ecological processes such as the uptake and transfer of nutrients. The increasing chemical pollution threatens these sediments, which can act as a sink for persistent organic pollutants such as certain pharmaceuticals. However, there is a considerable knowledge gap regarding the chemical impact on sediment-dwelling organisms such as *Lumbriculus variegatus*. Existing studies assessing chemical effects in *L. variegatus* primarily focus on survival, growth, and reproduction, neglecting biochemical and behavioural responses. However, these additional sublethal endpoints have become more important in recent years as they provide crucial insight into chemical effects. This study addresses this gap by exposing *L. variegatus* to the antidepressant fluoxetine, assessing various endpoints: survival, growth, reproduction, respiration, biochemical responses related to cellular energy (e.g. lipids), oxidative stress (e.g., catalase), neurotoxicity (acetylcholinesterase) and serotonin levels as well as behavioural analysis (chemical avoidance, phototaxis, and feeding behaviour).

Two sequential experiments were conducted by exposing *L. variegatus* to fluoxetine through sediment, following OECD guidelines. Six concentrations between 0.0025 and 25 mg/kg were tested in 28-day exposures with five replicates and ten organisms per replicate. Fluoxetine exposure significantly impacted the growth and reproduction of *L. variegatus*. Additionally, worms showed behavioural changes even at low, environmentally relevant concentrations in the phototactic and feeding assay. The chemical avoidance assay showed a significant response at 0.025 mg/kg, with organisms failing to avoid lead contamination, unlike the control. These effects will be linked to the biochemical analysis in a subsequent step.

This study introduces novel approaches for evaluating the impact of exposure on the behavioural responses of *L. variegatus* and links this response to physiological and biochemical effects. The results show that fluoxetine exposure significantly affected the physiological and behavioural responses of *L. variegatus*, even at environmentally relevant concentrations. This indicates that non-conventional endpoints like behavioural assays provide essential tools for chemicals like fluoxetine, designed to affect the hormonal pathways at low concentrations.

2.06.P-We103 Evaluating the use of an in vivo bioassay battery for sediment quality assessment in small streams

***M. Carmen Casado-Martinez*[1]*, Rébecca Beauvais[2], Sebastian Hoss[3], Sergio Cirelli[4], Emmanuel Schaad[4], Aurea C. Hernández[4] and Benoit J.D. Ferrari[2], (1)Swiss Centre for Applied Ecotoxicology Eawag (EPFL), Lausanne, Switzerland, (2)Swiss Centre for Applied Ecotoxicology, Switzerland, (3)Ecossa, Germany, (4)University of Bern, Switzerland*

Under the Water Framework Directive (WFD), a tiered approach is recommended for sediment quality assessment. A first tier consists of chemical analyses and the evaluation against sediment quality standards (EnQS). Exceedance of EQS should trigger additional investigations to verify the possibility of potential adverse effects, in particular if the EQS is considered “uncertain”. The Technical Proposal for Effect-Based Monitoring and Assessment under the WFD concluded that *in vivo* bioassays could already be considered for implementation. However, a guidance document would be useful to help identifying a suitable battery of tests depending on the type of pressures, and to facilitate the assessment of the results. The Ecotox Centre carried out a monitoring study with the aim of extending the assessment of water quality using effect-based methods. To this end, water quality was assessed at sites with extensive, agricultural or agricultural-urban land use using a comprehensive bioassay battery of largely standardised water and sediment bioassays. This presentation will provide an overview on the results of sediment bioassays.

The battery of sediment bioassays included the tests with the ostracod *Heterocypris incongruens*, the nematode *Caenorhabditis elegans*, and the insect *Chironomus riparius*. Physico-chemical analyses included sediment properties, metals, and organic contaminants (PAHs, PCBs, and organic substances including 91 pesticides and degradation products). The ecotoxicological quality of sediments was assessed by means of existing toxicity thresholds. Measured concentrations were compared with EQS. Sediments from sites under extensive land use were less toxic than those from agricultural or agricultural-urban land use, which was supported by lower measured chemical contamination. Sites affected by agricultural-urban land use showed the highest potential risk (exceedance of EQS for all substance types), which agreed with a medium or unsatisfactory ecotoxicological quality. Sediments from agricultural watersheds showed medium or unsatisfactory ecotoxicological quality. Only slight exceedances of the EQS for metals, PAHs, PCBs were observed, while several pesticides exceeded the EQS. Our results support the implementation of an in vivo bioassay battery, in particular in areas that are not expected to be at risk because they are located far from known local sources and to take effects of not routinely analysed chemicals into account.

2.06.P-We104 Utilizing Natural Deep Eutectic Solvents for Eco-Friendly Analysis of Chemical Pollutants in Marine Sediments

Mariana Elizabeth Rodrigues[1]*, Fernanda Tavares*[1]*, Micaela Sofia dos Santos Justo*[2]*, Daniel Asfaha*[3]*, Rodrigo Villalobos*[4]*, Susana Carvalho*[3]*, Geert-Jan Witkamp*[1] *and Andreia Sofia Filipe Farinha*[3]*, (1)Water Desalination and Reuse Center, King Abdullah University of Science and Technology, Saudi Arabia, (2)Red Sea Reasearch Science, King Abdullah University of Science and Technology, Saudi Arabia, (3)King Abdullah University of Science and Technology, Saudi Arabia, (4)Red Sea Research Center, King Abdullah University of Science and Technology, Saudi Arabia*

Marine sediments reflect the dynamic interactions between terrestrial and aquatic ecosystems and can be considered archives of environmental processes. Conventional chemical characterization methods often involve hazardous solvents, presenting ecological impact and safety challenges. This study explores Natural Deep Eutectic Solvents (NADES) as an eco-friendly solvent alternative in the extraction of chemical components within marine sediments. NADES are a combination of two or more natural compounds, typically hydrogen bond donors and acceptors, which results in a mixture with unique properties, making them promising candidates for efficient extraction of target compounds. Therefore, they can be applied in the extraction of chemical contaminants from solid samples. This work proposes a novel approach for the simultaneous extraction of inorganic and organic contaminants in marine sediments. The NADES extract is characterized via High-Resolution Inductively Coupled Plasma Mass Spectrometry (HR-ICP-MS) for (ultra)trace inorganic elements, and via Fourier-Transform Infrared (FTIR), Thermogravimetric analysis (TGA), and High-Performance Liquid Chromatography (HPLC) to investigate the presence of organic pollutants. The comparison with traditional extracting methods will be discussed, NADES is expected to preserve the integrity of extracted pollutants during the analytical process. Ultimately, using a one-step extraction can contribute to the development of fast and reliable methods supporting greener and more responsible research practices in marine environmental science.

2.06.P-We105 Metals Distribution in Sediments in Select Creeks in Metro Vancouver, Canada

Enoch Gampson[1] *and* ***Matt Dodd, PhD***[2]*, (1)Environment and Sustainability, Royal Roads University, Canada, (2)School of Environment and Sustainability, Royal Roads University, Canada*

Watersheds in Metro Vancouver, the third largest metropolis in Canada, contain mixes of varying land use including park, residential, commercial, industrial, institutional, and agricultural. Storm water which typically empties directly into rivers or creeks in these watersheds can potentially introduce pollutants such as metals that are picked up as the storm water flows along these areas with varying land use. Forty-seven sediment samples were collected from 23 creeks in Metro Vancouver to assess how the surrounding land use influence metal distribution in the sediments. Total metal concentrations were determined by x-ray fluorescence and the physicochemical properties of surface water were also evaluated. There were no discernible statistically significant relationships between the surrounding land use and surface water quality parameters including the pH (which ranged frm5.5 to 8.27), total dissolved solids (13.5 to 410 ppm) and electrical conductivity (18.9 to 903 µS/cm). The pH of some sampled sediments where however lower and correlated with sites with high metal concentrations. The mean concentrations in the sediments were Ag: 1.1, As: 1.9, Ba: 486, Cd: 1.8, Cr: 54, Cu: 28, Fe :34448, Mn: 915, Ni: 29, Pb: 21, V: 92 and Zn 141 mg/kg. The concentrations of Ag, As, Cd, Cr, Cu, Pb and Zn in sediments from some of the creeks exceeded either the Canadian Council of Ministers of the Environment (CCME) interim freshwater sediment quality guidelines or the threshold effect level. Sediments in creeks closer to highways with heavy vehicular activities contained significantly higher concentrations of As, Cd, Cu, Pb and Zn. Principal component analysis indicated good correlation between these elements corroborating the common anthropogenic origin. Fe, Ni and V were attributed to natural weathering from the geological formation of the study area. Enrichment factors, contamination factors, geo-accumulation indices and pollution load index (PLI) for the sediment samples differed among the land uses. The calculated contamination factors followed the sequence: Cd>Ag>As>Pb>Zn>Mn>Cu>Ba>Cr>Ni>V. PLI exceeding 1 that indicated polluted sediments were noted for four creeks situated in industrial land use catchment areas. Additional investigations including determining the areal extent of contaminants in the identified creeks and the types of industries in the impacted watersheds are ongoing. Seasonal variability of metal levels in the sediments will also be conducted.

2.06.P-We106 Organic contaminants in sediment cores from the lake of L'Albufera Natural Park (Valencia, Spain)

Yolanda Soriano Juan[1], *Eugenia Gimeno Garcia*[2], *Julian Campo*[3], *Carmen Hernández-Crespo*[4], *Vicente Andreu Andreu*[5] *and Yolanda Pico*[6], *(1)University of Valencia, Spain, (2)Desertification Research Centre, (3)CIDE (CSIC UV GV), Spain, (4)Water and Environmental Engineering University Research Institute (IIAMA), Polytechnic Universitat Politècnica de València, Spain, (5)Environmental Quality and Soils, Superior Council of Scientific Investigations (CSIC), Spain, (6)Centro de Investigaciones sobre Desertificación, Universidad de Valencia, Spain*

Sediments of lakes and other shallow waters have been considered in different studies as excellent archives for defining long-term variations of contaminants in the environment. For this reason, records derived from the chemical analysis of sediment cores could be useful to trace the history of contaminant emissions in a selected area. This study is aimed to assess the vertical variation of pharmaceuticals and other organic and inorganic contaminants (OICs) in sediment cores of two different sites from the lake of L´Albufera Natural Park (Valencia, Spain), to ascertain whether these cores are able to provide information regarding the historical variation of the accumulation of contaminants in sediments. A sediment core sampler was used to extract the cores from the lake and then were cut into 7 segments of the same thickness using a stainless-steel cutter. The organic contaminants were extracted using methanol-Mc Ilvain buffer (pH 5.6)-EDTA and the metals using acid digestion on microwave oven, the detection was performed by an Orbitrap Exploris 120 mass spectrometer (Thermo Scientific) and an ICP-MS ICAP6500 DUO (Thermo Scientific), respectively. Organic contaminants were determined both using wide target screening against a positive list of compounds, and non-target screening applying ddMS2 of the 4 more intense ions in each cycle as well as all ions fragmentation. Several organic contaminants, especially pesticides and pharmaceuticals such as azoxystrobin, imazalil, tebuconazole, bisphenol A, butyl paraben, ethyl paraben, salicylic acid and codeine were detected in superficial sediment from 0-10 cm and in the deeper layers. Generally, the higher heavy metal concentrations appear in the more recent sediments (depth < 20 cm), reflecting the increased agricultural and industrial activities in the area during the 20th century. This study showed that organic contaminants were lixiviated in different amounts through sediments columns, and their occurrence cannot be directly related with the age of them. However, these sediments can also be used to examine contamination mechanisms, which are significant for predicting future contamination tendencies, and assessing potential environmental risks in important areas as L'Albufera Natural Park.

2.06.P-We107 To Peat or Not to Peat, That Is the Question. Exploring Coconut Husk as an Organic Matter Enrichment Alternative in Sediment Toxicity Test.

Davide Asnicar *and Benjamin Patrick de Jourdan, Huntsman Marine Science Center, Canada*

The utilization of standardized artificial sediment in toxicity assessments offers increased repeatability and enhances consistency across bioassays and laboratories. Artificial sediment is required for most OECD (Organisation for Economic Co-operation and Development) guidelines, particularly in studies assessing the impact of chemicals on benthic communities.

While peat is conventionally incorporated into artificial sediment formulations for toxicological testing, it is not a sustainable resource due to the long time it takes to form and the environmental impact of its extraction. Notably, peatlands, covering over 12% of Canada's land area, are pivotal in carbon sequestration, estimated to be 150-160 Gt of carbon. The extraction of peat leads to a carbon loss equivalent to 2.1 megatonnes of carbon dioxide emissions annually, accompanied by the potential release of other elements into the environment and aquifers. Consequently, the pursuit of less impactful alternatives is desirable, and aligns with the 2030 Agenda for Sustainable Development, endorsed by the OECD.

In the context of sediment toxicity experiments, peat serves as a source of organic matter (OM) in artificial sediment. Here we investigated the viability of coconut husk as an alternative to peat in formulating artificial sediments for toxicity testing. While prior suggestions have been made regarding the use of coconut husk, further research is necessary to ascertain the stability of OM values in sediment over chronic studies and to verify the affinity of the chemical of interest to coconut husk, especially when testing chemicals with diverse characteristics (e.g., different Kow).

Utilizing the Loss on Ignition method, we determine the quantity of coconut husk required to attain equivalent OM content in artificial sediment formulations, mirroring the mass used for peat.

To evaluate the efficacy of coconut husk as an alternative, parallel toxicity tests were conducted using artificial sediments created with peat and coconut husk under identical conditions. The results indicate that the presence of coconut husk does not introduce toxicity effects of the tested chemicals, suggesting its suitability as a viable alternative for toxicity testing.

2.06.P-We108 Acute Lumbriculus variegatus Test Assessing Physiological Responses to Chemicals: A Simplification of the Chronic OECD 225 Test

Esther Smollich[1,2], *Katharina Wilhelm*[2], *Sonja Zimmermann*[2] *and Bernd Sures*[2,3,4], *(1)Regulatory Affairs, ROCKWOOL, Belgium, (2)Aquatic Ecology, University of Duisburg-Essen (Uni DUE), Germany, (3)Centre for Water and Environmental Research (ZWU), University of Duisburg-Essen (Uni DUE), Germany, (4)Research Center One Health Ruhr, Research Alliance Ruhr, Germany*

With the OECD test guideline No. 225, a well-established chronic exposure description using *L. variegatus* exists, which provides valuable information on the bioaccumulation and reproductive effects of test substances and polluted sediments on the annelid. However, due to the test set-up only a restricted amount of annelid tissue is available and additional biomarker analysis, providing data on physiological responses of the test organism, is usually not possible. Thus, for such studies, e.g. on the activities of enzymes which are part of the xenobiotic metabolism or oxidative stress responses, a simplified test set-up is needed to allow for large numbers of replicates and the rapid removal of animals throughout the test period.

In this project, we developed a short-term, well-plate exposure set-up without sediment for *L. variegatus* with the aim of analyzing the annelids for biomarkers of physiological reactions to chemical exposures and tested the set-up with Cadmium as a positive control substance. We exposed annelids individually to two concentrations of Cd for up to 96 h and analyzed the activities of Glutathione-S-transferase (GST) and Catalase (CAT), as well as the concentration of Metallothionein (MT) in the annelid tissue at three time points during the exposure. Bioaccumulation was also assessed for each time point, to be able to relate biomarker effects to internal Cd concentrations. The chosen aqueous Cd exposure concentrations were also tested in an OECD 225 chronic exposure study.

We found a significant Cd bioaccumulation in both experimental set-ups. In the short-term study we saw a significant increase of MT concentration after 24 h, 48 h and 96 h of exposure. Additionally, compared to the negative control, the CAT activity of the annelids significantly increased after 48 h of exposure and subsequently significantly decreased after 96 h. Our results match the known potential of Cd to induce oxidative stress, as CAT is part of the defensome against reactive oxygen species and hydrogen peroxide, and MT is involved in metal detoxification mechanisms. Our study presents a novel experimental set-up for assessing molecular biomarkers in the common test species *L. variegatus* and provides first data on the validation of this novel method.

2.06.P-We109 Beneath the Surface: Exploring Genotoxic Effects of Polycyclic Aromatic Hydrocarbons (PAHs) and Metabolic Responses in Capitella teleta, a Sediment Dwelling Species

Ghaliya AlNoaimi[1]*, Martina Santobuono*[2]*, Elettra D'Amico*[3]*, Henriette Selck*[2] *and Nico van den Brink*[1]*, (1)Wageningen University & Research (WUR), Netherlands, (2)Roskilde University (RUC), Denmark, (3)INM, Roskilde University (RUC), Denmark*

Marine environments face persistent exposure to contaminants, including PAHs with hydrophobic properties making them prone to partition into the sediment. Sediment also serves as the main food source for many benthic species, posing potential risks to these organisms. *Capitella teleta*, for instance, it lives in, and feeds on organic rich sediment. It is a key organism of the benthic community and is therefore selected as a model species to assess its' vital role in the fate of many contaminants including PAHs. *C. teleta* is recognized for its' ability to accumulate PAHs, potentially resulting in biotransformation. *C. teleta* is known to have the capacity of biotransforming various contaminants via Cytochrome P450 monooxygenase (CYP450) and phase 2 enzymes, it is also a distinguished species as it exhibits 96 functional CYP enzymes. Nevertheless, information on biotransformation and effects of PAHs in *C. teleta* is scarce. The aim of this study is to identify & quantify the involvement of major CYP enzymes in the biotransformation of Benzo[a]Pyrene (BAP) via functional and gene-expression assays. In addition, we aim to quantify the genetic damage caused by exposure to BAP. This study also aims to establish a baseline for a future multigenerational study, designed to understand the associated longer-term effects of PAH exposure on *C. teleta.* BAP is a PAH known to be mutagenic and carcinogenic and was selected for this initial phase of the research. The study design followed a 28-day exposure to a range of concentrations (0-150 ug/g wet sediment) in triplicates, with overlaying filtered seawater of 31% salinity, and constant aeration. As this study aims to assess genotoxicity, the Comet assay will be used to quantitatively assess DNA damage. Additionally, to understand the biotransformation process of BAP in *C. teleta*, ECOD, a biochemical assay used to measure the activity of a group of CYP enzymes will be performed, in combination with Reverse Transcription Polymerase Chain Reaction (RT-qPCR) to give insights into specific gene-expression levels of various CYP enzymes at different time-points of exposure. Our hypotheses are as follows: 1) BAP may potentially cause genetic damage in *C. teleta.* 2) Chosen CYP enzymes may show an induction & up-regulation in expression as a bio-transforming response to BAP. The findings will also contribute to a broader understanding of PAHs' mode of action in *C. teleta.*

2.06.P-We110 To Avoid or Not to Avoid Rare Earth Element Contaminated Sediment? That is the Question for Daphnia magna

Chantal K.E. van Drimmelen[1]*, Andrew Hursthouse*[2] *and Safia El Toum*[3]*, (1)Ecotoxicology, University of Applied Science Hamburg, Germany, (2)University of the West of Scotland (UWS), United Kingdom, (3)Hamburg University of Applied Sciences (HAW), Germany*

There is still little known about the ecotoxicology of the current emerging contaminants Rare Earth Elements (REE). Most conventional ecotoxicity test focus on acute and chronic effects in media, but not in sediment. Our study focused on the potential of how an indirect effect of REE contaminated sediment could possibly have high environmental relevance in the form of active avoidance. The objective was to determine if sediment contaminated with two REEs, lanthanum (La) and gadolinium (Gd), leads to avoidance behaviour by pelagic organisms such as *Daphnia magna*. A round experimental vessel for the horizontal migration and a rectangle vessels for the vertical migration were 3D printed using transparent PETG filament. The vessels contained characterized sediment (Lufa 2.2) and M4 media without EDTA. The sediment was spiked with concentrations in the anthropogenic range of 25; 50; 75; 100 mg kg^{-1}, and environmental relevant concentrations of 0.001; 0.01; 0.1; 1; 10 mg kg^{-1} for both La and Gd. For each exposure, 3 adult *D. magna* were observed for 15 seconds after 0h, 1h, 2h, and 3h. Scoring of the daphnia was based on the location of the daphnia within the experimental vessel for the duration of the 15 seconds. All tests where repeated at least 5 times. Independent observations were collected by experimenters. The resutls indicated that REE contaminated sediment caused avoidance behaviour for *D. magna*. However the avoidance is related ot both the specific REE and its concentration. The results indicate that there is perceived stress by the daphnids, resulting in behaviour changes which may effect their energy metabolism and survival rate, e.g. by rendering them more susceptible to predators. The avoidance of REE-contaminated sediment affecting the behavior of pelagic organisms like daphnids could have further implications for the wider freshwater ecosystem.

2.06.P-We111 Assessment of the Toxic, Neurotoxic and Genotoxic Effects of Sediments from the Lower Basin of the Papaloapan River, Veracruz, Mexico.

Alma Sobrino-Figueroa*[1] *and Alberto Perez-Rojas*[2]*, (1)Hidrobiology, Metropolitan Autonomous University (UAM) Iztapalapa, Mexico, (2)Autonomous Metropolitan University-Iztapalapa, Mexico

The Papaloapan River is an important system in our country that flows into the Gulf of Mexico. This river receives a continuous supply of toxic compounds due to the industrial, agricultural and livestock activities that take place on its banks. In this study, an evaluation of the presence of compounds with toxic, neurotoxic and genotoxic effects in the sediments of the river bed and associated systems was carried out, to detect the areas with the highest degree of contamination. 10 samples were collected in the final part of the river (18° 18' - 18° 47' N and 95° 44' - 95° 51' W) during the dry and rainy season for 3 years (2018, 2019 and 2022). The following parameters were evaluated from the samples: pH, volatile sulfides, ammonium, organic matter, organic carbon, conductivity and texture. The toxicity of sediments was determined with bioassays (*Daphnia magna* and *Pseudokirchneriella, subcapitata* in fresh water and *Artemia franciscana* and *Tetraselmis* sp. in brackish and marine environments). The evaluation of genotoxicity was carried out with the SOS-Chromotes test and the neurotoxic effect was determined with an *in vitro* assay. The information generated was integrated into a multivariate analysis to establish the degree of contamination of the sediments. The mortality percentages obtained in the toxicity bioassays with the sediments varied from 20 to 68%. The sediments with the highest toxicity were obtained from the areas near the mouth of the river and in the Embarcadero lagoon, in these sites the sediments also had genotoxic and neurotoxic effects. A direct relationship was observed between sediment toxicity and ammonia concentrations and conductivity, and between genotoxicity and organic carbon levels. Likewise, greater sediment toxicity was observed in the dry season. The areas with the highest degree of contamination were Embarcadero lagoon and the adjacent areas to the mouth of the river.

2.06.P-We112 Using Paleotoxicology to Study the Influence of Anthropogenic Compounds in the Last Century

***Olivia Wagner*[1]*, M. Carmen Casado-Martinez*[2]*, Tobia Berger*[1]*, Nicole Fahrni*[1]*, Nayan Gosain*[1] *and Aurea C. Hernández*[1]*, (1)University of Bern, Switzerland, (2)Swiss Centre for Applied Ecotoxicology Eawag (EPFL), Lausanne, Switzerland*

Plant protection products (PPPs) are currently a topic of high concern. However, more information is needed about the diversity of these agrochemicals and their actual levels and effects on the environment. As sediment cores provide historical records of past environmental contamination within a catchment, a comprehensive assessment of PPPs and heavy metals in lake sediments can help to unravel valuable information on the long-term effect of anthropogenic compounds in aquatic systems.

In this work, a multiproxy workflow that combines paleolimnological (hyperspectral scanning, μXRF) and paleotoxicological techniques (toxicity testing) and chemical analysis (trace elements, LC-MS/MS) was applied to investigate the impacts of PPPs and trace elements on sediment-dwelling organisms (ostracods) in the last century. This work reveals that sediments of two small eutrophic ponds located in the Bernese Mittelland (Switzerland) and known to be contaminated with PPPs cause toxic effects on sediment-dwelling organisms, namely ostracods. By performing in-situ toxicity tests, ostracods were found to show increased growth inhibition and mortality in more recent and older sediment layers of the pond. The obtained results were complemented with the analysis of ostracod fossils, revealing a decrease in the abundance and size of ostracods with increasing sediment age and depth. In addition, several PPPs detected in the ponds were found to correlate with ostracod fluxes, showing that the quality of recent sediment layers posed toxic risks to ostracods. The results also demonstrate that the sediments of the two studied ponds have been contaminated in the past (e.g., the 1960s) not only with PPPs but also with other toxic compounds such as trace elements (lead (Pb), copper (Cu), cadmium (Cd) and zinc (Zn)), and their high concentrations affected the abundance of ostracods in a greater level than PPPs.

This work contributes to the emerging field of paleotoxicology research in lakes and ponds and highlights the importance of interdisciplinary work to assess the fate and toxicity of anthropogenic compounds. Since ponds are biodiversity hotspots, this work highlights the urge and importance to address these valuable ecosystems in the context of anthropogenic pollution research and in policy decisions to improve their quality and ensure that these species-rich ecosystems persist in the future.

2.06.P-We113 Effects of repeated pulsed deltamethrin exposures on a benthic community

***Sarah Betz-Koch*[1]*, Jörg Oehlmann*[1,2] *and Matthias Oetken*[1]*, (1)Aquatic Ecotoxicology, Goethe University Frankfurt, Germany, (2)Kompetenzzentrum Wasser Hessen, Germany*

The increasing use of pesticides in agriculture is one of the main reasons for the ecologically poor status of water bodies and especially of streams around the world. Pesticide inputs via surface runoff have been shown to be linked to rainfall events, resulting in high peak concentrations and complex exposure dynamics in streams that can have various effects on the aquatic environment. Based on available effect data, regulatory acceptable concentration (RAC) are derived for surface waters to avoid unacceptable effects on the environment. Several studies have shown, that pesticides may exceed their RAC value during rain events over a period of time. Current effect data of different pesticides is mostly based on single substance tests with single target species conducted under laboratory conditions. However, in the aquatic environment, the biocoenosis is confronted with a variety of biotic and abiotic stress factors in addition to pesticide influx.

In an experimental approach using artificial indoor streams, a benthic community consisting of *Gammarus pulex*, *Chaetopteryx villosa*, *Lumbriculus variegatus*, and *Potamopyrgus antipodarum* was exposed to varying numbers of 12-hour deltamethrin pulses (one to four times) over a 35-day period with intervening recovery periods. The deltamethrin concentration for each pulse-like exposure was 0.64 ng/L (RAC value). At the end, various lethal and sublethal endpoints were determined to investigate whether there is a difference between a single exposure and up to four exposures, or whether the benthic community can recover after each pulse.

Preliminary results show that the ratio of survival and mortality of *C. villosa* within the treatment groups is significantly shifted after four pulsed exposures. In addition, the larvae of *C. villosa* exposed to deltamethrin tend to have lower energy levels. For *L. variegatus*, it was observed that the biomass tends to decrease with an increasing number of deltamethrin pulses. Our results indicate that unacceptable effects of multiple pulse-like deltamethrin exposures at concentrations equivalent to the RAC value on non-target aquatic invertebrates cannot be excluded. Moreover this experimental approach thus leads to more realistic effect data and can help to better assess the risks of pesticide exposure for aquatic organisms and to optimize regulatory risk assessment schemes.

2.06.P-We114 Flushing away the future: The effects of wastewater treatment plants on aquatic invertebrates
Daniel Enns[1]*, Sarah Cunze*[2]*, Nathan Jay Baker*[3]*, Jörg Oehlmann*[4] *and Jonas Jourdan*[4]*, (1)Goethe University Frankfurt, Germany, (2)Department of Integrative Parasitology and Zoophysiology, Goethe University Frankfurt, Germany, (3)Institute of Ecology, Nature Research Centre, Lithuania, (4)Aquatic Ecotoxicology, Goethe University Frankfurt, Germany*
Wastewater treatment plants (WWTP) are essential infrastructure in our developing world. However, with the invention and release of novel chemicals, in combination with frequent heavy rain events, most WWTPs fail to handle modern day tasks. Without upgrades, they are ineffective at fully removing micropollutants before treated effluents are released back into aquatic environments. Thus, WWTPs may represent additional point source impacts to freshwater environments, further pressuring aquatic communities. Studies – mostly focusing on single WWTPs – have shown that pollution tolerant taxa generally dominate impacted freshwater invertebrate communities. To expand on these findings, we analysed the effects of 170 WWTPs on invertebrate community composition. We selected suitable sampling sites upstream and downstream of the WWTPs and compared them using several diversity and pollution indices. In terms of abundance, the three most frequent and negatively impacted orders were the Plecoptera, Trichoptera and Gastropoda, while the Turbellaria, Hirudinea and Crustacea increased in abundance. Commonly used metrics showed no clear differences between upstream and downstream sites, however strong changes in community composition where observed (mean species turnover of 61%). This highlights the importance of analysing diversity from multiple perspectives, drawing right conclusions and assess ecological health adequately. Our results indicate that WWTPs change downstream conditions in favour of pollution tolerant taxa to the detriment of sensitive taxa. Responses on higher taxonomic levels can be informative, if analysed in combination with responses of lower taxonomic levels. Group responses can be driven by a few taxa, or opposing responses of species in the same group can result in an overall low order-level response. Upgrading WWTPs via additional treatment steps or merging might reduce adverse impacts, given upstream sections are in a good chemical and structural condition.

2.06.P-We115 Decrypt the complex – Recent exposure influences neonicotinoid tolerance in a cryptic amphipod species complex
Jana Kabus[1]*, Vanessa Hartmann*[1]*, Ioannis Karaouzas*[2]*, Spase Shumka*[3] *and Jonas Jourdan*[1]*, (1)Aquatic Ecotoxicology, Goethe University Frankfurt, Germany, (2)Institute of Marine Biological Resources and Inland Waters, Hellenic Centre for Marine Research, Greece, (3)Faculty of Biotechnology and Food, Agricultural University of Tirana, Albania*
Cryptic species are rarely considered in ecotoxicology, resulting in misleading outcomes when using a single morphospecies that encompasses multiple cryptic species. This oversight contributes to the lack of reproducibility in ecotoxicological experiments and promotes false extrapolation of findings. The important question of ecological differentiation and the sensitivity of closely related cryptic species is rarely tackled, resulting in a substantial gap in our understanding of the vulnerability of individual species within a complex. Often non-target organisms such as amphipods are threatened by fertilizers and pesticides that are inserted in the river systems through run-offs. To better understand mechanisms influencing the tolerance of cryptic species complexes we tested the complex of the amphipod *Gammarus roeselii* against the neonicotinoid thiacloprid. The *G. roeselii* complex is a widely distributed amphipod all over Europe with a diversification hot spot in the Balkans. We sampled eleven populations in Greece and Germany belonging to four different MOTUs (Molecular Operational Taxonomic Units). Through COI barcoding we evaluated the MOTU status and calculated the genetic diversity for each population. We then tested the vulnerability to the neonicotinoid thiacloprid of each MOTU in a series of acute toxicity assays. Environmental and hydrological parameters as well as sediment in-vitro assays were used to evaluate the overall conditions of the sampling sites and a possible anthropogenic influence. With these parameters a PCA was carried out and the results of the EC_{50} values (acute toxicity test) and genetic diversity were checked for correlation.

We found that the tolerance (EC_{50} values) although MOTU-specific, are mainly and significantly different between the populations. The genetic diversity doesn't correlate with the tolerance. The first Principal Component of the environmental parameters tested correlates significantly negative with the EC_{50} values.

These results indicate a strong influence of recent chemical exposure to the same or a similar pesticide rather than the influence of deep phylogenetic differences within the cryptic species complex. Our findings highlight the need to not only check the cryptic status of test organisms but also take the environment of each sampling site into account when analysing acute toxicity tests. These results show the importance of an integrative approach at analysing global stressors on aquatic systems.

2.06.PC New Developments in Sediment Ecotoxicology and Risk Assessment

2.07 Pollinator Risk Assessment in a Changing Landscape

2.07.T-01 The Revised EFSA Bee Guidance (2023) One Year On: An Industry Stakeholder's Perspective and Recommendations
*Christian Berg[1], Elizabeth Collison[2], Silvia Hinarejos[3], Denisa Cupi[4], Stefan Kroder[5], Mark Miles[6], Raymond Layton[7], Natalie Ruddle[8], **Christof Schneider**[9], Amanda Sharples[10], Verena Tänzler[11] and Mila Arabadzhieva[12], (1)Ecotoxicology, FMC Agricultural Solutions, Germany, (2)Corteva Agriscience, United Kingdom, (3)Sumitomo Chemical Agro Europe SAS, France, (4)Novozymes A/S, (5)ADAMA Deutschland GmbH, Germany, (6)Bayer AG, (7)Gowan, (8)Syngenta, (9)BASF SE, Germany, (10)FMC, United Kingdom, (11)Bayer AG, Germany, (12)CropLife Europe*
The European regulation of plant protection products (PPP) requires an evaluation of the risks to human health and the environment before the European Union level approval of active substances and national registration of formulated products (Reg (EU) 1107/2009).

In May 2023 the European Food Safety Authority (EFSA) published their revised bee pollinator guidance document. At the time of abstract submission (November 2023) this document is not adopted or implemented for use within the pesticide regulatory framework of the European Union.

In 2023 CropLife Europe (CLE) conducted an impact analysis for a range of uses of typical PPP across the European Union following the EFSA 2022 DRAFT bee Guidance document. Since the EFSA draft was published several changes have been made to the final document following a public commenting period. CLE has updated its analysis using the final inputs using the same toxicity and good agricultural practices (GAP) dataset as used in 2023. In addition to this, further analyses which were not included in 2023 have been conducted to investigate the performance of the proposed sublethal effects assessment and time reinforced toxicity (TRT) based on tier I assumptions.

This presentation reviews the performance of the new EFSA guidance proposal in the light of the outcome of an impact analysis performed for a range of PPP and uses, and case studies conducted by industry to test the useability and outcomes of applying the new draft proposal to real-life risk assessment situations.

It is recommended that the regulatory community proceed with caution with regards to a full and immediate implementation for regulatory purposes. Further development of approaches at lower tiers is still required and a road map is needed as not all aspects can be implemented, training is needed, and a working user-friendly calculator tool is required.

2.07.T-02 A National Authorities View on the Revised EFSA Bee Guidance Document
***Jens Pistorius**, Abdulrahim Alkassab, Ina Wirtz, Jakob Eckert and Tobias Jütte, Institute for Bee Protection, Julius Kühn Institute (JKI) - Federal Research Centre for Cultivated Plants, Germany*
The indisputably high economic and ecologic importance of honey bees justifies the necessity of a high level of protection of bees and bee colonies. Plant protection products (PPPs) are subject to a risk assessment.

In order to achieve the desired level of protection for honey bees in the regulatory context, numerous global efforts are underway to constantly improve testing methods and to refine risk assessment methodologies and risk assessment schemes on the basis of scientific knowledge but also to refine possible risk mitigation option. All risk assessment schemes rely on data generated at the laboratory, semi-field or field-level on the basis of reliable, if possible test methods that are validated as OECD guidelines. As a fundamental principle in different risk assessment schemes, a tiered approach is proposed, with laboratory tests in the first tier as a starting point, moving on to higher tier tests if the result of the first tier suggests that a risk cannot be excluded.

In Europe, revised EFSA guidance document on the risk assessment of plant protection products on bees published in 2023, defines the specific protection goal (SPG) for honey bees (*Apis mellifera*) to not exceed a colony size reduction of 10 % following exposure to plant protection productswhich contains numerous changes in approaches, calculations and assessments, as well as statistical calculations. In the talk, the view of a national risk assessment authority, the Julius-Kühn Institute will discuss the applicability, feasibility and potential areas of future improvements.

2.07.T-03 Interpreting Acute Oral, Acute Contact, Glass Plate And Chronic Tests Within One Single Framework
***Jan Baas**[1], Dick Belgers[2], Anna Huang[1], Arrienne Matsers[1] and Ivo Roessink[3], (1)Wageningen Environmental Research*

(WUR), Netherlands, (2)Environmental Risk Assessment, Wageningen University & Research (WUR), Netherlands, (3)Wageningen University & Research (WUR), Netherlands
Recently, it was shown that acute oral, acute contact and chronic tests for bees can be interpreted within one consistent framework, with one set of parameters: the BeeGUTS framework. Since all tests can be interpreted within one consistent framework results from one test can be extrapolated to any other test.

What is missing in this framework are indirect exposure tests. In these tests organisms are put on treated glass plates (or leaves) and take up the compound of interest through their legs and/or cuticle, which can generate an effect. In an indirect exposure test, the exposure concentration is expressed in g/surface area of the treated medium (glass plate or leave) and the actual dose is unknown. This hampers the interpretatiion and the extrapolation potential of such test as the relation between the exposure and the dose is unknown. This research aimed at including the indirect exposure test in the BeeGUTS framework, which would allow to also extrapolate results from the acute oral, acute contact or chronic tests to the indirect exposure test.

An indirect exposure test with bees exposed to Imidacloprid was carried out at the WENR laboratories and was used to translate the exposure from ng/cm^2 sprayed surface to an actual dose (in ng/bee) by using the BeeGUTS framework with known parameter values for Imidacloprid. Here the model was used to calculate the exposure from observed effects using known parameter values instead of calculating the parameters from observed effects and a known exposure. The assumptions that were made is 1) that toxicity is a combination of dose, kinetics and intrinsic sensitivity of an organism, independent of the test and 2) the concentration in a glass plate test is constant over time and the dose is linear with the exposure concentration in g/surface area.

These assumptions gave an almost perfect prediction of the effects in the indirect exposure test using the parameters of the chronic test as a starting point. This implies that we can now do one single test and predict the outcome of all other tests for Imidacloprid, but the BeeGUST framework showed that the general principles apply to the majority of tested compounds.

2.07.T-04 Pesticide use negatively affects bumble bees across European landscapes
*Jessica Knapp[1], **Charlie Nicholson**[2], Marie-Pierre Chauzat[3], Mark Brown[4], Jane Stout[5] and Maj Rundlöf[2], (1)Lund University, Sweden, (2)Department of Biology, Lund University, Sweden, (3)ANSES, French Agency for Food, Environmental and Occupational Health & Safety, France, (4)Department of Biological Sciences, Royal Holloway University of London, United Kingdom, (5)School of Natural Sciences, Trinity College Dublin, Ireland*
While we know some pesticides negatively affect bees, the scale of these effects beyond single substances in focal fields has remained unknown. Our work, funded by the European Commission, answered recent calls for a more realistic assessment of the risks posed by mixtures of commonly used pesticides at landscape scales. We conducted a field-based study spanning 106 sites across eight European countries, deploying 316 Bombus terrestris colonies. We show that the multiple pesticides found in bumble bee-collected pollen are associated with reduced colony performance (fewer offspring) during crop bloom, especially in simplified landscapes with intensive agricultural practices. These findings confirm that the regulatory system fails to sufficiently prevent pesticide-related impacts on non-target organisms, even for a eusocial pollinator species where colony size may buffer against such impacts. Furthermore, our findings support the need for post-approval monitoring of both pesticide exposure and effects to confirm that the regulatory process is sufficiently protective in limiting the collateral environmental damage of agricultural pesticide use.

2.07.T-05 Ecological Effect Models for Bee Risk Assessments
***Amelie Schmolke**, Matthias Becher, Wally Bluhm, Oliver Jakoby and Johannes Lückmann, RIFCON GmbH, Germany*
Ecological effect models were identified as valuable tools for the evaluation of possible risks during the registration of plant protection products in Europe. With the publication of the revised EFSA Bee Guidance Document (EFSA 2023), such tools become increasingly important for the higher-tier risk assessment of bees which focuses on potential effects on colonies and populations. Ecological effect models have the potential to provide important and reliable tools that can be used to increase the reliability of data generated from labor- and people-intensive field studies. In addition, the great diversity of bee species, their different levels of sociality and their ecological traits indicate that models are needed to extrapolate recorded effects of surrogate species. In the context of the risk assessment for bees exposed to plant protection products, colony and population models have already been developed. Model applications include, for instance, the extrapolation of exposure-effect responses from organism to colony or population level, the estimation of observed effects in field-based studies to other species or environmental conditions as well as the comparison of possible mitigation scenarios. We will present and discuss different models for honey bees, bumble bees and solitary bees that are currently available. We will provide an overview of the current state of the art and discuss how bee models can be used in combination with tailor-made field studies or field-based study data. Furthermore, we will also address model performance evaluation, which is identified as prerequisite for model acceptance by authorities.

2.07.P Pollinator Risk Assessment in a Changing Landscape

2.07.P-Tu147 The Revised EFSA Bee Guidance – First Hands-on Experiences In Risk Assessment And Lessons Learned So Far

*Melanie Gibbs[1], **David Spurgeon**[2], Michael Fryer[3] and Ben Woodcock Dr[2], (1)Biodiversity, UK Centre for Ecology & Hydrology (UKCEH), United Kingdom, (2)UK Centre for Ecology & Hydrology (UKCEH), United Kingdom, (3)Ecotoxicology, UK Health Security Agency, United Kingdom*
We reviewed the European Food Safety Authorisation (EFSA) revised Pollinator guidance document published in 2023 with the aim of supporting future development of the GB regulatory framework for pollinators post-EU exit. Our objectives were to provide a road map for identifying best practice by summarising the uncertainties, data gaps, data limitations and research gaps in current regulatory risk assessment frameworks. We found that the currently proposed approaches still fail to adequately account for differences in key biological traits that may influence the sensitivity and exposure of the c. 260 UK bee pollinator species to plant protection products. In particular, understanding exposure risk for ground nesting bees is limited. Development of ground nesting species (e.g., *Andrena*) as models for higher tier studies to compliment the use of the cavity nesting *Osmia bicornis* would be a major step forward. The absence of large, replicated, field trials that are realistic in terms of cropping area, landscapes and agronomic practice, along with failure to capture and predict synergistic interactions or factors that affect sensitivity to pesticides (e.g., disease) continues to hinder progress around designing effective higher tier assessments. A lack of linkages between individual-level effects and colony- or population-level effects for honey bees, bumble bees and wild bee species has made it difficult to define specific protection goals. But, with models like BEEHAVE, steps towards achieving this are now much closer to being operational. Post-approval monitoring of a broader range of bee species would greatly improve our capacity to support longer-term assessments of hazard or risk that could not realistically be achieved via standard pre-approval risk assessment protocols. Post-approval monitoring would also provide an opportunity to improve our understanding of emerging risks under field conditions, the scale over which pollinators forage on blocked treated crops, and synergistic effects. We highlight the need of a framework for reactive implementation of mitigation measures to help protect bees and maintain viability of plant protection products.

2.07.P-Tu148 The Natural Variability of Honey Bee Colonies - How to Meet the Requirements of the New EFSA Bee Guidance

*Anja Russ[1], Ines Hotopp[2], **Markus Persigehl**[2], Abdulrahim Alkassab[3] and Jens Pistorius[3], (1)tier3 solutions GmbH, Leverkusen, Germany, (2)Tier3 Solutions GmbH, Germany, (3)Institute for Bee Protection, Julius Kühn Institute (JKI) - Federal Research Centre for Cultivated Plants, Germany*
The revised EFSA guidance document on the risk assessment of plant protection products on bees (2023) defines the specific protection goal (SPG) for honey bees (*Apis mellifera*) to not exceed a colony size reduction of 10 % following exposure to plant protection products. For bumble bees and solitary bees no threshold could yet be defined due to a lack of data.

The natural variability of honey bee colonies ranged between 10 % and 53 % around the mean of the initial colony strength in five different large-scale field studies that included 18 to 48 control colonies. Despite this relatively large number of colonies, four out of five studies would not have enough replication and would likely fail the equivalence test under the new requirements of the EFSA bee guidance. Under realistic conditions, a 10 % reduction in the colony size will be hardly detectable when the natural variability is high among honey bee colonies. Several measures are proposed to reduce the natural variability, e.g. increase the number of colonies in the study, use colonies derived from sister queens and select those from an excess of colonies that are most similar in colony strength, to name only some. The revised EFSA bee guidance also suggests adding experimental colony data from the following year, if the number of replicates was insufficient to achieve adequate power in the equivalence test, for example, due to high variability in the first study year. However, these proposals could increase the variability among the colonies. Increasing the number of replicates would also potentiate the time for colony assessments. These should ideally be done by one person to minimize the estimation error, but even a skilled assessor can handle hardly more than 36 colonies per day. Hence, different environmental conditions and continued colony development over the days of the assessments would add variability to the data. Also, the required spatial extent of the study leads to different landscape characteristics, causing differences in weather conditions and food supply among the colonies.

2.07.P-Tu149 Does the distinction among honeybee subspecies matter for pesticide risk assessment?

***Annelise de Souza Rosa Fontana**[1], Maria Benito[1], Raquel Martín Hernández[2], Mariano Higes[2], Alice Pinto[3], Dora Henriques[3], Simone Tosi[4], Adna Dorigo[5], Roberta Nocelli[6], Osmar Malaspina[5] and Juan Rodríguez Gomez[1], (1)Complutense University of Madrid, Spain, (2)Centre for Beekeeping and Agri-environmental Research, (3)Polytechnic Institute of Bragança, CIMO/SusTEC, (4)University of Turin, Italy, (5)São Paulo State University (UNESP), Brazil, (6)Federal University of São Carlos, Brazil*
The recent framework devised by the European Food Safety Authority (EFSA) reports a lack of research data on potential differences in the toxicological sensitivity among honeybee (HB) subspecies. *Apis mellifera* is recognized by the Organisation for Economic Co-operation and Development (OECD) as a model organism for risk assessment (RA) studies. However, it shows considerable variation, as reflected by at least 24 subspecies. We therefore used the mortality to investigate and to compare the responses among three European subspecies exposed to pesticides. Newly emerged bees from three HB subspecies (*A. m. iberiensis* - AMI, *A. m. ligustica* – AML, and *A. m. carnica* – AMC) were subjected to a unique concentration of each pesticide (tau-fluvalinate, TAU and flupyradifurone, FPF). The trials for all the 3 subspecies were carried out at the same period, under equal conditions, and in accordance with the OECD (guideline 245). There is clear evidence that the three subspecies responded distinctly to the pesticides. Mostly, AMI was the most affected subspecies, showing the highest mortality rates. This evidence contradicted our expectations since AMI presents a more defensive behavior than the other two subspecies. By using a primary endpoint posed by the OECD (mortality), our findings provide essential

insights for further research into this topic. We are currently investigating a set of sublethal effects at molecular level. Our outcoming results will directly contribute to four of the nine knowledge gaps outlined by the EFSA's framework. We will address it further for the EFSA risk assessment proposals. Our study represents the first comparative approach of responses to pesticides among three honeybee subspecies. We have brought a new approach that is up to date overlooked in risk assessment studies.

2.07.P-Tu150 From Individual to Colony Level Effects: How Should Colony Structure and Timescales be Considered?
*Mark Miles[1], **Julian Haas**[2], Vanessa Roeben[2], John Herrmann[2], Verena Taenzler[2] and Daniel R Schmehl[1], (1)Bayer AG, (2)Bayer AG - Crop Science Division, Germany*
In May 2023 European Food Safety Authority published their revised revised Pollinator guidance document. At the time of abstract submission (November 2023) this document is not adopted or implemented for use within the pesticide regulatory frame of the European Union. For screening and tier I risk assessments the revised scheme does not propose to use trigger values but directly compares the outcome of the risk calculation to a specific protection goal (SPG) using a combined effect approach. For honey bees it is proposed that this can be achieved in 3 steps; 1) quantification of effects at individual levels, 2) extrapolation of the individual level effects to colony and 3) combination of effects at the colony level.

The extrapolation step 2 assumes a conservative 1:1 propagation of individual to colony level effects for all experiments, i.e., using dietary and contact exposure. Multiple concerns have been raised about this approach as it does not consider several factors such as the population structure (e.g., pupal bees are not being fed so there is no dietary exposure and the different time scales of acute and chronic effects). In this paper we investigate the level of conservatism based on this assumption and suggest alternatives that could be used as a tier 2 refinement before directly generating higher tier effect studies. These approaches include: i) consideration of colony structure, ii) use of TK/TD models (e.g., BeeGUTS), iii) application of colony level population models (e.g., BEEHAVE), iv) use of colony level ecotoxicological models (e.g., $\text{BEEHAVE}_{\text{ecotox}}$) and v) comparison with the outcomes of semi-field and field effects studies.

We make recommendations on how the extrapolation at step 2 can be achieved in a more realistic way and discuss future options such as implementation of a modeling framework and applicability to tier I and II risk assessments for bumblebee colonies and solitary bee populations.

2.07.P-Tu151 Acute Toxicity of Dichlorvos and Carbendazim to Apis mellifera Larvae Reared In vitro
Jigarkumar Rameshbhai Rana, Ph.D.[1]*, Pritee Singh[2] and Nadeem ahmad Khan[2], (1)Ecotoxicology, Jai Research Foundation, India, (2)Jai Research Foundation, India*
A wide variety of agricultural crops are pollinated by the honeybee (*Apis mellifera* L.). For foraging, the honeybee covers a distance of 3 - 8 km from the hive, sometimes even longer. Honeybee carries many of the toxic compounds that exist in its environment during foraging. Although honeybees are non-target organisms for most pesticide applications, they nevertheless are exposed to pesticides while collecting pollen, nectar, saps/resins, and water. Hence, larvae are exposed to pesticides in contaminated nectar, pollen and wax. The reported high loss rates of managed honeybee colonies have been attributed to diverse stressors including pesticides. It is more common to check the pesticide toxicity on adult worker honeybee than that on larva due to challenge in rearing larvae *in vitro*. Herein, we aimed to assess the acute toxicity of an organophosphate insecticide, Dichlorvos 76% EC (DCL) and a systemic fungicide, Carbendazim 50% WP (CBD) to *Apis mellifera* larvae reared *in vitro*. In our recent study, we exposed honeybee larvae (reared *in vitro*) to DCL and CBD according to OECD Test Guideline 237. DCL and CBD were exposed to honeybee larvae at a range of 0.005 to 3.8 µg/larva and 0.3 to 200.0 µg/larva, respectively. The median lethal dose (LD_{50}) of DCL and CBD was calculated for larva at 72 h following single diet exposure. The LD_{50} value for DCL was 0.121 (0.061 – 0.242) µg/larva. While there was no effect of CBD on larvae, the LD_{50} value was greater than 200.0 µg/larva (100 µg a.i./larva). These findings reflect an evaluation of effects of DCL and CBD on honeybee larvae. There is also further scope to check long-term toxicity of developing honeybees after repeated exposure. Overall, our research is useful for determining acute toxicity of pesticide to *Apis mellifera* Larvae.

2.07.P-Tu152 Testing the Flight Ability of Honeybees to Return to the Hive After a Single Oral Exposure to Sublethal Doses of Deltamethrin
Katarzyna Winiarska*, Agnieszka Fulczyk and Agnieszka Żmijowska, Łukasiewicz Research Network-Institute of Industrial Organic Chemistry Branch Pszczyna, Poland*
Plant protection products (PPPs) are only allowed on the market after a thorough environmental risk assessment. To carry out the assessment, it is necessary to perform a number of ecotoxicological tests on non-target organisms, including the honeybee (*Apis mellifera* L.). It is suspected that the chemicals used may disturb bees' physiological functions and orientation in the field, which are important when flying in search of bee forage. The consequence of this phenomenon is shortening the distance of beneficial flights and reducing the number of insects returning with food. This leads to weakening of the bee colony and its increased susceptibility to diseases. From the point of view of apiary management, the efficiency of honey production decreases and financial expenditure on maintaining the apiary increases. Due to the increasing environmental pollution with plant protection products and their residues, the package of tests required for registration of plant protection products is gradually expanding. In July 2021, the Organization for Economic Co-operation and Development (OECD) introduced Guideline No. 332, which covers the study of the impact of sublethal doses of chemical substances and their mixtures on the effectiveness of return flights of honeybees (*A. mellifera* L.). One of the chemicals actively used in agriculture is deltamethrin.

It is an active substance with highly effective insecticidal effect. An organic chemical compound from the group of synthetic pyrethroids. It is a neurotoxin intended to combat pests with biting and sucking mouthparts in vegetable, fruit and ornamental crops, as well as to protect grain. Although it should be applied outside the period of honeybee activity, these insects may be exposed to residues found in the environment.

A semi-field study was carried out, in which bees were marked and exposed to a number of sublethal doses of deltamethrin (contained in the diet) in the laboratory, then the bees were released in the field (1 km from the apiary), and their return to the hive was recorded. The number of returns of foragers exposed to the tested chemical and the unexposed control group was compared. The monitoring period lasted 24 hours from the moment the bees were released in the field. The comparison was possible by monitoring experimental bees using radio frequency identification (RFID) tagging technology.

2.07.P-Tu153 Weeds in Cropped Fields – Effects on Honeybee Colony Development Using BEEHAVEecotox
Matthias Becher, Johannes Lückmann, Wally Bluhm, Marcus Metz, Amelie Schmolke and ***Oliver Jakoby****, RIFCON GmbH, Germany*
Weeds in treated fields can potentially be one exposure route for foraging honeybees. Whereas the first EFSA Bee Guidance (2013) regarded this scenario relevant if at least 10% surface area of a treated field is covered by attractive weeds at the time of application, the revised bee guidance document (EFSA 2023) considers this scenario relevant depending on the crop and the timing of application. In either case, lower tier risk assessments often indicates a potential risk for honeybees from weeds in treated fields. However, the relevance of this scenario as a potential threat for a colony and its strength is unclear and depends on a number of factors.

While empirical data or studies on this subject are very limited, computer simulations can be a very useful and cost-effective way to shed some light on this complex issue. Therefore, we used the recently developed ecotox module BEEHAVEecotox of the honeybee model BEEHAVE to improve our understanding of potential effects of weeds on honeybee colony development in the light of the upcoming bee risk assessment. BEEHAVE is an established, agent-based computer model that has been evaluated and used by EFSA, researchers, and industry. It simulates foraging behaviour in a realistic landscape and colony development in detail.

We analysed different simplified scenarios with colonies placed close to arable fields, which are either free of weeds or covered by a certain proportion of weeds. The attractiveness of these weeds was considered higher or lower in comparison to the crop. Furthermore, the weeds were either assumed in flower throughout the year or only during the application period of a pesticide. In addition, the simulations included varying toxicity of the applied pesticide.

The obtained results emphasise the trade-off between risk to pesticide exposure and the additional resources provided to bees. They are presented and discussed in the context of the the honeybee risk assessment.

2.07.P-Tu154 Using the BEEHAVE Honey Bee Model Across Climates: Queen Egg-Laying Emerging From Weather, Pollen Storage and Brood Size Rather Then Being Imposed
Dominik Lammers[1], Juergen Groeneveld[2], Volker Grimm[2] and ***Andreas Focks****[3], (1)University of Potsdam, Germany, (2)Helmholtz Centre for Environmental Research (UFZ), Germany, (3)Institute of Mathematics, Osnabrück University, Germany*
Multiple stressors increase the risk of honey bee colony collapse and winter mortality. Empirical studies to determine the relative importance of stressors and critical stress levels are not feasible because most stressors and colony characteristics cannot be controlled. Modelling of honey bee colonies can help to fill this gap. The BEEHAVE model takes into account local land use, including pesticide use, weather, mite infestation and beekeeping practices, and has been used in more than 20 studies. However, it is based on an imposed egg laying rate which is only representative of average central European conditions. We developed a modified version, BEEHAVE-PPE (Pollen Pheromone Egglaying), where the maximum egg laying rate depends on pollen storage. We assumed that daily pollen foraging, and thus pollen uptake, depends not only on the weather, but also on brood size, brood pheromones, and temperature. BEEHAVE-PPE was successfully calibrated using demographic and weather data from the ECOBEE study in France. We then applied the calibrated model to three sites across Europe (Spain, Romania, Ireland) where a previous study commissioned by the European Food Safety Authority (EFSA) had used the original BEEHAVE model, but with the imposed egg-laying and resource availability shifted along the time axis. The EFSA simulations were not validated, for the lack of data, but they were indirectly checked for consistency. The BEEHAVE-PPE results captured some aspects of the EFSA simulations, but differed in others and were overall more variable between sites. In conclusion, our results indicate that it is possible to let the egg-laying rate in honey bee colonies emerge from the local climate and the effects of brood pheromones. Although our new version of BEEHAVE is too experimental to be used in applications, it suggests that it would be worthwhile to experimentally study the effects of brood pheromones, temperature and other factors on pollen foraging and, in turn, the queen’s egg-laying.

2.07.P-Tu155 A TKTD module for BEEHAVEecotox – combining BEEHAVEecotox and BeeGUTS
Dominik Lammers, Thomas G Preuss and ***Vanessa Roeben****, Bayer AG - Crop Science Division, Germany*
Honey bees provide the important ecosystem service of pollination to wild plant species and cultivated crops. Thus, they are a

crucial part of the environmental risk assessment of plant protection products in the European Union. In this context, mechanistic modeling offers a powerful tool to predict the exposure and effects on bees in the field and find increasing acceptance within the regulatory framework.

The $BEEHAVE_{ecotox}$ model is the first honey bee model to mechanistically link the realistic exposure in the field with subsequent effects on different levels of the bee colony. It uses standard regulatory study data to derive dose-response functions of effects resulting from contact and oral exposure and also considers larval mortality.

In parallel, the BeeGUTS model was developed, which is a TKTD model for the interpretation and extrapolation of honey bee survival data. The model provides one consistent framework integrating the effects from acute contact, acute oral, and chronic oral studies into one set of parameters by considering toxicity as a process in time. This new integrative approach moving from single point estimates of toxicity and exposure to a holistic link between exposure and effect.

Both models have been validated with independent datasets and provided good predictions of honey bee effects within their domain of applicability. Since the $BEEHAVE_{ecotox}$ model was developed with a modular modelling approach in mind, it allows to exchange or add modules when new knowledge is available.

In this poster we will present the first results of the integration of a new toxicity module into $BEEHAVE_{ecotox}$ using BeeGUTS. The poster will highlight the challenges and differences between the two aproaches and compare predicted results of semi-field studies.

2.07.P-Tu156 Predicting environmental pollution status and pollen diversity at the pan-European scale using citizen science monitoring data

Bas Buddendorf[1]*, Hans Baveco*[2]*, Alison Gray*[3]*, Jozef van der Steen*[4]*, Flemming Vejsnæs*[5]*, Ole Kilpinen*[5]*, Fani Hatjina*[6]*, Robert Brodschneider*[7]*, Kristina Gratzer*[7]*, Amadeo Rodriguez Fernández-Alba*[8]*, María Murcia Morales*[9]*, Kostas Kasiotis*[10]*, Norman Carreck*[11]*, Andreia Quaresma*[12]*, Alice Pinto*[12]*, Dirk de Graaf*[13]*, Ellen Danneels*[13]*, Marco Pietropaoli*[14]*, Valters Brusbardis*[15] *and Ivo Roessink*[16]*, (1)Environmental Risk Assessment, Wageningen University & Research (WUR), Netherlands, (2)Wageningen Environmental Research (WUR), Netherlands, (3)University of Strathclyde, United Kingdom, (4)AlveusAB, Netherlands, (5)Danish Beekeepers Association, Denmark, (6)ELGO Dimitra, Greece, (7)University of Graz, Austria, (8)Chemistry and Physics Department, University of Almería, Spain, (9)University of Almería, Spain, (10)Benaki Phytopathological Institute, Greece, (11)Carreck Consultancy, United Kingdom, (12)CIMO, Instituto Politécnico de Braganca, Portugal, (13)Ghent University, Belgium, (14)Istituto Zooprofilattico Sperimentale del Lazio e della Toscana, Italy, (15)Latvian Beekeepers Association, Latvia, (16)Wageningen University & Research (WUR), Netherlands*

The natural environment is under pressure as a result of human activities. In order to survey and monitor landscape quality, there is a need for a general approach that allows for an integrated assessment of the contamination and habitat quality at large spatial scales and over the course of a season. The INSIGNIA-EU project aims to address this need. The honey bee (*Apis mellifera* L.), an important pollinator species, is used a biomonitoring tool, utilising the central-place foraging behaviour of honey bees to collect information on the environmental quality of the surrounding area.

Data on pollen, pesticides, VOC/PAHs, heavy metals, and microplastic were collected by 315 Citizen sicentists (CS) in the 27 EU countries in 2023. Sites were chosen to cover different landscapes based on CORINE landscape classes such that an equal spread in space, land-use classes, and diversity was achieved. Clustering of the 315 CS locations was performed to determine similarity of the surrounding landscape and to define a sampling frame. Subsequently, grid cells were compared against clusters to filter out grid cells that were outside of the sampling frame. Prediction of the probability of a pollen family or a pollutant being present in a location (i.e., multi-class classification) was achieved using random forest models. Separate models were created for pollen and the different types of pollutant.

The distribution of apiaries across land-use classes and the diversity was not even, this can be explained by the fact that, for example, beekeepers do not tend to keep bees in heavily forested areas for a lack of foraging resources. Consequently, monitoring and modelling results are context dependant. Large-scale differences can be seen, as well as local changes over the course of a growing season for both pollen and pollutants.

Our approach linked land-use to the pollen and pesticide data generated during the INSIGNIA EU to create predictive maps of: 1) pollen diversity, and 2) pollutants. This study represents an unprecedently large and comprehensive dataset on the status of environmental pollution and pollen diversity. The maps created in this study can be used by, for example, beekeepers to find suitable locations for their apiaries. Moreover, these maps will show, in time and space, where mitigation measures may be needed for different types of pollution, allowing authorities and managers to take efficient and targeted action.

2.07.P-Tu157 SolBeePop-ecotox: a population model for higher-tier risk assessments of solitary bees

Amelie Schmolke[1]*, Nika Galic*[2]*, Vanessa Roeben*[3]*, Thomas G Preuss*[3]*, Mark Miles*[4]*, Olaf Klein*[5] *and Silvia Hinarejos*[6]*, (1)RIFCON GmbH, Germany, (2)Syngenta AG, Switzerland, (3)Bayer AG - Crop Science Division, Germany, (4)Bayer AG, (5)Eurofins Agroscience Services Ecotox GmbH, Germany, (6)Sumitomo Chemical Agro Europe SAS, France*

Solitary bees are considered in pesticide risk assessments of pollinators and explicitly addressed in the new guidance on bees by EFSA (2023). In agricultural landscapes, solitary bees occur in a large diversity of species. A few species are managed specifically for crop pollination. Their solitary life style distinguishes them from honey bees and bumble bees, and their ecology can result in differences in exposures to pesticides as well as long-term outcomes on the population level. Studies have been conducted to assess risks to solitary bee populations from pesticide exposure via treated fields. However, such studies are time- and resource intensive and focus on the combination of a single species, crop and year. With the population model for solitary bees, SolBeePop$_{ecotox}$, we demonstrate the application of a model that can be applied in to expand the use of study data. Available data from semi-field studies with the red mason bee, *Osmia bicornis*, were used to assess the model performance, simulating bees foraging in tunnels over control and insecticide-treated oilseed rape fields. Effects are implemented in the model using a simplified toxicokinetic-toxicodynamic model, BeeGUTS, adapted specifically for bees. We applied the model to simulate hypothetical semi-field studies with additional solitary bees species, including a cavity-nesting species, the alfalfa leafcutter bee, *Megachile rotundata*, and two soil-nesting species, the alkali bee, *Nomia melanderi*, and the hoary squash bee, *Eucera pruinosa*. The model application demonstrates how models can inform higher-tier risk assessments, expanding available empirical data to untested conditions and become important tools to support pesticide risk assessments.

2.07.P-Tu158 Risk assessment of bees from the use of biocide – exposure assessment

*Adriana Lipkova[1], **Ella Laakkonen**[1], Jaana Laitinen[1], Domenica Auteri[2] and Csaba Szentes[2], (1)European Chemicals Agency (ECHA), Finland, (2)European Food Safety Authority (EFSA), Italy*

During 2019, ECHA received a mandate from the European Commission to develop a guidance for assessing the risk to pollinators (including bees) from the exposure to biocides. According to the mandate, ECHA should take into account the revised EFSA Guidance document on the risk assessment of plant protection products on bees, which was released in May 2023.

In 2023, ECHA has finalised a first version of the guidance document (GD) which provides a methodology to assess the risk to bees that are exposed to biocides. This is done by following a tiered approach for the exposure and the effect assessment. In the risk assessment of honey bees, the magnitude dimension of the Specific Protection Goals is applied as a threshold for acceptable effects. The GD proposes a quantitative risk assessment approach to assess the risk to bees from the biocidal product type (PT) 18 (insecticides, acaricides and products to control other arthropods) emission scenarios. The possible sources of exposure covered in the GD are (1) large scale spraying, (2) application of manure/sludge to agricultural soil or grassland, (3) small scale spray around the house, and (4) irrigation of private gardens with treated water. While the focus in the first version of the ECHA guidance is on PT18 active substances, there may be instances where a PT18 active substance in a product in another PT also warrants an assessment when the exposure is considered significant enough to warrant further consideration.

The aim of this presentation will be to provide the audience with an overview of the methodology to assess the risk to bees that are exposed to biocides. In particular, the relevant sources of exposure from the use of biocides will be described. The tiered approach starting from screening step and proceeding to Tier, Tier 2 and Tier 3 will be explained. This method in the new ECHA Bee guidance will provide a quantitative approach for the exposure assessment of bees that has been lacking in the previous ECHA guidance documents for the risk assessment of biocides.

2.07.P-Tu159 Biocides and Pesticides perspective on the risk assessment of pollinators: ECHA and EFSA Bee guidance and developments for other pollinators

***Ella Laakkonen**, European Chemicals Agency (ECHA), Finland*

In March 2019, EFSA received a mandate from the European Commission to revise the 2013 bee guidance document for plant protection products (PPPs). As a crucial aspect of the revision, EFSA was requested to consider the EU Commission activities on the revision of the specific protection goal.

In December 2019, the European Commission mandated ECHA to develop a guidance for assessing the risks to arthropod pollinators (including bees) from biocides exposure. Although ECHA and EFSA developed their guidance documents (GDs) independently, the two GDs were aligned as far as possible, in relation to respective legal frameworks for pesticides and biocides.

The revised EFSA guidance on the risk assessment of plant protection products on bees was published in May 2023. A first version of the ECHA Guidance on the assessment of risks to bees from the use of biocides was published in April 2023, and a final version is expected by end of March 2024. Regarding non-target arthropod pollinators other than bees, in 2022 ECHA published a scientific report on European arthropods and their role in pollination.

The aim of this presentation is to provide the audience with an overview on the new developments of guidance in the area of risk assessment of pollinators from the exposure to biocides and PPPs. The development process, scope and biocide-specific aspects regarding risk assessment of bees different from PPP assessment will be described. The commonalities and differenceses between the two GDs for the risk assessment of bees will be highlighted, as well as the identified research needs.

In addition, the state of play with regards to knowledge on non-bee pollinators and future needs for guidance development will be presented.

2.07.P-Tu160 Investigation of Key Parameters to Adapt Ecotoxicological Testing to Microbial Pesticides – An Example With a Social Insect and an Aquatic Invertebrate

Florine Ory[1]*, Magdaléna Cornement*[2]*, Julie Masse*[3]*, Helene Eckenstein*[2]*, Stephen Vinall*[4] *and Stefan Josef Hoeger*[2]*, (1)IES - Innovative Environmental Services Ltd., Switzerland, (2)Innovative Environmental Services (IES) Ltd., Switzerland, (3)IES, Switzerland, (4)2 Venture Road, Mambo-Tox/IES/i2L, United Kingdom*

There is a growing interest in developing biopesticides as sustainable tools in the global plant protection market. Biopesticides are naturally occurring substances that control pests by biological mechanisms. In contrast to synthetic chemicals, microbial pesticides are relatively specific and have targeted modes of action that include, resources competition, infectivity, and pathogenicity, rather than toxicity alone. Such mechanisms present potential ecological risks to non-target organisms and must be assessed considering concrete environmental scenarios (*e.g.* exposure routes, development, and life cycles). Current testing guidelines adapted to chemicals toxicity must be adjusted according to the ecological characteristics of the tested organisms, to properly assess the associated risks. Here, we evaluated the effect of a widely used microbial pesticide on a non-target social insect and an aquatic invertebrate by adapting different parameters of the study protocols to better mimic the reality of a microbial exposure. Honey bee larvae and young daphnids were exposed to the bacterium *Bacillus thuringiensis* and the effect on their survival and development was assessed. A microbiology-based method was used to verify the bacterial dose administrated to both test systems over the exposure period. The testing parameters were successfully adapted to evaluate the effect of *B. thuringiensis* on the development of honey bee larvae and young daphnids. The challenges and opportunities associated with the ecological interactions (*e.g.* exposure routes) in ecotoxicological testing were highlighted and discussed. These investigations are essential to ensure a correct ecological risk assessment of emerging microbial control agents for non-target organisms.

2.07.P-Tu161 Oral exposure-driven effects of a novel spider venom-based biopesticide on survival, gut microbiome and head transcriptome of adult worker honeybees

Artur Miguel Paiva Sarmento[1]*, Luis Cunha*[1]*, Mari Gigauri*[1]*, Angharad Gatehouse*[2]*, Francesco Pennacchio*[3]*, Martin Edwards*[2]*, Campbell Tang*[4]*, Ilaria Di Lelio*[3]*, Elia Russo*[3] *and José Paulo Sousa*[1]*, (1)University of Coimbra, Centre for Functional Ecology, Portugal, (2)School of Natural and Environmental Sciences, Newcastle University, United Kingdom, (3)Department of Agricultural Sciences, University of Napoli "Federico II", Italy, (4)Centre Process Innovation (CPI), United Kingdom*

The escalating use of plant protection products in recent decades contributed to the degradation of numerous ecosystem services by exerting heightened pressure on non-target organisms (NTOs), many of which play crucial roles as service providers. To overcome these issues, the European Union through the Farm to Fork Strategy and its aim of reducing the use of chemical pesticides by 50% and the use of more hazardous pesticides by 50% by 2030, targeted the development of novel and more environmentally friendly products (the "low-risk pesticides"). Biopesticides derived from natural molecules of animals, plants, bacteria and minerals are considered a promising alternative to conventional chemical pesticides. One source of molecules currently receiving attention are proteins from insect antagonists, such as the neurotoxin from the venom of the spider *Segestria florentina* (SFl6), which when fused to bovine serum albumin (BSA) proved to be toxic to different insect pests of important crops. Although biopesticides are often considered to have a reduced environmental impact, their effects on NTOs can be challenging to predict, mainly because of the lack of appropriate tools incorporated into the regulatory framework. The study aimed to determine the effects of the fusion protein SFl6-BSA upon oral exposure on *A. mellifera*, the key model organism for pesticide Environmental Risk Assessment to pollinators. The effects were evaluated, after acute and chronic exposure, on the survival, gut microbiome and head transcriptome of adult worker honeybees. Acute and chronic oral toxicity tests were performed according to the Organization for Economic Cooperation and Development Guidelines for the Testing of Chemicals - Tests No. 213 and 245, respectively. DNA (gut) and RNA (head) extractions were made using NZY Isolation kits (NZYTech), following the manufacturer protocols. Sequencing was made using an Illumina NovaSeq platform at Novogene facilities (United Kingdom). We demonstrated that acute oral exposure to SFl6-BSA had no adverse effects on honeybees. On the other hand, when bees were subjected to chronic exposure, it caused no significant effects on survival but induced changes in the gut microbiome and alteration in gene expression profiles. The responses revealed by the "omic" approaches, coupled with regular testing procedures could be considered valuable tools for further research and inclusion in regulatory frameworks.

2.07.P-Tu162 Beyond Managed Bees: Understanding Non-Target Arthropods for Enhanced Pollination Services in EU Agricultural Systems

Grzegorz Sylwester Sowa[1]*, Steven Droge*[2]*, Mykola Rasko*[3] *and Lorraine Maltby*[1]*, (1)School of Biosciences, University of Sheffield, United Kingdom, (2)Environmental Risk Assessment, Wageningen University & Research (WUR), Netherlands, (3)University of Coimbra, Centre for Functional Ecology, Portugal*

Pollination, an essential ecosystem service (ES), plays a vital role in sustaining life on Earth, especially for humans. However, the current emphasis on a limited set of non-target arthropods (NTAs) in risk assessment neglects the broader spectrum of species. EU Member States express concerns about the inadequacies of existing methodologies and the ambiguity surrounding the level of protection afforded. Recognizing representative NTAs beyond managed bees, which drive ES delivery, becomes crucial for targeted risk assessment and ecological relevance. This study aims to identify and compare the distribution of NTAs in EU agriculture, analysing variations across different crops and EU geographical zones. The study concentrated on six annual crops (wheat, maize, barley, oilseed rape, potato, beet) and three perennial crops (apple, grape, olives) chosen for their significant contribution to EU production and data availability. Arthropod data for arable crops was sourced from an existing database [1] and a literature review on perennial crops was conducted using CAB Abstracts. The EU-focused invertebrate dataset, excluding pest species, underwent non-metric multidimensional scaling analysis to compare NTAs compositions. Representative NTA families were identified based on criteria like abundance, dominance, diversity, and distribution. Surprisingly analysis reveals that, among perennial crops, only olives and grapes exhibit close grouping. Wheat appears closely associated with oilseed rape and potatoes, despite the latter two being flowering crops. Unexpectedly, the separation by crop and EU zones is not straightforward. While olives and grapes cluster, apples in all three zones seem more like other crops from the central zone. Identified key NTAs families include *Andrenidae* (mining bees), *Apidae* and *Halictidae* (bees), *Noctuidae* (owlet moths), and *Syrphidae* (hoverflies). The recognized families, extending beyond conventional test species, highlight the imperative for more precise testing strategies oriented towards ES to enhance guidance in risk assessment within agricultural ecosystems. Specifically, because they represent a wide range of traits and may have different sensitivities and handle exposure and recovery differently. The findings underscore the necessity for a more precise and ecosystem-service-oriented approach in developing risk assessment guidance for pesticide use in agriculture.

[1] Riedel et al. 2016. EU. EFSA Supporting Publications, 13, 956E.

2.07.P-Tu163 Chronic Bumblebee Feeding Test under Natural Environmental Conditions – Lessons Learned so Far

*Annika Alscher[1], **Johannes Lückmann**[1], Nadja Schnetzer[1], Lea Franke[2], Julian Fricke[2] and Olaf Klein[2], (1)RIFCON GmbH, Germany, (2)Eurofins Agroscience Services Ecotox GmbH, Germany*

According to the revised EFSA Bee Guidance (EFSA 2023) semi-field and field testing on bumblebees is proposed to gain insight into the risks for bumblebee colonies after pesticide application to flowering crops. If the lower tier risk assessment shows a strong dominance of the dietary exposure route, it is recommended conducting feeding tests with a two-week exposure period under field conditions without having agreed study protocols in place. Annex C of the revised guidance presents a rather rough methodological description that lacks detailed information about feasibility of such tests and the generation of comparable and reproducible data. In particular, the proposed test method includes a positive control, but does not define a specific substance or feeding concentrations for the test organisms.

We conducted feeding tests with free flying bumblebee colonies under natural environmental conditions, and at two different sites in Germany. The commercially available small colonies were placed randomly along a linear structure in the landscape with 10 m distance between single colonies to reduce risk of worker drift between colonies of different treatment groups. Colonies were offered a spiked sugar solution via a feeder installed beneath the nest inside the nest box over a period of two weeks and were monitored the following six weeks. During study duration bumblebees could forage for pollen and nectar. Endpoints assessed were colony weight as a proxy for colony strength as a specific protection goal of EFSA, mortality and queen production.

Dimethoate EC 400 (active substance dimethoate) and Dimilin 25 W (active substance diflubenzuron) were tested with a range of concentrations as positive controls. Dimethoate is regularly used for higher tier testing as a positive control in pollinator studies and acts on adult mortality whereas diflubenzuron is known to impacts larval development. As a negative control, colonies were fed with untreated sugar solution. The obtained results are presented and discussed.

2.07.P-Tu164 Non-Apis Bee Risk Assessment in the Absence of a Specific Protection Goal: Decision-Making With Limited Options

***Julian Haas**[1], Mark Miles[2], John Herrmann[1], Verena Taenzler[1], Daniel R Schmehl[3], Kirsten Henn[4] and Johannes Lückmann[4], (1)Bayer AG, Germany, (2)Bayer AG, (3)Bayer CropScience LLC, (4)RIFCON GmbH, Germany*

Recently, EFSA published their “revised guidance on the risk assessment of plant protection products on bees”. In addition to honeybees, the guidance requires the risk assessment for two additional bee groups: bumble bees and solitary bees. Unlike for honeybees no specific protection goal was defined for these groups. According to the European Commission the risk assessment would therefore require field studies with these bee groups as default. Given the lack of lower tier risk assessment, several risk management strategies have been proposed. Field studies may not be necessary if lower tier risk assessments for honeybees and non-target arthropods show no effects, which raises several follow-up questions such as the exact definition of “lower tier” or “no effects”. Other risk management proposals include laboratory studies with surrogate species from the respective bee group in combination with toxicity thresholds (LD_{50} of > 100 µg/bee considered as non-toxic) or semi-field testing with surrogate species. Here, we investigated the feasibility of these proposals with regards to data and method availability and compared the outcome of different risk management strategies to the outcome of the honeybee risk assessment for a substantial number of compounds. The analysis aims to provide an overview about several risk management strategies for non-*Apis* bees in the absence of specific protection goals and will help to inform stakeholders about the practicability of EFSA’s revised guidance for non-*Apis* bees.

2.07.P-Tu165 Evaluation of the oral toxicity of the fungicide difenoconazole on native bees of the species Scaptotrigona postica and its subeffects.

***Gabriela Reani Rodrigues Garcia**[1], Rafaela Garcia da Silva[2], Joyce Oliveira Costa[1], Annielly Fernanda de Sousa Silva[2], Janete Brigante[1], Eny Maria Vieira[3] and Michiel Daam[4], (1)University of São Paulo (USP), Brazil, (2)Dqfm, USP, Brazil, (3)DQFM, University of São Paulo (USP), Brazil, (4)CENSE, New University of Lisbon*
Bees are insects of great importance for biodiversity and agricultural production, as they are responsible for promoting pollination, fruit generation, and providing honey, wax, propolis, and pollen. In Brazil, there is a wide variety of native bees known for not having stings or venom. Focusing on the bee, popularly known as Mandaguari (*Scaptotrigona postica*), its role as a pollinator is highly efficient, as the number of individuals per hive can reach more than 20,000 bees, positively impacting the pollination process. This study aimed to determine and compare the lethal concentration of the analytical standard difenoconazole and the commercial product SCORE (LC_{50}), as well as their lethal dose (LD_{50}), for the species of bee *Scaptotrigona postica*. Additionally, the study aimed to analyze the protein profile of Mandaguari in response to exposure to this fungicide using the biochemical test of polyacrylamide gel electrophoresis. For this study, foraging adult bees were collected in the early morning and brought to the laboratory. The bees were acclimated in a BOD incubator at a temperature of 26 ± 1°C, with food replenishment until the test. Bees were exposed to the following standard diphenoconazole concentrations 20; 15; 12; 7; 2.5 and 1.5 mg mL^{-1}, already for the commercial product, SCORE, the following concentrations were tested: 0.0065; 0.005; 0.0035; 0.025; 0.015; 0.0005 mg mL^{-1} The LC_{50} was determined to be 19.99 g L^{-1} (48h) and the LD_{50} 0.095 mg a.i./bee (48h) for the difenoconazole standard, and for the commercial product SCORE, the LC50 was 0.00682 g L^{-1} (72h) and the LD50 was 0.03136 µg a.i./bee (72h). It was observed that for the tested concentrations of both products, the higher concentrations showed mortality rates between 80 and 100%, as well as physical effects such as difficulty in flight and feeding. Finally, regarding the protein profile, an intensification of some enzymes, such as catalase and peroxidase, was observed in individuals exposed to difenoconazole, a strategy used by bee organisms for detoxification and tolerance.

2.07.P-Tu166 Toxicity of imidacloprid and thiamethoxam to Scaptotrigona postica bees

*Joyce Oliveira Costa[1], Annielly Fernanda de Sousa Silva[2], **Gabriela Reani Rodrigues Garcia**[1], Rafaela Garcia da Silva[2], Janete Brigante[1], Michiel Daam[3] and Eny Maria Vieira[4], (1)University of São Paulo (USP), Brazil, (2)Dqfm, USP, Brazil, (3)CENSE, New University of Lisbon, (4)DQFM, University of São Paulo (USP), Brazil*
Native bees play a fundamental role in pollination, contributing to reproducing approximately 90% of flowering plant species and 80% of economically important crops. However, pesticide contamination threatens this species' survival, resulting in reduced biodiversity in ecosystems and food supply. Therefore, it was necessary to determine safe doses of pesticides, such as imidacloprid and thiamethoxam, to ensure that the bee's function and survival are not compromised. For this purpose, a preliminary oral bioassay was conducted, involving the collection of *Scaptotrigona postica* bees in the morning, between 07:00 and 08:00. Adult bees were collected at the hive entrance using a 250 mL plastic cage containing a 50% (w/v) sucrose solution. Five solutions with concentrations of 1000, 100, 10, 1, and 0.1 µg L^{-1} of the standard for each pesticide were tested. The tests were conducted in triplicate, in addition to the control group, to obtain a concentration range where sample mortality varied between 10% and 90%. For each cage, 200 µL of the contaminated solution was offered, and deaths were recorded 6 hours after the test started and then at 24-hour intervals up to 96 hours. After the preliminary bioassays, the following concentrations were tested for imidacloprid 672, 599, 484, 325, and 240 µg L^{-1} of the standard, obtaining LD_{50} (72h) of 0.00228 µg imidacloprid per bee. For thiamethoxam, solutions with concentrations of 1654, 790, 546, 375, 246, 194, and 100 µg L^{-1} of the thiamethoxam standard were tested. The LC_{50} (24h) was 336.3 µg a.i. thiamethoxam L^{-1}. The design of the definitive tests followed the same experimental procedure as the preliminary tests. The results of the bioassays indicate a mortality of up to 52% in samples contaminated with imidacloprid-containing solutions and 8 to 100% for thiamethoxam, indicating that the species *Scaptotrigona postica* is more susceptible to neonicotinoids compared to *Apis mellifera* used as a reference in exposure protocols.

2.07.P-Tu167 Toxicity of tiametoxam insecticide on the stingless bee Scaptotrigona postica Latreille, 1807

*Annielly Fernanda de Sousa Silva[1], Joyce Oliveira Costa[2], Gabriela Reani Rodrigues Garcia[2], Rafaela Garcia da Silva[1], Janete Brigante[2], Michiel Daam[3] and **Eny Maria Vieira**[4], (1)Dqfm, USP, Brazil, (2)University of São Paulo (USP), Brazil, (3)CENSE, New University of Lisbon, (4)DQFM, University of São Paulo (USP), Brazil*
Native bees play an essential role in pollination, contributing significantly to the reproduction of various crops, especially those of economic relevance. However, there is observed population decline in these insects, correlated with contamination by pesticides, primarily neonicotinoids. In order to assess whether the use of the commercial product thiamethoxam may be harmful to bees of the species Scaptotrigona postica L., toxicity bioassays were conducted in the laboratory. Adult bees were exposed to Actara® 250WG, which contains the active ingredient thiamethoxam, through two acute exposure routes: oral and contact. Acute toxicity bioassays were conducted following the OECD Nº. 213 and 214 protocol guidelines. Bee collection was performed between 7:00 and 8:00 a.m., directly at the hive entrance using a 250 mL plastic cage containing a 50% (w/v) sucrose solution. After preliminary bioassays, the following solutions were tested for oral exposure concentrations: 0.0015, 0.003, 0.005, 0.010, 0.025, and 0.05 ng μL^{-1}, and for contact exposure, applied doses were 0.5, 0.8, 0.95, 1, 1.5, and 2.0 ng a.i./bee. Definitive tests followed the same experimental procedure as the preliminary ones. Actara® presented oral LC_{50} values of 0.12277, 0.01503, 0.00738, 0.00371, and 0.0021 ng a.i. μL^{-1}, and oral LD_{50} values of 0.36697, 0.06378, 0.0342, 0.01851, and 0.01159 ng a.i./bee, respectively, for 6, 24, 48, 72, and 96 hours. The contact bioassay LD_{50} was 2.16726, 0.96173, 0.76224, 0.62911, and 0.46252 ng a.i./bee, respectively, for 4, 24, 48, 72, and 96 hours. Within the first 24 hours, whether through ingestion of contaminated food at higher concentrations or direct contact of insects with thiamethoxam at higher doses, 80% mortality of bees was observed.

2.07.P-Tu168 Method Optimisation for Large Scope Pesticide Multiresidue Analysis in Bee Pollen: a Pilot Monitoring Study

Maria Antonietta Carrera[1,2]*, Lorena Manzano Sánchez*[2]*, María Murcia Morales*[2]*, Amadeo Rodriguez Fernández-Alba*[3] *and María Dolores Hernando Guil*[4]*, (1)CSIC-EEZA, (2)University of Almería, Spain, (3)Chemistry and Physics Department, University of Almería, Spain, (4)Spanish National Research Council (CSIC-EEZA), Spain*

Despite providing numerous advantages for agriculture, the extensive use of pesticides is known to have negative environmental impact through soil, water, and nontarget plant contamination, but also through animals' and consumers' exposure. In this scenario, the analysis of pesticides in natural products like bee pollen has a cross-sectional value, since it can shed light on pollinators' safety, and it can be a helpful tool for environmental monitoring. Moreover, due to the growing popularity of bee pollen as food supplement, the analysis of pesticides in this bee product is also important for food safety purposes.

The present study focused on the optimization of an analytical method for the evaluation of pesticides contamination in bee pollen. QuEChERS methodology was employed for pesticides extraction, and a new automated clean-up approach for final extracts purification was developed. Subsequently, a mass spectrometry-based method was validated for the targeted analysis of 353 pesticides included in the EU monitoring priority list. The newly developed method was then employed to evaluate the pesticide contamination in 80 bee pollen samples purchased from different countries within and outside the EU. Finally, the results obtained were used to tentatively assess the safety of bee pollen for human consumption following the EU guidelines.

The new automated approach for the clean-up of pesticide extracts from bee pollen proved to be a reliable alternative to the classical clean-up methodologies, and the optimized mass spectrometry-based analytical method was fully validated and applied to assess the presence of a wide range of pesticides with a very low limit of quantification (5 µg/kg) in bee pollen. The sample analysis showed the presence of 77 different pesticides in bee pollen, including several chemicals whose use is no longer allowed. 85% of the samples were contaminated with pesticides, sometimes reaching concentrations higher than the maximum residue levels imposed by the EU in honey and other apiculture products. Nevertheless, the risk assessment showed that consumers are not exposed to an unacceptable risk when consuming the analysed bee pollen.

The experimental methods validated in this study, together with the wide range of data collected on bee pollen contamination with pesticides, represents a step forward towards the comprehension of environmental and food safety threats, and provide a solid basis for future cross-sectional studies.

2.07.P-Tu169 New approaches for the analysis of residues of plant protection products in non-typical matrices collected by solitary leafcutter bees (Megachile rotundata F.) in a semi-field test design

Ralph Kirchmaier[1]*, Arne Mewis*[2]*, Dietke Kleinhenz*[2]*, Julian Fricke*[3]*, Olaf Klein*[3]*,* ***Silvio Knaebe***[4]*, Carmen Gimeno*[5] *and Ignacio Gimeno Rodrigo*[5]*, (1)Eurofins Agroscience Services EcoChem GmbH, Germany, (2)Chemistry, Eurofins Agroscience Services EcoChem GmbH, Germany, (3)Eurofins Agroscience Services Ecotox GmbH, Germany, (4)Eurofins Ecotox GmbH, Germany, (5)Eurofins Trialcamp, Spain*

In the new EFSA bee guidance document, exposure is a focal point to decide if there is a risk for wild pollinator species through the application of plant protection products (PPPs). So far no standardised protocols are available to determine the transfer rates of a foliar applied PPP to the different bee matrices. In order to provide analytical evidence of the effects of PPPs on wild pollinator species, it is necessary to develop novel methods for preparation, extraction and analysis of those matrices, which are important and closly linked to the biology of these species. Due to the intrest in other bee species exposure routes besides nectar and pollen have not been in the focus so far. This information is of upmost importance as there is a difference of exposure of wild bee species to honey bees. Authorities need this information for a proper risk assessment for non-Apis bees. In 2022 a first successful attempt was made to supplement a standardised Tier II semi-field test design based on the recommended concept for *O. bicornis* with another bee species (*Megachile rotundata*). In 2023 this test design was refined and a residue sampling component was included for different matrices. The active ingredient chosen for this trial was the fungicide BOS WG 500 (active ingredient boscalid) as it is not toxic to bees and stable in the environment. Residue samples of provision mass (larval diet), nesting material (leaves from brood cells), foliage from clover and nectar and pollen from Phacelia flowers were collected. In the laboratory a methodology was developed to analyse foliage from clover and nectar and pollen from Phacelia. Furthermore, a standardised methodology was developed to separate nesting material from the provision mass for later analysis. Also an analytical method for provision mass and nesting material (cocoons made of plant leaves) was developed. In order to develop an extraction method which is not only applicable for boscalid, but also to various other PPPs, an approach based on the QuEChERS multi-method was aimed for. Methodological sampling procedures and analytical results for different non-typical matrices will be presented with respect to their potential for the use in risk assessments.

2.07.P-Tu170 New experiences and insights of two-year testing with the leafcutter bee Megachile rotundata in a semi-field test design

Julian Fricke[1]*, Ignacio Gimeno Rodrigo*[2]*, Olaf Klein*[1]*, Carmen Gimeno*[2] *and* ***Silvio Knaebe***[3]*, (1)Eurofins Agroscience Services Ecotox GmbH, Germany, (2)Eurofins Trialcamp, Spain, (3)Eurofins Ecotox GmbH, Germany*

According to the revised EFSA Bee Guidance Document a point of focus is the risk for wild pollinator species through the application of plant protection products (PPPs). This information is of upmost importance as there is minimal knowlegde on exposure of wild bee species. Authorities need this information for a proper risk assessment for non-Apis bees. As a consequence a study design with the solitary red mason bee *Osmia bicornis* L. was developed by the ICPPR non-Apis working group with recommendations for a standardised Tier II test design. With the knowledge on differences in exposure pathways between the solitary bee *Osmia bicornis* and the leafcutter bee *Megachile rotundata*, it is expected that the same PPPs will impact those species differently. So far no standardised protocols are available for solitary bee studies with *Megachile.* The main objective of these two-year tests, conducted in Spain, was to develop a standardized test design based on the recommended design for *Osmia* and to gain further insight into the risk assessment of different routes of exposure by collecting different matrices for residue analysis. *M. rotundata* was released as emerged adults in tunnels containing a bee attractive flowering crop as food and nesting resouce (*Medicago sativa* in 2022 and *Trifolium sp.* in combination with *Phacelia tanacetifolia* in 2023). The study included an untreated control and two treatments one sprayed with dimethoate (2022) and the other with fenoxycarb (2023). After application, the bees were exposed not only by the food items but also via contact to the treated crop. This included not only pollen and nectar, but also plant material (leaves) for brood cell construction. Evaluated endpoints were assessed for the whole reproductive period: Establishment of actively nesting females, flight activity observations and the production of brood cells/cocoons. The assessed endpoints were evaluated with respect to their potential for the use in the risk assessment of PPPs. The obtained results are presented and discussed.

2.07.P-Tu171 Definitive Methodology for the Acute Contact Test on the Solitary Bee Megachiles rotundata. -LD50 Toxic Reference

Josep Antoni Aguilar-Alberola[1], Eugenia Soler[2] and ***Carmen Gimeno**[1]**, (1)Eurofins Trialcamp, Spain, (2)Eurofins Trialcamp S.L.U., Alcasser (Valencia), Spain*

After carrying out two acute tests with contact application in 2022 (the results were presented in a poster at the ICPPR), the previously developed methodology has been repeated in a new test carried out in 2023. The objective has been to corroborate that the methodology is appropriate for the management and feeding of the study organisms. In addition, the mortality results of the control groups and the LD_{50} values obtained using a reference toxicant (dimethoate) have been compared. This allowed us to find out if the values were similar or there may have been a wide variability that did not allow comparable results to be obtained over time. In this test, a mortality of 10 % was recorded in the control group 96 hours after application (in the previous tests, mortality was 6.7 % in both tests). The LD_{50} values at 24, 48, 72 and 96 hours for the reference item were very similar in the 3 tests carried out (they varied from 0.179 to 0.237 µg dimethoate/organism). These results show us that the developed methodology is adequate for the maintenance and survival of the study organisms and allows comparable mortality results to be obtained over time within a very narrow margin of variation. Due to this, it is considered that an appropriate methodology is already available to carry out contact acute studies using *Megachiles rotundata*.

2.07.P-Tu172 Selection of an Application Diet for an Acute Oral Test on the Solitary Bee Megachiles rotundata.

Josep Antoni Aguilar-Alberola[1], Eugenia Soler[2] and ***Carmen Gimeno**[1]**, (1)Eurofins Trialcamp, Spain, (2)Eurofins Trialcamp S.L.U., Alcasser (Valencia), Spain*

In order to comply with the EFSA requirements regarding studies carried out with solitary bees, a series of preliminary tests were carried out with *Megachiles rotundata* to find out the best diet that can be offered to them. This diet must meet the necessary requirements for the study organisms. These requirements are not only that it contains the necessary nutrients to keep the organisms alive but also that it is palatable enough to feed on that diet and in sufficient quantity to be dosed with the test products. For this test, different types of base diet were used in acclimatization (50 % and 67 % (w/v) aqueous sucrose solutions and pollen paste), to which a small amount of pollen was added or not (except in the case of pollen paste). The groups that had high survival rates were divided into two subgroups, one was without starvation and the other group was starved for 2 hours before exposure. During the exposure phase, the consumption at 6 and at 24 hours were monitored. The results were clear regarding the type of diet. The groups fed with aqueous sucrose solutions with some pollen on the tip of the syringe had high survival rates, while most organisms fed the same diet, but without pollen, were dead within 24 hours. As for consumption, it was very low in all cases during the first 6 hours, regardless of the starvation period. Consumption was acceptable throughout the 24 hours. Due to this, new oral application tests will be carried out using the diets described above, always with the presence of pollen and by monitoring consumption for 24 hours to corroborate the results. Additionally, new ways of providing the food will be tested to find out if it can have any type of effect on the results.

2.08.P Potential Impacts of Anthropogenic Contaminants in the Changing Arctic and Antarctic Ecosystems, Interacting With Other Human Derived Stressors

2.08.P-Tu173 High Concentrations of Novel Flame Retardants in Indoor Dust from a Cruise Ship in the Arctic

***Veronica van der Schyff**[1]*, *Verena Meraldi[2], Andrew Luke King[3] and Lisa Melymuk[4], (1)Faculty of Science, Masaryk University, RECETOX, Czech Republic, (2)Hurtigruten Expeditions, United Kingdom, (3)Norwegian Institute for Water Research (NIVA), Norway, (4)RECETOX, Masaryk University, Czech Republic*

The cruise liner industry is the fastest-growing tourism sector. As sea ice decreases and technology becomes more advanced, more cruise ships venture into the once-inaccessible Polar regions. The number of cruise ships –particularly expedition cruises– in the Arctic has increased by 118% between 2012 and 2018. Due to the unique operational environment of cruise liners, stringent fire safety measures are prescribed by the International Maritime Organization (IMO). The International Code for Fire Safety Systems requires that the construction and other material, including textiles, upholstered furniture, and bedding, must pass tests for non-combustibility, fire resistance, flammability, the spread of flame, smoke, and toxicity. In 2023, we collected passive air samples and dust from three expedition cruise ships operating in the North Atlantic and Arctic regions.

The first ship was built in 2002, but renovated in 2020, and is propelled by Marine Biofuel. The second ship was built in 2020 and is a battery-operated hybrid electric ship. The third ship is fueled by Marine Gas Fuel and was built in 2003. All ships have a passenger capacity of approximately 550. The air and dust samples were analyzed for 197 compounds, including 10 PBDE congeners and 24 novel flame retardants. BDE-47 (4.63-25.42 ng/g), BDE-99 (3.88-29.3 ng/g), and BDE-209 (148-2587 ng/g) were detected in 100% of the dust samples. The novel flame retardants, DBDPE (0.13-7.36 µg/g), and DBE-DBCH (159-1317 µg/g) were detected at high levels in 90% of dust samples. TBCO was detected in 62% of dust (6.95- 139.32 µg/g). To our knowledge, the concentrations of DBDPE, DBE-DBCH, and TBCO were higher than most reported indoor dust concentrations. Novel brominated flame retardants have been quantified in Arctic air, soil, and marine biota. More ships are accessing the Polar regions, and may be an additional source of point pollution of harmful chemicals. The presence of high concentrations in a relatively small expedition cruise ship raises concern, considering that other cruise ships can house more than 10 000 passengers (excluding crew). More research is needed to characterize the impact of chemicals used in cruise ship environments on polar regions.

2.08.P-Tu174 Antarctic Threads: Textile Microfibers and Chemical Additives in the wild scallop Adamussium colbecki from the Ross Sea

Emma Ferrari[1]*, Roberta Russo*[2]*, Elisa Bergami*[3]*, Valentina Ferrari*[3]*, Maria Vittoria Barbieri*[4]*, Aleix Balasch Garcia*[5]*, Giovanni Birarda*[6]*, Lisa Vaccari*[6]*, Ethel Eljarrat*[5] *and Ilaria Corsi, PhD*[2]*, (1)University of Siena, Siena, Italy, (2)University of Siena, Italy, (3)Department of Life Sciences, University of Modena and Reggio Emilia, Italy, (4)ONHEALTH, Institute of Environmental Assessment and Water, Spanish National Research Council (CSIC), Spain, (5)Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain, (6)ElettrañSincrotrone Trieste, Italy*

Plastic pollution, driven by microplastics and synthetic fibers, poses a threat to Antarctic biodiversity from both global and local sources. Microfibers, released during the use and washing of synthetic textiles, contribute to secondary microplastics and carry associated chemical additives. Despite being considered "The Last Ocean," the Ross Sea faces emerging anthropogenic impacts, including climate change and microplastics. This study addresses the gap in research on chemical additives from synthetic textiles in Antarctic marine organisms, focusing on the scallop Adamussium colbecki, a vital species in coastal areas. Further investigation is needed to understand the potential hazards posed by these additives to marine life in the region. This study investigates the presence of textile microfibers in the Antarctic scallop *Adamussium colbecki*, a keystone species of Antarctic coastal areas, along with the content of associated chemical additives as organophosphates (OPEs) and phthalates plasticizers. Specimens from Terra Nova Bay, Antarctica, collected during expeditions in 2004 and 2019, were examined for microplastic contamination and chemical additives. Antarctic scallops showed significant microfiber presence (91.6%, averaging 4.9 ± 2.2 microfibers per individual), mainly black (35%), blue (29%), and red (10%). Chemical analysis identified 15 out of 34 compounds, with prevalent OPEs and notable phthalates. Textile analysis revealed a match between chemical additives in scallops and those in scientific personnel's clothing, suggesting local contamination. Limited analysis prompts further investigation into potential local sources, such as wastewater sewage plants, releasing textile microfibers into Antarctic marine environments.

2.08.P-Tu175 Exploring Heavy Metal Toxicity in the Antarctic Marine Ecosystem: Investigating the Defensive Role of Metallothioneins in Trematomus eulepidotus

Elisabetta Piva[1]*, Margherita Carnera*[2]*, Sophia Schumann*[2]*, Sara Pacchini*[1]*, Luciano Masiero*[2]*, Daniela Pellegrino*[3]*, Paola Irato*[2] *and Gianfranco Santovito*[2]*, (1)Department of Biology, University of Padova, Padova, Italy, (2)Department of Biology, University of Padova, Italy, (3)Department of Biology, Ecology and Earth Sciences, University of Calabria, Italy*
The Antarctic continent, despite its remote location, faces the threat of human-induced environmental changes, including the well-known presence of heavy metal contamination. This study explores the impact of heavy metal pollutants on an endemic Antarctic fish *Trematomus eulepidotus*, specifically examining the role of metallothioneins (MTs) in metal regulation and ROS scavenging. The Antarctic fish, are known to be among the few to express two distinct isoforms of metallothioneins, 1 and 2. In the intricate landscape of metal regulation and defense against environmental stressors, this dual expression emphasizes their extraordinary adaptability to the challenging conditions of their habitat. In this study *T. eulepidotus* specimens were exposed to 100 µg/l of cadmium (Cd) and copper (Cu), and the expression of *mt-1* and *mt-2* genes were analyzed across various organs. Results reveal interesting and distinct organ-specific responses to metal exposure, with the liver and kidney exhibiting elevated MT expression, particularly for *mt-2*. Cadmium exposure induces a significant rise in *mt-1* transcription in the liver, suggesting its potential role in cellular protection against Cd toxicity. In the kidney, both Cd and Cu treatments lead to increased mRNA expression for both MT isoforms, indicating its prominent role in metal detoxification. Brain and gonads responses vary with metal exposure, highlighting the complexity of organ-specific reactions. Metallothioneins, though fundamental, constitute only a portion of the intricate network of the cell detoxification system, necessitating an exploration of

the roles played by both enzymatic and nonenzymatic antioxidant components for a comprehensive understanding. Despite being preliminary, these results advance our understanding of the molecular and functional evolution of Antarctic fishes and lay the groundwork for the potential use of metallothionein expression as well-established biomarkers for metal exposure and oxidative stress. Using Notothenoidea as bioindicator organisms in future biomonitoring campaigns becomes crucial in assessing the anthropogenic impact on the uniquely beautiful yet extremely fragile Antarctic marine ecosystem. Funded by the Italian National Program for Antarctic Research (PNRA), project No. 2018/B2Z1.01

2.08.P-Tu176 Assessing the Impact of Penguin Guano on the Antarctic Bivalve Aequiyoldia eightsii: Effects on Biomarker Responses

Erica Sparaventi[1]*, M. Laura Martín-Díaz*[2]*, Antonio Tovar-Sánchez*[1] *and Araceli Rodríguez-Romero*[3]*, (1)Department of Ecology and Coastal Management, Institute of Marine Sciences of Andalusia, Spanish National Research Council (ICMAN-CSIC), Spain, (2)Chemical Physics Department, Faculty of Marine and Environmental Sciences, Marine Research Institute (INMAR), University of Cadiz, Spain, (3)Department of Analytical Chemistry, Faculty of Marine and Environmental Sciences, Marine Research Institute (INMAR), University of Cadiz, Spain*

Antarctic penguins can recycle Trace Metals (TMs) in the upper layer of the Southern Ocean, via guano production. However, high levels of non-essential metals (e.g. cadmium (Cd), mercury (Hg) and lead (Pb)) have also been reported in guano. During the breeding season, along the Antarctic continent coasts, thousands of pairs of penguins inhabit their colonies, characterized by a huge amount of guano deposited on land. The recycled TMs, either from guano leached into coastal waters or directly released into the sea, could affect benthic communities of shallow Antarctic seawaters, although the effect has not been studied yet. Here, we aimed to study the impact of Gentoo (*Pygoscelis papua*) penguins' guano on the Antarctic bivalve *Aequiyoldia eightsii*, from Livingston Island (South Shetland Islands), one of the most abundant benthic species in Antarctic waters. We analyzed possible oxidative stress and adverse effects in the selected species after exposure to five different guano concentration treatments (from 0 (control) to 6.7 g L^{-1}), over a 10-day period. The experiment was ran per duplicate in 25 L plastic aquariums, located outdoor to ensure natural photoperiod and temperature. Four specimens were collected from each treatment on day 2, 4, 7 and 10 for biomarkers analysis. Detoxification metabolism was examined in digestive gland, by the determination of Phase I and II and antioxidant enzymatic activities (Ethoxyresorufin O-deethylase (EROD), Gluthatione S-transferase (GST), Gluthatione peroxidase (GPX), Gluthatione reductase (GR)). Lipid peroxidation (LPO) and DNA damage were measured as biomarkers of effect. The data showed a notable decline in EROD activity over time; a positive induction for GST was observed at day 10. GPX, GR activities, LPO and DNA damage did not show exposure concentration- or time-dependent patterns. Differences in GPX activity and DNA damage were observed between control and guano treatments at day 2 at day 10 respectively. The results suggest that metals released from guano are not significantly adverse for *A. eighstii*, which did not show a clear stress response to guano exposure; however, to the best of our knowledge, no data on these biomarkers in *A. eighstii* are available in the literature. Hence, the data obtained in this study are of great importance for a deeper understanding of the physiology of these Antarctic organisms. Nevertheless, further studies are needed to clarify the impact of penguin guano on marine ecosystem.

2.08.P-Tu177 Glacial and urban rivers role in the fate of Contaminants of Emerging Concern in Arctic coastal waters

Svetlana Pakhomova[1]*, Anfisa Berezina*[1]*,* ***Emma Knight***[1]*, Mathew Kuttivadakkethil Avarachen*[2] *and Evgeniy Yakushev*[1]*, (1)Norwegian Institute for Water Research (NIVA), Norway, (2)Norwegian University of Science & Technology (NTNU), Norway*

Arctic coastal waters have been subject to high levels of pollution with a wide list of contaminants that can be either delivered with ocean currents and by atmospheric transport from distant regions or may originate from local sources. Terrestrial freshwater input can alter concentration and composition of pollutants in marine water in the coastal zone. Freshwater plumes propagation, driven by local winds and waves, can affect different regions of the fjord, and shape the frontal zones by interacting with saline waters. The aim of this work is to assess the role of the freshwater plumes of glacial and urban rivers in the pattern of pollution in Arctic coastal waters by example of Svalbard fjords. As illustrative Contaminants (iC) in this study, we select polyfluoroalkyl substances (PFAS), microplastics (MPs), and mercury (Hg). PFAS and MPs belong to the group of Contaminants of Emerging Concern (CECs), and Hg to the group of Priority Hazardous Substances. Hg can become a new challenge with regard to climate change due to its release from the thawing permafrost and the change in the sea ice regime. All illustrative contaminants can be transported both by water and by air.

Field studies were performed in populated and unpopulated branches of Isfjorden in July 2023. Water samples were taken in pristine and urban rivers, river plumes and high saline fjord waters for PFAS, MPs, Hg analysis as well as nutrients, organic carbon, and carbonate system. Results showed clear difference of chemical composition in samples for three studied regions representing clean glacial, riverine and contaminated urban waters. Detailed results will be present at the Conference.

Track 3. Environmental Chemistry and Exposure Assessment: Analysis, Monitoring, Fate and Modeling

3.01.A Advances in Bioaccumulation Science and Assessment

3.01.A.T-01 Bioaccumulation Kinetics of Per- and Polyfluoroalkyl Substances in Pimphales promelas

Jaylen Lesean Sims[1]*, Alexander Robert Cole*[2]*, Christopher Schmokel*[3]*, Matt Simcik*[3] *and Bryan W. Brooks*[1]*, (1)Environmental Science, Environmental Science & Public Health, Baylor University, (2)Baylor University, (3)University of Minnesota*

Due to persistence, toxicity and ubiquitous contamination of water resources, there has been growing interest in understanding the disposition of per- and polyfluoroalkyl substances (PFAS) in the environment. However, bioaccumulation dynamics remain poorly understood for many substances within this group of chemicals, and kinetic-based information is lacking across environmental gradients. Therefore, the aim of this study was to examine uptake of 19 PFAS, which were selected at low levels not eliciting standardized adverse outcomes, by fathead minnows (*Pimphales promelas*) over 7 days. The PFAS mixture consists of short and long chain perfluoroalkyl carboxylic acids (PFCAs) and perfluoroalkyl sulfonates (PFSAs), a sulfonamide, and fluorotelomer sulfonates. Water, whole-body tissue, and plasma were collected at multiple timepoints, and samples were analyzed via liquid chromatography tandem mass spectrometry. Uptake kinetics were estimated for each PFAS with non-linear regressions for both tissue and plasma. Rapid uptake was observed in both tissue and plasma, reaching pseudo steady-state conditions with 72 – 96 hours. Increasing concentrations of PFAS in tissue and plasma were observed with increasing chain length for both PFCAs and PFSAs. Additionally, ratio based bioaccumulation factors (BAFs), blood:water partitioning coefficients (P_{BW}s), and apparent volumes of distribution (V_Ds), were estimated and relationships with chain length were examined. Significant relationships between BAFs, P_{BW}s, V_Ds, and chain length were observed for both PFCAs and PFSAs. For example, BAFs and P_{BW}s increased with increasing chain length, while V_D decreased with increasing chain length. Relationships between PFAS V_Ds and BAFs were also examined, and a significant relationship was observed for the PFCAs. These are initial results of an ongoing research effort, and recently, 14-d uptake and 7-d elimination studies of these PFAS in adult fathead minnows at differing pH and salinity conditions were completed. Analytical measurements are ongoing, and additional examination of the relationship between apparent V_D and kinetic-based BAFs is being performed, which promises to support the development of a predictive understanding for bioaccumulation of PFAS and ionizable organic contaminants, across environmental gradients, in PFAS contaminated sites.

3.01.A.T-02 Significant Bioaccumulation of NSO-Heterocyclic PAHs in Daphnia Magna Was Observed Under Controlled Exposure with Passive Dosing

Göksu Celik, MSc.[1]*, Stefan Stolte*[2]*, Marta Markiewicz*[3] *and Schylar Alexandra Healy*[4]*, (1)Institute of Water Chemistry, University of Vienna, Vienna, Austria, (2)Institute of Water Chemistry, Dresden University of Technology, Germany, (3)Institute of Water Chemistry, Technical University Dresden, Dresden, Germany, (4)Dresden University of Technology, Germany*

The ubiquity of heterocyclic polyaromatic hydrocarbons (heterocyclic PAHs) substituted with nitrogen, oxygen, and sulfur heteroatoms (also known as NSO-PAHs), along with their potential for persistence and high toxicity, has raised significant concerns regarding their hazard to aquatic life. Heterocyclic PAHs do not undergo mineralization in the standard ready biodegradability test and even in enhanced tests using adapted microbial communities. Their continuous release could lead to increasing environmental concentrations, thereby exacerbating the risks of adverse effects. However, information on their long-term effects is scarce and little is known about their bioaccumulation in aquatic organisms. Testing such hydrophobic compounds is also not trivial, because (i) the exposure concentration decreases rapidly and dramatically, (ii) they require a long time to reach equilibrium concentration in the exposed organism, and (iii) experimental artifacts often occur due to the use of total water concentrations instead of freely dissolved water concentrations, leading to significant underestimation of bioaccumulation. Given these environmental concerns and to address the testing challenges, the main objective of our work is to develop a reliable experimental design to investigate the bioaccumulation of four heterocyclic PAHs (log K_{OW} 5.2 to 6.9). We hypothesize that (1) chemical concentrations in water can be kept stable during exposure even at very low levels (ng/L) using a passive dosing method, and (2) *Daphnia magna* can be used for bioaccumulation assessment as it allows quicker uptake and depuration kinetics than e.g. fish and provides sufficient biomass for reliable chemical quantification in the organism. Stable exposure was achieved by using passive dosing at levels as low as 100 ng/L. Only 5 organisms equivalent to 15-35 mg wet weight (depending on the age of the animal) are necessary to quantify body burdens of tested chemicals. All tested heterocycles were very bioaccumulative with logarithm of lipid-corrected kinetic bioaccumulation factor (log BAF_{KL}) above 7. This study provides insights on our understanding of the environmental impact of NSO-PAHs by revealing high bioaccumulation in *D. magna*, and providing valuable insights for enhancing environmental risk assessments and regulatory measures.

3.01.A.T-03 Integrating in Vitro Intrinsic Clearance (OECD TG 319B) for BCF Prediction in a Regulatory Context – Fragrance Chemicals as Case Studies

Heike Laue[1]*, Karen Jenner*[2]*, Remo P. Badertscher*[1]*, Gordon Sanders*[3]*, Georg Kreutzer*[1] *and Andreas Natsch*[1]*, (1)Givaudan Suisse SA, Switzerland, (2)Givaudan UK Ltd, United Kingdom, (3)Givaudan International SA, Switzerland*

Bioaccumulation in aquatic species is a critical endpoint in the regulatory assessment of chemicals which usually involves the determination of the bioconcentration factor (BCF) in fish. *In vitro* intrinsic clearance ($CL_{IN\ VITRO,INT}$) determined in liver S9 fractions (RT-S9) from rainbow trout (OECD Test Guideline (TG) 319B) may be incorporated into appropriate *in silico* models for the prediction of BCFs. Although use of measured $CL_{IN\ VITRO,INT}$ improves BCF predictions, further confidence building and understanding of the applicability of the TG 319B and prediction models is needed for regulatory acceptance of this *in vitro* approach.

Here we show the integration of the TG 319B method for 10 fragrance chemicals into an environmental risk assessment as part of REACH dossiers for upgrades or registration of new molecules.

Substrate depletion assays were carried out according to TG 319B with 10 different fragrance chemicals (plus individual isomers) with log K_{ow} ranging from 4.4 to 8.3. Chemical concentrations were measured by GC-MS. The resulting $CL_{IN\ VITRO,INT}$ and measured log K_{ow} were used as input in the revised IVIVE by Nichols et al. and an empirical regression model developed based on *in vivo* BCFs, measured $CL_{IN\ VITRO,INT}$ in RT-S9 and log K_{ow} values. For 3 substances, metabolites in RT-S9 were identified by GC-HRMS and LC-HRMS to obtain additional information on the potential metabolic pathways. Due to global registration / RIFM safety assessments, BCFs were subsequently determined *in vivo* for 2 substances.

All fragrance chemicals were significantly biotransformed in RT-S9 with $CL_{IN\ VITRO,INT}$ ranging from 0.22 to 5.63 mL/h/mg protein. Predicted BCFs were similar with the IVIVE and the regression model and below the EU REACH B criterion of 2000 L/kg. The predicted BCFs with the two different models, a physiological based and an empirical model, were all within a factor of two, thus, increasing the confidence of the predicted BCF values. For the two substances with *in vivo* BCFs, the predicted BCFs were in excellent agreement supporting the good predictability of the *in vitro* approach.

Furthermore, glucuronic acid conjugates were identified as phase II metabolites which may be more easily excreted than the parent molecules confirming the low predicted bioaccumulation potential.

The in *vitro method* TG 319B in combination with two different BCF prediction models is well suited to assess the bioaccumulation potential in fish within a regulatory context.

3.01.A.T-04 Application of the Chemical Activity Approach to Assess the Bioaccumulation and Risks of PFAS in Aquatic and Terrestrial Wildlife at PFAS impacted Sites and Ecosystems

Frank Gobas[1]*, Sophia Shu Han Hsu*[2]*, Beatrice Chee*[2]*, Barry C Kelly*[2] *and Samantha Maika*[3]*, (1)Resource & Environmental Management, Simon Fraser University; School of Resource & Environmental Management, Canada, (2)Simon Fraser University, Canada, (3)Resource & Environmental Management, Simon Fraser University, Canada*

The presence of Per- and Polyfluoroalkyl Substances (PFAS) at many sites and ecosystems in the EU, US and elsewhere is generally considered to be of high concern because PFAS are known to bioaccumulate in both aquatic and terrestrial organisms and in humans and can exert adverse effects in wildlife and humans. However, there remains considerable uncertainty about the extent to which various PFAS bioaccumulate in wildlife species. As a result, it is difficult to interpret ambient concentrations in terms of risks to wildlife and to develop guidelines for risk management. Some of the difficulties are related to the high degree of ionization of PFAS in the environment; the high affinity of PFAS for proteins and polar lipids; and the fact that exposure and toxicity data are often expressed in different quantities, which prevents an accurate risk characterization, which involves the comparison of exposure and toxicity data. This study explores the application of the chemical activity approach for the development of aquatic and terrestrial bioaccumulation models for PFAS. This presentation discusses the development of a chemical activity meter and its application for bioaccumulation and risk assessment. The chemical activity approach for bioaccumulation assessment is tested by (i) comparing model predicted bioconcentration factors (BCFs, L/kg, wet wt.) of PFAS and measured BCFs obtained from Burkhard et al. 2021; (ii) comparing predicted and observed concentrations of individual PFAS in organisms of (a) the Lake Ontario food web (b) Canadian Arctic marine food web; (c) a piscivorous estuarine food-web and (d) Canadian Arctic terrestrial food web. Finally, the application of the chemical activity approach for risk assessment of PFOS at contaminated sites in the US is discussed. This includes the determination of risk levels in the risk characterization phase and the derivation of concentration based guidelines that can be used for risk management. We conclude that the chemical activity approach is useful for developing bioaccumulation & food-web bioaccumulation models for PFAS and for expressing exposure and toxicity reference data on a common basis, facilitating risk assessment and guideline development.

3.01.A.T-05 Temperature Effects on Organic Compound Uptake and Elimination Rates in Aquatic Species

Lea Grenc[1]*, Jiaqi Wang, MSc*[1]*, Paul van den Brink*[2] *and Jan A.J. Hendriks*[1]*, (1)Radboud University Nijmegen, Netherlands, (2)Wageningen University & Research (WUR), Netherlands*

Climate change has been driving significant increases in water temperatures. Presence of a wide array of chemicals of emerging concern has been confirmed in various waterbodies around the world. Understanding the dependence of toxicokinetics on temperature in environmental systems is pivotal, spanning from controlled laboratory conditions, typically around 20°C, to the diverse temperatures encountered in the field, ranging across different climate zones from tropical to polar regions. Despite extensive research on individual stressors, the interactions between rising temperatures and chemicals on aquatic species is not well understood.

The aim of this study was, therefore, to bridge this knowledge gap by investigating the relationship between temperature and the uptake and elimination rates of various organic compounds in aquatic animals, predominantly freshwater species.

A comprehensive dataset was compiled to observe the influence of temperature on uptake and elimination rates. We used the Arrhenius equation to establish a correlation between temperature and rates. Furthermore, we adjusted rates to account for organism mass using correlations already established for metabolic rates. Additionally, we integrated octanol water distribution coefficient (D_{OW}) to provide chemical-specific insights into uptake and elimination rates.

The application of the linearized version of Arrhenius equation yielded significant relationship between temperature and both, uncorrected and mass-corrected, uptake and elimination rates. Both showed the increase in uptake and elimination rates with increase in temperature. Additionally, mass correction allowed a generalized overview, revealing the role of organism size in toxicokinetics. Analysis of trendlines for individual chemicals across various species showed that chemicals with higher D_{OW} values exhibit higher uptake rates and, conversely, lower elimination rates compared to those with lower D_{OW} values.

The convergence of increasing water temperatures and the influx of emerging chemicals in the environment signals potential challenges for aquatic species. This study offers a comprehensive overview of temperature effects on organic compound uptake and elimination rates in aquatic species, elucidating the relationship between temperature, chemical compounds, organism characteristics, and toxicokinetics.

3.01.B Advances in Bioaccumulation Science and Assessment

3.01.B.T-01 Advances in Bioaccumulation Assessments of Transformed Nanomaterials Under Environmentally Relevant Conditions

***Sebastian Kuehr**[1], Brian Sinnet[2], Marco Kipf[2], Ralf Kaegi[3], Ralph A Sperling[4], Karl Andreas Jensen[5], Mark Rehkamper[6], Kuria Ndungu[1] and Anastasia Georgantzopoulou[1], (1)Norwegian Institute for Water Research (NIVA), Norway, (2)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (3)Process Engineering, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (4)Fraunhofer IMM - Institute for Microengineering and Microsystems, Germany, (5)Norwegian University of Life Sciences (NMBU), Norway, (6)Imperial College London, United Kingdom*

This study investigates the impact of transformation of engineered nanomaterials (ENM) during wastewater treatment plant (WWTP) processes on their bioavailability and bioaccumulation potential. ENMs released from WWTP by their effluent can accumulate in aquatic sediments.

Bioaccumulation is a concern as this process can increase e.g. ENM concentrations in organisms to a level that can potentially induce effects. *Hyalella azteca*, which is suitable for ENM testing, has been used in several bioaccumulation studies, but previous studies have often overestimated bioavailability by including the gut content during the body burden determination after acid digestion. This is even more problematic for sediment exposure, where the amphipod ingests the sediment.

Isotopically enriched ^{109}AgENM were synthesized for this study to allow tracking their fate at low environmentally relevant concentrations, overcoming the interference from the natural background.

Sludge from an experimental pilot WWTP (running with municipal wastewater) spiked with ^{109}Ag and Au ENM was used to spike artificial sediment for the sediment *H. azteca* bioaccumulation tests. With these tests we wanted to test the hypothesis that WWTP processes reduce the bioavailability and bioaccumulation potential of WWTP-transformable (e.g. AgENM) and chemically inert ENM (e.g. AuENM) under realistic conditions.

In our study the bioaccumulation potential will be assessed by measuring the body burden of ^{109}Ag or Au using Inductively Coupled Plasma - Mass Spectrometry (ICP-MS) and single particle ICP-MS (spICP-MS). In addition, the haemolymph of exposed organisms is isolated and analysed by spICP-MS in order to provide insights into the actual bioavailability of the respective ENM. Nano-specific endpoints as recently proposed for the bioaccumulation assessment of ENM using *H. azteca* will be used to exclude ENM-specific artifacts in the BAF determination.

The use of isotopically enriched ^{109}AgENM is suited for aquatic exposure to follow the fate in different exposure matrices, but also in exposed organisms, despite an elevated natural background. Also, the method of haemolymph isolation and measurement by spICP-MS has been shown to provide valuable data to assess the bioavailability of ENM. The combination of these approaches advances the understanding of the bioaccumulation of WWTP-transformed ENM under environmentally relevant conditions, providing insights into their fate and effects in aquatic ecosystems.

3.01.B.T-02 Biomagnification in Polar Bears: The Role of Interindividual Differences, Dietary Ingestion Rate and the Gut Microbiome

***Yuhao Chen**[1], Terrence Bell[2], Sarra Gourlie[3], Ying Duan Lei[4] and Frank Wania[5], (1)Chemistry, University of Toronto, Canada, (2)aDepartment of Physical and Environmental Sciences, University of Toronto, Canada, (3)Toronto Zoo, Canada, (4)University of Toronto, Canada, (5)Department of Physical and Environmental Sciences, University of Toronto, Canada*

Some of the most troublesome contaminants biomagnify, i.e., achieve higher fugacities in the tissue of an organism f_B than its diet f_D. Thermodynamically, the extent of a chemical's biomagnification is expressed as the fugacity ratio f_B/f_D, which is called a biomagnification factor (BMF) and exceeds 1 if the chemical biomagnifies. Over the past few years, we have developed an entirely non-invasive method towards studying the process of biomagnification that relies on the equilibrium sampling in silicone-film coated vessels and chemical analysis of paired dietary and fecal samples. When combined with dietary intake and egestion rates, the approach yields the thermodynamic limit to a chemical's biomagnification in an organism (BMF_{lim}). A feces-based biomagnification factor (BMF_F) can be estimated, whereby the fugacity in the feces f_F serves as an estimate of f_B. To mimic the seasonal change of food availability in the wild, the Toronto Zoo intentionally varies the feeding rate of polar bears throughout the year to induce hyperphagic and hypophagic periods. We determined BMF_{lim} and BMF_F for three zoo-housed female polar bears on three occasions with different feeding states, using polychlorinated biphenyls as examples of biomagnifying contaminants. All three bears had very high biomagnification capabilities (BMF_{lim} was as high as 200) owing to very efficient lipid assimilation, which can reach as high as 99.5%. We found differences in BMF_{lim} and BMF_F as high as a factor of 3 between bears. Much of that variability can be explained by the differences in the lipid assimilation efficiency. We further observed indications that a period of starvation can increase the lipid assimilation efficiency. The BMF_{lim} and BMF_F of a bear can increase during a period of hypophagia, by as much as a factor of 4. We characterized the gut microbiome in fecal matter using high-throughput 16S RNA gene sequencing to explore its potential influence on lipid assimilation and biomagnification in polar bears. A preliminary result showed the abundance of Enterobacterales is inversely related to the lipid assimilation efficiency and therefore also to *BMF*lim; while the abundance of Bacteroidale does the opposite.

3.01.B.T-03 Using An In Silico NAMs Approach To Predict Bioaccumulation In Fish: A Case Study For Anionic Surfactants Within A Regulatory Context

Jayne Roberts[1], *Andrea Gredelj*[1,2], *Steve Gutsell*[1], *Geoffrey Hodges*[1], *James Dawick*[3], *Lauren McAnally*[4] *and Marc Geurts*[5], *(1)Unilever - Safety and Environmental Assurance Centre (SEAC), United Kingdom, (2)Unilever, United Kingdom, (3)Innospec Limited, United Kingdom, (4)Innospec Limited, (5)Nouryon Chemicals B.V., Netherlands*

Bioaccumulation in aquatic organisms is a standard information requirement under EU REACH for registered substances exceeding 100 tonnes/annum. However, studies such as the fish bioaccumulation test (OECD TG 305) require a significant number of vertebrate animals. Ongoing research and regulatory efforts are directed towards establishing reliable New Approach Methodologies (NAMs) such as predictive techniques and frameworks based on *in vitro* tests and *in silico* modelling. Historically, the octanol-water partitioning co-efficient ($logK_{ow}$) has been used as a screening parameter for determining bioaccumulation potential with defined cut-off values. However, the use of $logK_{ow}$ is not considered appropriate for surfactants, due to experimental difficulties arising from their amphiphilic nature. Surfactants often show a stronger affinity for tissues (e.g. proteins, phospholipids) than storage lipids, therefore, the (phospholipid) membrane-water partition/distribution coefficient (K/D_{mw}) is proposed as a suitable, more biologically relevant descriptor that has also been able to overcome challenges in experimental determination. New guidance from ECHA suggests the use of $logK/D_{mw}$ in conjunction with information on toxicokinetics in aquatic organisms for bioaccumulation assessment of surfactants in a Weight of Evidence (WoE) approach to waive the need for OECD TG 305 vertebrate test. A tiered modelling approach including the use of *in vitro-in vivo* extrapolation (IVIVE) can be used to predict fish BCF of surfactants. One such model, applicable for ionisable chemicals and surfactants is the BIONIC v3 model. By integrating the partitioning behaviour and tissue distribution of a chemical in fish along with information on uptake and elimination kinetics, this model has been shown to produce reliable fish BCF value predictions for several anionic surfactants.

Here, we present a case study for the use of a NAMs approach for assessing bioaccumulation potential within a regulatory context for a series of anionic surfactants (alkyl isethionates). A combination of experimental $logD_{mw}$ and experimental *in vitro* biotransformation data (OECD 319B) was used as input to the BIONIC v3 model to demonstrate low bioaccumulation potential which provides WoE to negate the need for *in vivo* fish BCF studies. Challenges and recommendations for future work to strengthen this approach and demonstrate its applicability within a regulatory context will also be discussed.

3.01.B.T-04 Bioaccumulation and Trophic Transfer of Tire Particles and Associated Chemicals From Aquatic Invertebrates to Fish

Thibault Masset[1], *Florian Breider*[2], *Gabrielle Léger*[1], *Rébecca Beauvais*[3], *William Dudefoi, PhD*[4], *Kristin Schirmer*[4], *Alan J Bergmann*[3], *Etienne Vermeirssen*[3], *Nicolas Delorme*[5], *Arnaud Chaumot*[6], *Olivier Geffard Pr*[7] *and Benoit JD Ferrari*[3], *(1)EPFL, Switzerland, (2)Central Environment Laboratory, Ecole Polytechnique Fédérale de Lausanne – EPFL, Switzerland, (3)Ecotox Centre, Switzerland, (4)Environmental Toxicology, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (5)UR RiverLy - ECOTOX, Laboratoire d'écotoxicologie INRAE, France, (6)INRAE (Institut National de la Recherche Agronomique), France, (7)UR RiverLy, Institut national de recherche pour l'agriculture, l'alimentation et l'environnement (INRAE), France*

Tire and road wear particles (TRWP) are produced by the friction between the tires and the road. Data gaps have been identified regarding their fate and potential toxicological impact on the aquatic ecosystem. Benthic organisms could be exposed to TRWP and associated chemicals through direct contact and/or ingestion. While ecotoxicological studies have mainly focused on pelagic organisms, research concerning benthic organisms remains scarce. As 6PPD-Q has been shown to be highly toxic for some salmonids, it is of critical importance to identify the different routes of exposure for fish to tire-associated chemicals. Among benthic organisms, chironomid larvae and gammarids are commonly predated by fish and could participate in the trophic transfer of TRWP and its associated chemicals in aquatic ecosystems.

Here, we exposed chironomid larvae and gammarids to sediment spiked with 0.5 mass% of cryogenically milled tire tread (CMTT) particles as a proxy for TRWP. After exposure, the invertebrates were collected and subsamples underwent gut depuration before being collected, whereas other subsamples did not. Non-depurated subsamples were used as a surrogate for fish prey in an in vitro digestion scenario. The scenario reproduced the digestion of preys by fish (rainbow trout) for 27 hours using simulated fish digestive fluids. Depurated and non-depurated invertebrates as well as post-digestion gastrointestinal fish fluids were analyzed for organic chemicals and zinc. Pyrolysis-GC/MS analyses were performed on recovered organisms to assess whether ingestion of CMTT occured. Our results showed that chemicals were transferred to the invertebrates' tissues and biota-sediment accumulation factors could be determined. It was shown that invertebrates ingested CMTT that could accumulate in their guts. Chemical analyses revealed that the tire-associated chemicals were present and bioaccessible in the fish digestive fluids following in vitro digestion of CMTT-exposed invertebrates. Overall, our results (i) showed the bioavailability of tire-associated chemicals for fish feeding on contaminated prey and (ii) highlighted the potential for trophic transfer of both tire-associated chemicals and tire particles along the aquatic food chain.

3.01.B.T-05 Surfactant Bioconcentration: The Puzzle Unraveled

Michael McLachlan[1]*, Andrea Ebert*[2]*, James M Armitage*[3]*, Jon A. Arnot*[4] *and Steven Droge*[5]*, (1)Department of Environmental Science, Stockholm University, Sweden, (2)Helmholtz Centre for Environmental Research (UFZ), Germany, (3)AES Armitage Environmental Sciences, Inc, Canada, (4)Arnot Research and Consulting Inc. (ARC), Canada, (5)Environmental Risk Assessment, Wageningen University & Research (WUR), Netherlands*

Assessing the bioconcentration of surfactants is challenging. There are few in vivo data and a strong reliance on predictive tools. However, during the last 3 years in vivo bioconcentration studies for a range of cationic and anionic surfactants in fish have been published, making it possible to develop and evaluate predictive models of surfactant bioconcentration. Here we use the recent developments about surfactant partitioning to develop an interpretive framework to understand how BCF is influenced by surfactant properties (and structure) and environmental pH. We then evaluate this framework using measurements of the BCF and kinetic rate constants of surfactants in fish. Based on a theoretical foundation, equations are developed for the uptake rate constant, the elimination rate constant and BCF as a function of the membrane lipid/water distribution coefficient D_{MLW}, pK_a and pH. The equations are parameterized for a 10 g juvenile rainbow trout and visualized as plots of the output parameters as a function of the neutral fraction of the chemical in the water and log D_{MLW}. Good agreement between the modeled output parameters and in vivo measurements was observed. The framework provides a graphical visualization of the influence of physical chemical properties and pH on BCF. It facilitates understanding of the complex interaction of these parameters and provides a mechanistic interpretation. It can be used to predict the bioconcentration behaviour of untested surfactants and to pinpoint key deficits in our mechanistic understanding.

3.01.P Advances in Bioaccumulation Science and Assessment

3.01.P-Th119 The Decotabs as Standardized Food Substrate for Ecotoxicity Bioassays in Gammarus Fossarum

Anthony Gérard Edouard Mathiron[1]*, Vanessa Brosselin*[2]*, Guillaume Jubeaux*[2] *and Olivier Geffard Pr*[3]*, (1)Biomae, France, (2)BIOMAE - CARSO LSEHL, France, (3)UR RiverLy, Institut national de recherche pour l'agriculture, l'alimentation et l'environnement (INRAE), France*

Feeding rate inhibition is one of the first observed responses when animals are exposed to toxic stress. Its measurement is recognized as relevant tool for studying chemical compounds toxicity under laboratory condition and large-scale aquatic systems quality assessment through active biosurvey . The measurement of feeding rate in *Gammarus fossarum* is currently based on *Alnus glutinosa* leaf discs. However, using leaf discs introduces a risk of chemical contamination of collected leaves, and may be a source of variability in appetency between each leaves sampling. At last, this methodology needs to anticipate the number of experiments and store the leaves which are collected once a year over a very short period of time. Decomposition and consumption tablets (DECOTABs) represent a surrogate plant litter substitute to study the invertebrate consumption of organic matter in aquatic environments. Recently, DECOTABs have been proposed as substrate for the *Hyalella azteca* Bioconcentration Test (HYBIT). Developing DECOTABs for *Gammarus fossarum* bioassays would make it possible to source and control food composition (nutritional quality and presence of chemical inputs) and standardize its application in biomonitoring programs. Here, we started by investigating during 7 days the kinetic of alimentation on DECOTAB cubes with two different compositions (either TetraMin flake food or shrimp pellets), and we compared the results with those on leaf disks. Food consumption was higher on both TetraMin cubes and leaf discs compared to shrimp cubes, but no difference was observed between leaf discs and TetraMin cubes. Our results suggest that TetraMin DECOTABs are good candidate as substitute of leaf discs. Complementary experiments both in the lab and in the field will help to determine if TetraMin DECOTABs can be employed for ecotoxicity bioassays in *Gammarus fossarum*.

Key-words**:** ecotoxicology; behaviour; alimentation; survival; gammarids

3.01.P-Th120 HYBIT protocol application in European freshwater amphipods Gammarus fossarum: Case studies with terbutryn and 2,4,5-trichlorophenol

Anthony Gérard Edouard Mathiron[1]*, Vanessa Brosselin*[2]*, Nicolas Delorme*[3]*, Olivier Geffard Pr*[4]*, Guillaume Jubeaux*[2]*, Mathieu Coquerelle*[5]*, Anthony Catroux*[5]*, Mickael Nicolas*[5]*, Pascal Pandard*[6]*, Guillaume Cottin*[7]*, Alaa Bensetra*[8]*, Céline Le Cocq*[9] *and Cyril Sweetlove*[7]*, (1)Biomae, France, (2)BIOMAE - CARSO LSEHL, France, (3)UR RiverLy - ECOTOX, Laboratoire d'écotoxicologie INRAE, France, (4)UR RiverLy, Institut national de recherche pour l'agriculture, l'alimentation*

et l'environnement (INRAE), France, (5)CARSO-LSEHL, (6)Institut National de l'Environnement Industriel et des Risques (INERIS), France, (7)L'Oréal, France, (8)Analytical chemistry, L'Oréal, France, (9)L'Oreal Research & Innovation, France
The bioconcentration factor (BCF) is the ultimate decisive bioaccumulation criterion as part of the regulatory chemical safety assessment of pollutants. The *Hyalella azteca* Bioconcentration Test (HYBIT) provided a non-vertebrate alternative for fish bioconcentration studies. The aim of this study was to investigate the applying of the HYBIT protocol to other amphipod species, such as the European species *Gammarus fossarum*. To do so, we determined in semi-static conditions the kinetics of bioaccumulation and depuration of terbutryn (herbicide of the triazine family) and 2,4,5-trichlorophenol (bactericidal component) in gammarids by following the HYBIT protocol. Amphipods were exposed to chemicals dissolved in water for 3 days (uptake phase; 42.2 $\mu g.L^{-1}$ and 4.8 ± 0.2 $\mu g.L^{-1}$, respectively for terbutryn and 2,4,5-trichlorophenol), then transferred to controlled conditions for 3 days (depuration phase). Pools of individuals and water samples were collected and analysed at different intervals. First results show that the mortality rate remained below 20% regardless of the treatment (14.2% and 9.2%, respectively for terbutryn and 2,4,5-trichlorophenol), which meets one of the validity criteria of the HYBIT protocol. Water and gammarid tissue analyses allowed us to calculate BCFs values (BCF = 0.8 and 162 respectively for terbutryn and 2,4,5-trichlorophenol) which were compared to those in *H. azteca*. While BCFs were relatively similar in both species regarding 2,4,5-trichlorophenol, BCF was significantly lower in *G. fossarum* than in *H. azteca*. Overall, our study suggests that HYBIT protocol can be applied to a European amphipod species but also highlights that molecules can bioaccumulate differently in relatively similar species, making model predictions more difficult than expected.

Key-words: ecotoxicology; laboratory exposure; bioconcentration factor; gammarids

3.01.P-Th121 Uptake of Venlafaxine and its Metabolite O-Desmethyl-Venlafaxine in Lettuce under Hydroponic Conditions

*Zhen Wang[1], **Lucas Leonel Alonso**[2,3], Josephine Vosse[2,3], Damia Barcelo[2], Minghua Wang[4], Gianluigi Buttiglieri[2,3] and Sara Rodriguez-Mozaz[2,3], (1)Department of Pesticide Science, College of Plant Protection, State & Local Joint Engineering Research Center of Green Pesticide Invention and Application, Nanjing Agricultural University, China, (2)Catalan Institute for Water Research (ICRA), Spain, (3)University of Girona (UdG), Spain, (4)Nanjing Agricultural University, China*
The presence of antidepressants like Venlafaxine (VFX) and its metabolite O-desmethyl-venlafaxine (OD-VFX) in urban waters and reclaimed water presents concerns regarding their impact on organisms and the food chain, particularly in agricultural water reuse. This study investigates VFX and OD-VFX uptake and translocation in lettuce under hydroponic conditions, considering enantioselectivity. In a controlled hydroponic system, four treatment groups were studied: R/S-Lettuce-VFX, R/S-Lettuce-OD-VFX, Control-Lettuce, and Abiotic-Control. Solutions for each treatment, of 100 µg/L (50 µg/L each enantiomer) were prepared, renewed twice weekly, and sampled at 0, 2, and 4 weeks. Water samples were directly injected, while lettuce samples underwent bead-beating/SPE extraction and UPLC-QqLIT analysis. Both compounds were absent in the control hydroponic solution. Reduction in concentrations occurred in abiotic conditions, while higher concentrations in the output of lettuce systems were observed. Enrichment of R-enantiomer in OD-VFX treatments suggests aerobic degradation of the S-OD-VFX. Growth of lettuce was unaffected by the presence of the drugs. VFX and OD-VFX uptake occurred in roots and shoots at 2 and 4 weeks. OD-VFX exhibited higher uptake in roots, possibly due to its increased hydrophilicity, indicating facilitated transport. Root concentrations were consistently higher than shoots. OD-VFX showed lower translocation factor values, suggesting greater retention in roots than VFX. Enrichment of S-VFX in shoots aligns with reported preferential metabolism of R-VFX. The study revealed a chiral selectivity, with a higher transformation of R-enantiomers to metabolites. Notably, both drugs reached aerial lettuce tissue, emphasizing the need for future studies considering environmental concentrations and polluted water exposure in hydroponic conditions. In summary, VFX and OD-VFX uptake in hydroponically grown lettuce, primarily in roots, displayed chiral selectivity with metabolite transformation. Understanding their behavior under varying environmental concentrations is crucial for assessing their risks in agricultural settings utilizing polluted waters.

3.01.P-Th122 Bioturbation Affects Bioaccumulation of Per- and Polyfluorinated Substances (PFAS): Uptake from Sediments by a Rooting Macrophyte and a Benthic Invertebrate

***Ioanna Spyridoula Gkika**[1], Michiel Kraak[2], Cornelis A.M. van Gestel[3], Thomas L. ter Laak[4], Annemarie van Wezel[1], Robert Hardy[2], Mohammad Sadia[5] and Arie J. Vonk[2], (1)University of Amsterdam, Institute for Biodiversity and Ecosystem Dynamics (IBED), Netherlands, (2)University of Amsterdam, Institute for Biodiversity and Ecosystem Dynamics, Freshwater and Marine Ecology (FAME), Netherlands, (3)Amsterdam Institute for Life and Environment (A-LIFE), Vrije University Amsterdam, Netherlands, (4)KWR Water Research Institute, Netherlands, (5)University of Amsterdam (UVA), Netherlands*
Per- and Poly Fluorinated Substances (PFAS) are a widely used group of anthropogenic compounds, with a multitude of industrial and consumer applications. The widespread use of PFAS together with their persistence and bioaccumulation potential has led to global contamination of the abiotic and biotic environment. Nevertheless, their distribution across environmental compartments, including the potential uptake by aquatic plants, remains largely understudied. The aim of the present study was therefore to investigate the presence of PFAS from different chemical classes in sediments, to assess their bioaccumulation in an aquatic plant and a benthic invertebrate, and to examine the effects of bioturbation by a sediment dwelling invertebrate on the distribution and uptake of PFAS by the plants. To this end, sediments originating from a heavily PFAS-contaminated and a reference site were collected. Rooting macrophytes (*Myriophyllum spicatum*) were exposed to these sediments under laboratory conditions. After 28-days, in half of the replicates, a sediment dweller (*Lumbriculus variegatus*) was introduced and left there for another 28 days. At the end of the 56-day experiment, PFAS concentrations were quantified

in sediment, water, roots, shoots, and worms. The bioaccumulation of a variety of PFAS in the plants was determined in the presence and absence of the worms. In total 21 and 29 out of the 43 PFAS screened for were detected in the reference and contaminated sediments, respectively, with the concentrations and profiles varying significantly between the sediments. Several of these compounds were also found in the worms and almost all were detected in the *M. spicatum* tissues, with the sum of PFAS concentrations by far exceeding that in the original sediments. The PFAS distribution over the different compartments was affected by the presence of the worms, significantly reducing the PFAS concentrations in the plant tissues. This effect was more evident for the precursors, suggesting potential (bio)transformation of these compounds into their sulfonic acid end products when worms were present. Our results highlight that a wide spectrum of PFAS detected in aquatic environments can be taken up by macrophytes and benthic invertebrates and that the presence of a sediment dweller can affect PFAS distribution and bioaccumulation in aquatic ecosystems.

3.01.P-Th123 Trophic Transfer of Halogenated Organic Pollutants in a Wetland Food Web: Insights from Compound-Specific Nitrogen Isotope of Amino Acids and Food Source Analysis

Yanhong Zeng*, Yi-Ye Jiang, Xiao-Jun Luo and Bixian Mai, Guangzhou Institute of Geochemistry, Chinese Academy of Sciences, China*

Halogenated organic pollutants (HOPs) in wetlands are of particular concern because of their adverse effects on wetland biota. However, owing to the limitations of food source analysis techniques and trophic position (TP) quantification techniques (bulk-N-SIA), studies on HOPs trophic transfer have mainly focused on single aquatic food chains or terrestrial food chains, whereas few studies have been conducted on HOPs bioaccumulation and biomagnification behavior in wetland food webs, in which aquatic and terrestrial food chains interact. To address the above issues, this study developed a trophic position model (TP_{mix} model) using compound-specific nitrogen isotopic analysis of amino acids (AAs-N-CSIA) with multiple food source analyses (simmr and QFASA models). This model simultaneously considered a food web with diverse consumers and primary producers and was applied to construct a wetland food web in Southern China. We also investigated the trophic transfer of HOPs in food webs.

By comparing the plausibility of the feeding relationships between organisms and the reliability of the quantified TMFs of HOPs in the wetland food web, we found that the TP_{mix} model more accurately characterized the structure of the wetland food web and significantly improved the reliability of the TMFs compared to the TP_{bulk}, TP_{AAs}, and TP_{simmr} models. Food source analysis revealed that the food web consists of three interlocking food webs (kingfisher, crab, and amphibian (frogs)). The TMF calculated using TP_{mix} in the three food webs was significantly higher than that calculated using TP_{bulk}, indicating that TP_{bulk} seriously underestimated the HOPs biomagnification capacity. Additionally, the parabolic trends of TMF_{mix} across combinations of log K_{OW} in the aquatic food web (kingfisher and crab) were similar to those reported in previous studies. However, the parabolic trends of lg $TMFs_{mix}$ across combinations of log K_{OW} in amphibian (frog) food web were distinct from those of aquatic food webs (kingfisher and crab), which may be related to the differences in the biological composition of the food web and HOP bioaccumulation pattern between aquatic and terrestrial organisms. In summary, this study provides a new tool to accurately study the trophic transmission of HOPs in wetlands and terrestrial food webs with diverse species and complex feeding relationships.

3.01.P-Th124 Bioaccumulation, translocation and biomagnification of tetrabromobisphenol A and hexabromocyclododecane in mangrove wetlands from South China

Yuxin Sun*, School of Environment, South China Normal University, China*

Tetrabromobisphenol A (TBBPA) and hexabromocyclododecanes (HBCD) are of ecological concern due to their ubiquitous presence and adverse effects. There is a paucity of data on environmental fate of such compounds in mangrove wetlands. In this study, mangrove sediments, plants and biota were collected from the Pearl River Estuary (PRE) and Jiulong River Estuary (JRE) in South China to investigate bioaccumulation, translocation and biomagnification of TBBPA and HBCD. *γ*-HBCD and *α*-HBCD was the two main diastereoisomer of HBCD in mangrove sediments. Sediments were selectively enriched for (-)-*γ*-HBCD. TBBPA concentrations in mangrove sediments from Guangzhou rose during 2012-2015 and declined from 2015 to 2021. HBCD concentrations in the PRE mangrove sediments exhibited an increasing trend from 2012 to 2021. Tissue-specific accumulations were observed, varying with plant species and compounds. HBCD diastereoisomer patterns were similar for all plant species. γ-HBCD was the major diastereoisomer in roots, while α-HBCD dominated in stems and leaves. The predominance of α- HBCD in aboveground tissues may be ascribed to diastereoisomer-specific translocation, isomerization and/or metabolization in mangrove plants. Preferential enrichment of (−)-α-, (−)-β- and (+)-γ-HBCD was found in all mangrove plant tissues, suggesting the enantioselectivity for HBCDs in mangrove plants. Translocation factors of HBCD diastereoisomers and log Kow were negatively correlated, indicating passive translocation of HBCD, driven by water movement during transpiration. Sediment-root bioaccumulation factors and log TFs both showed no obvious correlation with log Kow of HBCD diastereoisomers. *α*-HBCD was dominant in the mangrove biota. A significant enrichment of (−)-*α*-HBCD was found in the biota. Bioaccumulations were seen for TBBPA and *α*-HBCD as their biota-sediment accumulation factors were greater than 1. (−)-*α*-HBCD had significantly greater BSAFs than (+)-*α*-HBCD, indicating the preferential bioaccumulation of (−)-*α*-HBCD. Biomagnification factors of TBBPA ranged from 0.83 to 1.51, which varied among feeding relationships and mangroves. Positive relationships were found between TBBPA concentrations and trophic levels of the biota species with trophic magnification factors of 2.17 for the PRE and 1.22 for the JRE, suggesting that TBBPA biomagnifies in the mangrove food webs. No biomagnifications were observed for ΣHBCD, *α*-HBCD and its enantiomers.

3.01.P-Th125 Optimization of a deep learning-based automated sorting robot for bioconcentration studies with the fresh amphipods Hyelella azteca

Cyril Sweetlove[1]*, Guillaume Cottin*[1]*, Céline Le Cocq*[2]*, Elsa Païva*[2]*, Alaa Bensetra*[3]*, Jan de Sonneville, PhD*[4] *and Kees-Jan Van Der Kolk*[4]*, (1)L'Oréal, France, (2)L'Oreal Research & Innovation, France, (3)Analytical chemistry, L'Oréal, France, (4)Life Science Methods, Netherlands*

Abstract

Bioconcentration factors are usually determined by fish flow-through tests performed according to the OECD 305 technical guidance (OECD, 2012) that are time consuming, expensive, and consumer of a large number of laboratory animals. Alternative test design using the freshwater amphipod Hyalella azteca for bioconcentration studies has been recently developed and highlighted a high potential with good correlation with fish BCF values. For bioconcentration studies using H. azteca, male amphipods should be preferred to female organisms. The manual sexing of male adult amphipods is obviously time consuming and requires care and skills. A deep learning-based automated sorting robot has been develop for H. azteca by the Life Science Methods company (https://www.lifesciencemethods.com).Nevertheless, for experimental reasons, an anesthesia step is necessary prior to the automatic selection. In this study, we showed that a single-pulse of 90 minutes of tricaine at the concentration of 1 g/L can be used and recommended for further studies since it allows time to select H. azteca males manually or automatically using the robot without any harmful effect to the organisms. In a second part we exhibited that the robot has the ability to select, sort and disperse the males of a whole batch of H. azteca as efficiently as manually but quicker with less risk to damage or stress the living organisms. In a last part of the study, the bioconcentration factor of two well-known organic substances (terbutryn and prochloraz) combining or not the use of an anesthetizing step, the automated selections of male and the HYBIT (H. azteca bioconcentration test) protocol was evaluated. The different BCFs values obtained in this study for prochloraz and terbutryn were in accordance with those indicated in the literature and showed that an anesthetizing step had no effect on the BCFs values. Therefore, these data validated the utility and interest for this novel gender-based sorting machine developed by life sciences methods for selecting males in order to perform bioconcentration studies with H. azteca.
Based on these initial results, and considering technological developments, the automated sorting robot is currently being further developed to improve sorting speed and enable sorting on the basis of developmental and phenotypic criteria for ecotoxicity tests associated with these bioconcentration tests under the HYBIT guideline

3.01.P-Th126 Assessing Bioaccumulation with the Biomagnification Factor (BMF)

Frank Gobas[1]*, Nicole Berg*[2]*, Aaron Redman*[3]*, Thomas Parkerton*[3] *and Louise Camenzuli*[4]*, (1)Resource & Environmental Management, Simon Fraser University; School of Resource & Environmental Management, Canada, (2)Resource & Environmental Management, Simon Fraser University, Canada, (3)ExxonMobil Biomedical Sciences, Inc., (4)ExxonMobil, Belgium*

The Bioconcentration Factor (BCF) has played a key role in identifying the bioaccumulation potential of organic substances in aquatic organisms. However, the BCF has some key limitations, including its onerous and difficult measurement in laboratory tests (especially for very hydrophobic substances); limited domain of applicability (i.e. water breathing organisms only); and lack of thermodynamically or biologically relevant criteria values that can be used to determine if a substance is truly bioaccumulative. It has been proposed that the biomagnification factor (BMF) is a more generally applicable metric (i.e. applies to water and air-breathing organisms) with thermodynamically and biologically relevant criteria values, that can be measured in laboratory based tests that are simpler than BCF tests and can also be derived from field data. One of the key questions for using the BMF in bioaccumulation assessments is how the BMF compares to the BCF and what this means for bioaccumulation assessment. To address this question, we compiled data from 258 dietary and 350 aqueous bioaccumulation studies in fish to provide a data base for the BCF and the BMF for the same chemical and the same fish species. This data base was used to investigate (i) the application of a linear regression relationship between the BCF and the BMF; and (ii) the application of the ADME-B(ioaccumulation) approach for regulatory bioaccumulation assessment. The data indicate a weak correlation between the BCF and the BMF for all data combined. This suggest that any correlation between the BCF and BMF is dependent on the chemicals selected. Comparing BCFs derived from dietary bioaccumulation tests using the ADME-B approach are in reasonable agreement with independently observed BCFs in the same fish species. The ability to derive both BCF and BMF data from the results of dietary bioaccumulation tests provides a weight-of-evidence approach where based on the BCF and BMF values for the substance, the substance can be categorized as non-bioaccumulative, bioaccumulative and very bioaccumulative.

3.01.P-Th127 Bioaccumulation of Caffeine in Organisms of Different Trophic Levels

Alma Sobrino-Figueroa[1] *and Sergio Alvarez-Hernandez*[2]*, (1)Hidrobiology, Metropolitan Autonomous University (UAM) Iztapalapa, Mexico, (2)Autonomous Metropolitan University-Iztapalapa, Mexico*

Caffeine is a natural constituent of more than 60 species of plants. It is found in the daily diet in beverages such as coffee, tea, chocolate, energy drinks and some soft drinks. It is considered the most consumed stimulant substance worldwide. It has been detected in concentrations between 1 and 3,293 µg/L in natural waters and treatment plants, since it is highly soluble in water. There are few studies on the effects that this compound can cause in aquatic organisms. For all of the above, the objective of this work was to evaluate the accumulation of caffeine in tissues of aquatic organisms of different trophic levels, the microalgae *Monoraphidium pusillum*, the cladoceran *Daphnia magna* and the fish *Danio rerio*. Bioassays were carried out where the organisms were exposed to four concentrations of caffeine (0.025, 0.05, 0.1 and 0.5 mg/L); the microalgae and cladocerans were exposed for 5 days and the fish for 10 days. At the end of the exposure period, the extraction was carried out

with a water-ethanol mixture (1:1), by means of sonication. The extracts were analyzed by fluorometry (262 nm) to determine the caffeine concentration. In the tests carried out with the microalgae, it was observed that the bioaccumulation factors varied from 1.6 to 15.8. In the bioassays with cladocerans, values of 3.4 to 7.5 were obtained and in the tests with fishes the bioaccumulation factors varied from 1.4 to 4.1.

3.01.P-Th128 Biodistribution of europium-doped polystyrene nanoplastics in terrestrial crustacean Porcellio scaber

Anita Jemec Kokalj[1], *Sara Novak*[1], *Gregor Marolt*[2], *Jernej Imperl*[2], *Rok Kostanjšek*[3], *Andraz Dolar*[1], *Laura Zantis*[4], *Thijs Bosker*[4] *and Damjana Drobne*[1], *(1)University of Ljubljana, Biotechnical Faculty, Slovenia, (2)University of Ljubljana, Faculty of Chemistry and Chemical Technology, Slovenia, (3)Department of Biology, University of Ljubljana, Biotechnical Faculty, Slovenia, (4)Leiden University, Netherlands*

The biodistribution of nanoplastics in organisms is currently largely unknown. One of the options is to track nanoplastics labeled with metals, such as for example europium (Eu). We investigated the biodistribution of two Eu-doped polystyrene nanoplastics (EuPSs) with different sizes ~ 100 nm, and 300 nm in woodlice *Porcellio scaber*. Dissolution of Eu from EuPSs in deionised water was negligible (0.9% and 0.0002% for 100 nm and 300 nm, respectively). Water suspension of EuPSs (10 µg Eu/g dry leaf) was applied onto the hazelnut leaves upper surface, and fed to woodlice for 14 days. In addition, a positive control, $EuCl_3$ was tested (10 and 100 µg Eu/g dry leaf). We used three approaches to track Eu in woodlice: the total Eu in the gut, hepatopancreas (digestive gland), and rest of the body using inductively coupled plasma mass spectrometry (ICP-MS), laser ablation (LA) ICP-MS to investigate the distribution on whole animal sections (chemically fixed using modified Karnovsky fixative and embedded in paraffin) and X-ray microtomography (micro-CT) on whole animals (fixed and dried using standard protocols for scanning electron microscopy). Both ICP-MS measurements and LA-ICP-MS revealed that most of Eu remains in the gut when animals are exposed to EuPSs. However, some Eu was also detected in the rest of the body (potentially the body surface) and in the digestive gland. The total concentration of Eu in the gland as measured by ICP-MS in the case of EuPS exposures was comparable to those of the lowest concentration of $EuCl_3$ salt (10 µg Eu/g dry leaf), but a much higher concentration of Eu was measured in the case of the highest concentration of $EuCl_3$ salt (100µg Eu/g dry leaf). This is the first study of using the micro-CT to map Eu in whole organisms. We managed to obtain representative 3D images of the internal anatomy of the animals and signals indicating the presence of Eu mainly in the gut. Although the unanimous interpretation of the distribution of the doped nanoplastic in the animal was obscured by a relatively low Eu signal, the detection of $EuCl_3$ (100 µg Eu/g dry leaf) in the hindgut epithelium proved the potential of micro-CT analysis in similar studies. Overall these results indicate that Eu was assimilated in the glands of woodlice. Either Eu dissolved from EuPSs in the acidic digestive tract or EuPSs entered the lumen of the glands. This will be investigated further with more specific methods.

3.01.P-Th129 Species-specific prey uptake and biotransformation of chiral polychlorinated biphenyls in riparian and aquatic food webs

Bixian Mai, *Guangzhou Institute of Geochemistry, Chinese Academy of Sciences, China*

The atropisomeric enrichment of chiral polychlorinated biphenyls (PCBs) can trace the movement of PCBs by food webs, but it is a challenge to elucidate the prey uptake and stereoselective biotransformation of PCBs in different species. The concentrations and enantiomer fractions (EFs) of chiral PCBs in invertebrates, fishes, amphibians, and birds were investigated. Chiral PCB signature was estimated in total prey for different predators based on quantitative prey sources. The nonracemic PCBs in snakehead (*Ophiocephalus argus*) were mainly from prey. EFs of PCBs in amphibians and birds were mainly influenced by biotransformation, which showed enrichment of (+)-CBs 132 and 135/144 and different enantiomers of CBs 95 and 139/149. Biomagnification factors (BMFs) of chiral PCBs were higher than 1 for amphibians and passerine birds and lower than 1 for kingfisher (*Alcedo atthis*) and snakehead. BMFs were significantly correlated with EFs of chiral PCBs in predators and indicative of atropisomeric enrichment of PCBs among different species. Trophic magnification factors (TMFs) were higher in the riparian food web than in the aquatic food web due to the high metabolism capacity of chiral PCBs in aquatic predators. The results highlight the influences of species-specific prey sources and biotransformation on the trophic dynamics of chiral PCBs.

3.01.P-Th130 Development and Evaluation of Aquatic and Terrestrial Food Web Bioaccumulation Models for Per- and Polyfluoroalkyl Substances

Barry C Kelly[1], *Jennifer Sun*[2], *Mandy McDougall*[3], *Elsie Sunderland*[2] *and Frank Gobas*[4], *(1)Simon Fraser University, Canada, (2)Harvard University, (3)Dillon Consulting, Canada, (4)Resource & Environmental Management, Simon Fraser University; School of Resource & Environmental Management, Canada*

There is a need for reliable models to predict the food-web bioaccumulation and assess ecological and human health risks of per- and poly-fluoroalkyl substances (PFAS). In the present study, we (i) develop food-web bioaccumulation models for PFAS and (ii) evaluate the performance of the model using available laboratory and field data. We employ a simple mass balance modelling approach, which has proven useful for modelling non-polar lipophilic contaminants in aquatic and terrestrial food webs. For the current PFAS models, we use six different distribution coefficients to represent equilibrium partitioning of a given PFAS in organisms and derive rate constant (k) values. These include distribution coefficients for albumin-water (D_{ALB-W}), transporter protein-water (D_{TP-W}), structural protein-water (D_{SP-W}), neutral lipid-water (D_{NL-W}), phospholipid-water (D_{MW}), and carbohydrate-water (D_{CW}). The models are designed to predict internal whole-body and tissue-specific concentrations (C_B, ng/g) and activities (a_B, unitless) of individual PFAS and can be applied to aquatic (freshwater, marine) and terrestrial food webs. Chemical activity, (a, unitless) is related and can be approximated by the chemical concentration (C, mol/m^3) and solubility or sorptive capacity (S, mol/m^3), i.e., a = C/S. A chemical-activity-based biomagnification factor (BMF) is determined as the ratio of the PFAS activity in the predator (a_B) and its diet (a_D), i.e., a_B/a_D. A predator-diet chemical activity ratio > 1 indicates the occurrence of biomagnification. Results show that model predictions of laboratory measured bioconcentration factors (BCFs, L/kg) and field based bioaccumulation factors (BAFs,, L/kg) of PFAS in fish were in good agreement with observed data. For example, mean model biases (MB, ideal MB =1) for predicted whole-body BCFs of PFAS was 0.98. Model predicted concentrations of PFAS in aquatic and terrestrial food webs were also in reasonable agreement with empirical observations. Modelling results indicate food web specific magnification of PFAS, with the highest degree of biomagnification occurring in food webs comprised of air-breathing wildlife. Albumin-water, structural-protein-water, membrane-water distribution coefficients ($D_{\text{ALB-W}}$, $D_{\text{SP-W}}$, D_{MW}) and renal clearance rate (CL_R) are among the most important model parameters. With further development and testing, these mechanistic models may be useful for future PFAS screening and risk assessment initiatives.

3.01.P-Th131 Metabolic activities in Rainbow trout (Oncorhynchus mykiss) S9 fractions from liver and extrahepatic organs as an alternative in vitro ecotoxicity assessment approach

*Marcel Reu, **Tanja Krimmling**, Melissa Thiede, Amani Alkufairi, Alexander Sattler, Kim Damrau, Jennifer Schuldt and Dieter Runge, Primacyt Cell Culture Technology GmbH, Germany*

Whole body biotransformation rate constants can be calculatet using an appropriate *in vitro* to *in vivo* extrapolation (IVIVE) model. These models use $CL_{\text{IN VITRO, INT}}$ rates derived with OECD Test Guideline 319B or 319A to estimate liver clearance rates, which are then extrapolated to a whole-body (*in vivo*) biotransformation rate constant. However, beside the liver, extrahepatic organs may also display Phase I and Phase II biotransformation activities and thereby play a role in metabolic clearance and bioaccumulation of compounds. To adress these questions, we have maintained rainbow trout (Oncorhynchus mykiss) under controlled housing conditions according to OECD 319A/B. Specimens of eight sexually immature animals were harvested and pooled, including liver, gill, intestine, brain, heart and spleen. S9 fractons were prepared to determine the Phase I and Phase II enzyme activities by Liquid Chromatography-Mass Spectometry analysis. Cytochrome P450 activities, glucoronidation and sulfatation activities were analyzed. The liver displayed the highest Cytochrome P450 activities of all organs tested. Chorzoxazone Hydroxylase activity was only detectable in liver, 1-OH-Midazolam Hydroxylase activity was mainly restricted to liver, minor activities could be detected in intestine. However, Phenacetin-O-Deethylation was also detectable of in the intestine (34%), gill (16%) and spleen (11%) compared to total enzyme activity. Diclofenac-hydroxylase activity was present in all organs, as well as Bupropion-4-Hydroxylase activity, which was more or less evenly distributed among all organs. Phase II activities were detected in the liver, gill, intestine and heart, but not in spleen or brain. In summary, the liver is the mahor organ for detoxification of compounds. However, extrahepatic organs, mainly intestine and gill, but also the brain, heart and spleen exhibit substantial cytochrome P450 activities. Phase II enzyme activities were also detected in the intestine and gill. Our results suggest that extrahepatic organs, mainly instestine and gill, should also be taken into account when bioaccumulation and *in vitro* clearance reates are determined for IVIVE modeling in rainbow trout.

3.01.P-Th132 A Food Web Bioaccumulation Model for Quantifying the Dietary Exposure to Persistent Organic Pollutants of Beluga Whales from the St. Lawrence Estuary, Quebec, Canada

***Jenny Oh**[1], Leslie J Saunders[2], James M Armitage[3] and Frank Wania[4], (1)Department of Chemistry, University of Toronto, Canada, (2)Concawe, Belgium, (3)AES Armitage Environmental Sciences, Inc, Canada, (4)Department of Physical and Environmental Sciences, University of Toronto, Canada*

The elevated levels of persistent organic pollutants (POPs) in beluga whales (*Delphinapterus leucas*) of the St. Lawrence Estuary (SLE), classified as an endangered species, may be linked to their current population stagnation, despite many recovery efforts. However, a quantitative assessment of the bioaccumulation of POPs in the aquatic food web leading up to the SLE beluga whales has not yet been done. Therefore, as part of the ongoing effort in their population conservation, further understanding the diet of the SLE belugas and modeling the bioaccumulation of contaminants through their food web may help shed light on the dietary exposure pathways of these whales. Here, we construct a food web with feeding relationships and diet compositions of male and female SLE beluga whales using previously reported stomach contents data and staple isotopic ratio measurements (i.e., $\delta^{13}C$, $\delta^{15}N$) in beluga muscle tissue. Eleven potential prey species of the belugas were identified, whose feeding relationships, diet composition, and trophic position were estimated from the diets reported for each species in the literature. Using these feeding preference matrices of the aquatic food web and organism-specific characteristics collected from the literature, we parameterized a previously published food web model, which utilises a mass balance approach to calculate steady-state concentrations of lipophilic chemicals in each of the organisms. The final assembled food web model includes phytoplankton, zooplankton (copepods and krill), seven invertebrate species, and nine fish species. We applied the model to quantify the bioaccumulation of several classes of POPs, including polychlorinated biphenyls, perfluoroalkyl sulfonamides, and halogenated flame retardants in the prey species of the SLE belugas. We also compared the predicted results with measured concentrations of these contaminants in the aquatic species of the SLE to evaluate the model performance, which consisted of analyzing 189 samples of the SLE prey species for all compounds of interest.

3.01.P-Th133 Enabling Regulatory Confidence in the Reliability of Stable Isotope Data Used to Describe the Trophic Position of Organisms in Bioaccumulation Studies

***Harriet Sleight**, Steph Jones, Pippa Kate Curtis-Jackson and John Crosse, Chemicals Assessment Unit, Environment Agency (England), United Kingdom*

An important environmental priority under the United Kingdom’s Registration, Evaluation, Authorisation and restriction of Chemicals (UK REACH) regulations is the identification of persistent, bioaccumulative and toxic (PBT) and very persistent, very bioaccumulative (vPvB) substances. Assessment of a substance's potential to bioaccumulate is usually determined from a measured bioconcentration factor in an aquatic species, in laboratory studies (e.g. according to OECD Test Guideline 305, 2012).

However, other scientific information can be used as part of a weight-of-evidence approach. This can include information on the ability of a substance to biomagnify in a food chain. An increasing number of publications use stable isotopes of carbon (^{12}C and ^{13}C) and nitrogen (^{14}N and ^{15}N) to describe the trophic position of organisms. When combined with data on the concentration of a substance in those organisms, biomagnification factors (BMFs) and/or trophic magnification factors (TMFs) can be calculated.

Very little regulatory guidance is available on the measurement and interpretation of stable isotope data, which reduces confidence in derived BMF/TMFs. This study aimed to address this by systematically reviewing: 1) best practice and recommendations for isotopic analysis across multiple disciplines; and 2) natural and anthropogenic sources of variation within stable isotope measurements.

Search strings were run on both "Scopus" and "WebOfScience" in July 2023. The results were combined (n = 2049) and duplicates (n = 805) removed, with 1244 discrete sources subjected to primary and secondary screening. Best practices were identified across sample collection, preparation, calibration, analysis and correction, and reporting stages. Potential sources of variation identified included: organism sex, size, age, specific tissue sampled, population sampled, season, climate and anthropogenic influences.

A draft guidance document was produced to facilitate assessments of stable isotope data, increasing regulatory confidence in the robustness and reliability of those data. In turn, this will facilitate the use of BMF/TMF studies in decision making. In addition to regulators, this work will be of interest to researchers at the inception stage of a bioaccumulation study that will rely on stable isotope data.

3.01.P-Th134 Temperature Mediated Bioconcentration and Behavioral Effects of Mirtazapine in Aquatic Invertebrates
***Daniel Cerveny**[1], Tereza Novotná[2], Johanna Björkman[3] and Tomas Brodin[4], (1)Swedish University of Agricultural Sciences (SLU), Sweden, (2)Department of Animal Protection and Welfare and Veterinary Public Health, Faculty of Veterinary Hygiene and Ecology, University of Veterinary Sciences, Czech Republic, (3)Department of Ecology and Environmental Science, Umeå University, Sweden, (4)Wildlife, Fish and Environmental Studies, Swedish University of Agricultural Sciences (SLU), Sweden*
Pharmaceuticals represent an important class of emerging contaminants that has been detected in surface waters worldwide, and due to their continuous input in the recipients via sewage treatment plant effluents, they have been recognized as pseudo-persistent pollutants. Because of their biological activity at very low concentrations and the fact that most of the drug target receptors have been evolutionary conserved across taxa, the risk of inducing detrimental effects in non-target aquatic organisms is not negligible. Those can include impairment in development, morphology, physiology, metabolism, and reproductive traits. On top of that, the pharmacological effects similar to those in human patients might be expected, for example changes in organism´s natural behavior as a result of exposure to neuroactive pharmaceuticals. It is generally assumed that non-target aquatic organisms deal with the pharmaceuticals similarly to humans, i.e. the parent drugs are being metabolized via phase I and II biotransformation pathways and subsequently excreted. However, differently from humans, the biological processes of ectothermic aquatic organisms are significantly affected by the temperature of their environment, which most likely also affect the detoxification mechanisms. In the present work, we have focused on how the temperature affects bioconcentration and biotransformation of commonly detected antidepressant mirtazapine in aquatic larvae of two macroinvertebrate species - *Aeshna juncea* and *Coenagrion hastulatum*. We have exposed these experimental organisms to 1 $\mu g\ L^{-1}$ of mirtazapine at 10 °C and 20 °C for seven days and then analyzed the parent drug and its main metabolite desmethylmirtazapine in each individual. In addition, both studied species have been subjected to behavior trial prior sampling to assess potential effects of mirtazapine on foraging and activity, representing important fitness related behavior traits. The results of our study show significant difference in ability to metabolize the studied drug between the selected species and a strong influence of temperature on bioconcentration in both organisms. Further, we have confirmed the effect of mirtazapine on studied behavior, which was disproportionally regulated by the temperature treatment as well. Our study underlines the need to study the adverse effects of emerging contaminants in the perspective of other environmental stressors.

3.01.P-Th135 Optimization of Avian In Vitro Substrate Depletion Assays to Study Biotransformation of Organic Chemicals
***Matthew Schultz**[1], Michelle Rau Embry[2], Robert J. Letcher[3], Christy A. Morrissey[4] and Markus Brinkmann[1], (1)Toxicology Centre, University of Saskatchewan, Canada, (2)Health and Environmental Sciences Institute (HESI), (3)Ecotoxicology and Wildlife Health Division, Environment and Climate Change Canada, Canada, (4)University of Saskatchewan, Canada*
Avian species play a critical role in aquatic and terrestrial ecosystems but are understudied with regard to bioaccumulation assessment, which historically has focused on aquatic species. Bioaccumulation in fish is often assessed using bioconcentration factor (BCF), a metric which is assumed to be protective of both aquatic and terrestrial organisms. In air breathing organisms such as birds, biomagnification factor (BMF) describes transfer of accumulated chemicals across trophic levels. Historically,

these metrics have been determined using costly *in vivo* testing in fish and rat models, with relatively limited work using birds outside of field studies. Recently, it has been suggested that a kinetic approach that views these metrics as the product of competing rates of whole-body uptake and elimination may be refined by incorporating tissue specific biotransformation rates derived from substrate depletion assays using isolated hepatocytes or liver S9 subcellular fractions. The present study seeks to bring avian biotransformation assays to a similar level as fish by optimizing and expanding the use of *in vitro* substrate depletion assays. Initial optimization efforts have focused on methods of isolation and cryopreservation, as well as assay conditions using mallard duck *(Anas platyrhnchos)* as a model species. *In vitro* intrinsic clearance rates of the benchmark biotransformation chemical pyrene, as well as 4-*n*-nonylphenol were determined across a variety of assay conditions including pH, temperature, and buffer composition. Cryopreservation and thawing protocol optimizations were investigated using commercially available, as well as freshly isolated hepatocytes and subcellular S9 fractions. Further research will apply these optimized assays to ten organic chemicals, including PAHs, PCBs, bisphenols, organophosphates, and neonicotinoids to generate high-quality substrate depletion data. This work also provides an opportunity to identify metabolites and evaluate biotransformation pathways and enzyme activities. The optimized assay will be applied to two additional species of birds, selected based upon ecological relevance, practicality, and life history traits to contribute to a robust database of biotransformation data. The prospective goal of this study is to create the foundation for a future ring trial or similar application to further inform avian wildlife risk assessment with regard to bioaccumulation.

3.01.P-Th136 Assessment of Methods for Determining The Membrane-Water Partition Ratio for Surfactants

Steven Droge[1], *Nina Jansen*[1], *Elin Barrett*[2], *Adriana C. Bejarano, PhD*[3], *Jens Bietz*[4], *Kristin Connors*[5], *James Dawick*[6], *Marc Geurts*[7], *Geoffrey Hodges*[2], *Eoin Kearney*[8], *Mark Miller*[8], *Diederik Schowanek*[9] *and Sabrina Wilhelm*[10], *(1)Environmental Risk Assessment, Wageningen University & Research (WUR), Netherlands, (2)Safety and Environmental Assurance Centre, Unilever Research, United Kingdom, (3)Shell Global Solutions, (4)Clariant Produkte (Deutschland) GmbH, Germany, (5)Procter & Gamble, (6)Innospec Limited, United Kingdom, (7)Nouryon Chemicals B.V., Netherlands, (8)Department of Chemistry, Durham University, United Kingdom, (9)Brussels Innovation Centre, Procter & Gamble, Belgium, (10)BASF Personal Care and Nutrition GmbH, Germany*

Surfactants are often classified as difficult to test chemicals (OECD Guidance 23), which may lead to uncertainty in their environmental fate and behaviour. A key factor hampering adequate fate modelling is that octanol-water partition coefficients (Kow) are often highly uncertain for surfactants, and poorly representative of the interaction energy of ionic surfactants with soil and tissue matrices. The phospholipid membrane-water partition ratio (Kmw) is a promising alternative chemical descriptor for surfactants instead of Kow, as it relates to partitioning into a critical cellular component and accounts for ionic interactions. Kmw can be determined by several experimental methods, but artificial phospholipid as dissolved unilamellar liposomes is considered the “gold standard”. Consistent Kmw values have been measured for a variety of surfactants using bilayer membranes coated on silica particles. Also promising computational approaches to calculate Kmw have been evaluated but require further calibration for surfactants. The overall aim of this study is to systematically evaluate three experimental methods and three computational approaches to determine Kmw for a diverse set of surfactants, covering nonionic, anionic, cationic, and zwitterionic structures. Based on this assessment, we aim to further establish confidence in the Kmw approach for different types of surfactants, provide guidance on the most cost-effective assay for specific surfactant classes, calibrate computation approaches, and make a next step towards standardization of validated test protocols. Here we present the Kmw measurements for 12 surfactants using three experimental methods, with benchmark dissolved unilamellar liposomes requiring dialysis systems, solid-supported lipid membranes (SSLM) which only require mild centrifugation, and HPLC columns with Immobilized Artificial Membrane coated silica (IAM-HPLC). The pros and cons of each experimental assay will be elaborated. Furthermore, the experimental data set allow for calibration of molecular computation methods, such as molecular dynamics and polyparameter LFER approaches. The data set provides relevant data to derive first tier estimates for surfactants on bioaccumulation and most likely also on baseline toxic potential, addressing ECHA’s 2023 Key Areas of Regulatory Challenge.

3.01.P-Th137 Scoping Key Sources of Uncertainty in Bioaccumulation Assessment: Biopartitioning and Biotransformation

Jon A. Arnot[1,2,3], *Steph Jones*[4], *Alessandro Sangion*[1], *Trevor N Brown, PhD*[1], *James M Armitage*[1], *Liisa Toose, M.Sc.*[1], *Michelle Rau Embry*[5] *and* ***Pippa Kate Curtis-Jackson***[4], *(1)Arnot Research and Consulting Inc. (ARC), Canada, (2)Department of Pharmacology and Toxicology, University of Toronto, Canada, (3)University of Toronto Scarborough, Canada, (4)Chemicals Assessment Unit, Environment Agency (England), United Kingdom, (5)Health and Environmental Sciences Institute (HESI)*

Bioaccumulation assessment is a critical endpoint of chemical hazard and risk assessment for ecological and human health. Bioaccumulation (B) assessment is challenging, with various metrics to consider, such as lab bioconcentration factors (BCFs), lab and field biomagnification factors (BMFs), and field bioaccumulation factors (BAFs), numerous regulatory criteria, and the natural diversity of biology and chemistry. Therefore, a weight-of-evidence approach for B assessment is often recommended in regulatory programmes.

An OECD Integrated Approach to Testing and Assessment (IATA) for Bioaccumulation was recently developed, by the Environment Agency (England), HESI and other key stakeholders. This “B IATA” provides guidance for B assessment and for addressing key sources of uncertainty in an efficient and scientifically defensible manner that reduces the need for animal testing. The foundation of the B IATA is supported by generic 1-compartment physiologically-based toxicokinetic (PBK) models that can integrate measured *in vivo* and *in vitro* data as well as *in silico* data.

Fundamental to the bioaccumulation phenomenon in aquatic and air-breathing organisms are two underlying processes: biopartitioning and biotransformation. Traditionally octanol has been used as a surrogate for biopartitioning of neutral organic chemicals to various biological compartments, most notably adipose tissue (i.e., storage lipids). It is now recognized that octanol is not always a reasonable surrogate for biopartitioning for all chemicals, particularly for polar (neutral) and ionizable organic chemicals. This work presents a critical review for measuring biopartitioning to protein and membrane lipids, and estimation methods for these properties. This compliments the B IATA framework, which allows for the use of higher tiered biopartitioning data to replace "octanol as a surrogate for biopartitioning". This work also presents a review of available methods for measuring (or estimating) biotransformation rates *in vivo*, from *in vitro* assays, and from *in silico* models. This review provides a starting point for developing IATAs specifically for addressing uncertainty in biopartitioning and biotransformation.

3.01.P-Th138 Regulatory Application of a Toxicokinetic-based Bioaccumulation Model

Elena Alonso, PhD[1], *Jose V. Tarazona*[2], *Stefan Reichenberger*[3], *Antje Gerloff-Elias*[4], *Martina Duft*[4] *and Ángeles Rico*[1], *(1)knoell Iberia S.L., Spain, (2)Institute of Health Carlos III (ISCIII), Spain, (3)knoell France SAS, France, (4)knoell Germany GmbH, Germany*

The bioaccumulation of active substances (a.s.) in organisms and their transfer through the food chain is a complex phenomenon involving several mechanisms, influenced by a wide range of biotic and abiotic variables. Although there has been significant progress in the consideration of bioaccumulation in the regulatory arena under global regulations, it is still quantified as a simple process driven mainly by lipophilicity (by considering the octanol–water partition coefficient; K_{OW}). Typically, in addition to K_{OW} , the Bioconcentration Factor (BCF) in fish is used as the cut-off criterion for hazard assessment and for the evaluation of secondary poisoning to birds and mammals. Therefore, more accurate methods covering the complexity of this process are deemed necessary for addressing the potential concerns related to the increase in the concentration of a substance in organisms over time. Hence, we propose a bioaccumulation model (considering toxicokinetic parameters) to be applied in support of the risk assessment of chemicals under different regulations. The model presented in this work is already validated and calibrated with independent data (Alonso *et al*., 2008) and is in consequence ready to use for regulatory applications. In this work, we investigate in detail the applicability and related challenges of this model for the "B" assessment under REACH Regulation (Annex XIII, 3.2.2) and for the refinement of secondary poisoning under Regulation 1107/2009 for Plant Protection Products. Additionally, we have described potential implementations of the model that would allow its application in other fields within the regulatory framework. Overall, it is concluded that the model can provide significant information to support the risk assessment of chemicals by reducing the uncertainty associated with the bioaccumulation process. The model can therefore be recognized as a versatile tool for regulatory applications involving bioaccumulation

3.01.P-Th139 Celebrating Some of the Many Scientific Contributions of Don Mackay: The Role of Chemical Fugacity and Activity in PBT, Exposure and Risk assessment

Alena K.D. Celsie[1], *Jon A. Arnot*[2] *and J. Mark Parnis*[3], *(1)Chemistry, Trent University, Canada, (2)Arnot Research and Consulting Inc. (ARC), Canada, (3)Trent University, Canada*

The hazard and risk from organic chemicals present in the environment are routinely evaluated using P (Persistence), B (Bioaccumulation) and T (Toxicity) data and criteria. We present a perspective on how models based on the equilibrium criteria of fugacity and chemical activity can contribute to PBT hazard evaluations as well as exposure and risk estimation, providing a consistent and integrated assessment process. The Registration, Evaluation, Authorisation and Restriction of Chemicals (REACH) regulations have set out guidelines for evaluating PBT characteristics using bright-line criteria, however, use of these guidelines can lead to the misidentification of some chemicals. For example, the use of the octanol-water partition ratio (K_{OW}) alone can misidentify chemicals with bioaccumulation potential in air-breathing species.

Overall persistence and chemical residence times have been advocated for because they are more representative of chemical degradation in the overall multi-media environment. Bioaccumulation is driven by toxicokinetic processes that can be estimated using fugacity-based models that treat uptake by respiration and diet, in single organisms or in food webs. Biomagnification within food webs is of regulatory concern and is particularly important for air-breathing organisms because the atmospheric capacity for chemical is usually relatively lower compared to the corresponding aquatic chemical capacity. Compounds with a baseline narcosis toxic Mode of Action (MoA1) are believed to fall in the domain of a 'narcotic fugacity' (or activity) endpoint, in which a factor 'N' is defined as the fraction of saturation vapour pressure, solubility, or activity that causes onset of narcosis. Ranges of fugacities and activities corresponding to narcosis can be defined for specific species or regions thus enabling comparison of species sensitivity and regional or temporal trends with respect to exposure and risk. Multipliers for chemicals with more specific MoA can be considered.

We promote some of the scientific advancements that Don Mackay pioneered showing that chemical fugacity and activity provide a means to integrate hazard and risk information in the environment in simple and relatively easy-to-use mass balance multi-media models.

3.01.P-Th140 Mixture Toxicokinetic Assessment of Pharmaceuticals in Daphnia magna using Liquid Chromatography Tandem Mass Spectrometry Analysis

Jasmin Uhlhorn[1], *Luigi Margiotta-Casaluci*[2], *Samuel K Maynard*[3] *and Thomas Miller*[4], *(1)Brunel University London, United Kingdom, (2)King's College London, United Kingdom, (3)Global Sustainability, AstraZeneca UK Ltd, United Kingdom, (4)Brunel University, United Kingdom*

Contaminants originating from anthropogenic activities are a source of environmental pollution. This includes pharmaceuticals that are released via various sources such as wastewater discharge from households, hospitals and manufacturing facilities. Pharmaceuticals are designed to target conserved biological pathways so the exposure of non-target organisms presents an environmental risk, necessitating a thorough examination of toxicokinetics (TK) to assess the potential for bioaccumulation. The work herein presents a liquid chromatography tandem mass spectrometry (LC-MS/MS) method capable of quantitatively measuring 90 pharmaceuticals, spanning various therapeutic classes (e.g., anticonvulsants, antidepressants, lipid regulators), at trace levels in *Daphnia magna*. The LC-MS/MS method was developed, optimised, and validated with acceptable linearity ($R^2 \geq 0.98$) and repeatability (≤15% RSD) across a dynamic range from low ng to μg g^{-1}. Optimisation involved comparison of different extraction solvents, volumes, lipid removal and SPE sorbents. Subsequently the validated method was applied to determine the internal concentration and TK profiles in *Daphnia magna* during 96-hour exposure experiments, which included a 48-hour exposure period, followed by a 48-hour depuration phase. Multiple sampling points enabled a temporal analysis to enhance understanding of uptake and elimination kinetics. Exposures were compared between individual pharmaceuticals and mixture-based experiments of 2, 5, 10 and 20 pharmaceuticals that were exposed simultaneously. The work aimed at exploring the potential of mixture exposures to reliably assess toxicokinetic parameters without the need for testing individual chemicals. This approach would reduce the number of animals required to experimentally determine bioconcentration or bioaccumulation during environmental risk assessments.

3.01.P-Th141 Integrated Approach for Testing and Assessment (IATA) for Bioaccumulation

Pippa Kate Curtis-Jackson[1], *Jon A. Arnot*[2], *Mark A. Bonnell*[3], *Michelle Rau Embry*[4], *Kellie A Fay*[5] *and Heike Laue*[6], *(1)Chemicals Assessment Unit, Environment Agency (England), United Kingdom, (2)Arnot Research and Consulting Inc. (ARC), Canada, (3)Department of Environment and Climate Change, Canada, (4)Health and Environmental Sciences Institute (HESI), (5)U.S. Environmental Protection Agency (US EPA), (6)Givaudan Suisse SA, Switzerland*

Bioaccumulation is the net result of competing rates of chemical uptake into, and elimination from an organism. Bioaccumulation assessment is an essential endpoint in national and international chemical regulatory programmes and treaties, e.g., the identification of Persistent, Bioaccumulative and Toxic (PBT) substances and Persistent Organic Pollutants (POPs). Bioaccumulation assessment is both a scientific and regulatory challenge due to the intricacy of the subject, the availability of reliable and relevant data, and lack of guidance in how data should be evaluated and weighted to inform decision-making. This process becomes more challenging considering variations in accepted data and the varying threshold criteria of different regulatory jurisdictions. A weight of evidence (WoE) approach is recommended by most established regulatory jurisdictions, such as REACH program in Europe, The Canadian Environmental Protection Act and the United Nations Stockholm Convention; however, there is no clear guidance for implementing a WoE approach for B assessment. Multiple lines of evidence (LoE) can be used to quantify, measure, and qualify the common metrics of bioconcentration factor (BCF), bioaccumulation factors (BAF), biomagnification factors (BMF) and trophic magnification factors (TMF). These LoE can comprise *in silico* predictions, combinations of *in vitro* and *in silico* data, e.g., *in vitro-in vivo* extrapolation (IVIVE), and laboratory or field data. Quantitative Structure Activity Relationship (QSAR) models for BCF and BAF, and biotransformation half-lives, as well as mechanistic bioaccumulation toxicokinetic (TK) models are established. Additionally, there are internationally recognised OECD test guidelines for the laboratory determination of *in vitro* fish biotransformation rates, BCFs, and BMFs. An OECD Integrated Approach for Testing and Assessment (IATA) for Bioaccumulation has been developed that encompasses the aforementioned LoE along with existing OECD testing guidance and WoE guiding principles to aid evaluators in the collection, generation, evaluation, and integration of multiple LoE for clear and transparent decision making in B assessment for aquatic and terrestrial environments. Three illustrative case studies representing both data poor and data rich chemicals are presented to illustrate the applicability of the IATA for B assessment.

3.01.P-Th142 Integrating In Vivo, In Vitro, and In Silico Approaches to Assess Chemical Toxicokinetics: A Cross-Species Comparative Analysis

Alessandro Sangion[1], *James M Armitage*[2], *Aaron Redman*[3] *and Jon A. Arnot*[1], *(1)Arnot Research and Consulting Inc. (ARC), Canada, (2)AES Armitage Environmental Sciences, Inc, Canada, (3)ExxonMobil Biomedical Sciences, Inc.*

Limited availability of high-quality measured toxicokinetic (TK) data introduces uncertainty in hazard and risk assessments for various chemicals. Terminal elimination half-lives (HL_T) are required in many contexts, including inter-species extrapolation of traditional toxicity data and in vitro-in vivo extrapolation (IVIVE) of bioactivity data obtained from New Approach Methods (NAMs). A key determinant of inter-species extrapolation is the differences in TK (e.g., biotransformation half-life, HL_B) between species from different taxa. Allometric scaling and the use of uncertainty factors (e.g., “factor of 10”) to extrapolate TK and toxicity data from once species to another are normally used. However, in most cases, these scaling factors are “arbitrarily” selected and may not be representative of the true uncertainty. The objective of this work is to apply bioinformatic tools to examine differences in HL_B and HL_T from various organisms (e.g., human, rat, fish) using different estimation methods including in vivo, in vitro and in silico data.

In vivo TK data and in vitro biotransformation rate data from hepatocyte, microsomal and hepatic S9 bioassays were obtained and critically evaluated using OECD testing guidelines and professional judgment to identify key sources of uncertainty in the data. OECD validated Quantitative Structure-Activity Relationships (QSAR) were used to predict HL_B and HL_T in mammals and fish. Allometric scaling based on body mass was applied to normalize the data and investigate TK differences between species. Variability in HL_B and HL_T between key species was scrutinized to test if commonly applied uncertainty factors for inter- and intra-species differences are supported by the data. There is general agreement in HL_B and HL_T estimates obtained from in vitro, in vivo and in silico methods for most chemicals supporting the advancement of non-animal methods for obtaining key TK parameters. For instance, based on a comparison of 218 chemicals the mean difference between body mass normalized rat and human in vivo HL_T is around 2 and an uncertainty factor of about 60 captures 95% of the variability in inter-species differences. This study supports the need for integrated and systematic testing methods for key TK processes to address the significant uncertainty that exists in TK data for thousands of chemicals and in the application of new and existing hazard data for human and ecological health assessment.

3.01.P-Th143 Contaminant Biomagnification in Humans: Interindividual Differences and the Role of the Gut Microbiome

Yuhao Chen[1]*, Terrence Bell*[2]*, Ying Duan Lei*[3] *and Frank Wania*[4]*, (1)Chemistry, University of Toronto, Canada, (2)aDepartment of Physical and Environmental Sciences, University of Toronto, Canada, (3)University of Toronto, Canada, (4)Department of Physical and Environmental Sciences, University of Toronto, Canada*

The process that can lead to concentrations of an organic contaminant in an organism exceeding those in its diet is called biomagnification. It is a highly undesirable property of a chemical, as it allows it to become enriched in organisms at the top of a food chain, increasing the likelihood of having a detrimental effect on the health of those organisms. Although of obvious importance to humans, biomagnification has hardly ever been studied in humans, because the available methods are highly invasive. Here we applied an entirely non-invasive method that relies on the equilibrium sampling and chemical analysis of paired dietary and fecal samples to determine the thermodynamic limit to biomagnification (BMF_{lim}) as well as the feces-based biomagnification factor (BMF_{f}) for a selection of polychlorinated biphenyl congeners in humans. Over a period of five days, we collected diet and feces from five volunteers. The volunteers (i) shared the same diet, relatively high in animal lipids, to eliminate the confounding factor of dietary composition and (ii) recorded both dietary intake and fecal egestion rates. Using equilibration with silicone film, we determined the fugacity capacity of diet and fecal matter for PCBs and also the PCBs' fugacity in diet and feces. As the gut microbiome has a strong influence on the ability of the digestive system to absorb the diet, and dietary lipids in particular, high-through-put 16S RNA gene sequencing was used to characterize the gut microbial community of the volunteers immediately prior to the experiment and again at the end of the five days. The individuals differ widely (by as much as a factor of 3) in their biomagnification capabilities even though they shared the same diet. This is due to divergent dietary digestion efficiencies, which influenced both lipid assimilation efficiency (ranging from 98 to 99%) and fecal egestion rate G_{F} (ranging from 150 to 390 mL/day). The gut microbiome varied widely between individuals and experienced shifts after the change in diet. We will discuss in detail the role of age, sex, ethnicity, and gut microbiome in relation to the measured BMF_{lim} and BMF_{F}. Preliminary results indicate that the oldest volunteer (i.e., M58) had the highest lipid assimilation efficiency lip% (~99%) and BMF_{lim} (~70); while the third oldest person (M32) had the lowest BMF_{lim} (~25) due to a low digestion efficiency (lip% = ~98 %; G_{F} = 390 mL/day).

3.01.P-Th144 Monitoring freely dissolved concentrations of hydrophobic pollutants improves understanding of pollutant transport and bioaccumulation with clarity on sustainable management options

Upal Ghosh*, Nathalie Lombard, PhD and Mandar Bokare, University of Maryland, Baltimore County*

The development of equilibrium passive sampling methods has accelerated over the last decade and enabled measurements of ultra-low concentrations of bioaccumulative chemicals in the aquatic environment. Yet, use in the regulatory context has been limited due to the lack of precedent and solid demonstrations tied closely to regulatory needs. Remedial investigations of sites contaminated with legacy pollutants like polychlorinated biphenyls (PCBs) have traditionally focused on mapping sediment contamination to develop a site conceptual model and select remedy options. This sediment-focused approach often leads to an incomplete understanding of the impacts of ongoing inputs to the water column and over-estimation of potential effectiveness of sediment remediation. Here we demonstrate how measurements of surface water, sediment porewater, and gas-phase PCB concentrations using polyethylene passive samplers were able to provide the first accurate mass balance of freely dissolved PCBs in the Anacostia River in Washington DC. This mass balance enabled identification of a major tributary and contaminated sediment hot-spots as the sources having the most negative impact on the water body, while also demonstrating that the atmosphere served as a sink for PCBs from the surface water. By coupling the mass balance model with a food web model for the river, we were able to connect the media concentrations to bioaccumulation in fish and evaluate a range of management options. We demonstrate that sediment cleanup alone will not be able to achieve target reductions of PCBs in fish and dissolved concentrations from the problem tributary needs to be controlled. The framework presented here for passive sampling and interpretation can be used to provide robust and sustainable solutions for other river systems.

3.01.P-Th145 "Chasing Chemical Echoes:Unveiling Bioconcentration and Bioaccumulation of Legacy POPs and Emergent Compounds in the Waters of King George Island (Antarctica)"

Cristobal Galban-Malagon[1]*, Victoria A Gómez*[1]*, Andrea Hirmas*[2]*, Thais Luarte*[2]*, Gustavo Chiang*[2]*, Juan Hôfer*[3]*, Ricardo Giesecke*[4]*, Karla Pozo*[5]*, Petra Pribylova*[6]*, Jakub Martiník*[7]*, Jordi Dachs*[8] *and Eduardo Castro-Nallar*[9]*, (1)Universidad Mayor, Chile, (2)Universidad Andrés Bello, Chile, (3)Pontificia Universidad Católica de Valparaíso, Chile, (4)Instituto de Ciencias*

Marinas y Limnológicas, Universidad Austral de Chile, Chile, (5)Universidad San Sebastián, Chile, (6)Recetox, Masaryk University, Czech Republic, (7)Recetox, RECETOX, Masaryk University, Czech Republic, (8)Environmental Chemistry, Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain, (9)Universidad de Talca, Chile
The industrial advancements of the last century have significantly impacted Antarctic ecosystems through the release of Persistent Organic Pollutants (POPs) into the atmosphere. These persistent, semi-volatile pollutants possess the capacity to traverse considerable distances, reaching polar regions. They exhibit a propensity for bioaccumulation and biomagnification within trophic networks, inducing deleterious effects on the local biota. Scant attention has been devoted to comprehending these processes within antarctic water column with few studies previously published. A critical aspect lies in elucidating the complex interplay of the biological pump in the transport of COPs within water columns and trophic networks, underscoring the integral role of phytoplankton in these processes. The target compounds of the present study are Polybrominated Diphenyl Ethers (PBDEs), Polychlorinated Biphenyls (PCBs), and Organochlorine Pesticides (OCPs). We studied the occurrence of these compounds in seawater, phytoplankton and zooplankton. Analysis of biomagnification factors has revealed noteworthy patterns; specifically, higher LogKow congeners of PBDEs did not exhibit an elevated concentration across trophic levels, in contrast to PCBs, while OCPs displayed an intermediary behavior. The present work explores potential causes affecting bioaccumulation patterns and delves into the influence of potential PBDE and some OCP metabolism at the invertebrate level, explaining why their behavior deviates from hydrophobicity expectations. Additionally, the discussion encompasses an exploration of potential oceanographic factors influencing the environmental fate of these compounds. Satellitely measured primary productivity and upwelling oceanographic conditions emerge as pivotal elements, seemingly playing a significant role in the trophic transfer of these compounds. This nuanced analysis adds a layer of insight into the broader context of POPs dynamics in polar environments.

3.01.P-Th146 Occurrence, distribution, and bioaccumulation patterns of contaminants in coral reef systems
***Micaela Sofia dos Santos Justo**[1], Mariana Elizabeth Rodrigues[2], Fernanda Tavares[2], Margarida Branco[3], Joao Curdia[3], Geert-Jan Witkamp[2], Darren Coker[3], Rodrigo Villalobos[3], Michael Berumen[3], Andreia Sofia Filipe Farinha[4] and Susana Carvalho[4], (1)Red Sea Reasearch Science, King Abdullah University of Science and Technology, Saudi Arabia, (2)Water Desalination and Reuse Center, King Abdullah University of Science and Technology, Saudi Arabia, (3)Red Sea Research Center, King Abdullah University of Science and Technology, Saudi Arabia, (4)King Abdullah University of Science and Technology, Saudi Arabia*
Coral reefs are exposed to multiple stressors caused by anthropogenic actions, which, combined with climate change, have resulted in drastic declines worldwide. The release of contaminants from different sources such as treated or untreated municipal, industrial, and agricultural wastes has been a major concern over the last decades. Yet, information on their concentration in such unique ecosystem is still scarce. Therefore, the present study aims to provide baseline knowledge on the distribution and concentration of organic contaminants (e.g., medicines, stimulants) and trace metals in the Red Sea coral reefs. Sediments, seawater, and reef fishes collected from three different areas with different levels of anthropogenic pressures (a total of 19 reefs) will be analysed to investigate the extent to which bioaccumulated concentrations of targeted compounds in fish can be predicted by concentrations in environmental compartments (water and sediments). We predict that the concentration of contaminants will increase according to the level of anthropogenic activities in the three different regions. Additionally, we expect to observe changes in the bioaccumulation patterns across three fish feeding traits (e.g., detritivores, corallivores, herbivores, carnivores). This study will contribute to provide scientific baseline information for future national environmental assessments and to guide ecotoxicology studies. It will also provide insight into cascading effects on associated species, underlining the potential health risk

3.01.P-Th147 Bioaccumulation Of Selected Pesticides In Freshwater Invertebrates
***Helena Švecová**[1], Kateřina Grabicová[1], Claire Duchet[2], David Boukal[3] and Roman Grabic[4], (1)University of South Bohemia in České Budějovice, Faculty of Fisheries and Protection of Waters, Czech Republic, (2)Faculty of Science, University of South Bohemia, Czech Republic, (3)University of South Bohemia in České Budějovice, Czech Republic, (4)University of South Bohemia in Ceske Budejovice, Faculty of Fisheries and Protection of Waters, Czech Republic*
Several extraneous stressors threaten aquatic ecosystems nowadays. Some of these stressors are rising temperatures due to climate changes or adverse effects of emergent pollutants related to human activity. To fill gaps in knowledge necessary to predict the responses of freshwater biota to these stressors, we performed a mesocosms experiment focused on the effect of pesticides on freshwater invertebrates under different temperatures. Mesocosm is supposed to imitate small-standing waters. The mesocosms were inhabited by common macroinvertebrates and plankton taxa from different trophic levels. We further limited observations to six relevant pesticides and their metabolites. The pesticide solution with environmentally appropriate concentration was added to the systems once at the beginning of each experiment. During a four-month experiment in winter and a two-month experiment in summer, we collected water samples and determined the change in pesticide concentration in the systems over time. At the end of the experiment, all macroinvertebrates were analyzed for concentrations of not only pesticides but also their metabolites. As expected, different species bioaccumulated individual pesticides differently. However, terbuthylazine dominated all examined species, accompanied by its metabolite terbuthylazine-desethyl. On the contrary, propiconazole showed significant differences in bioaccumulation among species depending on their way of life. Mesocosms experiments were part of the project supported by the Czech Science Foundation (No. 20-16111S, "Understanding the effects of multiple stressors on freshwater biota: Will climate change alter the impact of chemical pollution?") and by the Ministry of Education, Youth and Sports of the Czech Republic – projects "CENAKVA" (LM2018099).

3.01.P-Th148 Bioaccumulation Dynamics of Ionizable Pharmaceuticals in Freshwater Crayfish

Anna Koubová[1], *Antonín Kouba*[2], *Jaylen Lesean Sims*[3], *Adam Bořík*[2], *Bryan W. Brooks*[3] *and Vladimír Žlábek*[2], *(1)University of South Bohemia Ceske Budejovice, České Budějovice, Czech Republic, (2)University of South Bohemia in Ceske Budejovice, Faculty of Fisheries and Protection of Waters, Czech Republic, (3)Environmental Science, Environmental Science & Public Health, Baylor University*

Ionizable micropollutants are often bioaccumulative in aquatic biota. While pharmaceuticals are designed to exhibit high bioactivity at low doses in humans or animals, the dynamics of their bioaccumulation in invertebrates have been relatively understudied. Promoting the principles of the 3Rs (replacement, reduction, refinement) in animal welfare offers a promising avenue for encouraging innovation and aligning with European and international mandates aimed at reducing the use of vertebrates in research and regulatory practices. Freshwater crayfish play a prominent role in aquatic ecosystems and occupy significant niches within the trophic web. Notably, invasive crayfish species such as *Procambarus virginalis* and *Pacifastacus leniusculus* serve as excellent testing models, given their large body sizes and heightened sensitivity to environmental contaminants. This study seeks to expand upon recent mechanistic bioaccumulation modelling efforts that have traditionally focused on fish, guided by principles rooted in mammalian pharmacokinetics. In a series of 10-day bioconcentration experiments, comprising a 7-day uptake phase and a subsequent 3-day elimination phase, we monitored the concentration of diphenhydramine in crayfish hemolymph and whole body, while simultaneously calculating bioconcentration parameters. Both modelled and observed effects of the tested compound were rigorously assessed. The findings revealed the uptake and elimination kinetic parameters and the bioconcentration factor of model ionizables. Importantly, our research highlighted that water pH and dissociated compound quantity influenced the bioaccumulation dynamics. These bioconcentration experiments, driven by empirical data, shed light on the potential of crayfish as an invertebrate bioaccumulation model for ionizable pharmaceuticals, providing valuable insights for future studies in the ecotoxicology area. *The research was supported by the Czech Science Foundation (23-07274S) and by the Ministry of Education, Youth and Sports of the Czech Republic – project "CENAKVA" (LM2018099).*

3.01.P-Th149 Development of Meta-Analysis Techniques to Evaluate the Biomagnification Potential of Contaminants in Wildlife and Food-Webs For Environmental Risk Assessments

Kate Fremlin[1], *John E. Elliott*[2] *and Frank Gobas*[3], *(1)Biological Sciences, Simon Fraser University; Department of Biological Sciences, Canada, (2)Environment and Climate Change Canada, Canada, (3)Resource & Environmental Management, Simon Fraser University; School of Resource & Environmental Management, Canada*

There are many examples of chemicals that exhibit substantial variation in their estimated potential to biomagnify in organisms and food-webs, which often leads to uncertainty in how best to characterize them and make regulatory decisions for them. For example, field studies investigating the bioaccumulation of decabromodiphenyl ethane (DBDPE; CAS: 84852-53-9) in food-webs or wildlife have reported highly variable biomagnification factors (BMFs) and trophic magnification factors (TMFs) for DBDPE; consequently, regulatory decisions regarding the biomagnification potential of DBDPE have been inconclusive to date. Thus, we reviewed the literature for peer-reviewed studies reporting field-derived BMFs and/or TMFs for DBDPE with the objective to (i) develop a methodology using a weight of evidence approach and meta-analysis that can evaluate field-based biomagnification studies and (ii) apply it to DBDPE with the aim to inform regulatory decisions on whether DBDPE has biomagnification and/or trophic magnification potential. For the weight of evidence approach and meta-analysis, we developed several critical criteria with a scoring and categorization system to evaluate the quality and reliability in the reported BMFs or TMFs. For field studies with reliability scores above 50% (i.e., considered acceptable), one-sample t-tests indicated that the mean BMF of DBPDE was 0.56 (0.18 SE; $t(18) = -0.23$; $p > 0.05$) and the mean TMF of DBPDE was 0.95 (0.48 SE; $t(7) = -0.098$; $p = 0.92$) and thus not statistically different from 1. We also examined the log-linear relationship between reported BMFs and TMFs and their associated reliability score to evaluate if the quality of the study was related to the BMF or TMF. The reliability scores of the field studies marginally increased as the reported BMF ($p < 0.05$; $r^2 = 0.37$; $F_{1,15} = 10.5$) or TMF ($p = 0.36$, $F_{1,11} = 0.85$, $r^2 = -0.012$) in the study decreased. Typically, field studies with acceptable or reliable quality scores (i.e., > 50%) reported BMFs and TMFs that were less than or equal to 1, whereas field studies with unacceptable quality scores (i.e., < 50%) often reported BMFs and TMFs greater than 1. Ultimately, this weight of evidence approach and meta-analysis was effective for assessing the biomagnification potential of a super-hydrophobic substance like DBDPE and indicated that concentrations of DBDPE exhibit a limited potential to bioaccumulate and biomagnify in top predators and food-webs.

3.02.A Advances in Exposure Modelling to Inform Science-Based Environmental Solutions

3.02.A.T-01 Quantification and mapping of tyre wear emissions: from EU regional analysis to global projections

Yichen Sun[1], *Jikke van Wijnen*[2] *and Ad M. J. Ragas*[3], *(1)Environment Science, Radboud University Nijmegen, Netherlands, (2)Open University, Netherlands, (3)Environmental Science, Radboud University Nijmegen, Netherlands*

Tyre wear particle (TWP) emissions constitute one of the predominant sources of microplastic pollution in the environment. Numerous studies have endeavored to estimate annual national TWP emissions. However, a significant degree of variability exists in these estimations due to the diversity in the methodologies employed and the emission factors applied. The primary objectives of this study are to analyze the variability in the results obtained from different estimation techniques, and to provide a guidance for national estimates of TWP emissions. Our findings indicate substantial discrepancies in the per capita emissions estimated using the mass loss of tyres and emission factors across almost all Southern European countries and certain Northern European nations, with variances reaching up to 2 kg/y*cap. In contrast, Western and Eastern European countries show minimal variation in results despite differing methodologies. Furthermore, extrapolating from the estimations, we estimated annual TWP emissions of EU member states into various environmental compartments, including air, soil, sewers, and surface waters. Based on our research estimates, Germany, France, and Italy are considered the primary emitters of TWP, with annual emissions from each country exceeding 100,000 tons. It is imperative to highlight that a predominant portion of these emissions is deposited in soils adjacent to roadways. Despite the considerable overall emissions, only a limited fraction of these particles enters surface waters. Taking into account the variations in the coverage and efficiency of wastewater treatment plants, it is estimated that merely about 13,000 tons per year from these three countries make their way into surface To predict annual TWP emissions for nations lacking specific data to estimate TWP emissions (e.g., annual mileage data), a multivariate linear regression model was developed that uses demographic variables as input. The model's results, including per capita and total TWP emissions for 57 countries across six continents, illustrate that Luxembourg leads in per capita TWP emissions with 3.56 kg/y*cap, followed by the US with just over 3 kg/y*cap. On a national scale, China and India, the two most populous nations globally, have the highest annual emissions of 1.5 million tons and 870,000 tons, respectively. The predictive model proposed here significantly simplifies the preliminary estimation process for national TWP emissions by lowering data needs.

3.02.A.T-02 Application of the Abrasion Coefficient as Measure for Tyre Wear and Microplastics Emission Modelling
*Johannes Meesters[1], **Joris T.K. Quik**[1], Anne Hids[2], Jaap Slootweg[1], Yvette Mellink[2], David Lopez[3], Barouch Giechaskiel[4], Sebastian Gramstat[5], Theodoros Grigoratos[4] and Juan J Garcia[3], (1)National Institute for Public Health and the Environment (RIVM), Netherlands, (2)RIVM, Netherlands, (3)IDIADA, (4)Joint Research Centre (JRC) - European Commission, Italy, (5)Audi, Germany*
Tyre Wear due to the friction between the tyre and the road contribute towards the emission of microplastics and other pollutants. Measuring the abrasion rate of tyres in mg per driven km will be an important aspect of the new EURO7 emission standards. Here we propose a novel method for quantifying Tyre Wear based on an abrasion coefficient in mg per J friction work determined from abrasion rate measurements. This is done by estimating the level of friction work energy that the tyres are subjected to during driving manoeuvres which are dependent on the characteristics of the road, the vehicle and driver behaviour.

The friction work can be estimated for track, road and lab scale abrasion rate measurements. The abrasion coefficient (mg/J) is then estimated as the measured abrasion rate (mg/km) divided by level of friction per km track (J/km), in the case of track measurements. Such an abrasion coefficient is a much more generic measure for abrasion compared to the more commonly derived abrasion rates (mg/km) which are specific to a road type (e.g. highway versus urban roads), vehicle type and the specific manoeuvres performed. The model code is available from https://github.com/rivm-syso/tyre-friction-abrassion-emission.

The Tyre Wear Abrasion Model could allow calculating the effects of different future scenarios, such as transition to a more electrified fleet or towards heavier vehicles (i.e. SUVs). This allows for more targeted policy advice in view of the goals for microplastic pollution reduction of 30% by 2030 defined in the EU Action Plan “Towards Zero Pollution for Air, Water and Soil”. In this work the Tyre Abrasion Model is calibrated based on ADAC abrasion measurements as well as novel measurements from the LEON-T project. The utilisation of the model is illustrated for Tyre Wear as part of microplastics emissions in the Netherlands. This is done to compare Tyre Wear to other microplastics emissions in order to discuss their overall contribution towards (micro)plastic pollution.

3.02.A.T-03 Mapping emerging contaminants in sewage sludge treatments: Occurrence, degradation, and fate
*Marjorie Morales[1], Hans Peter Arp[1], Gabriela Castro[2], Alexandros G. Asimakopoulos[1], Erlend Sørmo[3,4], Gregory Peters[5] and **Francesco Cherubini**[1], (1)Norwegian University of Science & Technology (NTNU), Norway, (2)University of Santiago de Compostela, Spain, (3)Mina, Norwegian University of Life Sciences (NMBU), Norway, (4)Norwegian Geotechnical Institute (NGI), Norway, (5)Chalmers University of Technology, Sweden*
The use of sewage sludge (SS) as fertilizers is undergoing increasing scrutiny because of potential risks from the increasing amounts of pollution from hazardous metals and organic compounds entering wastewater. Among the hazardous organic compounds (HOCs), per- and polyfluoroalkyl substances (PFAS), a complex group of synthetic chemicals that have been used in consumer products, and organophosphate flame retardant (OPFRs), a variety of consumer products used as flame retardants and plasticizers, are of rising concern because of their long-lasting persistence in the environment and food products with harmful health effects in humans and animals. Improvements in SS treatment options that abate the presence of HOCs are needed to mitigate this threat to an expanding circular economy. Thermal treatments are becoming attractive in this context, also because they can co-deliver useful energy and materials. However, there is limited information on the efficiency by which they can remove toxic pollutants. This study provides an accurate mapping of the fate of various pollutants (PFAS, OPFRs, BPA and hazardous metals) through different treatment steps. This study compares conventional and thermal treatments of SS by integrating SS sampling from wastewater plants in Norway of 61 HOCs (PFAS and OPFRs) and 12 hazardous metals and laboratory analysis with detailed process simulations through Aspen Plus. The scenarios are based on individual (or combinations of) thermal/non-thermal treatments such as anaerobic digestion, de-watering, stabilization, drying, pyrolysis, incineration, and valorisation of co-products (biogas upgrading, heat and power cogeneration, biochar application to soils). The results show that conventional SS treatment leaves between 24 and 40% of OPFRs unabated, while almost no degradation occurs for PFAS. Thermal treatments can degrade more than 93% of OPFRs and 95% of measured PFAS (with the rest released to water bodies via effluents). The different treatment options vary how HMs are emitted across environmental

compartments. A rigorous statistical approach is secured by a large data sampling and the implementation of a Monte-Carlo uncertainty. Overall, this study increases the availability of empirical data for removal efficiency of different sludge treatment options with process modelling. This work serves as a valuable resource on process designs for informed science-based solution for the treatment of waste containing HOCs.

3.02.A.T-04 Assessment of Wood Preservative Emission Scenarios

Kevin J Rader, PhD[1]*, Richard F. Carbonaro*[1,2] *and Carol Mackie*[3]*, (1)Mutch Associates, LLC, (2)Manhattan College, (3)Regulatory Compliance Limited, United Kingdom*

The Organisation for Economic Co-operation and Development (OECD) Emission Scenario Document (ESD) for Wood Preservatives provides methods to estimate copper release from treated wood for various scenarios including treated sheet pilings in a flowing waterway. In this research, ESD equations for copper release from treated sheet pilings were reviewed and compared to basic mass balance equations used in surface water quality modeling to better understand their theoretical basis. A screening-level numerical model, similar to the Tableau Input Coupled Kinetics Equilibrium Transport Unit World Model (TICKET-UWM), was developed to assess the transport, fate, and effects of metals in rivers, streams, and other flowing waters. This model, called TICKET-2D, was used to quantify copper concentrations in the water column and sediment resulting from release from sheet pilings.

Analytical solute mass transport equations derived from plug flow systems, which are typically used to assess chemical fate and transport in rivers and streams, were functionally equivalent to the ESD equations. Therefore, the chemical behavior in the ESD generalized flowing waterway is best described using equations/models for rivers and streams on the basis of system geometry and mixing characteristics.

TICKET-2D considers the same chemical and physical processes as TICKET-UWM. It consists of a basic two-cell unit with an overlying water cell and a sediment cell. This unit repeats in the direction of flow to simulate flowing systems like rivers and streams. TICKET-2D verification simulations accurately reproduced output from the ESD equations when run with identical input parameters and specified K_D values. Calculations/simulations made with ESD equations and the TICKET-2D model demonstrate that the critical area for use classification is sediment since this is where PEC values exceeded PNEC values for simulations with long term copper emission rates.

3.02.A.T-05 Model Development for Assessing the Impact of Accidental Radioactive Releases into the Meuse River-Campine Canal

Amit Ravindra Ravindra Patil[1,2]*, Fabricio Fiengo Perez*[3]*, Jonathan Lambrechts*[4] *and Eric Deleersnijder*[4,5]*, (1)Institute of Mechanics, Materials and Civil Engineering, Catholic University of Louvain (UCLouvain), Belgium, (2)Belgian Nuclear Research Centre (SCK CEN), Belgium, (3)Aquafin, Belgium, (4)Institute of Mechanics, Materials and Civil Engineering, Université catholique de Louvain, Belgium, (5)Earth and Life Institute, Université catholique de Louvain, Belgium*

Emergency responses to accidental releases of hazardous materials, including radionuclides into aquatic environments require site-specific information. While monitoring systems can be helpful in identifying possible hazards, simulated data—such as the arrival of a potential plume—will be helpful in preventing exposure to radiation. In this context, we study the aquatic systems of the Meuse River and its connected canal network (Campine Canal) that flows across Belgium. Where the river contains not one but two (Chooz and Tihange) nuclear power plants (NPP) and the downstream flow across both power plants runs through many major Belgian cities, including Antwerp, and serves as primary source of drinking water in this region. In this study, the one-dimensional coupled shallow water and transport equation is solved for radionuclide concentration using the discontinuous Galerkin method in the SLIM modelling framework, where the model is applied for hypothetical accidental scenarios for both the NPPs. The scenarios were selected in reference to past nuclear accidents, where it was seen that the primary contamination was due to atmospheric releases with two dominant radionuclides: one is a long-lived ^{137}Cs and the other is a short-lived ^{131}I. Therefore, the scenarios selected are for atmosphere deposition considering varying wind speeds, as well as two river discharge scenarios for both radionuclides. In general, the simulated results show that, among the network of canals, the movement of radionuclides is slower in the Albert Canal (largest canal in the Campine network) compared to others, whereas the deposited plume travels relatively faster in the Meuse River. In fact, the movement is so slow that, in some scenarios, even if the distance through the Albert Canal is shorter, the radioactive plume reaches Antwerp earlier through other smaller Campine Canals. While the radioactivity level of ^{131}I in these smaller canals, during high flow conditions in the Meuse River becomes considerably low after up to 3 weeks of release, as opposed to the levels in the Albert Canal, which remain rather high. Hence, even though the arrival of radionuclide is slower in later parts of canal and preventive measures can be taken, the impact on drinking water in the Meuse River is immediate. Therefore, we would also present the ingestion doses for the general public for the different accidental scenarios.

3.02.B Advances in Exposure Modelling to Inform Science-Based Environmental Solutions

3.02.B.T-01 Antibiotics Pollution in the Three Gorges Reservoir Area: Current Status and Risk Analysis

Shiyang Li*, Wageningen University & Research (WUR), Netherlands*

The extensive use of antibiotics in human and veterinary medicine leads to environmental concerns, particularly their prevalence in ecosystems. To address this, the MARINA-antibiotics model, integrated with the SWAT tool for runoff, soil erosion, and water flow, was applied to assess antibiotic pollution in China's Three Gorges Reservoir Area (TGRA). This approach dynamically simulates the monthly fate of 30 antibiotics. The study focused on the TGRA river basin, estimating the load and concentrations of antibiotics in water and sediment. It factored in antibiotic concentrations in human and animal waste, wastewater treatment efficiency, population sizes, and manure management. The research also assessed the potential risks of antimicrobial resistance from these antibiotics.

Our findings indicate substantial spatial and temporal variations in antibiotic pollution within the TGRA, largely influenced by population distribution and animal farming activities, as well as fluctuations in streamflow. In the TGRA region, the total estimated antibiotics load was approximately 593.4 tons, with 84% originating from human sources and the remaining 16% from livestock production. Regarding the pathway of antibiotic transmission from land to rivers, point sources accounted for 99.38% of the load, while diffuse sources contributed a minor 0.62%. Notably, Oxytetracycline (OTC), Sulfachloropyridazine (SCP), and Ofloxacin (OFX) emerged as the most prevalent antibiotics, with respective loads of 82, 73, and 65 tons. The overall antibiotic loading density in the area was calculated to be 11.39 kg/km^2.

In our study of the fate of antibiotics in river systems, it was found that approximately 70% of these antibiotics eventually settle into the sediment, while 30% dissolve in the water.

Furthermore, the concentrations of antibiotics in water as predicted by our model were generally within an order of magnitude of the actual measured values, confirming the model's accuracy. Additionally, our study revealed a seasonal pattern in antibiotic contamination, noting increased levels during the dry season as compared to the wet season. Furthermore, an antibiotic risk assessment revealed that 6 out of the 45 river subbasins studied are at risk of antimicrobial resistance. These findings underscore the urgent need for effective management strategies to mitigate the environmental impact of antibiotic pollution and its associated risks in the TGRA and similar ecosystems.

3.02.B.T-02 Mapping the Risk of Ciprofloxacin in European Water Bodies: Incorporating the Impact of Bioavailability
Qiyun Zhang, Ph.D. candidate[1]*, Kristof Demeestere*[2] *and Karel De Schamphelaere*[1]*, (1)Ghent University - GhEnToxLab, Belgium, (2)Ghent University (UGent), Belgium*
The fluoroquinolone ciprofloxacin (CIP) is a widely prescribed antibiotic applied in human and veterinary health care. With its production and application, the compound has been detected in surface waters worldwide, which may lead to unwanted ecotoxicological consequences such as the development of antimicrobial resistance (AMR). On the other hand, recent studies have shown that the ecotoxicity and bioavailability of CIP is affected by water chemistry factors, namely, environmental pH and the dissolved organic carbon (DOC). Therefore, a comprehensive environmental risk assessment (ERA) for CIP needs to encompass the interplay between CIP and environmental conditions.

This study incorporated bioavailability into the ERA of CIP. With a CIP bioavailability model, the sensitivity of European water bodies to CIP, expressed by an environmental prediction no-effect concentration ($PNEC_{ECO}$), was estimated under four simulation scenarios. They are (1) the conventional scenario (no bioavailability incorporated), (2) the worst-case scenario (pH affects bioavailability, but DOC has no effect), (3) the average scenario (both pH and DOC affect bioavailability, weak CIP-DOC interaction), and (4) the best-case scenario (both pH and DOC affects bioavailability, strong CIP-DOC interaction). Probabilistic risk assessments were performed based on Monte Carlo simulation using CIP occurrence data and $PNEC_{ECO}$ obtained in different scenarios. Probability of risk (P_{risk}), uncertain risk ($P_{uncertain\ risk}$), and safe (P_{safe}) were assessed for Europe as a whole and for ten nations specifically.

Results indicate that the $PNEC_{ECO}$ had a high regional variability. Western Austria, northern and central Italy, southern Greece, and Norway appeared to be more susceptible to CIP. On the European scale, P_{risk} was between 9.8% (best-case) and 21.7% (conventional) across different scenarios, showing a clear influence caused by DOC. The country specific P_{risk} also presented high variations. The P_{risk} estimated for Spain and the Netherlands was below 10% in all scenarios, and that for France was 13-21%. The influences of pH and DOC were greater on the P_{risk} estimated for Germany and Portugal, which ranged from 32-67% and from 4-99%, respectively. Austria, Croatia, Czech, Hungary, and Slovakia observed probability of uncertain risk between 21% and 50%, while the incorporation of bioavailability could reduce uncertainties. Overall, the inclusion of water chemistry factors enables a more accurate ERA

3.02.B.T-03 Nano- and microplastic particles as vectors of exposure for plastic additive chemicals: Exploring the human health implications through the use of a multimedia food web model
Todd Gouin[1] *and Mick Whelan*[2]*, (1)TG Environmental Research, United Kingdom, (2)School of Geography, Geology and the Environment, University of Leicester, United Kingdom*
Nano- and microplastic particles (NMPs) may present a hazard in various ways, including a direct biophysical response to physical particle properties (e.g. size and shape), or as vectors for chemical exposure (e.g. plastic additive chemicals and/or those that might become sorbed to the particles from the surrounding environment). Evaluating risk requires reliable and relevant characterization of both exposure and hazard. The leaching of chemicals from NMPs has been identified as a potential exposure pathway in studies reporting effects associated with both in vivo and in vitro test systems. However, it remains unclear whether this exposure pathway is relevant to human health under environmentally relevant

conditions. Previously, the bioaccumulation food web model (ACC-HUMAN), has been used to estimate human exposure to hydrophobic organic chemicals as a result of consuming contaminated food and beverages obtained from the terrestrial and marine environments. Here, we describe a modification of the steady-state version of the ACC-HUMAN model to include dietary exposure to NMP containing either accumulated chemicals from the surrounding environment or chemical additives embedded in the plastic. Chemical transfer to the organism is described using a two-film resistance equation assuming spheroidal particles of different sizes. Various scenarios are presented, including the ingestion and subsequent bioaccumulation of chemicals associated with NMPs in terrestrial and marine food webs, with tissue concentrations accumulated in humans compared against a point of departure (POD), assumed to be 1 for a suite of hypothetical chemicals with varying physicochemical properties. Results suggest that exposure to NMPs with an inclusion level of plastic additive chemicals of 5% wt/wt with varying physicochemical properties needed to exceed a risk characterization ratio (RCR) of 1, would be significantly greater than current estimates of exposure to NMPs and subsequent leaching of plastic additive chemicals. The model can, thus, provide the basis for enabling a tiered evaluation of the relative human health risks posed by exposure to NMPs with varying levels of plastic additive chemicals.

3.02.B.T-04 Exposure Modelling Approaches to Support Environmental Decision-Making in Multiple Contexts: A Review of Select Case Examples at the U.S. EPA

Lindsay W. Stanek[1]*, Valerie Zartarian*[1]*, Rogelio Tornero-Velez*[1]*, Emily Snyder*[1]*, Jianping Xue*[2]*, Nicole DeLuca*[1] *and Elaine Cohen Hubal, PhD*[1]*, (1)U.S. Environmental Protection Agency (US EPA), (2)Retired*

Currently, jurisdictions and individuals are challenged to consider the full range of information required to manage and use chemicals in a way that protects and promotes public health. Research to apply and demonstrate approaches that leverage disparate information by combining both mechanistic and data-driven modeling to characterize human exposure to environmental stressors is critical for credible decision-making. For example, there are persistent environmental contaminants that are contributing to many human health outcomes, including lead (Pb) and perfluoroalkyl substances (PFAS). For Pb, much is known about its sources, and it has largely been eliminated from production of consumer goods in the U.S., but historical contamination still poses a human exposure risk. In contrast, despite some phase-out of some legacy PFAS, alternate chemicals within the same class of compounds are being introduced into product streams. We are conducting applied research on these two high priority chemicals using the latest modeling techniques to inform decisions at the national, regional, and local scale. EPA's Stochastic Human Exposure and Dose Simulation model for Pb (SHEDS-Pb) — a probabilistic, mechanistic human exposure model combined with a Pb deterministic biokinetic and uptake model — was developed and applied to estimate aggregate children's exposures and blood lead levels (BLL) from drinking water, dust, and soil to support EPA regulatory Pb decisions. On a regional level, we developed an advanced geospatial statistical approach using children's BLL to identify high Pb exposure locations at the census tract scale for two U.S. states. The resolution of results at this scale can help the most impacted communities target Pb actions for public health protection. For PFAS, limited existing fish tissue PFAS occurrence data, publicly available geospatial data, and census information were used to develop predictive models to identify potential areas of PFAS contamination. These findings are informing additional fish sampling in the Northwestern U.S. that will help EPA Regional partners better focus efforts to reduce human exposure to PFAS in impacted communities. These examples demonstrate our commitment to using state-of-the-science information and exposure tools to: characterize the scope and magnitude of the most important environmental health problems; develop new information to fill the most critical gaps; and advance methods and tools to inform public policy.

3.02.B.T-05 Power to the (usage) data – opportunities and limitations of model-based emission estimation for environmental exposure assessment of chemicals

Caterina Zillien[1]*, Leo Posthuma*[2]*, Erwin Roex*[2] *and Ad M. J. Ragas*[3]*, (1)Radboud University Nijmegen, Netherlands, (2)National Institute for Public Health and the Environment (RIVM), Netherlands, (3)Environmental Science, Radboud University Nijmegen, Netherlands*

With increasing numbers of chemicals used in modern society, assessing human and environmental exposure to them is becoming increasingly difficult. For example, measuring all >26,000 chemicals registered under REACH seems unrealistic and would be incredibly expensive. Currently, exposure assessment relies predominantly on empirical monitoring studies and is therefore per definition (1) retrospective and (2) limited in terms of the chemical spectrum covered. We argue that estimating emissions of chemicals based on production and usage data could offer a more efficient and systematic approach to tackle this issue. To illustrate the approach, a case study was conducted in the city of Nijmegen (NL) to estimate the emissions of active pharmaceutical ingredients (APIs) to wastewater. Input data included prescription data and hospital usage data on local level as well as over-the-counter sales on national level. Various routes of administration were considered and monthly emission loads to the wastewater treatment plant influent were calculated. The results suggest that model-based emission estimation on a city-level is feasible and in good agreement with wastewater measurements obtained via passive sampling. Results highlight the need to include excretion fractions in the conceptual framework of emission estimation but suggest that the choice of an appropriate excretion fraction has a substantial impact on the resulting model performance. Overall, model-based emission estimation could represent a complementary tool to environmental monitoring, particularly for compounds for which emission sources and emission pathways to the environment are known. Data availability and accessibility currently represent a major bottleneck for applying model-based emission estimation to other groups of chemicals of emerging concern beyond APIs.

3.02.P Advances in Exposure Modelling to Inform Science-Based Environmental Solutions

3.02.P-We116 A parametrized and regionalized Life Cycle Inventory Model to assess Tire and Road Wear Particles emissions

*Louisa Ainara Nina Ospital[1], Manuele Margni[2] and **Anne-Marie Boulay**[2], (1)CIRAIG Polytechnique Montreal, Canada, (2)CIRAIG - Ecole Polytechnique de Montreal, Canada*

Tire and Road Wear Particles (TRWPs), comprising degraded rubber, minerals, and road dust, are a significant global source of microplastics, estimated at 5.9 million tons in 2017. Recognizing the potential hazards to ecosystems and human health, this research addresses the limitations of current TRWP emission estimates. Indeed, current methodologies relying on emission factors (EFs) lack geographical applicability and often overlook critical parameters such as tire type, vehicle characteristics, road surface and driving styles. This study aims to improve the TRWP emissions inventory by incorporating these parameters, yielding context-specificity and reliable estimates. To calculate TRWP total emissions a bottom-up approach which integrates regional traffic activity rates with vehicle-specific EFs is employed. Initially, default EF values for six passenger and freight vehicles, distinguishing between large (10 µm to 500 µm) and fine (<10 µm) particle, were derived from an extensive literature review. Then, travelled vehicle-kilometers for the entire vehicle fleet were retrieved from international traffic databases. Finally, key parameters influencing tire wear, identified through a comprehensive review, were incorporated into the model as correcting multiplier factors for the default EFs. In addition, three archetypes, representing regional variations, were introduced. With 18 vehicle-specific default EFs and 8 key parameters, TRWP emissions were calculated for 34 countries. A sensitivity analysis under urban driving conditions emphasizes the relative impacts of influencing parameters, aiding prioritization for future investigations. Using default EFs, a comparison of TRWP total emissions with prior estimates demonstrates the model's reliability, with relative gaps of 8 to 34%. Corrected EFs reveal significant changes in emissions according to considered parameters, emphasizing potential underestimations in prior inventories. This parametrized and regionalized model offers a comprehensive understanding of global TRWP emissions, capturing diverse scenarios. Acknowledging data limitations regarding influencing parameters, the model is designed for continuous refinement as additional data becomes available. The results of this model can be used in future Life Cycle Inventories and Life Cycle Impact Assessments of TRWPs, especially to shed light on the magnitude of their impacts in comparison with the rest of the impacts associated with road transport.

3.02.P-We117 EXTRAPOLATION OF AIR RELEASE RATES BETWEEN DIFFERENT SUBSTANCES BEING USED UNDER SIMILAR CONDITIONS

***Yves Verhaegen** and Delina Lyon, Concawe, Belgium*

In any quantitative environmental risk assessment on the use of a chemical, the determination of release rates to air are key in achieving realistic exposure estimations. While release rates are typically available for volatile substances, useful information is scarce or lacking for structurally related semi- and non-volatile substances.

Therefore, we are proposing a simple method to extrapolate air release rates between chemicals with different vapour pressures and solubilities being used under similar conditions, based on evaporation theory. The method utilizes the vapour pressure, activity coefficient and air diffusion coefficient to extrapolate air release rates between chemicals. The extrapolation method is applicable to release from liquids and solids, but not to release from spray uses or uses that mainly give rise to airborne particles.

This poster describes the extrapolation method in more detail and its specific application to petroleum products as an example. This method can potentially be easily implemented in the REACH Environmental Release Category (ERC) concept to result in more realistic environmental risk assessments.

3.02.P-We118 Improving release estimates for the use of REACH registered petroleum and petrochemical-borne substances

***Yves Verhaegen**[1], David A Morgott[2], Craig Warren Davis[3,4], Joy Worden[5] and Thomas Vanfleteren[6], (1)Concawe, Belgium, (2)Pennsport Consulting LLC, (3)Toxicology & Environmental Science, Exxon Mobil, (4)Exxon Mobil, (5)QP Consulting Ltd, United Kingdom, (6)European Solvents Industry Group (ESIG, a Cefic Sector Group), Belgium*

In any quantitative environmental risk assessment on the use of a chemical, the determination of operational conditions (OCs), risk management measures (RMMs), and resulting local and regional release rates are key in achieving realistic exposure estimations. In the absence of specific data, release rates to air, water, soil and waste can be estimated by applying predefined release fractions (RF) on the local and regional use tonnage (for example, in kg/d). In REACH Guidance, default RFs are available for 25 generic use patterns (or Environmental Release Categories (ERC) in REACH terms). Industry sector groups (chemical manufacturers and their downstream customer industries) can further refine the ERC for each identified use of their chemicals into specific Environmental Release Categories (spERC), which describe the expected good practice conditions of use, and the corresponding RFs.

This poster describes recent collaborative efforts between the European Solvents Industry Group (ESIG), the European Solvents Downstream Users Group (ESVOC) and Concawe, the research association of European Fuel Manufacturers, to refine and where needed, develop additional spERCs that cover the uses of a wide range of petroleum derived substances: traditional solvents as well as complex substances whose precise composition is unknown or can only be partially characterized. Examples of such complex substances include gasoils, naphthas, mineral oils, white spirits, fuel oils, lubricants and refined base oils.

To refine and develop these spERCs, information from publicly available technical and scientific reports (for example, Emission Scenario Documents) as well as expert knowledge available at the manufacturers and downstream users are leveraged. Where feasible, sub-SpERCs supporting water solubility and vapour pressure dependent RFs are defined to allow further refinement of release estimates for the diverse range of substance properties. In the absence of specific data, generic operational conditions and RFs as defined in the REACH Guidance ERCs are adopted.

3.02.P-We119 Estimating Marine Chemical Emissions from Discharges of Sewage Treatment Plants into Freshwater Rivers

*Logan Insinga[1], **Christopher M Holmes**[1] and Juliet Hodges[2], (1)Applied Analysis Solutions, LLC, (2)Safety & Environmental Assurance Centre, Unilever, United Kingdom*

Changes in demographics are leading to greater urbanization and higher coastal populations which in turn is increasing the need to better understand chemical loading into coastal and marine environments. Many Home and Personal Care Products (HPCPs) are disposed of down the drain by the consumer, whereupon the ingredients typically are released into freshwater rivers having passed through upstream sewage treatment plants (STPs). Further transport to the marine environment can take place. However, there is a currently paucity of approaches to adequately estimate the extent of this emission route into the environment. Following on from previous work from our group estimating chemical mass discharged directly into marine environments, here we present an approach which utilizes data on hydrologic travel distance/time for inland STPs combined with estimated aquatic half-lives to estimate emissions from upstream STPs into rivers flowing to coastal areas. We have developed a spatially explicit fate and transport model to estimate emissions into the marine environment across 88 countries. This global model utilizes the HydroAtlas river dataset and covers 44,000 STPs in 34 countries which discharge into both freshwater and coastal waters directly. Ingredient mass discharged from freshwater STPs was estimated using hydrologic routing from the STP and estimated aquatic half-lives to the coastal discharge location. Discharged mass and percent of mass reaching the coast can then be calculated. Resulting information can be used to refine emission estimates of ingredients into marine environments based on population demographics, disposal scenarios, and STP hydrologic distance to the coast. Results can also be used to inform more refined marine exposure modelling for risk assessment purposes.

3.02.P-We120 European Monitoring Data Reveal Temporally Extended Pesticide Occurrence

***Larissa Zoë Herrmann**[1], Sascha Bub[2], Jakob Wolfram[2], Sebastian Stehle[2], Lara Petschick[2] and Ralf Schulz[3], (1)Rhineland-Palatinate Technical University Kaiserslautern-Landau (RPTU), Landau, Germany, (2)Rhineland-Palatinate Technical University Kaiserslautern-Landau (RPTU), Germany, (3)iES Landau, Institute for Environmental Sciences, Rhineland-Palatinate Technical University Kaiserslautern-Landau (RPTU), Germany*

Pesticides infiltrate aquatic ecosystems via various pathways, presenting substantial threats to non-target aquatic organisms. Traditionally, the evaluation of these risks has been limited to either acute or chronic assessments. However, it is imperative to advance our understanding of pesticide exposure patterns in aquatic environments and the profound impacts of pesticide applications and environmental dynamics. This knowledge is pivotal in establishing and verifying assumptions in ecotoxicological testing protocols. In this context, the utilization of comprehensive, large-scale monitoring data emerges as a transformative approach. This approach offers an expansive foundation for assessing aquatic exposure by examining sequential pesticide concentrations. This novel perspective will not only enhance our grasp of the dynamics of pesticide exposure in aquatic ecosystems but also contribute significantly to the development of ecotoxicological methodologies and the safeguarding of non-target aquatic species.

We investigated the likelihood of pesticides reappearing in European streams over medium-term (4 - 7 days) and long-term (8 - 30 days) periods, meaning their tendency to remain present at quantifiable levels for periods beyond the typical 96-hour (4-day) exposure duration, reflecting the minimum duration of chronic ecotoxicity testing. We collected and analyzed publicly available data on pesticide levels in European streams to establish probabilities of reoccurrence (POR) for approximately 360 different pesticides, ranging from less than 1% to 100%. By comparing medium-term and long-term probabilities of reoccurrence, we identified three categories that describe most pesticides: *(1)* occasionally, *(2)* repeatedly, and *(3)* continuously occurring substances. Fungicides were the most common among repeatedly occurring substances, while neonicotinoid insecticides and legacy compounds were found to continuously occur. The results of this study challenge the current understanding of how we assess the persistence and impact of pesticides and emphasize that substance-specific factors, such as physico-chemical properties, application recommendations, and regulations, influence how pesticides affect aquatic environments. This study underscores the need to evaluate pesticide exposure by considering consecutive concentrations, enhancing our understanding of the real exposure risks to aquatic ecosystems on a substance-by-substance basis.

3.02.P-We121 Modeling Global Environmental Fate of Short-, Medium- and Long-Chain Chlorinated Paraffins and Quantifying Global Source-Receptor Relationships for Remote Regions

***Chengkang Chen**[1], Li Li[2], Shaoxuan Zhang[3], Jianguo Liu[4] and Frank Wania[1], (1)Department of Physical and Environmental Sciences, University of Toronto, Canada, (2)School of Public Health, University of Nevada, Reno, (3)Peking University, China, (4)College of Environmental Sciences and Engineering, Peking University, China*

The long-term and widespread use of chlorinated paraffins (CPs), including short-, medium- and long-chain CPs (SCCPs, MCCPs and LCCPs), has resulted in extensive emissions and subsequent pervasive presence in the environment and the exposure of human and wildlife populations. Adverse effects of CP emissions may not only manifest in local source regions, but may also occur in remote regions, if CPs have the potential for long-range transport in atmosphere and oceans. However, a comprehensive understanding of the global spatiotemporal distribution of SCCPs, MCCPs and LCCPs is still lacking, which hinders us from quantifying the relative emission contributions of different source regions to the contamination of remote regions. Here, we apply the BETR-Global model with global emission estimates to simulate the global environmental fate of SCCPs, MCCPs and LCCPs. By feeding estimated emissions in East Asia, South Asia, Europe and North America separately into the model, we estimate their contributions to the environmental concentrations in three remote regions, namely the Arctic, Antarctica and the Tibetan Plateau. Through this work, we aim to: (i) identify the most CP contaminated regions globally and unveil the spatial and temporal distribution patterns in these regions; (ii) examine the temporal trends of environmental occurrence in the three remote regions, and how CP homologue groups fractionate and redistribute due to their varying potential for long-range transport; (iii) determine the regions contributing the most to CP contamination in remote areas, and explore how these contributions evolve in time and differ between SCCPs, MCCPs and LCCPs. This work not only advances a holistic view of the global environmental fate and transport of CPs, but also quantitively reveals how remote environments respond to the evolving use and emission of CPs in source regions. Such global source-receptor relationships are crucial for evaluating the effectiveness of potential global and regional CP emission-reduction strategies.

3.02.P-We122 Using fugacity model to explore transport dynamics of polychlorinated biphenyls in coastal environments
Yi Lun Hung[1] *and Tien-Hsuan Lu*[2]*, (1)Da-Yeh University, Taiwan (China), (2)Department of Science Education and Application, National Taichung University of Education, Taiwan*
Polychlorinated biphenyls (PCBs) are persistent organic pollutants that have affected the human living environment. Although PCBs have been banned in Taiwan, in recent years PCBs are still detected in Taiwan's coastal sediments and organisms including fish, shellfish and, mud shrimps. The aim of this study is to explore the spatial and temporal changes of PCBs in coastal environments based on the fugacity model. We construct a Level III fugacity model to describe the fate and transport of PCBs in coastal area near the industrial park to estimate the fugacities based on the PCBs measurements. Then, the estimated fugacities are used as the initial values in the Level IV fugacity model which describe the transport dynamics in the southward current scenario to simulate the time-course concentrations in two scenarios with emission sources and without emission sources for 3 months. Results show that PCBs are still released into the environment with estimated emission rate of 0.001 mol hr^{-1}. Using the fugacity models could help to understand the fate and transport of PCBs and inform the dynamics of PCBs in coastal environment. In the future, other media could be added into this model that can also be further used to explore the effect of other parameters, providing implications on the coastal transport dynamics of PCBs for environmental planning and management.

3.02.P-We123 Modelling Fate and Transport of Pharmaceutical Active Ingredients in a Swedish Lake Receiving Wastewater Effluents
Ekaterina Sokolova[1]*, Erik Kristiansson*[2] *and Mikael Gustavsson*[3]*, (1)Department of Earth Sciences, Uppsala University, Sweden, (2)Chalmers University of Technology, Sweden, (3)University of Gothenburg, Sweden*
Active pharmaceutical ingredients (APIs) from human pharmaceuticals are continuously emitted into the aquatic environment from effluents of wastewater treatment plants. While most APIs are emitted in very low concentrations, many are persistent and can accumulate in aquatic environments, and some are bioactive at very low concentrations. In this study, we present predicted environmental concentrations of 503 prescription APIs in Lake Ekoln, a sub-basin of Sweden's third largest lake, Mälaren. Our model considers the annual consumption of APIs, human metabolization rates, removal at the wastewater treatment plant, as well as biodegradation and mass transfer in the lake. The methodology included the following steps: identification of prescribed defined daily doses, active ingredient concentrations and structures; calculation of the physio-chemical properties of the compounds; calculation of emission into wastewater of each individual API; calculation of degradation and partitioning in wastewater treatment plant; and three-dimensional hydrodynamic modelling of API concentrations in the lake, accounting for biodegradation. The model was validated using measured concentrations in wastewater effluent and in the lake. The model demonstrates that even if a chemical is continuously emitted at a constant rate, the concentration in the lake varies by time, location, depth, and biodegradation rate, with the largest deviations seen for chemicals with short half-lives. For this lake, using the middle of the lake as a reference point, the maximum factors of potential differences stem from location, followed by depth, time, and then biodegradation. The model provided an accurate prediction of API concentrations in the lake, with 85% of the API median modeled values being within a factor of 10 from the measurements. One of the main conclusions from this work is that the concentration in a recipient can be modeled with a high level of accuracy directly from wastewater effluent concentrations. Thus, monitoring of recipients could, at least in part, be performed directly from samples of wastewater effluents. Finally, the accuracy of the model clearly demonstrates that it is possible to provide useful predictions on environmental concentrations when precise data are available on the consumption and emission of a chemical.

3.02.P-We124 Plastic Fate and Transport in Rivers: A Holistic Micro- / Macroplastic Perspective
David Mennekes[1,2] *and Bernd Nowack*[3]*, (1)Empa – Swiss Federal Laboratories for Material Science and Technology, Switzerland, (2)Environmental Systems Science, ETH Zurich, Switzerland, (3)Technology and Society Laboratory, Empa - Swiss Federal Laboratories for Material Science and Technology, Switzerland*
Over the last years micro- and macroplastic (or plastic debris) have been increasingly monitored providing a more and more detailed grid of sampling data. However, sampling data only provides spot information while the general desire would be continuous exposure data across catchments, rivers, or continents.

Here, we present a modeling approach for micro- and macroplastics in rivers and lakes on a country-scale. The model is based on existing small-scale modeling approaches and is parameterized using available monitoring or fate data and is coupled to a high-resolution release model. The model is able to predict concentrations of micro- and microplastics throughout a whole country and was first implemented for Switzerland. Our work aimed to compare dominating processes for micro- and macroplastics in order to increase our process understanding and derive exposure maps. In detail, we found that fate and transport are different for both size classes. On a catchment scale (e. g. the Rhine catchment in Switzerland) we observed about 45% and 98% retention for microplastic and macroplastics respectively. Moreover, we estimated that the accumulation of microplastics might be concentrated in lakes, while macroplastic accumulation, i. e. through beaching at river banks, is widely spread throughout the catchment. Also, macroplastic pollution in rivers and at river banks was found to be highly related to emission sites due to fast retention processes (i.e. beaching). In contrast, microplastic pollution was predicted to be spread over longer distances through water bodies.

Finally, understanding the fate and transport will help to decide on mitigation strategies in order to decrease plastic pollution and the potential risk to flora and fauna. Moreover, using the presented processes understanding can be applied to estimate emission data based on plastic concentration measurements in rivers.

3.02.P-We125 UTOPIA: Advancing Microplastic Understanding Through Process-Based Mass-Balance Modeling

Maria del Prado Domercq, PhD[1]*, Matthew MacLeod*[2]*, Antonia Praetorius*[3] *and Sam Harrison*[4]*, (1)Environmental Science, Stockholm University, ACES, Sweden, (2)Stockholm University, Sweden, (3)Institute for Biodiversity and Ecosystem Dynamics, University of Amsterdam, Netherlands, (4)UK Centre for Ecology & Hydrology (UKCEH), United Kingdom*

Plastic pollution is persistent and expands through all environmental compartments globally, however, the threat posed by plastic in the environment is still poorly characterized. Uncertainties about sources, transport, transformation and removal processes, and the properties of the plastic pollution itself still prevail. Simultaneously, plastic contributes to a complex profile of particulate pollution, characterized by a diverse range of composition, size, and shape, accompanied by a heterogeneous mixture of chemicals.

Inspired by evaluative unit world models for chemicals, here we present an open-source process-based mass-balance unit world model that provides a platform to synthesize knowledge about plastic pollution as a function of its measurable intrinsic properties.

Our modelling platform includes a reference set of equations to simulate transformation and transport plastic processes across a variety of soil, water, sediment and air compartments, as well a generic database of microplastic properties. Exposure indicators such as overall persistence (POV), characteristic travel distance (CTD) and transfer efficiency (TE), are derived enabling scenario analysis in comparative assessments of alternative plastic materials.

Our platform aims at providing a reference modeling platform for screening-level risk assessment that helps identification of knowledge gaps and key drivers of uncertainty, and that will support hypothesis generation to prioritize future environmental monitoring and process studies.

3.02.P-We126 A mass- balance model analysis of Small Microplastics (<100 µm) in highway stormwater runoff

Beatrice Rosso[1]*, Luca Vezzaro*[2]*, Carlo Barbante*[3]*, Andrea Gambaro*[1] *and Fabiana Corami*[4]*, (1)Department of Environmental Sciences, Informatics, and Statistics, Ca' Foscari University of Venice, Italy, (2)Department of Environmental and Resource Engineering, Technical University of Denmark (DTU), Denmark, (3)National Research Council (CNR), Institute of Polar Science (ISP), Italy, (4)Italian National Research Council (CNR), Italy*

Microplastics are ubiquitous in different urban and remote environmental compartments. Among them, the smallest microplastics (SMPs <100 µm) can be more easily transported in the environment, influencing the equilibrium of all the biogeochemical cycles, altering ecosystem dynamics and posing risks for biota and human health. Trafficked highways are considered one of the most important SMP sources since the highway stormwater runoff can wash off these pollutants emitted from vehicles, atmospheric deposition and other sources and reach receiving water bodies. However, there is a general lack of scientific literature about their analysis and consequently to their source, transport and fate pathways processes in the environment. Hence, a modelling analysis can overcome this lack of the SMP measurements and the discrepancies in literature data, due to different methods employed, units of measure and errors). These assumptions can be critical, as pollution levels in stormwater discharges are known to have a strong inter-event variability for micropollutants (and supposed to be also for SMPs).In this work, we developed a first dynamic event-based modelling approach to estimate the SMP fluxes from highway stormwater runoff, identify the most relevant pathways and show how the model can be used to assess the impact of end-of-pipe stormwater control measures on SMPs' emissions to the receiving water bodies. In this model, we employed a detailed novel SMP database based on our previously published studies, where we provide the temporal behaviour of the different SMP sources (road dust, dry and wet deposition) in the highway system context. The model results are extremely important to support the development of future pollution control options and strategies in the urban context, for instance for identifying and implementing the most cost-effective measures to decrease SMP emissions.

3.02.P-We127 Fugacity-based estimation of contaminated areas in coastal wetland receiving oxytetracycline from livestock wastewater

Yun He Chen[1], *Pei-Yu Yang*[2] *and Tien-Hsuan Lu*[3], *(1)Da-Yeh University, Taiwan, (2)Chaoyang University of Technology, Taiwan, (3)Department of Science Education and Application, National Taichung University of Education, Taiwan*

Oxytetracycline (OTC) is an important antibiotic used in the treatment and prevention of diseases in animal husbandry. Improper use and overuse of antibiotics leading to antibiotic resistance problems in the ecological environment and human health is an unignored problem. In Taiwan, current laws and regulations have not established standards for the discharge of antibiotics in livestock wastewater. Moreover, it is difficult to understand the potential impact of the use of OTC in the livestock industry on the water environment due to a lack of information on its environmental fate. Therefore, the aim of this study is to estimate the area of coastal wetlands affected by OTC discharged from drainage by quantifying OTC concentrations and fugacity model to provide implications for antibiotic management in coastal aquaculture. We collect water samples from drainage and coastal wetland and quantify OTC concentrations. On the other hand, a fugacity model is constructed to estimate the emission rate of OTC and to solve the area of contaminated coastal wetland based on the actual measurements. Results show that the average measured OTC concentration is 1.62×10^{-6} mol m^{-3}. Based on the developed fugacity model, emission rate is estimated as $2.68\times10^{-1}\pm3.31\times10^{-1}$ mol h^{-1} and the area of contaminated coastal wetland is estimated as 8.19×10^{13} or 6.69×10^{3} m^2. It should be noted that the area of the study coastal wetland is ~3.8×10^{7} m^2. Here we apply the actual OTC concentrations in drainage and coastal area to estimate the range of contaminated coastal areas by the developed fugacity model. Although it is needed to further discuss the true contaminated range, the study framework could be further used in coastal aquaculture management and provide implications for environmental policies.

3.02.P-We128 Improving the Parameterization of Forest Filter Effect in Environmental Fate Models: A Meta-Analysis Review of Particular Matter/Leaf Interaction

Hamed Dadkhah- Aghdash[1], *Elisa Terzaghi, PhD*[2] *and Antonio Di Guardo*[2], *(1)University of Insubria, Varese, Italy, (2)DiSAT, University of Insubria, Italy*

Particulate matter (PM) consists of different inorganic and organic components, and their aerodynamic diameters are in the range of 0.001–100 µm. PM is often associated with chemicals such as polycyclic aromatic hydrocarbons (PAHs) which can adsorb on it, especially the high molecular weight ones. PAHs originate from natural and anthropogenic sources and are among the most common air pollutants, especially in cities and industrial areas. For this reason, the improvement of the parametrization of the PM/leaf interaction is crucial for better understanding the role of plant biomass in the removal of PM (and PAHs) from air. While the main processes are currently accounted for in the available fate models (accumulation, dry and wet deposition of particles, rain dissolution, particle and wax erosion, degradation of chemical and mineralization of organic carbon, etc.) much is still to be done to fully understand the mass balance of PM in different environmental conditions (PM size classes and concentrations, meteorological parameter, species specific parameters such as leaf area index, specific leaf area, etc.) In this review, we collected and organized the available information on PM interaction between air and leaves. The analysis was performed on papers published between 1970 and 2023. For example, deposition velocity (V_d) data were collected, and this showed that many parameters are important in determining the extent of deposition velocity values: wind speed, differences in PM sizes. Among the environmental, scenario driven parameters of different ecosystems, some factors including the vicinity of plants to contamination sources, canopy morphology, period of exposure to pollution, meteorological conditions, orientation, surface area, cuticle roughness and integrity, and the presence of hairs on the surface of the leaves could influence the absorption and accumulation of particulates by leaves. This review will show and compare the available data influencing air/leaf PM accumulation as well as their association with PAHs. The objective is then to provide guidance to properly select simulation parameters for calculating PM mass balance in urban forests and choose the best species to mitigate PM pollution, especially in cities.

3.02.P-We129 Mass Balance Equations Model To Assess Environmental Fate of Micro- and Nanoplastics

Alberto Larraz[1] *and* ***Blanca Pozuelo***[2], *(1)Processes and Products Safety Unit, ITENE - Instituto Tecnológico del Embalaje, Transporte y Logística, Spain, (2)ITENE, Spain*

The presence of enduring plastic waste is ubiquitous, resulting in its widespread accumulation in the environment. Over time, this waste undergoes gradual degradation into micro- and nanoplastic particles (MNPs), characterized by dimensions ranging from 0,1 µm to 5 mm (microplastics) and less than 100 nm (nanoplastics). MNPs constitute an intricate amalgamation of polymers and chemicals intentionally incorporated into plastics to enhance their performance, functionality, and aging properties. Owing to their hydrophobic nature and small size, MNPs may also serve as vectors for the transmission of other hazardous substances into the human body (heavy metal, emergent contaminants as antibiotics and drugs, or pathogens such as bacteria).

Despite substantial advancements in the analysis of microplastics in environmental contexts, nanoplastic particles have rarely been addressed so far. Indeed, the examination of nanoplastics in intricate samples remains a formidable challenge for existing analytical techniques, necessitating significant enhancements in sample preparation methodologies. Consequently, a modelling approach that prognosticates the environmental fate of MNPs emerges as a crucial tool for comprehensive safety assessments.

In this context, we introduce SimpleBox4MNPs, an environmental fate model conceived as part of the PlasticsFatE project. This model is designed to predict the environmental destiny of MNPs, adapting the SimpleBox4Nano model to accommodate the specific behaviours of microplastics (MP) and nanoplastics (NP). Analogous to its predecessor, the new model is based in mass balance equations and primarily seeks to elucidate the fate of MNPs released into the environment, encompassing emissions into atmospheric, surface water, soil, and sediment compartments.

Significant improvements include an approach to the structural layer force and the consideration of particles larger than 100 nm, facilitating the differentiation of aggregation mechanisms between microplastics and nanoplastics. Additionally, the model incorporates a cascading fragmentation model to simulate size distribution, enabling the prediction of nanoplastic formation from microplastics.

In conclusion, the utilization of computational tools represents a distinct advantage in the realm of risk assessment, facilitating a comprehensive understanding of the ultimate fate and, subsequently, the anticipated exposure to MNPs in diverse environmental settings.

3.02.P-We130 Developing a Modelling Approach to Estimate Exposure of Coastal Birds to Heavy Metals: A Case Study of the European Shag Gulosus aristotelis

***Rosie J Lennon**[1], Alistair Boxall[2], Maria I Bogdanova[3], M. Gloria Pereira[3], Justyna P Olszewska[3], David Spurgeon[3] and Francis Daunt[3], (1)Natural England, United Kingdom, (2)University of York, United Kingdom, (3)UK Centre for Ecology & Hydrology (UKCEH), United Kingdom*

Many ecosystems are exposed to heavy metals due to emissions from a range of sources including industry, historic wastes, transportation or agricultural practices. Much modelling work has been done to assess how metals bioaccumulate in various species and food webs. However, very little work has been done to incorporate bird species into these models. At present, most avian risk assessment studies rely on empirical concentration data being collected directly from birds, which requires invasive sampling. Here, we present an approach to predict the exposure of a coastal bird species (European shag *Gulosus aristotelis*) to six metals (Cd, Cu, Pb, As, Ni, Zn), using an existing bioaccumulation model (MERLIN Expo) in conjunction with a newly developed avian model. Seasonal metal concentration data for sediment and plankton were obtained for two sites in the Firth of Forth estuary (Scotland), which represent a hypothesised exposure gradient and host two distinct populations of the European shag at the Isle of May (lower estuary) and Inchkeith (upper estuary). These data were used as model inputs to predict the bioaccumulation of each metal in 14 aquatic prey items at either site, for both seasons. Estimated prey concentrations were then used with avian site-specific biometric data and season-specific dietary data to estimate metal exposure (mg/day or mg/kg bw^{-1}) in individual shags belonging to either population, for both the summer and winter. Finally, the estimated daily exposure was compared to available avian toxicity thresholds (Zn, Cu and Pb only) to establish the level of risk. Patterns of bioaccumulation in prey species differed between the two sites; Ni presented higher rates of bioaccumulation in benthic species. Daily exposure for individual shags was predicted to be higher at the Isle of May compared to Inchkeith for all six metals, with Cu showing the largest difference between the two. Exposure was also found to be greater in winter compared to summer. In terms of risk, avian toxicity thresholds were surpassed for Zn and Cu in both populations, in both seasons. Further work is planned to evaluate this model using existing avian samples collected as part of a long-term monitoring programme for European shags in the Firth of Forth estuary. This approach could be useful as a risk assessment tool and/or to develop more sensitive predictions of metal exposure in coastal/marine bird species where population-specific data are available.

3.02.P-We131 Mechanistically Modeling the Long-term Human Exposure to Chlorinated Paraffins

***Chengkang Chen**[1], Li Li[2], Shaoxuan Zhang[3] and Frank Wania[1], (1)Department of Physical and Environmental Sciences, University of Toronto, Canada, (2)School of Public Health, University of Nevada, Reno, (3)Peking University, China*

The extensive production and widespread application of chlorinated paraffins (CPs), including short-, medium- and long-chain CPs, have led to their ubiquitous occurrence in the environment and subsequent human exposure. However, a critical knowledge gap persists regarding how the application patterns and temporal trends in environmental release can shape the long-term human exposure to CPs. Here we are using a modelling approach to examine and contrast time-variant human exposure of the general populations in three regions with differing application patterns and release trends for CPs — western Europe, China, and North America. We hypothesized that in regions where CPs are predominantly applied outdoors, such as in metalworking fluids (e.g., western Europe), environmental release occurs primarily outdoors, making far-field exposure more relevant. Conversely, in regions where CPs are primarily used indoors, such as in polyvinyl chloride products (e.g., China), dominant indoor release emphasizes the importance of near-field exposure. By using the model to link environmental release with human exposure, we examine: (i) how the temporal trends of human-body burdens in longitudinal cohorts vary among these regions, and how they depend on CP environmental release; (ii) whether the relative importance of far-field vs. near-field exposure differs due to varying application patterns; and further (iii) how any such difference in relative importance changes among different age cohorts and with various CP homologue groups. This work offers a pioneering and comprehensive understanding of long-term human exposure to CPs and identifies key factors driving this process. Furthermore, the integration of exposure modeling with emission estimation establishes a scientific foundation for identifying key exposure sources, efficiently managing health risks associated with CPs, and assessing the potential effects of future emission reduction strategies.

3.02.P-We132 Advancing Dermal Exposure Modeling: Integration, Evaluation, and Comparative Analysis within the EAS-E Suite Framework

***Alessandro Sangion**[1], James M Armitage[2], Lauren Hughes[1], Trevor N Brown, PhD[1], Liisa Toose, M.Sc.[1] and Jon A. Arnot[1], (1)Arnot Research and Consulting Inc. (ARC), Canada, (2)AES Armitage Environmental Sciences, Inc, Canada*

Quantifying chemical exposure by the dermal route is an important element of safety evaluations for product stewardship and regulatory decision-making. Recent risk evaluations under the Toxic Substances Control Act (TSCA) have highlighted the need for improving the scientific basis of dermal exposure modelling used in evaluating the dermal route of exposure for workers and consumers.

The objective of this presentation is to address uncertainty in the selection of appropriate dermal exposure models for decision-making. We have integrated a suite of dermal exposure models within the Exposure And Safety Estimation (EAS-E) Suite framework, facilitating the comparison and evaluation through a series of case studies. Chemical properties and parameters required to run the models are directly provided within the EAS-E Suite platform to facilitate model parameterization. The dermal exposure models included in EAS-E Suite are those used in the RAIDAR-ICE and PROTEX-HT models, American Industrial Hygiene Association's SkinPerm, US EPA's Consumer Exposure Model (CEM), as well as ECETOC's Targeted Risk Assessment (TRA) tools for Consumer and Worker Exposure.

Dermal exposure assessment can be conducted (i) as a "stand-alone" analysis, where models exclusively simulate chemical exposure through direct skin contact in specific scenarios, or (ii) as part of comprehensive multi-pathway exposure models, where dermal exposure is integrated into an aggregate exposure assessment. Some dermal exposure models focus on estimating the dermal absorbed dose within defined exposure scenarios while others are coupled with toxicokinetic models, enabling the calculation of systemic exposure metrics such as blood and urine concentrations following dermal or aggregate exposures.

The analysis of the different models has revealed that the primary equations for the dermal permeation coefficient (k_P, cm/hr) in most of the cases is the "SKINPERM" model developed by ten Berge. This agrees with previous analysis indicating that the "SKINPERM" Quantitative Structure-Activity Relationship model is the best performing model available for estimating k_P. Furthermore, the "SKINPERM" model can be parameterized using only the octanol-water partition coefficient (K_{OW}) and molar mass facilitating the application for thousands of data poor chemicals. Different data sets capturing a range of chemical properties and exposure scenarios (occupational vs consumer) were used for model comparisons and evaluations.

3.02.P-We133 Risk Assessment of UV Filters from Sunscreens and Other Cosmetic Products in Recreational Waters: A Case Study of Southern Poland

***Agata Wódkowska*[1]**, *Przemysław Mielczarek[2] and Agnieszka Gruszecka-Kosowska[3], (1)Faculty of Geology, Geophysics and Environmental Protection, University of Science and Technology (AGH), Poland, (2)Faculty of Materials Science and Ceramics, AGH University of Krakow, Poland, (3)Faculty of Geology, Geophysics and Environmental Protection, AGH University of Krakow, Poland*

UV filters are commonly used in Personal Care Products (PCPs) as they are essential for skin protection from sunlight. Despite being still poorly researched, due to their wide application hundreds of tons of UV filters are released into the environment each year, thus they are considered recently as emerging contaminants. Lately concerns were raised on their distribution and bioaccumulation in the various trophic levels, and even in humans as some UV filters act as Endocrine Disrupting Chemicals (EDCs).

This research aimed to provide screening studies on the UV filters in popular recreational water reservoirs in Southern Poland, and in the Dobczyce Reservoir as the reference site. The sampling campaigns were carried out in both winter and summer months reflecting lack and peak recreational activity, respectively. In the selected sampling points of each reservoir, water, suspended matter, and bottom sediment samples were collected.

The contents of the most often used in PCPs UV filters were investigated in our study, both organic: benzophenone-3 (BP3), 4-methylbenzylidene-camphor (4-MBC), octocrylene (OC), ethylhexyl methoxycinnamate (EHMC), butylmethoxydibenzoylmethane (BM-DBM), homosalate (HMS), methylene bis-benzotriazolyl tetramethyl butylphenol (MBBT), isoamyl methoxycinnamate (IAMC) and inorganic: titanium dioxide (TiO_2) and zinc oxide (ZnO). Analyses of UV filters were performed using Gas Chromatography Mass Spectrometry (GC-MS), Inductively Coupled Plasma Mass Spectrometry (ICP-MS), Inductively Coupled Plasma Optical Emission Spectrometry (ICP-OES), X-Ray Fluorescence (XRF), and Scanning Electron Microscopy (SEM).

Based on the UV filters contents the environmental and health risk assessment will be performed, using the US Environmental Protection Agency (USEPA) methodology and employing Monte Carlo modelling (DecisionTools Suite Lumivero) in order to determine variability and uncertainty of the results during current exposure.

The results of these preliminary studies in Southern Poland will bring new insides into temporal and spatial UV filter content changes in the recreational reservoirs, in both potentially polluted and unpolluted environments. As the threshold levels of UV filters are missing in the regulatory acts, the results of our studies might be meaningful in establishing the acceptable risk levels for this group of emerging contaminants.

3.02.P-We134 Environmental Risk Assessment Screening Proposal – applying country-specific dilution factors and refined input factors

Harald Streicher[1]*, Diego Robles*[1]*, Hattie Cerridwen Catherine Brunning, MChem; PhD Student*[2] *and Alistair Boxall*[2]*, (1)Beiersdorf, Germany, (2)University of York, United Kingdom*

Exposure assessment approaches for Human Safety Assessment differ significantly from respective Environmental Safety Assessments. Most Human Safety Assessments are concentration-based and focus on setting safe limits for individual products to protect consumers from potential health risks. The standard approach for Environmental Risk Approaches takes the total tonnage of a chemical (or the group of chemicals with the same mode of action) into account to evaluate and manage the environmental impact across all industries and applications. In cases where chemicals have different applications and uses with different exposure scenarios, we advocate for a combination of the two complementing approaches to facilitate environment-responsible ingredient decisions. Such a concentration-based approach can be applied and validated with conclusions from data-rich substances, e.g. alcohol-ethoxylates.

The HERA (Human & Environmental Risk Assessment on ingredients of European household cleaning products) report for Alcohol Ethoxylates (version 2.0, September 2009) includes an extensive Environmental Risk Assessment (ERA) for these chemicals. We developed an ERA screening for data poor chemicals and used the HERA data as a safety benchmark for our evaluation of Alkyl-PEGs. Predicted Environmental Concentrations (PECs) are derived for surface water and soil. Respective Predicted No-Effect Concentrations (PNECs) were derived for freshwater and soil applying standard methods and defaults.

In a first step towards refining the Environmental Risk Assessment we applied country-specific wastewater volumes and dilution factors to overcome the limitations of the overall default value. In a subsequent step we refined the input factors taking demographics and use-patterns into account.

By applying this proposed ERA screening method, we are confident that we can effectively identify critical ingredients within a larger portfolio of chemicals, leading to a more refined and accurate assessment of their potential environmental risks and ultimately supporting the development of more sustainable and environmentally friendly cosmetic formulations.

3.02.P-We135 Considerations for Applying the Parallel Artificial Membrane Permeability Assay (PAMPA) in the Screening of Gastrointestinal Absorption of Chemicals of Environmental or Occupational Concerns

Shenghong Wang, Zhizhen Zhang, Dingsheng Li and ***Li Li****, School of Public Health, University of Nevada, Reno*

Chemicals present in the environmental and occupational settings can exert adverse health effects on humans after gastrointestinal absorption into the systemic circulation. Parallel Artificial Membrane Permeability Assay (PAMPA) has gained advocacy for its application to measure the effective permeability towards pharmaceuticals. However, since chemicals of environmental or occupational concerns differ from pharmaceuticals in hydrophobicity and volatility, a thorough, mechanistic understanding of chemical mass transfer in PAMPA is warranted if we seek to expand the applicability of PAMPA. Here, we introduce an in-silico mass balance model, which describes chemical mass transfer in PAMPA based on inputs of fundamental physicochemical properties, e.g., molecular weight, partition coefficient, and dissociation constant. The model's performance is evaluated by an agreement between predicted and measured permeabilities of 1383 chemicals, which indicates that 95% of the estimated permeabilities are either fall in the same order of magnitude or more conservative than the measurements. The model predicts an inverted U-shaped dependence of permeability on the octanol-water partition coefficient (log K_{OW} for neutral compounds and log D_{OW} for ionizable compounds), with the maximum permeability occurring in log K_{OW} or log D_{OW} ranging between 0 and 2. The model estimates a high membrane retention rate for hydrophobic chemicals, as well as the loss of volatilization to the headspace of the PAMPA apparatus for highly volatile chemicals. Notably, the measured permeabilities of hydrophobic chemicals are remarkably sensitive to specific experimental conditions, e.g., frequency of stirring, and incubation time, making measurements under different conditions less comparable. More important, for highly hydrophobic chemicals (log K_{OW} or log D_{OW} greater than 3.8), steady-states mass transfer, which is the fundamental assumption of PAMPA can never be achieved. Therefore, the current design of PAMPA needs to be modified before its application to chemicals of environmental or occupational concerns. Our work provides an in-silico mechanistic approach in support of efficiently and defensibly predicting the permeability of chemicals and complements the current laboratory approach.

3.02.P-We136 An Extension to Current Model Averaging Methods for Benchmark Dose Estimation

Jens Riis Baalkilde[1]*, Niels Richard Hansen*[2] *and* ***Signe Marie Jensen***[1]*, (1)Plant and Environmental Sciences, University of Copenhagen, Denmark, (2)Mathematical Sciences, University of Copenhagen, Denmark*

In dose-response modeling, several models can often yield satisfactory fits to the observed data. In this case, the current practice used in risk assessment is to combine the fitted models using model averaging, which is a way to combine several models in a weighted average. One particular important parameter, used in risk assessment, is the benchmark dose, which is the dose level resulting in a predefined abnormal change in the response.

Current practice when applying model averaging is to use weights based on the Akaike Information Criterion of the individual models. We introduce an alternative to these weights, denoted the Stacking weights, which is the set of weights minimising the squared prediction error of the model averaged curve.

A simulation study was conducted to assess the performance of the Stacking weights compared to the currently used weights. The simulation study showed that the currently recommended weights performed well. The newly introduced Stacking weights performed similarly. Based on the promising results of the Stacking weights, they have been added as a feature in the R package "bmd".

3.02.P-We137 Daphnids response to physical toxicants; individual response and data capture approaches

Katie Reilly[1] *and Iseult Lynch*[2]*, (1)University of Birmingham, United Kingdom, (2)School of Geography, Earth and Environmental Sciences, University of Birmingham*

Physical toxicants in the environment, such as nanomaterials and microplastics, can pose an interesting challenge to organism once ingested. The observed toxicity can be due to a combination of factors- the physical presence of the toxicant and any associated inflammation response, the calorific deficit that is induced through the ingestion of particles reducing the food uptake, and the additional energy requirement to remove and depurate the particle where possible. Through this combination, there could be various changes to the available energy, which will be interesting to explore through dynamic energy budget models, taking into consideration toxicity responses and also starvation effects.

Daphnia are an excellent model through which to explore this, as they are filter feeders and therefore a realistic model organism to explore freshwater particle toxicology. Daphnia have also widely been used in ecotoxicity studies previously, for a range of toxicants including nanomaterials and microplastics, in addition to other environmental parameters such as food shortages. Life history data of Daphnia has also widely been explored and there is a wealth of data available as a starting point to develop the model.

This project explores that use of Daphnia chronic toxicity data (OECD 211) from a microplastics and surfactant co-exposure test in a Dynamic Energy Budget model, and explores the data capture templates and end points that would be useful to strengthen the experimental design, and model in due course. For example, ensuring that the individual Daphnid size is recorded at the release of the first brood is a useful measurement for the parameter estimation for the model, and including this in a data capture template for chronic exposures going forwards would be a useful, and not excessive, addition to chronic Daphnia exposure observations. By generating and creating comprehensive data capture templates, we can support the FAIR data principles, by facilitating the use of ecotoxicological exposures into more complex environmental questions going forwards.

3.02.P-We138 Environmental risk assessment of different forms of graphene-based materials in European freshwaters

Hyunjoo Hong[1] *and Bernd Nowack*[2]*, (1)Empa, Switzerland, (2)Technology and Society Laboratory, Empa - Swiss Federal Laboratories for Material Science and Technology, Switzerland*

The increasing use of graphene-based materials (GBMs) in diverse applications has been raising environmental concerns. Our previous study performed a material flow analysis, identifying GBM release pathways and estimated concentrations in various environmental compartments. Although the importance of considering forms of GBMs in realistic characterization of the environmental risk assessments of pollutants, the different forms of GBM, including pristine graphene, graphene oxide, and reduced graphene oxide, has not been accounted in the environmental risk assessments yet.

To address this critical gap, we propose a form-specific approach for environmental risk assessment. This approach combines predicted environmental concentration (PEC) derived from MFA with a predicted no-effect concentration (PNEC) calculated from the form-specific Probabilistic Species Sensitivity Distribution analysis to derive the risk characterization ratio (RCR). By calculating form-specific risk characterization ratios of individual GBMs, our study aims more accurate environmental risk assessment and enables to inform effective risk management strategies.

Our study reveals that the PECs of all forms of GBMs are extremely low. The PNECs of different forms of GBMs are comparable, indicating similar toxicity of different forms. Furthermore, the RCRs for all forms of GBMs are well below 1, indicating a negligible environmental risk. This study significantly enhances our understanding of the potential environmental risks associated with GBMs and lays the groundwork for further investigations into their actual environmental impact. By providing a form-specific approach for assessing the environmental impacts of GBMs, our research contributes to a more sustainable future by reducing uncertainties, improving decision-making processes, and enhancing environmental protection.

3.03.A Advances in High Resolution Mass Spectrometry Based Non-targeted Analysis for Exposure Monitoring and Assessment of Human and Environmental Samples

3.03.A.T-01 Automated Prediction of Toxic Chemicals in Complex Mixtures

Yvonne Kreutzer[1]*, Ida Rahu*[2]*, Helen Sepman*[1] *and Anneli Kruve*[1]*, (1)Stockholm University, Sweden, (2)Department of Materials and Environmental science (MMK), Stockholm University, Sweden*

Exposure to toxic chemicals, including endocrine disruptors, poses significant risks to both ecological and human health. To discover such chemicals, high-resolution mass spectrometry (HRMS) is commonly employed. Simultaneously, samples are complicated chemical mixtures where thousands of HRMS features are detected. Pinpointing and identifying the chemicals causing the toxic effects remains time-consuming, and often only a fraction of the toxicity is explained.

To address this, we are developing *in-silico* data analysis tools for risk-based prioritization using HRMS features of unknown chemicals. We hypothesize that combining unsupervised and supervised learning allows extracting toxicity-relevant information from the tandem mass spectra.

Unsupervised molecular network approaches, based on HRMS spectra from compounds with known toxicity, offer a promising strategy for extracting structure and toxicity-relevant information independent of direct library matching. Each HRMS spectrum represents a node; similar spectra are linked with the edges. Detected HRMS spectra from samples can be mapped to the developed network, allowing a spectral similarity-based toxicity evaluation prior to the identification of the detected features. The network approach yields sensitivities above 0.6 for nr.ahr and nr.er.lbd targeting assays.

Furthermore, we evaluated the combination of deep-learning autoencoders coupled with random forest-based toxicity prediction. We found that autoencoder models are capable of extracting compound-specific information with the ability to reconstruct the original spectrum from the compressed latent space information with an average cosine similarity of 0.73. Notably, these models exhibit a reduced emphasis on low-intensity peaks, hinting at their potential application in spectral noise removal. Ongoing research aims to enhance these approaches, providing numerical results by the time of the conference.

3.03.A.T-02 A stochastic approach for parameter optimization of feature detection algorithms

Mohammad Sadia[1]*, Youssef Boudguiyer*[1]*, Rick Helmus*[2]*, Antonia Praetorius*[3]*, Marianne Seijo*[1] *and Saer Samanipour*[4]*, (1)University of Amsterdam (UVA), Netherlands, (2)Institute for Biodiversity and Ecosystem Dynamics (IBED), University of Amsterdam, Netherlands, (3)Institute for Biodiversity and Ecosystem Dynamics, University of Amsterdam, Netherlands, (4)University of Amsterdam, Netherlands*

Abstract:

Feature detection plays a crucial role in non-target screening (NTS), requiring careful selection of algorithm parameters to minimize false positive (FP) features. In this study, a stochastic approach was designed and evaluated to optimize the parameter settings of feature detection algorithms used in processing high resolution mass spectrometry data for NTS. This approach was validated by its application to four open-source algorithms (OpenMS, SAFD, XCMS and KPIC2) within patRoon platform for processing extracts from spiked drinking water samples containing 46 per- and poly-fluoroalkyl substances (PFAS). The designed method is based on stochastic strategy involving random sampling from variable space and the use of Pearson correlation to assess the impact of each parameter on the number of detected suspect analytes.

Using our optimizing approach, the optimized parameters led to improvement in the algorithm performance either by increasing suspect hits in case of SAFD and XCMS, or reducing the total number of detected features (i.e., minimizing FP) for OpenMS. These improvements were further validated on three different drinking water samples as test dataset. The optimized parameters resulted in lower false discovery rate (FDR%) compared to default parameters. This approach effectively increased the detection of true positive features (confirmed across different scenario of defining the true positive), and underscored the advantage of using the consensus of data from multiple algorithms to priorities the overlapped features as a true feature to be subsequently used in the NTS. This work also indicated the necessity to perform parameter optimization initially in the NTS workflow, using a sample spiked with the targeted group of chemicals to optimize algorithm parameter settings, by maximize the detection of the true-positive features (suspect hits).

3.03.A.T-03 A data analysis pipeline integrating ion mobility and high-resolution mass spectrometry for non-target screening in environmental studies

Sade Julien*, Laboratory of Water, Environment and Urban Systems (LEESU), Marne-La-Vallée, France*

The goal of this study is to develop a pipeline for analysis of HRMS data including ion mobility in the field of environmental studies, to overcome the challenges posed by proprietary vendor software and to take advantage of recent open data formats and softwares. Especially, it was developed to avoid alignment problems and data format limitations encountered with proprietary software. The pipeline includes a condensed and convenient data format (Apache Parquet) to allow for the compatibility of data with various programming languages and open-source packages. For example, data can be imported directly in DEIMoS, a recent Python package allowing the processing of HRMS data with ion mobility. It incorporates fast signal processing algorithms for peak detection and alignment. The processed data will be further used with other open-source packages used in environmental studies, such as patRoon, to enable extensive interrogation of a number of spectral libraries for the identification of unknown compounds. This comprehensive pipeline will be implemented in HRMS analysis of environmental samples, especially for surface waters impacted by urban wet weather discharges of wastewater. It is anticipated to facilitate the identification of contaminants of interest in polluted waters, as part of environmental monitoring performed in the Paris region. The pipeline will also be used in conjunction with ecotoxicological analyses for extensive data modeling of toxic contamination in complex environmental mixtures.

3.03.A.T-04 Exposomics meet Quantitative Non-Target Screening: A tool for Semiquantitative Analysis of Emerging Contaminants in Human biofluids and Tissues

Reza Aalizadeh[1]*,* ***Ruben Gil-Solsona***[2,3]*, Varvara Nikolopoulou*[1]*, Nikiforos Alygizakis*[4]*, Nikolaos S. Thomaidis*[1] *and Pablo Gago Ferrero*[2]*, (1)National and Kapodistrian University of Athens, Greece, (2)Institute for Environmental Assessment and*

Water Research, Spanish Research Council (IDAEA-CSIC), Spain, (3)Department of Chemistry, Laboratory of Analytical Chemistry, National and Kapodistrian University of Athens, Greece, (4)Environmental Institute, Slovakia
The term exposome was firstly coined by C. Wild as life-course environmental exposures from prenatal period onwards, including exposure to exogenous chemicals. However, to holistically understand human external chemical exposome, nontarget strategies are highly encouraged. Nontarget analyses (NTS), despite their unbiased results, have been weighed down in exposomics field by their lower sensitivity compared to low resolution, as well as the lack of other analytical validation characteristics (recovery values, matrix effects (ME) or specificity). However, the main challenge is its qualitative nature. Although classical target strategies are constrained to a small set of pre-selected chemicals, the derivation of accurate concentrations made target strategies the ultimate choice.

Recently, new strategies have emerged to NTS a semiquantitative analysis using machine learning algorithms to learn from how chemicals ionize in the ionization source. Generally, the concept of ionization mode of action is established based on working solvents and it can provide acceptable interpretations on ionization-concentration relationship. Despite recovery values effect can be reduced by using simple sample treatments, the ME is still having an important impact. Therefore, it is necessary for development of specific ionization-efficiency algorithms to compensate for matrix effect in case solvent-based ionization efficiency fails to resolves the bias from ME.

In this work, we have trained six different tools (solvent, human serum, urine, brain, placenta and semen) to obtain semiquantitative results from NTS. Different sample preparation methods have been used: deproteinization strategy with acetonitrile (semen and serum), CAPTIVA cartridges clean-up (urine) or lysis and pre-concentration with SPE cartridges (tissues). Recovery values were satisfactory for almost all tested chemicals, so the method was built to counteract matrix effects in the quantitation process.

Molecular descriptors were filtered using ant-colony optimization, and the best ones were kept training each model. We have tested the tool then with different real non-spiked samples, comparing quantitative (using a real calibration curve) with the semi-quantitative ones, with values between 50-200 % of the accurately calculated value.
Our tool opens the possibility to perform comprehensive NTS of human samples in a semiquantitative manner, virtually obtaining a wide characterisation of the human chemical exposome.

3.03.A.T-05 Comprehensive suspect screening workflow for the analysis of xenobiotics and metabolites in human biofluids
***Mikel Musatadi**[1], Inés Baciero-Hernández[1], Ailette Prieto[2], Maitane Olivares[3], Nestor Etxebarria[4] and Olatz Zuloaga[2], (1)Research Centre for Experimental Marine Biology and Biotechnology (PiE-UPV/EHU), Spain, (2)Analytical Chemistry, University of the Basque Country (UPV/EHU), Spain, (3)Analtytical Chemistry, Research Center for Experimental Marine Biology Biotechnology "Plentziako Itsas Estazioa", University of the Basque Country (PiE-UPV/EHU), Spain, (4)Department of Analytical Chemistry, University of the Basque Country (UPV/EHU), Spain*
Suspect and non-target substance screening (SNTS) methods are gaining prominence for deciphering the human exposome due to their ability to analyse a broad chemical spectrum in human biofluids. Nevertheless, SNTS methods using human biofluids are infra studied in comparison to other samples, such as environmental matrices. Therefore, the need of comprehensive workflows with robust and reliable quality control/quality assurance (QC/QA) measures are demanding. In this study, we developed a suspect screening workflow to identify exposome-related xenobiotics and phase II metabolites in diverse human biofluids, specifically, human urine, breast milk, saliva, and ovarian follicular fluid. These samples were extracted with appropriate sample preparation protocols and analysed using ultra-high-performance liquid chromatography coupled with high-performance tandem mass spectrometry (UHPLC-HRMS/MS). The parameters and criteria introduced in the workflow were optimize to ensure the simultaneous annotation of 183 xenobiotics. In that sense, the "peak rating" parameter was compulsory to eliminate the labour-intensive manual review of chromatographic peaks and also to avoid the chromatographic peak area threshold that could eliminate low abundance peaks. Additionally, the impact of endogenous molecules on xenobiotic annotation we carefully examined employing inclusion and exclusion suspect lists in the post-processing step. To assess the workflow's performance, limits of identification (LOI) were determined, as well as type I (false positives) and II errors (false negatives) in both standard solutions and spiked biofluids. Remarkably, 80.3% of the suspects achieved LOIs below 15 ng/mL. Regarding type I errors, only two cases were identified in standards and spiked samples. Conversely, type II errors increased from 7.7% in standards to 17.4% in real samples. Notably, the use of an inclusion list for endogenous molecules proved advantageous, preventing 18.7% of type I errors, while the exclusion list led to 7.2% of type II errors despite the annotation workflow being less time-consuming.

3.03.B Advances in High Resolution Mass Spectrometry Based Non-targeted Analysis for Exposure Monitoring and Assessment of Human and Environmental Samples

3.03.B.T-01 Harnessing Molecular Ions by GC-APCI-IM-HRMS for Simultaneous Target, Suspect, and Nontarget Screening of Hydrophobic Contaminants in Sediments
***Xiaodi Shi**[1], Håkon A. Langberg[2], Anna Sobek[3] and Jonathan P. Benskin[4], (1)Stockholm University, Stockholm, Sweden, (2)Norwegian Geotechnical Institute (NGI), Norway, (3)Environmental Science, Stockholm University, Sweden, (4)Department*

of Environmental Science (ACES), Stockholm University, Sweden
The increasing diversity of chemicals used by society requires new analytical methods to determine regulated contaminants, while simultaneously collecting nontarget data to identify unknown compounds. However, due to the extensive fragmentation during electron impact ionization (EI), gas chromatography (GC)-based screening suffers from the complexity of fragment ions and infeasibility for *de novo* identificiation, resulting in the scant census of hydrophobic organic contaminants (HOCs). Herein, atmospheric pressure chemical ionization (APCI) was hyphentated to GC-high resolution mass spectrometry (HRMS) to presuerve (quasi-)molecular ions, which are subsequently separated by ion mobility (IM) to derive instrument-independent collision cross section (CCS) for forensic identifcation. A novel analytical workflow was developed for simultaneous target, suspect, and non-target screening of HOCs using background sediment samples from the Baltic Sea. The chemical space of this method was defined by 87 contaminants analyzed as target compounds with 1.44<log K_{OW}<16.8 and 4.76<log K_{OA}<16.9. After optimization of instrumental parameters, 78% of our targets yielded (quasi-)molecular ions as base peaks; instrumental detection limits of GC-APCI-IM-HRMS in MS^E mode for 86% of our target compounds are similar to or lower than those of GC-MS using EI in selective ion monitoring mode. Four-dimensional information (i.e., formula, CCS, retention time, and fragments) of 463 GC-amenable compounds were collected for suspect screening. Observed CCS of 26 target compoundss matched values in libraries, while CCS of 61 target compounds were reported for the first time. From the sediment samples, 12 compounds were annotated through 4D suspect screening using strict criteria. Leveraging CCS as a dimension of size, 705 unknown features were prioritized as potential organohalogens. This strategy was validated by the identification of natural brominated compounds. The utility of the method was further demonstrated through the application to archived sediments samples with different contaminantion levels and geographical locations from Arctic shelf seas, the Japanese Sea, and a Norwegian lake. Therefore, GC-APCI-IM-HRMS is a promising next generation technique for resolving complex mixtures of HOCs through fully exploitation of molecular ions. This study also accentuates the urgent need to extend CCS libraries and retrain *in silico* tools for HOCs.

3.03.B.T-02 Improved target, suspect- and non-target analysis of environmental contaminants in wastewater using hydrophilic-lipophilic balanced SPME and GC-EI&CI-TOFMS

*Lucie Katharina Tintrop[1], **Marleen Vetter**[2], Steffen Braekling[2], Sonja Klee[2] and Thorste Schmidt[1], (1)University of Duisburg-Essen (Uni DUE), Germany, (2)TOFWERK AG, Switzerland*

Wastewater plants can release aqueous effluents containing harmful pollutants, posing risks to ecosystems and human health. Given the dynamic nature of wastewater composition, regular target and non-target analyses are frequently conducted. Due to its complimentary polarity range, gas chromatography mass spectrometry (GC-MS) is often employed alongside liquid chromatography (LC) MS to evaluate potential hazard profiles, to identify compounds and to gain a more complete overview of the potential hazards present. However, conventional GC-EI-MS is limited in its identification confidence for some compounds due to unspecific fragmentation pattern, absent molecular ion signals or by not being available in reference libraries, leading to a lack of compound identification. Additionally, with little to no prior knowledge of sample constituents, a broad extraction method is paramount.

For this study, 24h effluent samples were collected from an industrial plant over two months. Analytes were enriched by headspace solid phase microextraction (SPME) using a novel hydrophilic-lipophilic balanced (HLB) fiber coating (CTC, CH). An 7890A GC (Agilent, USA) was coupled to a newly developed dual ionization source time-of-flight (TOF) MS (ecTOF, TOFWERK, CH). Here, a standard 70 eV electron ionization (EI) source and a medium pressure chemical ionization (CI) source are operated quasi-simultaneously. Furthermore, the system allows for a simple selection of different CI reagents ions (e.g., $[NH_4]^+$, $[N_2H]^+$, $[H_3O]^+$) between chromatographic runs, which enables the adjustment of reactant selectivity and the degree of fragmentation.

This talk will outline different approaches for compound identification by using the simultaneous acquired EI and CI mass spectra. The additional CI information with its selection of different CI reagents ions is shown to be highly valuable for the identification process. The available GC-EI&CI TOF-MS data is further used to adapt the widely used LC-based workflow to report confidence of identification for compounds found in the wastewater samples. Moreover, the novel HLB-SPME material was tested as a solvent-free headspace extraction of the wastewater constituents and shown to extract a broad range of analytes. In combination with the GC-EI&CI TOF-MS, this methodology can be used to complement commonly employed methods such as LC-ESI-HRMS used in industrial wastewater monitoring.

3.03.B.T-03 Combining Advanced Analytical Methodologies to Describe Extractable Organic Fluorine in Human Serum

***Lara Cioni**[1,2,3], Vladimir Nikiforov[1], Jonathan P. Benskin[4], Ana Carolina Coelho[2], Melanie Lauria[5], Silvia Dudášová[6], Oliver Lechtenfeld[7], Therese Nøst[2], Merle M. Plassmann[8], Thorsten Reemtsma[6], Torkjel Sandanger[2] and Dorte Herzke[1], (1)Norwegian Institute for Air Research (NILU), Norway, (2)The Arctic University of Norway (UiT), Norway, (3)Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain, (4)Department of Environmental Science (ACES), Stockholm University, Sweden, (5)Department of Environmental Science, Stockholm University, Sweden, (6)Helmholtz Centre for Environmental Research (UFZ), Germany, (7)Department of Analytical Chemistry, Helmholtz Centre for Environmental Research (UFZ), Germany, (8)Stockholm University, Sweden*

Per- and polyfluoroalkyl substances (PFAS) have received international attention due to their persistence, ubiquitous occurrence in wildlife and humans, and potential environmental and health impacts. Since >4700 PFAS exist and <1% of these chemicals are analyzed in human blood, there are growing concerns that PFAS exposure might be underestimated. This concern is supported by studies where the extractable organic fluorine (EOF) in human blood could not be explained by traditional target PFAS analyses. In particular, a study in pooled serum samples, collected from the Tromsø (Norway) population in 1986, 2007 and 2015, showed that EOF concentrations were only partially explained by target PFAS and oxidizable precursors. In the present study, the same extracts were analyzed by direct infusion Fourier-transform ion cyclotron resonance mass spectrometry (FT-ICR-MS) and liquid chromatography high resolution-Orbitrap-mass spectrometry (LC-Orbitrap-HRMS). These analyses were used for suspect screening for >5000 PFAS and 342 fluorinated pharmaceuticals and estimate their contribution to EOF in human serum. With FT-ICR-MS 365 suspect PFAS were observed. However, by the LC-Orbitrap-HRMS, only 5 suspect PFAS could be identified. Only 1 PFAS suspect, the perfluoro-4-ethylcyclohexane (PFECHS), was confirmed with standards. Since PFECHS is not oxidizable, it was not surprising that this suspect was detectable before and after the TOP assay. PFECHS contributed to 2-4% of the EOF. However, after PFECHS inclusion, PFAS concentrations did not fully explain the EOF found in serum. Screening of fluorinated pharmaceuticals revealed 9 suspects, but only 3 (teriflunomide, lansoprazole and pantoprazole) were confirmed with standards. Additionally, 5 metabolites of these pharmaceuticals were identified. Overall, fluorinated pharmaceuticals accounted for between 0-56 % of the EOF. The portion of EOF explained by pharmaceuticals in 2007 was significantly higher than in 1986, and in 2015 it was significantly higher than in 2007. The use of suspect screening with FT-ICR-MS and LC-Orbitrap-HRMS in combination with the TOP assay facilitated the description of the EOF in pooled serum. While a large portion of the EOF found in pooled serum from the Tromsø population remains unidentified in 1986, the detection and quantification of fluorinated pharmaceuticals and their metabolites in serum from 2007 and 2015 showed that these compounds can contribute significantly to the EOF.

3.03.B.T-04 Wide-Scope and Nontarget Screening of Persistent Anthropogenic Chemicals in Swedish Waters using Feature-Based Molecular Libraries

***May Britt Rian*[1]**, *Bénilde Bonnefille*[2] *and Jonathan W. Martin*[3], *(1)Department of Environmental Science, Stockholm University, Sweden, (2)Department of Environmental Science, Stockholm University / Science for Life Laboratory (SciLifeLab), Sweden, (3)Stockholm University, Sweden*

A major challenge in nontarget analysis of environmental waters is to identify anthropogenic chemicals in highly complex matrices with abundant substances of natural origin. Using liquid chromatography-high resolution mass spectrometry, we aimed to identify and structurally characterize persistent chemicals of anthropogenic origin in a nation-wide survey of Swedish groundwaters (n=55), surface waters (n=125) and drinking waters (n=95). In combination with a wide-scope target (n=220) analysis, we used a nontarget workflow and a 'persistence-prioritized' feature-based molecular library from municipal wastewaters (n=34) and urban stormwaters (n=16) to identify persistent and frequently occurring organic contaminants in environmental waters. A library was created for unbiased screening of persistent chemicals by comparison of peak area signals in paired wastewater effluent and influent (n=7): 26 % of detected features in wastewaters were classified as persistent (i.e. n=12,115 features with effluent peak area > 80 % of influent) or potentially persistent (i.e. n=1,077 features with effluent peak area 50-80% of corresponding influent). In groundwater monitoring, as an example, we detected 3,043 of the prioritized molecular features in the environmental samples, and these are currently prioritized for identification or *in-silico* structural annotation. However, among these 3,043 features were melamine, 1,3-diphenylguanidine, 1H-benzotriazole, and 5/4-methyl-1H-benzotriazole (confidence level 1), which are known persistent, mobile and potentially toxic chemicals, demonstrating strong promise for this approach for discovery of persistent chemicals in environmental waters. In wide-scope target screening we also detected many pharmaceuticals, pesticides, and industrial chemicals in municipal source samples (e.g. wastewaters) and environmental samples (e.g. groundwaters). With a large nontarget dataset and a novel approach using feature-based molecular libraries refined on detection frequency and persistence, we show that unbiased screening and molecular characterization is possible in high-throughput to detect and identify anthropogenic micropollutants of concern in environmental waters.

3.03.B.T-05 Target, suspect and nontarget screening of contaminants in indoor dust with SUPRAS sample preparation

***Ana Ballesteros-Gómez*[1]**, *Joaquín Ballesteros*[2] *and Soledad Rubio*[1], *(1)Analytical Chemistry, University of Córdoba, Spain, (2)CAOSD, ITIS Software, University of Málaga, Spain*

Indoor dust has been recognised as a relevant source of indoor exposure to contaminants. The comprehensive characterization of such a heterogeneous matrix and such a variety of compounds is complex and sample treatment is a critical step. The potential of SUPRAS to efficiently extract a wide polarity range of compounds and to simplify and improve the green properties of sample treatment in this area are discussed. SUPRAS made up of inverse aggregates of hexanol in tetrahydrofuran:water mixtures, which have been previously and successfully applied to the target determination of a variety of organic contaminants in different environmental matrices before, were employed. Analysis was done with liquid chromatography and high resolution mass spectrometry. Twelve samples from public buildings (six educative buildings, two food stores, two nightclubs, one office and a coffee shop) were collected in South Spain. A total of 146 compounds were detected by target (~33%), suspect (~55%) and non-target screening (~12%). Around 86% of all the compounds were identified (or tentatively identified) with levels of confidence equal or higher than 3. Novel designer drugs of abuse, unreported organophosphorus compounds and well-known organic contaminants, such as bisphenols, parabens, phthalates and flame retardants are reported. Differences with previous studies on wide screening of indoor dust reveal the influence of the employed databases for data processing and of the extraction method together with the different contamination profiles given by the sample location.

3.03.P Advances in High Resolution Mass Spectrometry Based Non-targeted Analysis for Exposure Monitoring and Assessment of Human and Environmental Samples

3.03.P-We139 Case Study on the Development of a Liquid Chromatography-High Resolution Mass Spectrometry Method for Non-Targeted Detection of β-Lactam Containing Antibiotics and their Transformation Products

Kathryn Gerry[1] *and Andreas Häner*[2]*, (1)Analytical Chemsitry, Scymaris Ltd., United Kingdom, (2)Group SHE, F. Hoffmann-La Roche Ltd., Switzerland*

Antibiotics are prolifically used to treat infections in both humans and animals; their cumulative toxic effects on aquatic organisms are not well understood and their presence might lead to the development of antibiotic resistant bacteria. They are therefore understandably recognised as chemicals of emerging concern (CECs). The β-lactam functionality is considered responsible for antibiotic/antibacterial activity and therefore detection of β-Lactam containing chemicals and their transformation products are of special interest.

In this work a case study is presented for the determination of β-lactam containing transformation products in an environmental fate biodegradation study on a common antibiotic using liquid chromatography-high resolution mass spectrometry. During this analysis a selection of antibiotics were fragmented to elucidate common fragments that indicate the presence of the β-lactam ring. These fragments were then used to detect β-lactam containing transformation products in study samples. The challenges of using this approach on labile moieties is discussed along with a comparison of the benefits and disadvantages of in-source or all ion fragmentation (AIF) over data dependent scanning.

3.03.P-We140 Structural Investigations of Transformation Products of the Anticoagulant Drug and Rodenticide Warfarin

Christian Piechotta[1] *and Jannik von Törne*[2]*, (1)BAM Federal Institute for Materials Research and Testing, Germany, (2)Analytical chemistry, reference materials, BAM Federal Institute for Materials Research and Testing, Germany*

Warfarin (Coumadin) is one of the most popular anticoagulant drugs used as a therapeutic in humans to prevent thrombosis, atrial fibrosis, and fibrillation since the 1950s. Because of its ability to hinder blood coagulation by blocking vitamin K-depending carboxylation of blood clotting precursors, it is also used as a rodenticide worldwide. Until today it has been partially substituted by far more potent anticoagulant rodenticides (ARs), so-called superwarfarins.[1] Numerous studies are confirming secondary and tertiary poisoning with ARs in non-target-animals and wildlife. Up to now, relatively little is known about persistence and toxicity of ARs and naturally, nor technically formed transformation products (TPs) in the environment, food chain, and transformations occurring during wastewater treatment.[2] Herein, we present liquid- and gas chromatographic methods coupled to (high-resolution) mass spectrometry for the analysis of warfarin's transformation products. Methodologies such as UV-irradiation, ozonation, and chlorination were utilised to simulate technical water treatment. Resulting compounds were elucidated and examined by numerous analytical methods. Moreover, the oxidative phase I metabolism was mimicked by an electrochemical flow cell to synthesise and confirm major metabolites.[3-5] The further aim is the toxicological assessment of all substances formed, as well as, the quantification of warfarin and its TPs under environmentally relevant conditions employing the introduced methods.

3.03.P-We141 Identification of Biomarkers for Citrate Plasticizers through Non-Targeted Analysis and Their Application in Urine Samples.

Hyeri Jeon[1]*, Sunghoon Yeo*[1]*, JinYeong Heo*[1]*, Daeho Kang*[2]*, Junho Jeon*[2]*, Bongjin Moon*[3]*, Sungkyoon Kim*[4]*, Na-Youn Park*[1]*, In-Kyu Lee*[5]*, SuBeen Park*[5]*, Eun-Hee Lee*[6] *and Younglim Kho*[1]*, (1)Department of Health, Environment & Safety, Eulji University, Korea, Republic of (South), (2)Department of Environmental Engineering, Changwon National University, Korea, Republic of (South), (3)Department of Chemistry, Sogang University, Korea, Republic of (South), (4)Department of Environmental Health Sciences, Graduate School of Public Health, Seoul National University, Korea, Republic of (South), (5)Department of Food Technology & Service, Eulji University, Korea, Republic of (South), (6)Graduate School of Health Science, Far East University, Korea, Republic of (South)*

Plasticizers are chemicals that make plastic flexible, mainly using a group called phthalates. These substances are known to cause endocrine disruption, leading to regulatory restrictions on their use in many countries. As a result, there is a growing trend towards the use of alternatives, with citrate plasticizers being one of them. However, there is insufficient research on the metabolites of citrate plasticizers upon human exposure. Therefore, this study aimed to identify the metabolites of citrate plasticizers by exposing them to human liver microsomes (HLM) and conducting non-targeted analysis. Furthermore, we intend to identify biomarkers through the analysis of urine samples collected for the measurement of plasticizer exposure levels.

The target substances were ATBC and ATEC. After exposure to HLM, metabolites were explored using LC-Q-TOF-MS. The major metabolites of ATBC were identified as ADBC and DBC, while ATEC metabolites were identified as ADEC and DEC. In this study, quantitative analysis was conducted on 124 samples using the commercially available standard substance, DEC, and the synthetically obtained DBC. As a result, the median value for DBC was 38.45 ng/mL, while DEC was 1.54 ng/mL. Additionally, non-targeted analysis revealed the presence of un-synthesized ADBC and ADEC in some samples. Through this study, metabolites of citrate plasticizers were estimated through non-targeted analysis, and their confirmation was achieved using urine samples. Based on this, non-targeted analysis can be employed to explore metabolites and contribute to epidemiological studies for measuring exposure levels of alternative plasticizers.

Acknowledgments: This work was supported by Korea Environment Industry & Technology Institute(KEITI) through Technology Development Project for Safety Management of Household Chemical Products Program(or Project), funded by Korea Ministry of Environment(MOE)(1485019252(NTIS), RS-2022-KE002023(IRIS)).

3.03.P-We142 Harmonizing Sample Pre-Treatment for Multiclass Analysis of Endocrine Disrupting Compounds and its Metabolites in Human Urine – a Target and Suspect Screening Approach

Julen Segura Abarrategui[1]*, Sandra Perez Solsona*[2] *and Nicola Montemurro*[3]*, (1)Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain, (2)Onhealth, Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain, (3)Department of Environmental Chemistry, Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain*

Humans are exposed to environmental contaminants that can harm our health. Urine is a convenient and non-invasive biological sample for assessing this exposure. It can be easily obtained and processed, making it a valuable reference in studying environmental contaminants.

Urine contains different matrix components that can interfere with the quantification process of the analytes of interest. As it is a complex matrix, an appropriate pre-treatment of the sample is of vital importance. In addition, given the small amount of biological sample that is usually available, it may be necessary to use the same sample extract for target (TS), suspect (SS), and non-target (NTS) screening analysis, with the compromises that this entails.

Sample pre-treatment for SS and NTS focuses on removing the matrix while extracting the maximum number of compounds and minimizing the matrix effect. Selective pre-treatment is not possible due to the need to extract analytes with different physico-chemical properties. TS aims to eliminate matrix interferences and develop a selective pre-treatment for the compounds of interest. The objective of this investigation is to optimize a sample pre-treatment suitable for both TS and SS, for a multiclass/multiresidue analysis of endocrine disrupting compounds and their metabolites in human urine. Liquid chromatography - low resolution mass spectrometry is used for TS due to its high sensitivity, while liquid chromatography - high resolution mass spectrometry is used for SS and metabolite detection. Different sample treatment methods, including solid phase extraction, liquid-liquid extraction, and dilute and shoot method, have been tested to achieve the objective.

The best process for the TG study was found to be liquid-liquid extraction employing acetonitrile without using glucuronidase to hydrolyze the metabolites. Recovery (R.) values of 97-115 % and matrix effect (M.E.) values of (-13) - 0 % were obtained for bisphenols and R. values of 80-119 % and M.E. values of (-20) - 10 % were obtained for benzophenones, among other compounds.

The importance of the study lies in the harmonization of sample preparation for both types of analysis with the purpose of saving on costs and experimental time. Moreover, it is intended to search new metabolites in order to unravel the different metabolic pathways of them, in addition to achieving its optimal characterization in human urine samples.

3.03.P-We143 A metabolomic approach to the effects of contaminants of concern in fish liver cultures

Carolina P. Rocha[1]*, Mariana Louro*[2]*, Mónica Almeida*[3]*, Carolina Frazão*[3]*, João C. Marques*[4]*, Marta Sousa Silva*[2]*, Miguel Oliveira*[3]*, Carlos Cordeiro*[2] *and Ana M. M. Gonçalves*[4]*, (1)University of Coimbra, MARE - Marine and Environmental Sciences Centre / ARNET – Aquatic Research Network, Portugal, (2)BioISI—Biosystems and Integrative Sciences Institute, Plant Functional Genomics Group, Portugal, (3)University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Portugal, (4)Department of Life Sciences, University of Coimbra, MARE - Marine and Environmental Sciences Centre / ARNET – Aquatic Research Network, Portugal*

Advances in knowledge regarding adverse outcome pathways in ecotoxicological studies have developed hand-to-hand with the refinement of analytical techniques.Resorting to non-target mass spectrometry combined with metabolomics for toxicological assessments has greatly contributed to understanding organisms' coping mechanisms against stressors while allowing an assessment of the impact of persistent contamination of systems or individual-specific traits – numerous scenarios with biological relevance that have been mostly overlooked. To date, most ecotoxicological studies still lack complexity in design, needed to enhance ecological and environmental relevance. To address the issue, New Approach Methodologies (NAMs) come as methodologically advantageous alternatives, enabling high-throughput toxicology, while attending ethical considerations in line with the 3R's principles. The present study proposes to further support the relevance of applying metabolomics, based on untarget mass spectrometry techniques, to provide a deeper and broader understanding of organisms' exposure to contaminants, while identifying underlying contamination events. To this end, four adult *Sparus aurata* from a local fish farm were acclimated in controlled conditions and fed daily until satiation, which was stopped 48h before sacrifice for liver removal. After careful removal, livers were cut into cubes ~2x2mm, and cultured in DMEM media. Samples were immediately exposed for 24h to environmental contaminants, after which liver cultures were collected, frozen in liquid N_2, and stored at -80ºC until analysis. Experimental conditions included: i)single exposure to 5 concentrations of polystyrene microbeads (~1µm diameter) and 5 concentrations of zinc; ii)3 direct mixtures of PS and Zn concentrations used in single exposures. Preliminary results show that: i)fish differ in numerous metabolites - analyses are ongoing to understand which are derived from reactions to the contaminants' exposure; ii) there is an early separation of samples by individual fish, rather than by treatment; iii) numerous compounds from unknown sources (eg. Tonalid,used in perfumes;Levofloxacin,an antibiotic) were detected. The present works intend, finally, to further highlight non-target high-throughput analyses as a powerful tool to provide further knowledge for legislative and regulatory processes, to effectively act towards a lesser impact of human activities, safeguarding ecosystems (and human) health.

3.03.P-We144 PFAS residues in fish from England and Catalonia: trend, bioaccumulation and dietary exposure
Eva Junque[1]*, Marta Llorca*[2]*, Katie Reilly*[1]*, Marinella Farre*[2] *and Iseult Lynch*[3]*, (1)University of Birmingham, United Kingdom, (2)Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain, (3)School of Geography, Earth and Environmental Sciences, University of Birmingham, United Kingdom*
Per- and polyfluoroalkyl substances (PFAS) are synthetic chemicals that persist in the environment, bioaccumulate in tissue and have become ubiquitous contaminants. The original chemicals and their degradation products have a negative impact on human health and are a threat to the environment, therefore many countries worldwide recommend they be monitored at some level. It has been recognized that dietary intake is a significant route of exposure for human populations, especially through consumption of fish.

Despite the existence of over 10,000 PFAS compounds, the limited availability of reference standards poses a challenge, with standards available for less than 2% of these substances. To overcome this limitation, non-targeted approaches using liquid chromatography─high-resolution tandem mass spectrometry (LC-HRMS) are crucial, enhancing the analytical coverage of PFAS in environmental samples and aiding in the identification of new compounds and transformation products.

In this study, LC–HRMS will be used for suspect screening and quantitative target analysis of PFAS in the most frequently consumed fish species in England and Catalonia. Sampling will be conducted between January and March 2024 in the main PFAS hotspots in each region. In England, fish samples will be obtained from fish farms close to Liverpool, Birmingham, and London, while in Catalonia, samples will be collected from rivers in the vicinity of Barcelona.

The research aims to compare the trends of PFAS contamination between the two regions, identify emerging PFAS compounds, and determine compliance with current EU and UK Legislation, focusing on Maximum Residue Limits and Tolerable Daily Intakes established by the European Food Safety Authority (EFSA) and UK REACH in the studied populations. Additionally, the study will investigate determinant factors influencing PFAS concentrations, such as trophic level and fish weight.

This form of comprehensive analysis, utilizing LC-HRMS, provides valuable insights into the current status of PFAS contamination in river fish, investigating both environmental and public health concerns. The evaluation can be used to assess the impact of regulations on PFAS and to assist authorities in their decisions on how best to protect the environment and consumers from exposure to PFAS through food.

3.03.P-We145 Analysis of Volatile PFAS and Other Contaminants in Plants, Soil and Water Using High Resolution GC/MS and an Accurate Mass PFAS Library
Jose Juan Rivero Marabé Mr.[1]*, Sofia Nieto*[2]*, Tarun Anumol*[2]*, Matthew Giardina*[2]*, Matthew Curtis*[2]*, Luann Wong*[3]*, Gabrielle Black*[4] *and Thomas Michael Young*[5]*, (1)Agilent Technologies, Inc., Spain, (2)Agilent Technologies, Inc., (3)Civil & Environmental Engineering, University of California Davis (UC Davis), (4)Department of Civil and Environmental Engineering, University of California Davis (UC Davis), (5)University of California San Francisco (UC San Francisco)*
Per- and polyfluoroalkyl substances (PFAS) are emerging contaminants that are found in water, air, soil as well as wildlife and attract growing attention. A subset of PFAS that have been detected in the environment can be volatile or semi-volatile in nature. Therefore, a variety of analytical techniques are necessary for their detection. GC/MS is typically used for detecting volatile and non-polar PFAS compounds. However, one of the challenges in PFAS analysis by GC/MS is a lack of publicly available libraries containing a comprehensive selection of the PFAS EI spectra. Therefore, an accurate mass GC/MS library for PFAS detection was created.

Soil and plant samples were sampled from two fields in California that have historically received biosolids as well as an organic field and extracted with methylene chloride and SPME. The drinking water samples were collected at two different locations in California and represented two different water source categories: a small surface water and a mixed surface and ground water. Water samples were extracted on a multi-mode SPE and solvent exchanged to EtAc.

We have screened the water, soil and plant samples for PFAS using an accurate mass library. A variety of chemicals of industrial origin, drugs, PAH, flame retardants, PCB and pesticide residues have also been identified using the NIST Mass Spectral EI Library and Pesticide PCDL.

3.03.P-We146 What's in the Dust? GC×GC-MS Based Non-Target Screening of House Dust

***Andriy Rebryk** and Peter Haglund, Department of Chemistry, Umea University, Sweden*

Air pollution is responsible for ca. 8.9 million premature deaths every year. In addition, WHO reported that 99% of all people worldwide breathe polluted air in their ambient environment. Moreover, studies showed that European citizens spend up to 90% of their time indoors. Hence, respective outdoor air quality guidelines and indoor air quality guidelines were introduced. These cover a limited number of pollutants, such as particulate matter, carbon monoxide, benzene, PAHs, and chloroethylenes. However, there are >100,000 registered chemicals in use in Europe alone. Those can pose potential health risks. Therefore, it is important to establish what chemicals of potential concern are emitted and what are their levels in indoor media that can accumulate them and to which residents are constantly exposed, such as house dust. For this, a two-dimensional gas chromatography-mass spectrometry (GC×GC-MS) based non-target screening (NTS) workflow was established. Dust samples were collected in three European cities: Umeå (Sweden), Munich (Germany), and Lviv (Ukraine). Additionally, NORMAN Network collaborative trial sample and NIST Standard Reference Material 2585 house dust were analyzed. Ca. 60 mg of each sample were extracted by ultrasonic extraction in two steps: with dichloromethane (DCM) and then with acetone. To clean-up the samples from matrix elements, such as fatty acids, that interfere with the detection of other compounds, solid-phase extraction (SPE) using aminopropyl cartridges was used. SPE cartridge was conditioned with DCM, sample extract was loaded, and eluted as two fractions: Fr. 1 with DCM and Fr. 2 with methanol:DCM (1:1, v/v). Both fractions were analyzed using LECO Pegasus BT 4D GC×GC-TOFMS. The MS data were matched against NIST23 spectral library, filtered, and aligned. Preliminary results showed >2500 tentatively identified compounds (NIST23-matched features) in the five samples. These were divided into 43 classes. One of the most abundant constituents of Fr. 1 were plastic additives phthalates, such as di(2-ethylhexyl) phthalate, whereas Fr. 2 contained, among other compounds, a mixture of tertiary amines known as DIMLA 1214, whose increased use was reported during the COVID-19 pandemic. Principal component analysis demonstrated close grouping of the Munich, Lviv, and NORMAN samples, whereas the Umeå and NIST samples were well-separated from the aforementioned and from each other, suggesting unique sets of contaminants.

3.03.P-We147 Quantitation and screening of drugs in indoor dust from different environments in Spain

***Cristina de Dios Pérez**, University of Cordoba, Spain*

Quantitation and screening of drugs in indoor dust from different environments in Spain

In this study a novel microextraction approach based on supramolecular solvents (SUPRAS) is employed for sample preparation of indoor dust prior to the determination of drugs by with liquid chromatography and high-resolution mass spectrometry. 45 drugs of abuse and 34 pharmaceuticals were quantitated. SUPRAS of different composition were tested for maximum recoveries. Samples from different environments (offices, classrooms from education buildings, hairdressers, nightclubs, cafes and restaurants) were collected in South Spain and analysed. Acquisition for target and suspect screening was performed with independent data acquisition (IDA) and libraries from the equipment vendor containing retention time values under the same chromatographic conditions. Identification criteria for was determined on the basis of exact mass (≤5 ppm) and isotopic pattern fit (mSigma ≤50) of both major parents and fragment ions and retention time fit (±0.25 min).

Results showed the ubiquity of drugs of abuse, such as cocaine and cannabis and the identification of novel designer drugs. These results show the ubiquity and high levels of drugs in indoor dust, which have been scarcely reported and it could constitute a relevant source of human exposure.

3.03.P-We148 Development of a tandem mass spectral library for source fingerprinting of monoterpene derived organic aerosol in Beijing

***Daniel Bryant**[1], Rhianna L Evans[2], Jack Davison[3], Thomas F Cornell[2], Andrew R Rickard[2,4] and Jacqui F Hamilton[2,4], (1)Chemistry, University of York, York, United Kingdom, (2)Chemistry, Wolfson Atmospheric Chemistry Laboratories, University of York, United Kingdom, (3)Ricardo Energy & Environment, United Kingdom, (4)Wolfson Atmospheric Chemistry Laboratories, National Center for Atmospheric Science, United Kingdom*

Exposure to fine particulate matter ($PM_{2.5}$) can lead to severe human health effects, with the Global Burden of Disease study estimating $PM_{2.5}$ contributed to 4.2 million premature deaths globally in 2015. Organic aerosol (OA), a complex mixture of thousands of compounds, from a variety of sources is the dominant source of $PM_{2.5}$ in many regions. Liquid chromatography (LC) coupled to high resolution tandem mass spectrometry ($HRMS^2$) is a powerful technique for both targeted and non-targeted analysis of OA. However, due to the complexity of OA samples and lack of authentic standards, precursor source identification, structural elucidation and subsequent quantification is challenging.

This study outlines the development of an open-access tandem mass spectral library known as **O**pen **A**ccess **O**rganic **A**erosol (OA^2), for the improved identification of OA species from a range of precursors. Using a flow reactor, monoterpenes underwent photo-oxidation to produce OA, which was collected and analysed using LC-$HRMS^2$. By combining MZmine 3 and SIRIUS outputs, a spectral library file containing features with tandem mass spectral data and a predicted molecular formula was generated from each sample.

An untargeted MZmine methodology was then applied to ambient samples collected in summertime Beijing. The untargeted method allowed for the detection of features which were then screened against OA^2 library files. This allowed for the matching of MS^2 data between the ambient sample and species within the library with a known precursor. This methodology increased the confidence of source identification of analytes within the sample and highlighted significant monoterpene derived OA formation in Beijing.

The aim of developing OA^2 as open source is to involve the wider community in developing the next stage of the library, the inclusion of more precursors and mixtures from both biogenic and anthropogenic species, collected across a range of different atmospheric oxidative conditions.

3.03.P-We149 An robust protocol for non-target analysis of PFAS in drinking water: from qualitative identification to quantification of unknowns

Yong-Lai Feng*, Anca Baesu and Yan Li, Health Canada, Canada*

Per- and polyfluoroalkyl substances (PFAS) are a class of thousands of synthetic chemicals, many of which have been used worldwide to make products resistant to water, heat, and stains since the 1950s. Studies show that exposure to even trace amounts of some PFAS is linked to harmful health effects. The EPA has set a health-advisory level of 70 ppt for the combined concentration of PFOA and PFOS in drinking water. The current monitoring program in Canada only targets the most researched PFAS and the number of PFAS characterized in exposure assessments is still very small compared to the total number registered for commercial use, let alone their transformation products and metabolites in the environment. Non-target analysis (NTA) has emerged as a tool used to identify and prioritize chemicals for human exposure assessment. Unlike targeted analysis, there are no established processes for NTA method development and validation, and although efforts have recently been made to harmonize NTA workflows, knowledge gaps still remain. While the sample preparation step determines the chemicals that are extracted, data acquisition and analysis determine chemical identification. Furthermore, quantitation of unknown FPAS without reference standards remains another challenge. Therefore the goals of this study were to develop an robust NTA method from sample preparation to data analysis to provide information on from qualitative identification to quantitative levels of unknown PFAS in drinking water. The influence of data acquisition methods on FPAS identification was evaluated. The study showed that several new PFAS alcohols in drinking water were identified, indicating that PFAS could be transformed to their unknown transformation products in the treatment process. In this study, FluoroMatch was compared with other data screening tools for identification accuracy. A retention time prediction model was used to increase confidence in the identification. A newly developed quantification model was also used to provide quantitative information for those unknown PFAS following the targeted analysis protocol without using their authentic reference standards. The results showed that NTA can be potentially standardized from qualitative identification to quantitation of unknown compounds as in targeted analysis. Therefore, NTA can be a powerful tool in both rapid screening/prioritization and quantitation of unknown and emerging contaminants for human exposure assessment.

3.03.P-We150 Highly sensitive quantification and selective identification of contaminates with a TOF high resolution instrument

Jianru Stahl-Zeng[1]*, Michael Scherer*[2] *and Josep Lliberia*[3]*, (1)AB Sciex Germany GmbH, Germany, (2)SCIEX, Switzerland, (3)Sciex Spain, Spain*

In order to ensure safety in the global water supply, testing for adherence to federal and international requirements is necessary. The tests monitor for chemical residues is necessary. Traditionally, contaminate residue analysis has been performed by triple quadrupole mass spectrometers, due to their selectivity, sensitivity and quantitative power. Accurate mass instruments can afford additional levels of confirmation, however they have traditionally suffered from a lack of sensitivity and precision, especially when performing MS/MS experiments to meet the testing requirements for the regulatory guidelines.

In this poster, both quantitation and screening performance will be demonstrated by using a SCIEX ZenoTOF 7600 system with scheduled Zeno MRM^{HR}. The use of the Zeno trap on the ZenoTOF 7600 system allows for >90% of duty cycle related losses to be recovered during MS/MS experiments across the entire mass range. Experimental gains correlated strongly with theoretical gains during this analysis. Enabling the Zeno trap yields a minimum of 5x intensity gain, with gains up to 13x as fragment masses decrease. Further, since the selectivity afforded by accurate mass MS/MS analysis often results in little to no chemical noise, the gains in signal-to-noise approached the gains observed in raw signal.
The developed quantitative method was applied to a variety of environmental samples in order to compare to traditional triple quadrupole mass spectrometry.
Advantage of high-resolution instrument to screen unknown samples and identify unknown substances by using different workflows will be also demonstrated here.

3.03.P-We151 Study of Tap Water Potential as a New Source of Contaminants of Emerging Concern for Population Exposure

Luis Muñiz de Bustamante*, University of Cordoba, Spain*

The continuous overproduction of chemicals leads to the release in the environment of thousands of chemical compounds. Many studies have found evidence that wastewater effluents contain tens of thousands of organic pollutants, highlighting the impossibility of eliminating all contaminants in wastewater treatment plants. For most of these compounds, chemical and toxicological information is either scarce or unknown, so they are known as chemicals of emerging concern (CEC). These effluents are discharged directly into different water bodies, where the presence of CECs has been also reported. Since these water bodies are the usual source for the production of drinking water, which is treated using target methods for removing specific organic pollutants, CECs can reach tap water.

CECs exhibit a wide range of polarity and chemical properties, rendering traditional extraction techniques, such as solid phase extraction or liquid-liquid extraction inefficient for the multi extraction of CECs. Furthermore, while traditional target approaches allow the detection and determination of known chemical compounds based on their correspondence with analytical standards, suspect and non-target approaches, mainly based on liquid chromatography high-resolution mass spectrometry (LC-HRMS), allow to detect and identify thousands of chemicals without standards.

Seeking to overcome the drawbacks of traditional approaches for extraction and determination of CECs, this research proposes the use of supramolecular solvents (SUPRAS) for the extraction of CECs from tap water and their analysis by LC-HRMS. For this purpose, tap water (n=53) from 12 countries around the world have been analyzed with the developed suspect screening workflow. Fifty-three CECs belonging to personal care products, stimulants, UV filters, surfactants, sebacates, industrial chemicals, lipids, plasticizers, cleaning products, and adhesives categories were identified in the analyzed samples. The concentration of chemicals identified with a level of confidence above 2b have been semi-quantified and a subsequent tentative evaluation of risks to human health has been performed. Some of the identified compounds showed values of risk quotient (RQ) above 1, the limit considered safe for humans, indicating a potential risk to human health. These results prove that the combination of SUPRAS and suspect screening analysis can be an effective strategy for discovering new contaminants and sources of exposure to humans.

3.03.P-We152 High Resolution Mass Spectrometry Solutions to the Challenge of Non-Target Transformation Product Identification Presented by the 2023 EFSA Drinking Water Guidance Document

Rory Mumford[1]*, Daniel T Evans*[2]*, Jim Ferguson*[3]*, Christopher Kirkman*[2] *and Kalumbu Malekani*[3]*, (1)Environmental Fate and Metabolism, Smithers, Shawbury, Shrewsbury, United Kingdom, (2)Environmental Fate and Metabolism, Smithers, United Kingdom, (3)Environmental Fate and Metabolism, Smithers*

The EFSA guidance document on the impact of water treatment processes on residues of active substances or their metabolites in water abstracted for the production of drinking water was issued in August 2023 (DOI: https://doi.org/10.2903/j.efsa.2023.8194). In general, the guidance covers the identification and exposure assessment of transformation products (TPs) of Biocidal and Plant Protection Products (PPPs) using experimental and *in silico* methods. This does not just cover the effects of water treatment on the active substances, but also on their transformation products along with an impact assessment covering the environment, human health, and domesticated animals.

Drinking water treatment is generally performed in several ways; the simplest being filtration (over activated carbon or sand) to absorb contaminants, to active breakdown with processes such as chlorination with sodium hypochlorite or chlorine, chlorination with chloramine, pre-oxidation with chlorine dioxide, ozonation, ultraviolet (UV) disinfection or a combination of several processes. The guidance provides methods for simple laboratory procedures which are intended to be performed without the need for complex and expensive equipment.

However, performing the laboratory tests is not the major challenge when considering this guidance. The number and complexity of potential transformation products can be great when considering the multiple processes involved. This undoubtedly will lead to extensive efforts to identify many transformation products creating the major challenge of non-target identification of potential TPs by LC-MS/MS or other structure elucidation techniques. This will likely be more challenging in the absence of any radiolabelled substances for active ingredients or their metabolites.

This presentation focusses on the strategies that can be employed using High Resolution Mass Spectrometry (HRAM) with (U)HPLC to perform non-target identification using available tools such as instrument automation and software interrogation on samples derived from water treatment processes.

3.03.P-We153 Stormwater Ponds as a Hotspot for Chemical Pollution and their Impact in Recipient Water Bodies and Drinking Water Productin

Victoria Eriksson, Oksana Golovko, Karin Wiberg and ***Alberto Celma****, Swedish University of Agricultural Sciences (SLU), Sweden*

Street run-off stormwater is often polluted with a wide range of organic pollutants as a result of traffic, pest control, road wear, buildings and other human activities. Although most organic micropollutants occur in low concentrations, many of them are highly toxic and, thus, even low concentrations might threaten the environment by harming aquatic organisms. Also, human health can be affected since, in Sweden, the vast majority of drinking water is produced from surface water bodies.

In this work, we have investigated both influent and effluent water streams from a stormwater pond impacted by heavy traffic and residential and industrial areas. In addition, in case of a heavy rain event, the nearby pump station for municipal wastewater gets overloaded and direct discharge of untreated wastewater is diverted to the stormwater pond under study. To investigate the impact of rain in the fate of organic micropollutants in the pond and its implications, water samples were collected both at dry periods (base flow) and rain events. Additionally, the outlet of the stormwater pond under study mouths in a large surface water body in Sweden, which serves a source for drinking water production for a large number of inhabitants. Thus, water samples were also collected in connection with heavy rain events at the inlet of a drinking water production facility a few kilometres downstream of the effluent of the stormwater pond.

Mixed-mode solid-phase extraction (SPE) and ultra-high pressure liquid chromatography coupled to high resolution mass spectrometry (UHPLC-HRMS) were used for wide-scope screening of organic micropollutants of the samples permitting to expand the chemical coverage in comparison with conventional sample analysis strategies. Data revealed the presence of a large set of chemicals resulting from different human activities in both the influent and effluent streams from the stormwater pond. Yet, several of the identified compounds were also found in the inlet water sample of the drinking water production facility. In total, 59 organic micropollutants were identified, being vehicle related compounds and pharmaceuticals the most frequently detected compounds.

In this communication, we aim at presenting the analysis workflow as well as highlighting the most relevant aspects and implications of the identified compounds for the drinking water production.

3.03.P-We154 Mosaic-Project: Suspect Screening in 545 Water Bodies in Southern Germany
***Anna-Jorina Wicht**[1], Vanessa Ivenz[2] and Manfred Sengl, PhD[2], (1)Bavarian Environment Agency (LfU), Augsburg, Germany, (2)Bavarian Environment Agency (LfU), Germany*
The monitoring-project MOSAIC intends to give a broad overview on the pollution status of Bavarian surface waters, with special focus on smaller rivers. Sampling sites were selected based on land use and potential point sources in the catchment area. A broad range from areas with high industrial density to rather agriculturally influenced sites is covered. 545 different water bodies were sampled quarterly and analysed by target analysis for a set of more than 240 parameters.

In addition to the parameters already addressed by target analysis, suspect screening is an upcoming and promising tool to identify further contaminants in the water samples. Samples were analysed by direct injection and LC-HRMS. Compounds were identified by MS/MS. A large set of more than 1000 compounds including pharmaceuticals, industry chemicals, pesticides and biocides as well as some metabolites was analysed by suspect screening.

To improve the quantitative information of suspect screening measurement, semi quantification of carbamazepine and terbutryn was compared to target measurements in more than 700 samples. For samples with concentrations > 20 ng/L suspect screening and target measurements agreed well. Thus, semi quantification by internal standard provides the opportunity to roughly estimate concentrations of suspect compounds in surface water samples.

Suspect screening can additionally be used to provide a first estimate on the relevance of newly regulated compounds that are not addressed in standard monitoring programmes. For the revised WFD new compounds with EQS proposals are discussed. These were screened by suspect screenings in all 545 samples. Data show that the pharmaceuticals carbamazepine, diclofenac and sulfamethoxazole were detected in more than 50% of the investigated water bodies, whereas compounds such as the insecticide thiamethoxam and the antibiotic erythromycin were detected infrequently.

Screening a set of 37 common pharmaceuticals revealed, that ten of them were present in more than 66% of water bodies. The highest detection frequencies were determined for gabapentin, venlafaxine, carbamazepine, lamotrigine and metoprolol.

This project has the potential to gather a comprehensive overview of compounds present in smaller rivers and streams beyond just information on priority substances. Suspect screening strategies enable to get insight in the expected detection frequency of contaminants of emerging concern and compounds coming to regulatory interest.

3.03.P-We155 Suspect and non-target screening of legacy and emerging pollutants in the freshwater system of South Korea
***Gyojin Choo**[1], Heon-Jun Lee[2], Wonjin Sim[2], Sol Choi[2] and Jeong-Eun Oh[3], (1)Kangwon National University, Korea, Republic of (South), (2)Pusan National University, Korea, Republic of (South), (3)Department of Civil and Environmental Engineering, Pusan National University, Korea, Republic of (South)*
This study investigated the occurrence, distribution, and bioaccumulation of various environmental pollutants, including both legacy and new persistent organic pollutants (POPs), as well as contaminants of emerging concern (CECs). The analysis was conducted through suspect and non-target screening (SNTS) using gas chromatography coupled to quadrupole time-of-flight mass spectrometry (GC-Q-TOF/MS) in both biotic and abiotic media of the freshwater system in South Korea. A total of 348 compounds, comprising 17 polychlorinated dibenzo-dioxins/furans (PCDD/Fs), 18 polychlorinated naphthalenes (PCNs), 62 polychlorinated biphenyls (PCBs), 41 polybrominated diphenyl ethers (PBDEs), 7 novel brominated flame retardants (NBFRs), 10 organophosphate flame retardants (OPFRs), 8 benzotriazole UV filters (BUVs), 8 volatile methylsiloxanes (VMSs), 27 plasticizers, 3 synthetic musk compounds (SMCs), 16 polycyclic aromatic hydrocarbons (PAHs), 17 phenols, and 114 pesticides, as well as unknown chemicals, were identified and qualified using an in-house database and the National Institute Standard and Technology (NIST) library, respectively. As a result of suspected screening using an in-house database,

a total of 93 compounds were identified at least once in the environmental matrix (river, sediment, and biota). The number of compounds identified in each group was 24 pesticides, 21 plasticizers, 15 PAHs, 10 phenols, 7 VMS, 3 SMCs, and 3 BUVs except for NBFRs, PBDEs, PCBs, and PCNs groups. When prioritizing pollutants based on detection frequency in river water, sediment, and crucian carp samples, 2-Methylphenol (o-cresol) emerged as the highest priority material, detected in 32 out of 47 samples. Evaluating the peak intensity of detected compounds in river water revealed that polychlorinated phenols (PCPs) accounted for 29-39% of the total combined peak intensity across all four water systems. In sediment, PCPs, the most dominant compound group, accounted for 37-67%. In carp, similar to other matrices, PCPs were the most dominant at 31-34%, followed by volatile organic compounds (VOCs) and PAHs. Detailed information of growth-dependent accumulation and contamination patterns of major contaminants will be presented during conference.

3.03.P-We156 Improving Nontarget Screening by Homologous Series Analysis: a Case-study in Swiss Sludge

Pablo Antonio Lara Martín[1]*, Lena Schinkel*[2]*, Yves Eberhard*[2]*, Walter Giger*[3]*, Michael Berg*[2] *and Juliane Hollender*[4]*, (1)Universidad de Cadiz, (2)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (3)Giger Research Consulting, (4)Environmental Chemistry, Environmental Chemistry, Eawag, Swiss Federal Institute of Aquatic Science and Technology, Switzerland*

Only a fraction of the potential chemical contaminants are nowadays regulated or regularly monitored in the environment. Advances in high resolution spectrometry (HRMS) allow for an easier and faster identification of new compounds with no previous selection of target analytes (nontarget screening, NTS). We have conducted a national survey in Switzerland to perform NTS of organic contaminants in sewage sludge, representing fingerprints of the corresponding wastewater and therefore population usage and exposure to chemical compounds. Identification of contaminants has been improved over previous works by relying not only on reference standards and MS/MS libraries, but also by conducting analysis of homologous series exploring different combinations of elemental compositions and repeating units to plot Kendrick mass defects plots. By performing online search in MS/MS spectral libraries and using available standards, up 78 contaminants could be identified at level 1 and semi-quantified including octocrylene, galaxolidone and triclosan. Samples from 3 WWTPs had a very distinctive chemical fingerprint compared to the rest (e.g., higher abundances of plasticizers), suggesting the existence of local pollution sources and/or different usage/consumption patterns in the areas served by the aforementioned WWTPs. NTS screening was completed through the identification of over 100 different series with more than 3 components each were annotated, spanning over a wide range of elemental compositions: CHO (n = 66, e.g., polylethyelene glycols), CHN (n = 12, e.g., C6-C34 alkylamines), CHNO (n = 28, e.g., alkylbetaines), CHSO (n = 12, e.g., linear alkylbenzene sulfonates), CHPO (n = 4, e.g., trialkyl phosphates), CHNSO (n = 4, e.g., alkyl isothiazolinones), CFO (C6-C12 perfluroalkyl acids), and CFSO (C4-C9 perfluoalkyl sulfonic acids). Most of the identified chemicals were either naturally occurring products (e.g., fatty acids and other cellular components) or high production volume chemicals such as synthetic surfactants and polymers. Homologous series analysis allowed to establish links among different features that were overlooked by the preliminary and more conventional NTS approach only relying on MS/MS libraries, analytical standards and prioritization of features through statistical analyses, resulting in a 4-fold increase in the number of tentatively identified compounds, and therefore allowing to explore the acquired data in a more comprehensive way.

3.03.P-We157 What are Contaminants of Emerging Concern (CECs) in Swedish Landfill Leachate?

Tsz Yung Wong[1]*, Alberto Celma*[2] *and Oksana Golovko*[2]*, (1)Swedish University of Agricultural Sciences (SLU), Uppsala, Sweden, (2)Swedish University of Agricultural Sciences (SLU), Sweden*

Landfills are the destination of much unrecyclable waste, but they are not the final destination for contaminants. Contaminants of emerging concern (CECs) are harmful organic chemicals used extensively in consumer and industrial products that can eventually enter the environment through landfills. Before Sweden introduced stricter regulation on waste management, a wide variety of residues was deposited in landfills, underscoring the importance of investigating the occurrence and levels of CECs in order to fully understand their ecological and human health impacts. Non-target screening (NTS) and suspect screening (SS) by Ultra High Performance Liquid Chromatography-Electrospray Ionization- High Resolution Mass Spectrometry (UHPLC-ESI-HRMS) are widely used strategies for identifying unknown compounds in samples. The goal for this study is to create a list of representative CECs in Swedish landfill leachate for future monitoring and quantification.

In our study, samples (untreated and treated leachate) were collected from five different Swedish landfills with the variations of different locations, age, and treatment methods. Both individual samples and pooled samples were prepared before analysis. Given the high sensitivity of the UHPLC-ESI-Orbitrap instrument, analysis of pooled samples addresses the common challenges of extensive data processing required for individual analysis. Extraction was performed on homemade multi-layer Solid Phase Extraction (SPE) cartridges in order to capture a wide spectrum of CECs. Preliminarily, pharmaceuticals, personal care products, industrial chemicals, and Per- and Polyfluorinated Substances (PFAS) were identified in the landfill leachates. Overall, our study helps to bridge the knowledge gap regarding the occurrence of CECs in Swedish landfills and lays the groundwork for future monitoring and regulatory efforts.

3.03.P-We158 Exploring Non-Target Screening and Differential Analysis in Assessing Nature-Based Reactive Barrier Treatment of Micropollutants in Treated Wastewater

Charlotte Guy[1]*, Geoffroy Duporte*[2]*, Linda Luquot*[3] *and Elena Gomez*[2]*, (1)French National Centre for Scientific Research (CNRS), France, (2)HydroSciences Montpellier, University of Montpellier, CNRS, IRD, France, (3)Geosciences Montpellier, University of Montpellier, CNRS, France*

Population growth and increasing water demand have exacerbated water resource scarcity. Treated wastewater (TWW) is a valuable alternative resource, but its complex composition, including micropollutants, raises concerns about reuse risks. Reactive barriers (RB) made with natural materials offer a solution to remove TWW contaminants. Evaluating RB process effectiveness and comprehending contaminant fate remain challenging. Recent advances in High Pressure Liquid Chromatography (HPLC) coupled with High-Resolution Mass Spectrometry (HRMS) and non-target analysis (NTA) provide an opportunity to identify contaminants and evaluate RB processes. The study aims to develop an NTA approach to assess RB effectiveness and understand the quality of water treated with RB concerning emerging contaminants (ECs).

In a serie of batch experiments, TWW was mixed with a RB under two conditions: TWW in contact with RB (TWW+RB) and TWW alone (TWW). After one hour of contact, samples were extracted and analyzed using HPLC-HRMS. NTA workflow and statistical comparison between the two sample conditions were applied for data treatment. Additionnaly, a quantitative method was applied to 28 pharmaceutical residues. Sorption (%) was calculated by comparing concentrations in TWW+RB and TWW experiments. NTA's applicability for sorption estimation was investigated using intensities from differential analysis.

Differential analysis show significant differences in compounds that decrease or increase after contact with BR. A prioritization workflow identified and annotated 115 compounds. Natural products predominantly increased after RB contact, while compounds exhibited a significant 75% decrease in peak area are mainly pharmaceuticals. Among the 28 quantified pharmaceuticals, 18 were detected in the TWW influent, with concentrations ranging from less than 10 ng/L to over 1 µg/L. Notably, 61% of these molecules were sorbed at more than 50%. The sorption of ECs estimated by NTA correlated satisfactorily with sorption quantified through target analysis, although caution regarding the matrix effect is necessary. NTA provides a comprehensive view of RB treatment performance, giving information on the compounds released by the barrier and its sorption capacity. NTA emphasizes the benefits of RB treatment while highlighting the need to study compounds reloaded by RB. It is a powerful tool for understanding the advantages of nature-based reactive barrier treatment in improving the quality of TWW.

3.03.P-We159 Quaternary Ammonium Compounds in Produced Water Wastewater

***Matteo Ottaviani**[1], Neri Bonciani, MA, PhD[2], Nikoline Juul Nielsen[3], Karen Feilberg[4] and Jan Christensen[3], (1)Technical University of Denmark (DTU), Denmark, (2)Danish Offshore Technology Centre, Denmark, (3)University of Copenhagen, Denmark, (4)DTU Offshore, Technical University of Denmark (DTU), Denmark*

Produced water (PW) is a significant byproduct of oil and gas production, sometimes exceeding the hydrocarbon production in volume, and it constitutes a major wastewater stream in the Danish North Sea offshore production. While existing regulations address dispersed hydrocarbon content, there are currently no limiting regulations addressing other potentially hazardous compounds, including production-related chemicals such as biocides, hydrogen sulfide scavengers and scaling inhibitors added during the oil production process. Quaternary ammonium compounds (QACs) are a class of cationic surfactants, they have anti-fouling and biocidal proprieties and they are of concern for the environment, since there is a lack of data about the concentration range and degradation of these compounds in the offshore waste stream. In this study quaternary ammonium compounds benzododecinium, benzyldimethyltetradecylammonium, didecyldimonium, benzyldimethylhexadecylammonium are investigated together with non-target analysis of production chemicals on PW wastewater from Danish offshore production platforms. The analysis is performed by SPE extraction and subsequent analysis by LC high-resolution MS using an electrospray ionization source. This study can help to better understand the quality of the offshore wastewater and provide input to environmental impact assessment and mitigation strategies to reduce the overdosing of production chemicals in hydrocarbon production.

3.03.P-We160 Scaling up Suspect Screening Analysis (SSA) in environmental water samples: a case study of contaminants of emerging concern in wastewater

***Helena Rapp Wright**[1], Beatriz Galindo-Prieto[2], Stav Friedman[3], Margarita White[3] and Leon Barron Dr[3], (1)Imperial College London, United Kingdom, (2)Environmntal Research Group, Imperial College London, United Kingdom, (3)Environmental Research Group, Imperial College London, United Kingdom*

Contaminants of emerging concern (CECs) are increasingly being shown to occur in water samples across the world. Consequently there is a constant need for reliable analytical methods for identification and determination at low levels (ng/L-µg/L). Sample pre-treatment (e.g., solid-phase extraction) is widely applied to reach the required sensitivity but is usually time-consuming. New direct-injection methodologies have emerged which combined with liquid chromatography-high resolution mass spectrometry (LC-HRMS) offers enough sensitivity to rapidly identify large numbers of chemicals. The aim of this study is to monitor a wide number of CECs using direct injection suspect screening analysis (SSA) in a national wastewater monitoring campaign.

Influent 24h-composite samples were collected across 18 wastewater treatment plants in England (2021-2023). Samples were only filtered using 0.2 µm PTFE filters and transferred to LC amber vials for storage and/or analysis. SSA was performed using a Shimadzu LCMS-9030 LC-QTOF-MS instrument, a Shim-pack Velox 2.1 × 100 mm, 2.7 µm biphenyl column, a 17 min LC gradient and 40 µL of injection volume. ESI-HRMS was run in positive and negative ion mode, and fragmentation was performed in data independent analysis. Shimadzu LabSolutions Insight Explorer Library Screening software containing ~1295 compounds, and four points of confirmation were used: ±0.5 min retention time, ±5 ppm mass accuracy, isotopic distribution score >20 and a library identification similarity index score >45. In addition, the signal-to-noise ratio was >3:1 and a >1,000 peak intensity threshold was used.

A total of 140 samples were analysed, where 292 unique compounds were matched to library data. Drugs showed the highest number of compounds detected including antidepressants. Confidence levels were assigned following the Schymanski framework. To investigate a spatial comparison between sites, an investigation of stable isotope labelled internal standards (SIL-IS) stability between batches and replicates was performed. A selection of SIL-IS was investigated to use their peak height for normalisation to achieve a hierarchical cluster analysis across all samples. For the first time, direct-injection SSA was successfully applied as a high-throughput technique to a national wastewater sampling campaign. This works presents the first investigation of a high spatiotemporal wastewater analysis across England (~28 % of the country's population).

3.03.P-We161 Suspect Screening Reveals the Presence of Ultra Short Chain PFAS in Australian environmental Water Systems

*Sara Ghorbani Gorji[1], Rachel Mackie[2], Pritesh Prasad[3], **Emma Knight**[4], Xuan Qu[3], Kevin Thomas[2] and Sarit Kaserzon[2], (1)Queensland Alliance for Environmental Health Sciences (QAEHS), University of Queensland, Australia, (2)University of Queensland, Australia, (3)Qaehs, University of Queensland, Australia, (4)Norwegian Institute for Water Research (NIVA), Norway*

The class of Per- and polyfluoroalkyl substances (PFAS) comprises hundreds of thousands of chemical compounds, with many causing significant environmental contamination. Recent regulatory changes have pushed industries to seek alternatives with shorter carbon chains, like short-chain fluorinated options (C4-7) and ultra-short chain products ($C \leq 3$). While there's been considerable focus on tracking both short and long-chain PFAS (C>4), Ultra Short Chain (USC) PFAS have been less explored due to analysis difficulties. Consequently, gaps persist in understanding how USC PFAS spread in the environment and the associated risks.

This research aims to fill this void by studying the presence and destiny of USC PFAS in different environments across Australia—groundwater, surface water, wastewater, and drinking water sources. The study involves creating a new High-Resolution Mass Spectrometrysuspect screening method combined with a targeted LC-MS/MS method. Our investigation identified fourteen distinct USC PFAS compounds, including eight not previously reported in Australia, such as PFPrA, PFMeS, PFEtS, PFPrS, MeFMeSA, FPrSA, H-PFEtS, H-PFPrS, Cl-PFPrS, H-PFPrA, PFPrSi, PFPr-OS, and NTf2.

Although toxicity data for USC PFAS are scarce, their widespread presence in the environment, especially PFPrS at higher concentrations, emphasizes the need for improved monitoring efforts. Analyzing trifluoroacetic acid (TFA) remains challenging due to background levels and contamination, requiring further research and method refinement. Overall, this study offers critical insights into the prevalence and behaviour of USC PFAS, emphasizing the urgency for continued research and regulatory focus on this emerging contaminant class.

3.04.A Analysis, Assessment and Management of Contaminants of Emerging Concern and Their Transformation Products in the Environment

3.04.A.T-01 Per- and Poly-fluorinated alkyl substances (PFAS) at the Environment Agency UK

***Alun James**, Environment and Business, Environment Agency United Kingdom, United Kingdom*

Per- and Poly-fluorinated alkyl substances (PFAS) are a group of widely used synthetic substances. They are extremely persistent in the environment and as a result they have been dubbed the "Forever Chemicals". This along with their widespread use means many are now ubiquitous in our environment

Source site screening work has been undertaken to asses the risk from PFAS emission to the environment for over 10000 potential sites across the UK that considers the site types and environmental setting. This work has been used to produce risk maps that inform monitoring strategies and engagement strategies. Recent monitoring undertaken across England has shown how PFAS are detected in >65% of surface water samples, >20% of groundwaters and in all saline and freshwater fish analysed. Biota analysis has also shown how PFAS are now ubiquitous in freshwater and saline fish from around the country. While PFOS still remains the dominant PFAS detected in fish samples, the presence of those shorter chain PFAS used as replacements are such as PFBA, PFPeA, PFBS and 6:2 FTSA are found in water samples. We are also using a number of emerging analytical methods such as TOP Assay and Passive sampling to improve our understanding of PFAS and reduce monitoeing costs.

Investigations into high risk sectors such as contaminated land, landfills wate water treatment works and manufacturing sites is helping to build a detailed picture of FAS sources and identify those that pose the highest risk to human and environmental health.

Our work has shown how PFAS are being detected across England's environment however the data also shows how 19 of the PFAS included in our monitoring suite of 45 PFAS are not being detected. Data is also showing how many areas of the country are not impacted by PFAS with reported concentrations being below the limit of quantification. By presenting the data in a clear manner we hope to provide an accurate, unbiased representation of PFAS in the English environment.

3.04.A.T-02 Background concentrations and spatial distribution of per- and polyfluoroalkyl substances (PFAS) in surface waters of the greater Melbourne area, Australia

Tanya Paige[1]*, Thish De Silva*[2]*, Saman Buddhadasa*[3]*, Shiva Prasad*[3]*, Dayanthi Nugegoda*[4] *and Vincent J. Pettigrove*[5]*, (1)RMIT University, Australia, (2)National Measurement Institute Australia, Australia, (3)National Measurement Institute, Australia, (4)School of Science, RMIT University, Australia, (5)Aquest Research Group, RMIT University, Australia*

Little is known about the background concentrations of per- and polyfluoroalkyl substances (PFAS) in Australian urban waterways and whether their presence and concentrations are associated with particular catchment land-uses.

A survey was conducted of 33 per- and polyfluoroalkyl substances (PFAS) in streams and wetlands (n = 65) in Greater Melbourne, Australia, to determine background concentrations and major catchment land-uses contributing to PFAS pollution. Sites consisted of streams and constructed urban wetlands with independent catchments that were classified by their dominant catchment land use – either residential, industrial, municipal wastewater treatment plants, or rural. Melbourne was considered a suitable city to establish background concentrations as there is no manufacturing of PFAS and few point sources of PFAS pollution. Surface water and samples collected from 65 sites were analysed for thirty-three PFAS.

Twenty-two out of thirty-three targeted PFAS were detected, with at least one PFAS species was detected in 98% water samples. While diffuse PFAS pollution was detected across the urban waterways, significant differences between land-use types were observed depending on the PFAS congener and also on the PFAS class (perfluorosulfonic acids (PFSAs) or perfluorocarboxylic acids (PFCAs)). Results suggests that different types of PFAS-containing products were used in the various catchment land-uses and that congeners transported diffused through air and water to varying degrees. Results will be discussed based on occurrence patterns across the different land-use types for total PFAS and individual PFAS compounds.

3.04.A.T-03 Increasing Atmospheric Depositions of Trifluoroacetate (TFA) Over the Last Three Decades

Finnian Freeling[1]*, Thomas A Ternes*[2] *and Karsten Nödler*[3]*, (1)TZW: DVGW-Technologiezentrum Wasser (German Water Centre), Germany, (2)G Qualitative Hydrology, German Federal Institute of Hydrology (BfG), Germany, (3)TZW: DVGW Water Technology Center, Germany*
