Trifluoroacetate (TFA) is a very persistent and very mobile (vPvM) contaminant that occurs ubiquitously in the environment. Among many anthropogenic sources, TFA can be formed in the atmosphere through the oxidation of certain perfluoroalkyl-containing substances, such as hydrofluorocarbons (HFCs), hydrochlorofluorocarbons (HCFCs), hydrofluoroolefins (HFOs), and hydrochlorofluoroolefins (HCFOs), which were introduced as substitutes for ozone-depleting chlorofluorocarbons (CFCs) and find wide application as refrigerants, fire extinguishing agents, and physical blowing agents. The usage of numerous precursors has considerably increased over the last decades. Therefore, with increasing emissions of these compounds, the TFA levels in precipitation are expected to rise. In this study, archived plant leaf samples from the German Environmental Specimen Bank (ESB) were used as a biomonitoring tool to give insights into the temporal trends in the atmospheric depositions of TFA in Germany over the last three decades. The TFA concentrations of investigated deciduous and coniferous tree leaf samples mostly ranged from tens to hundreds of µg/kg based on dry weight. With the exception of one site, significant (p<0.05; Mann-Kendall tests) positive temporal trends in TFA concentration were found for all of the tree species. The uptake and transpiration of water by vascular plants to replace the water lost due to photosynthesis provides a mechanism for bioaccumulation of TFA. Consequently, increasing levels of TFA in the studied perennial plants are likely a product of both phytoaccumulation over multiple years and an upsurge in the anthropogenic emissions of gaseous TFA precursors, leading to an increasing atmospheric deposition of TFA in the Northern Hemisphere over the last three decades. This study has shown that the analysis of plant matrices can be an efficient biomonitoring tool to evaluate the temporal and spatial presence of TFA in the terrestrial environment. It is expected that the atmospheric formation and deposition of TFA will continue to grow in the coming years mainly due to rising global emissions of fluorinated refrigerants and the switch to the latest generation of refrigerants, namely HFOs, as they generally degrade faster and with larger TFA yields than their predecessors.

3.04.A.T-04 Formation of trifluoroacetic acid from the aqueous photolysis of aryl-CF3 compounds

Shira Joudan*, Zhefei Guo and Azka Attar, Department of Chemistry, University of Alberta, Canada*

Concentrations of trifluoroacetic acid (TFA) in the environment exceed the expected concentrations based on emissions of TFA and its known precursors. In 2020, 54 pharmaceuticals and 117 agrochemicals had aryl-CF_3 functionalities, and there are reports of TFA forming from some of these molecules. Limitations of previous research arise from not monitoring all transformation products throughout the experiment leaving uncertainty in reaction mechanisms and some miscalculated kinetics. A common aryl-CF_3 motif is para-hydroxybenzotrifluoride (p-OHBF) including in the pharmaceutical fluoxetine and the pesticide difenopenten. The objective of this work was to test the photochemical reaction of p-OHBF to determine kinetics, quantum yield and product formation with an emphasis on TFA vs F^-. Photochemistry experiments of p-OHBF were performed in quartz test tubes using a photoreactor with UVB lights and dark controls were performed in the same tubes. p-OHBF and its carboxylic acid reaction product were quantified using HPLC-UV, while TFA and F^- were quantified using ion chromatography with conductivity detection. The formation of other transformation products were explored via ^{19}F NMR and non-target mass spectrometry. The direct photochemistry of p-OHBF was accelerated at higher pH and slower at lower pH, confirming previous reports. Rate constants were 0.016 h^{-1} (pH 4.3, quantum yield 0.17), 0.012 h^{-1} (pH 7.4, quantum yield 8.1

x 10^{-3}), and 0.0097 h^{-1} (pH 8.2, quantum yield 1.2 x 10^{-3}). Base-catalyzed defluorination of p-OHBF was observed in the dark to form the carboxylic acid and F^- at pH 7.4 and 8.2, but did not occur at pH 4.3. Kinetic analysis determined the maximum TFA formation at pH 4.3 is 9.32%, at pH 7.4 is 3.49% while at pH 8.2 is 1.89%. This shows that especially at acidic conditions, p-OHBF can be converted to nearly 10% TFA, and not solely undergo defluorination. TFA was only observed in photochemistry experiments, while defluorination is primarily a base catalyzed reaction that is also relevant at pH 7.4. All experiments have fluorine mass balance greater than 90%. Overall, if up to 10% of an Ar-CF_3 molecule is converted to TFA from direct photolysis only, this may add up to a large source in sunlight waters when accounting for other formation pathways such as indirect photolysis or biotransformation. This workflow is a tool that can be applied systematically to Ar-CF_3 molecules to assess their contributions to the presence of TFA in the environment.

3.04.B Analysis, Assessment and Management of Contaminants of Emerging Concern and Their Transformation Products in the Environment

3.04.B.T-01 IN SILICO TENTATIVE IDENTIFICATION OF PHARMACEUTICAL BIOTRANSFORMATION PRODUCTS IN RECEIVING WATER

Olukemi Oloyede Mx[1]*, Russell Davenport Prof*[2]*, Irene Bramke, PhD*[3] *and Leon Barron Dr*[1]*, (1)Environmental Research Group, Imperial College London, United Kingdom, (2)Newcastle University, United Kingdom, (3)AstraZeneca, Netherlands*

Water and effluent quality monitoring methods in the UK are predominantly focused on organic matter (nitrogen, phosphorus levels) whereas pharmaceuticals and their biotransformation products (BPs) are not monitored routinely in river water. Antimicrobials such as sulfamethoxazole and clotrimazole are pharmaceuticals that are of particular concern, increasingly being detected in surface water and soils across Europe, are prone to causing antimicrobial resistance and are toxic and mobile in the aquatic environment.

This work aims to fill a research gap in the lack of predictive understanding of pharmaceutical transformation and degradation; high resolution analytical methods have been developed for in silico identification of pharmaceuticals and their BPs but do not provide information about the mechanisms or pathways of transformation. It will determine the biotransformation rate of prioritised compounds (including those in the EU WFD "watch list") and investigate their transformation pathways to help gain a better understanding of their breakdown in river water. The microbial and chemical data derived from these studies will be used to create a machine learning based model that can help predict the biotransformation of pharmaceuticals in river water.

Suspect screening in high resolution mass spectrometry (HRMS) analysis has been used to detect and identify compounds and 900 BPs in wastewater impacted rivers and the use of online predictive transformation tools such as BioTransformer 3.0 (BT 3.0) and EAWAG-Biocatalysis/Biodegradation Database/ Pathway Prediction System (EAWAG—BBD/PPS) have been used to predict BPs that could be formed in environmental microbial transformation (EMT). Compounds of interest were prioritised on the basis of occurrence (frequency across sites and peak height) and risk quotients (RQs), resulting in a shortlist that includes carbamazepine, lamotrigine and venlafaxine. Stability studies are being conducted them in riverwater with the use of LC-MS/MS and HRMS analysis.

Future work will include the application of the retention time model to other pharmaceuticals in order to identify other BPs in HRMS data, as well as assessing identified BPs in terms of environmental risk e.g. predicted no effect concentration (PNEC). Biological analytical methods (metagenomics, metatranscriptomics, qPCR) will also be conducted to observe the resident enzymes and/or microbial communities that may be involved in the observed transformations.

3.04.B.T-02 Computational Assessment of Antibiotic Transformation Product Activity: Molecular Dynamics Simulations and Free Energy Calculations

Paul Löffler[1]*, Foon Yin Lai*[2]*, Henning Henschel*[3] *and Anders Karlen*[3]*, (1)Aquatic Sciences and Assessment, Swedish University of Agricultural Sciences (SLU), Sweden, (2)Department of Aquatic Sciences and Assessment, Swedish University of Agricultural Sciences (SLU), Sweden, (3)Medicinal Chemistry, Uppsala University, Sweden*

The global proliferation of antimicrobial resistance (AMR) poses a significant threat to human, animal, and the environmental health within the concept of One Health. Current evaluations of AMR and associated environmental risks predominantly focus on antimicrobial parent compounds, often neglecting their transformation products (TPs). Being generated through organismal excretion and/or transformed during wastewater treatment, TPs frequently emerge through subtle alterations in molecular structure, often resulting in increased stability and persistence, ultimately infiltrating surface water ecosystems. Given the structural similarity between TPs and their parent compounds, the potential interaction of TPs with the target protein of their parent compounds remains a critical concern for the emergence of AMR genes in the environment. This study used the open-source molecular dynamics software, GROMACS, together with PyAutoFEP for free energy calculations to assess the binding affinity differences to the respective target protein between TPs and their parent compounds. We explored several sulfonamide TPs, as well as TPs from trimethoprim and multiple antivirals, like nevirapine, lamivudine, or acyclovir. Many TPs exhibited predicted binding affinities within the similar range as the parent compound, with some showing increased affinity, suggesting potential activity. This research highlights the importance of expanding our approach for AMR assessment by recognizing the significance of antimicrobial transformation products.

3.04.B.T-03 Pesticide transformation product occurrences in surface waters as ground water pollution risk indicators in the context of an extended residence time aquifer

Tom Galle[1]*, Michael Bayerle*[1]*, Denis Pittois*[1]*, Viola Huck*[1] *and Julien Farlin*[2]*, (1)Erin, Luxembourg Institute of Science and Technology (LIST), Luxembourg, (2)Water Management Administration Luxembourg, Luxembourg*

Luxembourgish groundwater aquifers have recently been impacted by high concentrations of several pesticide transformation products (TP) that led to regulatory issues for about 1/3 of the drinking water supplies (Luxembourg considers all transformation products to be relevant and applies the 100 ng/L legal threshold). The consequent application restrictions or complete bans of certain pesticides triggered switches in compound uses in several cultures. A leaching risk analysis had been conducted to orient agricultural counseling on the least impacting parent compounds and transformation products. However, since the leaching simulations relied on literature environmental property data of the pesticides (like fraction of TP generated), there was some uncertainty on the true impact of the identified TPs. Residence times of ground waters in the main aquifer spanning on average between 10 and 20 years (with proportional recovery times once these waters are contaminated), a faster validation approach was needed. The hypothesis was established that the interflow component in surface waters would be a good indicator to estimate the amount of transformation products available for groundwater leaching. In that perspective passive sampling campaigns were established on four river basins of distinct hydrogeology to quantify the masses of parent compounds and transformation products transported during an entire year and supported by grab sampling in the descending limbs of seasonal flood waves. Additional parameters included conductivity, DOC, Abs280 and macro-anions. All the predicted transformation products were identified and their occurrence varied in amount and timing in the different catchments according to their application, metabolization in soils and hydrogeological setting. This contribution discusses the influences of spatial use variability and hydrological connectivity of agricultural source plots to the magnitude of the occurrences as well as its potential link to the leaching modelling and its parametrization.

3.04.B.T-04 Identification of Neonicotinoid Transformation Porducts in Aquatic Environments

Carly Beggs[1]*, Sara Ghorbani Gorji*[2]*, María José Gómez Ramos*[3]*, Clement Matthew Chan Dr*[4]*, Kevin Thomas*[5] *and Sarit Kaserzon*[5]*, (1)QAEHS - The University of Queensland, Australia, (2)Queensland Alliance for Environmental Health Sciences (QAEHS), University of Queensland, Australia, (3)University of Almería, Spain, (4)School of Chemical Engineering, University of Queensland, Australia, (5)University of Queensland, Australia*

Despite their increasing scrutiny and discontinued use in several countries, neonicotinoid insecticides are still widely used in Australia, with over 400 neonicotinoid-containing products registered for use. The aquatic environment is a major sink of neonicotinoid insecticides from sources such as agricultural runoff, and wastewater treatment plant effluents released into environmental waters, which may put aquatic species at increased risk of harm from neonicotinoid exposure.

Photodegradation is an important factor in the environmental fate of aquatic contaminants and is the primary process of environmental degradation of neonicotinoids in aquatic environments. Several studies have investigated neonicotinoid degradation kinetics, with findings suggesting all neonicotinoids follow first-order or pseudo first-order kinetic degradation; and are preferential toward transformation over mineralisation. However, little is known about transformation pathways, the structures of the final stable transformation products, or the risk of these transformation products to the aquatic environment.

The aims of this study are to identify environmentally relevant transformation products and their transformation pathways from four commonly used neonicotinoids (i.e., clothianidin, dinotefuran, imidacloprid and thiamethoxam) and assess risk of the identified transformation products to the aquatic environment.

Neonicotinoids from analytical standards and commercial formulations were exposed to UV radiation over a time course from 0-24 hours. Neonicotinoid parent compounds were quantified at various time points to investigate degradation kinetics. Samples were analysed by high resolution mass spectrometry using both suspect screening and non-target workflows to identify transformation products and elucidate transformation pathways. Finally, the US EPA’s Toxicity Estimation Software Tool was used to investigate *in silico* toxicity of the identified transformation products to investigate the potential risk to aquatic environments.

Results indicate that each of the studied neonicotinoid parent compounds degrade to 3-4 environmentally relevant transformation products upon UV exposure, which we were able to elucidate transformation pathways for. Several of the identified transformation products are estimated to be of greater toxicity to aquatic organisms compared to parent compounds, suggesting neonicotinoids pose a greater threat to the aquatic environment than previously perceived.

3.04.C Analysis, Assessment and Management of Contaminants of Emerging Concern and Their Transformation Products in the Environment

3.04.C.T-01 Advancing Surface Water Monitoring: A Comprehensive Strategy Integrating Tailored Pesticide Screens and Advanced Analytical Techniques

Pulasthi Serasinghe[1]*, Hao T.K Nguyen*[2]*, Thish De Silva*[2]*, Caryn Hepburn*[3]*, Dayanthi Nugegoda*[4] *and Vincent J. Pettigrove*[5]*,*

(1)RMIT University, Australia, (2)National Measurement Institute Australia, Australia, (3)Waters Corporation, Australia, (4)School of Science, RMIT University, Australia, (5)Aquest Research Group, RMIT University, Australia
The continuous introduction of new pesticides globally poses challenges for effective environmental monitoring. This study proposes an innovative approach to identify priority pesticides for regional waterway monitoring. The method involves leveraging local pesticide registration data, assessing high toxicity to non-target aquatic organisms, and considering pesticides typically excluded from routine laboratory screening. To detect these priority pesticides in surface waters, a suspect screening analytical approach was developed, utilizing two passive sampling methods and high-resolution mass spectrometry (HRMS). The investigation focused on 181 priority pesticides across 32 waterway sites within Greater Melbourne, Victoria Australia, encompassing diverse catchment land uses. Liquid chromatography coupled with quadrupole-time-of-flight mass spectrometry (LC-QTOF-MS) in data-independent acquisition mode (DIA) was employed for pesticide detection. Through a suspect screening workflow using Waters UNIFI software, 21 pesticides were tentatively detected at 22 sites, with confirmation of 5 pesticides using certified reference materials (CRMs). Notably, the study identified several newly emerging pesticides in Australian surface waters, previously undocumented. Confirming priority pesticides before their inclusion in routine screening enhances the efficiency and cost-effectiveness of monitoring programs. However, practical, and analytical limitations make confirming the presence of numerous compounds challenging. This study demonstrates the effectiveness of a regional screening approach, combining broad-field sampling and suspect screening through HRMS. This comprehensive strategy enhances understanding of emerging pesticide levels in specific regions, aiding in the prioritization of pesticides for routine screening programs.

3.04.C.T-02 A New Method for Detecting and Quantifying Phthalate Exposure Using Blubber from Bottlenose Dolphins (Tursiops truncatus)

***Maggie Knight**[1], Miranda Dziobak[2], Emily C Pisarski[3], Ed Wirth[3], Amanda Moors[4], Randall S Wells[5], Wayne E. McFee[6] and Leslie B Hart[2], (1)Department of Biology, Graduate Program in Marine Biology, College of Charleston, (2)Department of Health and Human Performance, College of Charleston, (3)National Oceanic and Atmospheric Administration (NOAA), (4)National Institute of Standards and Technology (NIST), (5)Mote Marine Laboratory, Chicago Zoological Society's Sarasota Dolphin Research Program, (6)Coastal Marine Mammals Assessment Program, NOAA National Centers for Coastal Ocean Science*
Phthalates are plasticizing chemicals added to a variety of consumer products. They are considered endocrine disruptors, which may adversely impact mammalian development, reproduction, and metabolism. Phthalates are not permanently bound to the products to which they are added, increasing the likeliness of environmental exposure for humans and wildlife. Recent studies in bottlenose dolphins (*Tursiops truncatus*) demonstrated prevalent exposure to phthalates, but current detection methods rely on urine samples collected during catch-and-release health assessments. These events are logistically complicated, expensive, and require animals to be handled. This study developed a protocol for phthalate ester metabolite (mPAE) detection in bottlenose dolphin blubber, a type of sample that can be collected remotely. We used solid phase extraction and high-performance liquid chromatography-tandem mass spectrometry to analyze blubber samples (n=27) collected during health assessments conducted in Sarasota Bay, FL, USA in 2016, 2017, 2022, and 2023. Detectable concentrations of three mPAEs (mono-2-ethylhexyl phthalate (MEHP), monoethyl phthalate (MEP), mono-isodecyl phthalate (MIDP)) were observed in 37% of sampled dolphins (n=27). The most commonly detected mPAEs included mono-2-ethylhexyl phthalate (MEHP; n=6; geometric mean: 4.57 ng/g wet weight; range: 5.2 to 12.4 ng/g ww), monoethyl phthalate (MEP; n=2; geometric mean: 44.9 ng/g ww; range: 39.7 to 50.1 ng/g ww), and mono-isodecyl phthalate (MIDP; n=3; range: 26.0-27.4 ng/g ww). These findings from blubber correspond with observations from urine in which measurement of MEHP and MEP was also most common. mPAE detection in blubber offers another surveillance tool that does not have the limitations of catch-and-release health assessments. Blubber can be obtained via remote biopsy methods, which are used globally to monitor marine mammal populations, thereby facilitating exposure assessments in other at-risk populations.

3.04.C.T-03 What is in our electrical and electronic plastic waste? Non target and target screening approaches for the identification and determination of hazardous substances

***Gabriela Castro**[1], Miguel Cobo Golpe[2] and Isaac Rodriguez Pereiro[3], (1)University of Santiago de Compostela, Spain, (2)Analytical Chemistry. Institute for Research on Chemical and Biological Analysis, Universidade de Santiago de Compostela, Spain, (3)Analytical Chemistry. Institute for Research on Chemical and Biological Analysis, University of Santiago de Compostela, Spain*
Waste of electrical and electronic equipment (WEEE) remains as one of the fastest growing global wastes, mainly fuelled by rapid technological advances and accelerated obsolescence. This residue contains both valuable and hazardous substances, which difficult their recycling in an environmentally sound way. Recently, the European Commission presented a new circular economy action plan that has WEEE reduction as one of its priorities. To date, recycling to recover reusable components as Cu and precious metals from WEEE is the goal. However, due to the limited number of facilities and high costs, landfilling, incineration, and exportation to other countries remain as the main alternatives, posing environmental and human risks due to the presence of toxic substances.

Plastics constitute 20% of WEEE (WEEEP), which contain high concentrations of additives to prolong lifespan. The main limitation to achieving an actual sustainable circular economy is the lack of information regarding the chemical additives used in the different plastics and applications. The presence of hazardous organic compounds (HOCs) in the plastic waste of these devices carries profound environmental implications. Notably, HOCs like brominated flame retardants (BFRs), polychlorinated biphenyls (PCBs), and polybrominated diphenyl ethers (PBDEs) are of paramount concern. These hazardous compounds, together with other unidentified substances, arising from the additives used and from the physicochemical transformations during plastic treatment or production, further complicate the recycling of WEEEP.

Herein, a non-target screening analysis of WEEEP was carried out to identify volatile and semi-volatile additives using gas chromatography coupled to mass spectrometry (GC-QTOF-MS). More than 300 substances were tentatively identified, belonging to different families commonly used as plastic additives, flame retardants, PAHs, plasticizers, and UV filters. The semi-quantification of predominant additives was conducted across 48 WEEEP samples collected from different handling and dismantling facilities. Tetrabromobisphenol A (TBBPA) and triphenyl phosphate (TPhP) were the substances detected in the highest concentrations ranging from 14.0 to 7,292 $\mu g\ g^{-1}$.

3.04.C.T-04 Spatial Distributions, Seasonality, and Ecological Risk Assessment of UV Absorbents in the Habitat of Endangered St. Lawrence Estuary Beluga in Canada

Amina Ben Chaaben[1]*, Mathieu Babin*[1]*, Frank Wania*[2]*, Hayley Hung*[3]*, Magali Houde*[4]*, Liisa Jantunen*[5]*, Huixiang Xie*[1] *and Zhe Lu*[1]*, (1)Institut des Sciences de la Mer de Rimouski (ISMER), University of Quebec at Rimouski (UQAR), Canada, (2)Department of Physical and Environmental Sciences, University of Toronto, Canada, (3)Air Quality Processes Research Section, Environment and Climate Change Canada, Canada, (4)Aquatic Contaminants Research Division, Environment and Climate Change Canada, Canada, (5)Atmospheric Science and Technology, Environment and Climate Change Canada, Canada*

St. Lawrence (SL) Estuary beluga whales (Delphinapterus leucas) are endangered cetaceans population in Canada. Exposure to various contaminants is a major stressor affecting the health and recovery of this whale population. Nonetheless, as important factors influencing exposure, the prevalence and distribution of many emerging contaminants in the water of their habitat are poorly understood. UV absorbents (UVAs) are derived from sunscreens, personal care products, plastics, and other products to protect skin from sunburn or prevent the materials from UV-induced color change or degradation. UVAs have been detected in the tissues of SL Estuary beluga whales and their food web, demonstrating the presence of UVAs in the habitat of SL Estuary beluga and the potential input of these contaminants from the rivers draining into this system, such as the SL River and the Saguenay River. This study aims (i) to investigate the distribution and seasonality of two groups of UVAs, UV filters (UVFs) and benzotriazole UV stabilizers (BZT-UVs), in the dissolved phase and the suspended particulate matter (SPM) of the surface water in the habitat of the SLE beluga, and (ii) to conduct an ecological risk assessment of these contaminants in the SL surface water. Water samples were collected from 60 locations in the beluga habitat (the SL Estuary, SL River, and Saguenay River; 2019-2020) (Quebec, Canada) to conduct the spatial distribution study. In addition, between April and October 2023, water samples were collected from 3 sites in the SL Estuary for the seasonality study. UVFs concentrations (3-1570 ng/L) were generally greater than BZT-UVs (<Method Detection Limit (MDL)-43 ng/L) in the water samples. Compared to the SL Estuary, the river samples showed higher detection frequency and concentrations of four BZT-UVs and three UVFs in the dissolved phase. High abundances of UVAs on SPM were found in the SL, suggesting that the ingestion of SPM could be an important exposure pathway of aquatic organisms in the beluga habitat to BZT-UVs and UVFs. The seasonality study is ongoing, and an ecological risk assessment analysis will be presented. This study establishes a baseline for monitoring UVAs in St. Lawrence beluga whales' habitat.

3.04.D Analysis, Assessment and Management of Contaminants of Emerging Concern and Their Transformation Products in the Environment

3.04.D.T-01 Contaminants of Emerging Concern in Urban Stormwater in the San Francisco Bay Area

Rebecca Sutton[1]*, Katherine Peter, PhD*[2]*, Edward P. Kolodziej*[2]*, Alicia Gilbreath*[1]*,* ***Diana Lin***[1]*, Jennifer Dougherty*[1]*, Da Chen*[3]*, Jia Liu*[4]*, Andrew Patterson*[5] *and Christopher Higgins*[6]*, (1)San Francisco Estuary Institute, (2)University of Washington, (3)Jinan University, China, (4)Southern Illinois University, Carbondale, (5)Eurofins Environment Testing (EET), (6)Colorado School of Mines*

An urban estuary that supports a population of over 7 million people, San Francisco Bay (California, USA) serves as a useful laboratory for studies of anthropogenic contaminants in urban stormwater and impacts on receiving waters. The majority of the region is served by separate storm drain systems, which channel stormwater flows directly to the Bay without treatment. Although small local tributaries make up only 6% of the freshwater entering the Bay, they contribute a disproportionately large percentage of the pollutant load for many legacy pollutants of concern (e.g., polychlorinated biphenyls, dioxins, polycyclic aromatic hydrocarbons, trace metals, and pesticides). However, far less is known about the role of urban stormwater in delivering contaminants of emerging concern (CECs) to the Bay, a data gap generally observed for receiving waters around the world. To begin to address this data gap, the Regional Monitoring Program for Water Quality in San Francisco Bay has conducted a four-year screening study to evaluate the concentrations of key classes of CECs in stormwater. Sampling sites have been selected primarily based on the extent of upstream urban land uses, with an emphasis on proximity to roadways. Complementary sampling occurred in less urban reference watersheds, at near-shore estuarine sites with tidal mixing, and in the open Bay to evaluate contaminant occurrence and inform our understanding of contaminant transport pathways into estuarine waters. Four classes of compounds were monitored using a suite of liquid chromatography tandem mass spectrometry (LC-MS/MS) methods, including per- and polyfluoroalkyl substances (PFAS), organophosphate esters, bisphenols, and several chemicals associated specifically with urban stormwater, including vehicle tire ingredients and the transformation product N-(1,3-dimethylbutyl)-N′-phenyl-p-phenylenediamine-quinone (6PPDQ). Results from this broad screening study will be summarized. Findings are already informing the development of a sustained stormwater CECs monitoring and modeling approach for San Francisco Bay.

3.04.D.T-02 Ecotoxicological risk assessment (ERA) of pesticides transformation products occurring in small waterbodies: case of ponds.
Gaspard François Léopold Conseil[1]*, Damien Banas*[2]*, Olivier Cardoso*[3]*, Christophe Rosin*[4] *and Sylvain Milla*[2]*, (1)University of Lorraine (UL), Nancy, France, (2)University of Lorraine (UL), France, (3)French Biodiversity Agency (OFB), France, (4)French Agency for Food, Environmental and Occupational Health & Safety (ANSES), France*
In Europe, particularly in France, many small waterbodies (SWB) are scattered throughout the hydrographic network but are not included in the monitoring networks of the Water Framework Directive (WFD), making them understudied areas. Ponds constitute a portion of these SWB and serve as valuable wetlands that provides both ecosystem and economic services. Due to their closeness to agricultural areas, they could exergue fluctuating contamination state, particularly in terms of Plant Protection Products (PPPs). The increased occurrence of PPPs and their residual forms (i.e. transformation products (TPs)) in wetland ecosystems has required the inclusion of these substances in water surface contaminant monitoring. There is a growing awareness concerning those products for which little is known about, especially in terms of occurrence and ecotoxicity.

Our focus lies in detecting these TPs across various ponds to gather data on their presence and subsequently identify potential ecotoxicological effects associated with them. This study's double objective is to establish pollution profiles of ponds (n=12) through chemical analysis, targeting 86 molecules and then to conduct an ecotoxicological risk assessment (ERA). This assessment was based on the measured concentrations (MEC) of PPP detected in ponds. Furthermore, ecotoxicological data were compiled, combining multiple data sources, in order to calculate a risk quotient (RQ) and identify TPs that could be harmful for this specific aquatic environment.

Concerning the occurrence, each pond displays varying composition and levels of PPP and TP. It has been quantified from 2 to 21 molecules among the ponds, going from 4,7 ± 0,2 to 648,5 ± 33,5 ng/L. TPs from current and banned pesticides were detected, like flufenacet-oxa and 2-hydroxyatrazine. Flufenacet-esa and MCPA were found at the µg/L level in the most polluted pond. Then, following the ERA, the pesticide risk was mostly driven by herbicides from the triazines group.

This study demonstrates that the risk depends on both the diversity of molecules present in the system under consideration and the concentration levels that may constitute a hazard to the wildlife reliant on these environments. The simultaneous presence of multiple pesticides might elevate the risk for aquatic organisms across all the sampled locations. This work brings newest data concerning pesticide risk in a little-studied environment with an emphasis on the transformation products.

3.04.D.T-03 Grouping persistent and mobile substances based on persistent and mobile substructures to avoid regrettable substitution and prioritize assessments
Hans Peter Arp[1,2]*, Sivani Baskaran*[3]*, Raoul Wolf*[2]*, Parviel Chirsir*[4]*, Emma Helena Palm*[5]*, Emma Schymanski*[4]*, Zhanyun Wang*[6] *and Sarah Hale*[7]*, (1)Geotechnics and Environment, Norwegian University of Science & Technology (NTNU), Norway, (2)Norwegian Geotechnical Institute (NGI), Norway, (3)Norwegian Geotechnical Institute (NGI), Oslo, Norway, (4)Luxembourg Centre for Systems Biomedicine (LCSB), University of Luxembourg, Luxembourg, (5)Luxembourg Centre for Systems Biomedicine, University of Luxembourg, Luxembourg, (6)Technology and Society Laboratory, Empa – Swiss Federal Laboratories for Material Science and Technology, Switzerland, (7)DVGW: TZW*
There is an interest by regulators and scientists working with chemical hazard assessment to transition from a one-substance-at-a-time approach to a substance-group approach. Two main motivations for this are to expedite hazard assessments related to the large amounts of substances being introduced to the global chemical market, and avoiding regrettable substitution caused by drop-in substitution. The idea of substance grouping based on the relationship between chemical structure and hazard has been applied in several cases already. Many of the very first hazardous organic substances to be regulated globally as pollutants were groups sharing a similar structure, including DDT-derivatives, dioxins, and PBDEs. This presentation will provide an overview of strategies for grouping hazardous substances based on chemical structure and how these substance grouping approaches may be applied in relation to persistent and mobile substances, as as these are a class of substances receiving increasing, global attention. This work will be particularly relevant to identify groups substances with either a common chemical moiety, or common transformation products, that are considered persistent, mobile and toxic (PMT) or very persistent and very mobile (vPvM) [1]. Since approaches are needed now to better assess and regulate them to protect drinking water sources, we explore how grouping persistent and mobiles substances based on specific molecular substructures will support PMT/vPvM substance prioritization for risk governance and assessments.

3.04.D.T-04 Cigarette Butts as a Source of Organic Pollutants
Pavla Fojtíková[1]*, Monika Křížová*[2]*, Josef Troup*[2] *and Šárka Klementová*[2]*, (1)University of South Bohemia in České Budějovice, Czech Republic, (2)University of South Bohemia Ceske Budejovice, Faculty of Science, Czech Republic*
Cigarette butts (CBs) are small residues with mixed composition. Produced in large amounts, their accumulation in the environment has become alarming. It is possible to classify more than 7000 chemical components generated either in the burning process or when distilled from the tobacco. The aim of our research is to describe the rate of release of phenolic compounds and polyaromatic hydrocarbons (PAHs) from CBs.

At first, attention was paid to the determination of phenolic compounds and PAHs in fresh CBs. Subsequently, the changes in the content of these compounds in CBs during exposure of the butts to external conditions were monitored. An analysis of the soil on which the cigarette butts were exposed was also carried out. Based on the measured data, it is possible to describe the fate of selected organic pollutants after discarding a cigarette butt into the environment. This research provides missing information on the phenolic content in CBs and the rate of their release into water. It also provides a description of the kinetics of the release of PAHs during exposure to cigarette butts. It thus complements previously published information on CBs as a source of environmental contamination.

3.04.P Analysis, Assessment and Management of Contaminants of Emerging Concern and Their Transformation Products in the Environment

3.04.P-Th150 Spatial and Seasonal Variations of Emerging Contaminants, Microplastics and Per- And Polyfluoroalkyl Substances (PFAS) in Pampulha Lake, a UNESCO Heritage Site in Brazil

*Ramon Domingues[1], Maria Clara Starling[2], Cristiane Vidal[1], Mariana A. Dias[1], Vinicius Sarracini Santos[1], Daniel A S Rodrigues[3], Camila Amorim[3], Matt Simcik[4], Thiago Alencar Neves[3] and **Cassiana Carolina Montagner**[5], (1)Institute of Chemistry, Universidade Estadual de Campinas (UNICAMP), Brazil, (2)Department of Sanitary and Envioronmental Engineering, Federal University of Minas Gerais (UFMG), Brazil, (3)Universidade Federal de Minas Gerais, Brazil, (4)University of Minnesota, (5)Universidade Estadual de Campinas (UNICAMP), Brazil*

The Pampulha Lake is part of a modern ensemble considered one of the main tourist attractions in Belo Horizonte, Brazil. The ensemble was included in UNESCO's World Heritage List in 2016. Despite its cultural and recreational importance to the local population, Pampulha Lake has gone through a process of deterioration of its water quality over time. Not only does the lake have no riparian forest, but it also receives domestic sewage and stormwater from drainage systems from neighborhoods within the watershed. As a result, the lake is vulnerable to anthropogenic pollution. Although recreation and fishing are prohibited, illegal fishing is common in the lake. This study provides the first broad assessment of the occurrence of emerging contaminants (EC) such as pesticides, pharmaceuticals, personal care products, hormones, microplastics (MP), and per- and poly-fluoroalkyl substances (PFAS) in the lake. Sampling was conducted under different weather conditions and throughout the lake to analyze potential seasonal and spatial patterns of occurrences. For organic compounds, sample preparation was carried out by solid-phase extraction (SPE), and a range of 29 analytes was quantified using LC-MS/MS. MP sample preparation used Fenton's reagent, followed by density separation using NaI ($p = 1.6$ g cm^3). The final MP samples were analyzed by optical microscopy, and chemical characterization was made using near-infrared hyperspectral imaging (NIR-HIS) and micro-FTIR. MP were found at 28 – 450 items m^{-3} concentrations throughout the samples. The total sum of ECs varied between 250 and 1600 ng L^{-1}, and PFAS were observed at levels between 34 and 70 µg L^{-1}, an alarming environmental concentration. Seasonality affected the concentration of several ECs, such as atrazine, simazine, caffeine, and microplastics, but PFAS levels were unaffected. Spatial variations were also observed for the concentrations of many pollutants, indicating possible sources related to anthropic activities. Risk assessment indicates that concentrations observed in this study for 8 PFAS and 2 EC could threaten aquatic life. Our results suggest that a monitoring plan is needed to identify sources of pollution better and provide information for elaborating remediation strategies.

3.04.P-Th151 Particles in the Aquatic Environment: Heteroagglomeration with Natural Suspended Particulate Matter

***Frank Von der Kammer**[1], Helene Walch[2], Thilo Hofmann[3], Nada Bâsić[4] and Raisibe Florence Lehutso[4], (1)Vienna University, Austria, (2)Umweltbundesamt, Austria, (3)University of Vienna, Austria, (4)Environmental Geosciences, University of Vienna, Austria*

The determination of nanoparticles (NPs; manufactured nanomaterials, nanoplastics, natural colloids) transformation in the aquatic environment is a prerequisite for understanding nanoparticle fate and informed risk assessments. Environmental transformation comprises four main routes: dissolution/leaching, abiotic transformation/degradation, biotic transformation/degradation and (hetero-)agglomeration.

Heteroagglomeration kinetics are crucial for the understanding of NP transport processes. Parametrization of this process between NPs and suspended particulate matter (SPM) was hampered by the spatial and temporal variability of SPM floc composition and conformation/size. Analytical methods were either unsuitable or required unrealistic NP concentrations. The SPM used in most studies was either unrealistically simple (silica particles, clays) or rather unique (natural SPM).

After a thorough analysis of mechanisms of floc formation and the relevant building blocks of natural, riverine SPM and the reproducible laboratory synthesis of stable model SPM flocs, we designed a method to determine kinetics under environmentally relevant conditions, allowing well controlled laboratory experiments as well as standardization for risk assessment. The heteroagglomeration attachment efficiency (a) constitutes the most suitable parametrization of particle-particle interactions. The presented test matrix combines synthetic model SPM flocs with the model freshwater composition suggested in OECD TG 318, both designed to represent agglomeration-relevant characteristics of natural systems. The test matrix was employed in a newly developed stirred-batch method, addressing the shortcomings of existing strategies to determine (a). A highly sensitive analytical approach allowed to work at realistic concentrations of NP (5 ppb) and SPM flocs (20 and 40 ppm).

The test system was evaluated by testing the heteroagglomeration of CeO_2 nanoparticles in four different combinations of floc and water chemistry.

- Natural flocs in natural water
- Natural flocs in synthetic (TG318) water
- Synthetic flocs in natural water
- Synthetic flocs in synthetic water

The results show the applicability and precision of the invented test system and the synthetic flocs but also some differences between results from natural and synthetic water chemistry which can be explained by the type and quality of the NOM. Calculated transport distances for 50% unassociated NPs reached up to 370 km, what is unexpectedly high.

3.04.P-Th152 Occurrence and Distribution of Per- and Polyfluoroalkyl Substances in Serbian Surface Water
Natasa Durisic-Mladenovic[1], *Marinella Farre*[2], *Jelena Živančev*[1], *Marta Llorca-Casamayor*[2], *Igor Antić*[1], *Maja Buljovčić*[1] *and Dušan Rakić*[1], *(1)University of Novi Sad, Faculty of Technology, Serbia, (2)Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain*
The widespread use of per- and poly- fluoroalkyl substances (PFASs) in a numerous industrial and commercial applications causes contamination of different environmental compartments, representing *important risk factors*. The data dealing with the occurrence and distribution of PFASs in the Balkan Region including the Republic of Serbia are scarce and often limited regarding the number of analyzed compounds, so the intention of this work is to contribute to data on the chemical status of surface water with respect to this class of emerging pollutants. Thus, the aim of this study was to investigate the seasonal (summer vs. winter) and spatial distribution of selected PFASs in surface water samples of a few international rivers (Danube, Tisa, and Sava) and of an important irrigation canal system (Danube-Tisa-Danube), taken in the northern Serbian province of Vojvodina, a region known for high agricultural activity. Surface water samples were collected before and after the wastewater (WW) discharge point of each selected settlement, and in this way contribution of WW to the PFASs occurrence was also assessed. Sample preparation was based on the application of PFASs-specific solid-phase extraction sorbent followed by analysis on ultra-high performance liquid chromatography coupled with high-resolution mass spectrometry. Selected surface water recipients differed among each other regarding the water flow bringing to different dilution of compounds presented in WW. Additionally, the size of nearby settlements and industrial activities are markedly different. The results will give insight into the occurrence and distribution (including seasonal variation) of PFASs in the main water systems of Serbia where absence of WW treatment plants has detrimental environmental effect, which cannot be estimated without revealing the levels and distribution of organic contaminants.

3.04.P-Th153 Combining Liquid Chromatography-High Resolution Mass Spectrometry and in Vivo Models to Assess Unexpected Thyroid-Active Transformation Products From the Degradation of Diclofenac
Rafael Reis[1], *Rebecca Dhawle*[2], *Romain Girard*[3], *Zacharias Frontistis*[2], *Dionissios Mantzavinos*[2], *Peter de Witte*[4], *Deirdre Cabooter*[4] *and David Du Pasquier*[3], *(1)KU Leuven, Leuven, Belgium, (2)University of Patras, Greece, (3)Watchfrog S.A., France, (4)KU Leuven, Belgium*
Diclofenac (DCF) is an environmentally persistent, nonsteroidal anti-inflammatory drug (NSAID) with thyroid-disrupting properties. The extensive use of this endocrine-disrupting chemical (EDC) and its inadequate removal from wastewater result in its detection across all continents, including Antarctica. Efforts are being made to remove EDCs from wastewater using electrochemical advanced oxidation processes (eAOPs). However, these novel remediation technologies generate transformation products (TPs) with largely unknown chemical and biological characteristics.

Herein, to comprehensively assess the safety of eAOPs, DCF was electrochemically degraded using a boron-doped diamond anode. Liquid chromatography coupled to high-resolution mass spectrometry (LC-HRMS) was used to perform suspect and non-targeted screening to analyze the TPs of DCF and elucidate its potential degradation pathways. To assess their biological impact, the thyroid axis activity of DCF and TPs was determined using the Xenopus Eleutheroembryo Thyroid Assay (XETA).

For the first time, this study revealed that exposure to DCF disrupts the thyroid hormone (TH) signaling in amphibians, by diminishing the activity of tadpoles' thyroid endocrine system. Unexpectedly, as DCF degradation progressed, the overall *in vivo* thyroid activity transitioned from an anti-thyroid effect in non-treated samples to a pro-thyroid effect in intermediately treated samples. This implies the emergence of thyroid-active TPs with distinct modes of action compared to the original compound. It is hypothesized that this pro-thyroid effect was caused by TPs generated through the oxidative cleavage of DCF's benzylic ring, giving rise to an aliphatic side chain with electronegative groups. Molecular docking analysis revealed that these TPs have strong binding affinity to the thyroid receptor, potentially triggering TH-like responses. Moreover, acute toxicity occurred in intermediately degraded samples, indicating the formation of TPs exhibiting higher toxicity than DCF. Nevertheless, both acute toxicity and thyroid-stimulating effects were mitigated with a prolonged degradation time.

In conclusion, the radical transformation of EDCs by eAOPs can produce TPs with unpredictable chemical and biological features, potentially posing risk to the environment and public health. This highlights the necessity of holistic and reliable chemical and biological tools for the environmental risk assessment of these remediation technologies.

3.04.P-Th154 Occurrence of organic pollutants and source apportionment in urban groundwaters

Francesc Labad-Roig[1], *Sergio Santana-Viera*[2], *Enric Vázquez*[2], *Anna Jurado*[2] *and Sandra Perez Solsona*[3], *(1)CSIC - Spanish National Research Council, Spain, (2)Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain, (3)Onhealth, Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain*

The escalating exploitation of groundwater (GW) has raised awareness about the need for quality recognition and studies addressing the presence of contaminants in GW. Various pollutants, including pharmaceuticals, personal care products, artificial sweeteners, and industrial chemicals, may infiltrate in urban GW. The Directive 2006/118/EC amendment (2022) on groundwater quality and protection was issued [2]. While it covers persistent organic substances like carbamazepine and sulfamethoxazole, it does not yet encompass 24 other persistent compounds, including PFAS [1]. Our study focused on analyzing 122 pollutants covering a broad polarity range in urban groundwater, surface, sewer, rain water runoff (street &roof) samples from Barcelona using an evaporative enrichment methodology combined with LC-Orbitrap-MS to detect organic compounds including pharmaceuticals, industrial chemicals, and tire wear substances. Special attention was paid to the very mobile contaminants, whose analysis is particularly challenging. Multivariate statistical analysis was used to identify the origin and quantify the proportions of the different sources. In this study, groundwater, surface water, sewer, urban runoff (street and roof) water samples were collected in Barcelona metropolitan area. Two enrichment techniques were used: multisorbent solid phase extraction and vacuum-assisted evaporation. Prior to LC-MS analysis, eluates were evaporated and reconstituted in 0.5 mL of 5% or 95% of acetonitrile for analysis by C_{18} or HILIC, respectively.

This study demonstrates the use of a combined analytical approach for the determination of a variety of organic compounds. Multivariate statistical analysis (Principal component analysis and Mixing Ratios Calculations model) allowed to capture differences between sources. The study highlighted a clear need for updating existing monitoring schemes. This will allow to monitor water quality in a more comprehensive way and to ultimately assess the threat of groundwater contamination with respect to its use as resource for drinking water

[1] Directive of the European Parliament and of the council, 2022. DIRECTIVE OF THE EUROPEAN PARLIAMENT AND OF THE COUNCIL amending Directive 2000/60/EC establishing a framework for Community action in the field of water policy.

3.04.P-Th155 Spatial and Temporal Analysis of Contaminants of Emerging Concern (CECs) in Dublin Bay: Presenting a Marine Biofilm as New Sampling Device

Enrique Jacobo Díaz-Montaña[1], *Chloe Richards*[2], *Brendan McHugh*[3], *Evin McGovern Dr*[3], *Belinda Huerta*[4] *and Fiona Regan*[5], *(1)DCU Water Institute, School of Chemical Sciences, Dublin City University, Ireland, (2)DCU Water Institute, Dublin City University (DCU), School of Chemical Science, (3)Marine Institute, Ireland, (4)Chemistry, Southern Conneticut State University, (5)Water Institute, Dublin City University (DCU) School of Chemical Sciences, DCU Water Institute, Ireland*

Contaminants of Emerging Concern (CECs) are a mainly created by humans and they reach the marine environment mostly directly from land-based sources, but there are cases in which they are emitted or re-mobilized in the marine environment itself. CECs are a concern because of their high levels of human usage, and the biological effects exerted on nontarget organisms. This group of compounds is being considered in the European Union in the Marine Strategy Framework Directive Descriptor 8, together with the Water Framework Directive and the Regional Sea Conventions.

Therefore, the main objective of this study was to determine and quantify existing CECs present along the Dublin coast. This objective was threefold: (i) the use of biofilm as a sampling device, considering micro and macrofouling, using a lobster cage as support for the biofilm; (ii) the determination of CECs in 8 beach locations in Dublin Bay, including a UNESCO Biosphere; (iii) and the measurement of CECs in Poolbeg Marina over 5 days.

The biofilm study comprised a separate evaluation of micro and macrofouling which showed the same profile where the sunagents (avobenzone and octocrylene) presented the highest concentrations, particularly the avobenzone. Octocrylene showed significant differences between both fouling types, presenting a concentration of 0.15 ng/L in macrofouling and of 0.38 ng/L in microfouling. Thus, some compounds were equally quantified by both fouling types, but there are others that showed significant differences. The spatial analysis of CECs showed that four compounds represent the biggest proportion of the CECs determined. Malahide beach presented the highest concentration of these compounds, between 225 to 10,000 ng/L. On the contrary Dun Laoghaire and Howth Harbours presented the lowest concentration of these compounds because mainly boat activities predominate instead of swimming. The temporal analysis was carried in a marine location in close proximity to the outlet of the tertiary wastewater treatment plant. This location did not show any upward or downward trend in measured CECs during the sampling week. This is a conclusion in itself because it implies that there is a constant concentration of marine contaminants. With these results demonstrating a wide range of chemical type and location, it is necessary to consider the possible cumulative effect on the different species that can nest or inhabit the UNESCO biosphere – near each of the sampling sites.

3.04.P-Th156 Skimming the lake surface microlayer - how to catch highly lipophilic pollutants in surface water

Armin Zenker[1] *and Simone Tinguely*[2], *(1)School of Life Sciences, University of Applied Sciences and Arts Northwestern*

Switzerland (FHNW), Switzerland, (2)University of Applied Sciences and Arts Northwestern Switzerland (FHNW), Switzerland
UV filters are used extensively in sunscreen products, but also in other cosmetic products and industrial goods to reduce the harmful effects of UV radiation. Apart from the direct exposure during swimming activities, UV filters are released into the aquatic environment in large quantities via sewage treatment plants. In this study we investigated the presence of UV filters in small, remote, prealpine and alpine mountain lakes. These lakes are not affected by UV filter inputs from sewage treatment plants, however recreational swimming activities in summer are thought to lead to inputs. Since most of the common UV filters are very lipophilic, we studied the concentrations of UV filters in the surface microlayer of the lakes instead of taking grab samples.

The fate of the UV filters was investigated in four different lakes, three of which are located in the canton of Graubünden and one in the canton of Zurich. The size of the lakes varied between 20’000 and 360’000 square metres. After sampling, the organic UV filters were preconcentrated by Oasis HLB solid phase extraction and afterwards determined on a high performance liquid chromatography coupled to triple quadrupole mass spectrometer.

The studied UV filters were ingredients currently used in sunscreens which were as follows 2-ethylhexylsalicylate (EHS), 2-phenylbenzimidazole-5-sulphonic acid (PMDSA), avobenzone (AB), ethylhexyl methoxycinnamate (EHMC), octocrylene (OC) and oxybenzone (OB).

The concentrations of UV filters reached values of up to 112 µg/L for OC, followed by 3.4 µg/L for AB and 2.4 µg/L for PMDSA. The UV filters EHS and EHMC were found in concentrations ranging from 0.02 to 1.2 µg/L whereas OB was in the range of 0.01 and 0.02 µg/L. The sampling of the surface microlayer showed very high values for OC, which has not been observed in surface waters so far based on previous literature. This is of particular concern as OC has a high potential for bioaccumulation which can lead to high concentrations in biota.

3.04.P-Th157 Assessing the risk of booster biocides for the marine environment: a case study at the Belgian Part of the North Sea

David Vanavermaete[1], Kris Hostens[2], Gert Everaert[3], Koen Parmentier[4], Colin Janssen[5] and ***Bavo De Witte**[6]*, *(1)ILVO, (2)Flanders Research Institute for Agriculture, Fisheries and Food (ILVO), Belgium, (3)Ocean & human health, Flanders Marine Institute (VLIZ), Belgium, (4)Institute of Natural Sciences, Ecosystems Physico-Chemistry (ECOCHEM), Belgium, (5)Blue Growth Research Lab, Ghent University (UGent), Belgium, (6)Marine Research, Institute for Agriculture and Fisheries Research (ILVO), Belgium*
The biofouling of submerged surfaces such as ship hulls is often prevented by using copper-based anti-fouling paints containing booster biocides. These booster biocides enter the water column and may affect non-target organisms. So far, the environmental risks for booster biocides have barely been quantified in the North Sea. In this study, the concentration of five commonly used booster biocides as well as tributyltin has been measured at five dredged spoil disposal sites in the Belgian part of the North Sea and the harbour or ports of Nieuwpoort, Oostende, and Zeebrugge. In four out of five dredged spoil disposal sites, a concentration with a risk characterization ratio (RCR) of more than 1 was observed in 97% of the samples. This indicates that the current ambient booster biocide and tributyltin concentrations may pose a risk to the marine environment. Tributyltin, for example, has been banned since 2008, but was still detected with an RCR of 237 to 546. The contamination observed in a specific harbour or port corresponds to the respective dredged spoil disposal sites and can be linked to the type of traffic. Additionally, different hotspots were observed. For Irgarol, for example, a 55-fold higher concentration has been observed at one sample location in the Port of Oostende compared to the median concentration in that port.

High RCR values detected for booster biocides and tributyltin indicate the importance to monitor these components such that hotspots may be discovered, and that actions can be taken in time if the concentration of a component exceeds the threshold at which unreversible damage to the marine environment may be expected.

3.04.P-Th158 Wide-Range Target Screening of Pharmaceuticals in Serbian Rivers: Occurrence and Seasonal Distribution

***Jelena Živančev**[1]*, *Olga Gómez Navarro[2], Nicola Montemurro[3], Sandra Perez Solsona[2], Igor Antić[4], Maja Buljovčić[4], Dušan Rakić[4] and Natasa Durisic-Mladenovic[4], (1)University of Novi Sad, Serbia, (2)Onhealth, Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain, (3)Department of Environmental Chemistry, Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain, (4)University of Novi Sad, Faculty of Technology, Serbia*
In recent decades, the impact of anthropogenic activities on water resources, primarily on surface water, has grown significantly due to population growth, and expansion of urban, industrial, mining, and agricultural sectors in both developed and developing countries. Additionally, surface waters are increasingly contaminated because they also serve as recipients of municipal and industrial wastewater containing a wide variety of pollutants, which even after treatment end up in rivers and other water bodies. The number of contaminants of emerging concern that may be present in surface waters is enormous, and their fate and ecological impact are still largely unknown. Among numerous contaminants of emerging concern, pharmaceuticals cause global concern because they contribute to the development of antibiotic-resistant bacteria and threaten the long-term survival of many species. For broad surveillance of these pollutants, a target screening approach is used to help

clarify the chemical quality of surface waters. In light of the foregoing, the main objective of this study was to screen the presence of pharmaceuticals in several rivers in Serbia by using wide-range target analysis with liquid chromatography-tandem high-resolution mass spectrometry (LC-HRMS). This research is focused on the Danube, Tisza, Sava, Tamiš, and Begej rivers in order to characterize their chemical status taking into account that wastewater in Serbia has been mainly directly discharged without treatment into surface watercourses. Water samples were collected during two campaigns, the first organized during the winter and the second during the spring in order to obtain a more comprehensive spatial and seasonal distribution of the compounds of interest. Samples were prepared using housemade multilayer SPE cartridges, while the obtained extracts were analyzed by LC-HRMS. The results obtained in this study will bring new information about the quantified levels of the identified pharmaceuticals, about the most prevalent compounds in the studied Serbian rivers, and spatial patterns in the detection of compounds at the sampling locations. Furthermore, the dataset on pharmaceutical contamination of surface watercourses in Serbia will be compared to the relevant data from other parts of Europe, creating a solid basis for future monitoring programs and expanding existing knowledge on the spread of these contaminants in the water resources of the Western Balkans.

3.04.P-Th159 Analysis of Antiozonants, Vulcanizing Agents and Other Hazardous Organic Compounds in Tire Rubber Particles

Andres Duque-Villaverde[1]*, Daniel Armada*[2]*, Thierry Dagnac*[3] *and Maria Llompart*[2]*, (1)Department of Analytical Chemistry, Nutrition and Food Science, University of Santiago de Compostela, Spain, (2)Department of Analytical Chemistry, Nutrition and Food Science, CRETUS, Spain, (3)Unit of Organic Contaminants, Apartado 10, Agronomic and Agrarian Research Centre (AGACAL-CIAM), Spain*

During the tire manufacturing process, many chemical agents are added to the rubber, and many of them can be considered as environmental pollutants. Some of these hazardous organic compounds are the antiozonant 6PPD (N-(1,3-dimethylbutyl)-N′-phenyl-p-phenylenediamine) or the vulcanizing agent DPG (1,3-diphenylguanidine). One way of recycling end-of-life tires consists of shredding them to obtain crumb rubber, the largest source of intentional microplastic pollution. This granulate material is used as infill in artificial turf sports fields and as playground flooring. The European Commission announced its ban on September (2023), allowing manufacturers 8 years to adapt to this new regulation. This prohibition shows the importance of alternative infill materials.

In this work, an analytical methodology for the determination of 11 hazardous organic compounds in tire rubber particles is proposed. The method is based on a simple extraction step using ultrasound energy (Ultrasound Assisted Extraction, UAE), followed by LC-MS/MS analysis. Small amounts of sample and solvent are required, as well as a short extraction time. The method was applied to a wide variety of real samples, including crumb rubber from football fields and playgrounds. In addition, several alternative materials were also analyzed for comparative purposes (sand, cork, and thermoplastic elastomers). The antiozonant 6PPD showed the highest concentration levels in the newly constructed fields, reaching values up to 0.2% w/w while DPG was detected in end-of-life tires at concentrations about 100 µg/g.

3.04.P-Th160 Accurate Microplastics Characterization on Aluminum-Coated Filter Using QCL IR Chemical Imaging

Wesam Alwan[1]*,* ***Andreas Kerstan***[2]*, Darren Robey*[1] *and Torika Kumanayaka*[3]*, (1)Agilent Technologies, Inc., Australia, (2)Hewlett-Packard-Str. 8, Agilent Technologies, Inc., (3)Agilent Technologies LSAG, Australia*

Indeed, microplastic pollution has become a significant environmental concern due to its potential impacts on ecosystems and human health. QCL Infrared Chemical Imaging System represent an innovative approach to imaging and spectral analysis, particularly in the context of microplastic identification and other applications that require chemical characterization of materials.

Depending on the level of suspended solids presents, ASTM D8333 describes the steps required for microplastics sample preparation. Regardless of analysis technique used, samples with various levels of microplastics eventually require a filtration step. At present, for QCL IR Imaging systems microplastics sample introduction can be achieved directly on gold-coated filters.

To minimize the cost associated with gold-coated filters while maintaining easy and efficient sample introduction method, accurate microplastics characterization with IR QCL can be performed on aluminum-coated polyester filters. This study outlines the utilization of QCL IR Imaging in achieving accurate microplastics characterization on aluminum-coated filters in terms of particle detection, particle count repeatability, particle size accuracy and identification of common microplastics.

3.04.P-Th161 Assessment of Volatile Organic Compounds (VOC) in underground water from around fuel station in Okinni Oshogbo, Osun State, Nigeria

Fatai Afolabi[1]*, Gbadebo Clement Adeyinka*[2] *and Joshua Toyin Adeleke*[3]*, (1)Department Physical and Chemical Sciences,*

Federal University of Health Sciences Ila-Orangun, Nigeria, (2)Chemical Engineering, Mangosuthu University of Technology, South Africa, (3)Physics, Osun State University, Nigeria
Levels and possible toxicity of volatile organic compounds (VOC) were investigated from underground water in six locations around the vicinity of the fuel station within the Okinni locality, Osun State, Nigeria. Samples were collected and analyzed following the standard procedure. A total number of seven VOCs were detected with varying concentrations, they were: benzene, toluene, chlorobenzene, ethylbenzene, m, p-xylene, o-xylene, and dichloromethane (DCM). The concentration of benzene in this study was 0.241 mg/L which was higher than the Maximum Contaminant Level of 0.005 mg/L recommended by the United States Environmental Protection Agency (USEPA). Also, higher than the 0.01mg/L permissible limit in drinking water as provided by the World Health Organization (WHO). Toluene ranges from 0.1125 mg/L to 67.194 mg/L which was greater than the threshold value of 1.0 mg/L in drinking water by USEPA in all locations except for locations L4, (where it was not detected) L5 and L6, and were higher than 0.7 mg/L permissible concentration limit in drinking water as recommended by WHO. The observed values of chlorobenzene range from 3.323 to 17.976 mg/L and were in multiple fold higher than the permissible value of 0.1 mg/l by USEPA. It was observed that the concentration of ethylbenzene in the sampling sites was far higher than 0.7 mg/L recommended by USEPA and the 0.3 mg/L threshold value permissible by WHO except for sites L3 which has values of 0.632 mg/L in this study, the concentration of isomers of xylene observed ranges from 0.124 mg/L to 18.427 mg/L and 0.735 to 22.105 mg/L for m, p-xylene and o-xylene respectively. It was higher than 5.0 mg/L and 10.0 mg/L permissible value in water by WHO and USEPA respectively in all the studied sites except for locations L4-L6. The concentration of DCM ranges from 0.644 mg/L to 6.253 mg/L. It was higher than the threshold value of 0.005 mg/l recommended by USEPA in all the studied sites. Most of the detected VOCs belong to the gasoline hydrocarbon VOC group. This suggested that they were mostly leachate from the fuel station. Thus, using the water samples collected from these locations for domestic activities could expose the people of these communities to serious health issues. Therefore, there is a need for urgent attention from the relevant authorities to safeguard the health of this populace.

3.04.P-Th162 Degradation of phenol and sulfamethoxazole with persulfate and ozone with nano-MnO2–biochar composites

Seok-Young Oh[1] *and Hyungwoo Lee*[2]*, (1)Civil and Environmental Engineering, University of Ulsan, Korea, Republic of (South), (2)Civil and Environmental Engineerig, University of Ulsan, Korea, Republic of (South)*
In this study, nano-MnO_2–biochar composites were synthesized as catalysts to promote the oxidation of recalcitrant organic contaminants. The MnO_2 nanoparticles coated on biochar were hypothesized to enhance the oxidation of phenol and sulfamethoxazole (SMX) using ozone and/or persulfate. The optimal percentage of MnO_2 coating on the surface of biochar was determined, and the synthesis of nano-MnO_2-coated biochar was confirmed via scanning electron microscopy–energy dispersive X-ray spectroscopy (EDS), X-ray diffraction, and EDS line mapping analyses. Compared with oxidation using ozone or persulfate in the presence of either nano-MnO_2 or biochar, the synthesized nano-MnO_2–biochar composite markedly enhanced the oxidation of phenol and SMX. This was probably due to the spreading of MnO_2 nanorods on the surface of biochar and the synergistic involvement of nano-MnO_2 and biochar as catalysts. X-ray photoelectron spectroscopy analysis confirmed the involvement of Mn^{3+} in MnO_2 to promote oxidation using ozone or persulfate. The co-existence of ozone and persulfate could also promote oxidation. Hydroxyl radicals (OH×) and persulfate radicals (SO_4^-×) were major reactive oxygen species for ozone and persulfate systems, respectively. Results suggest that the synthesized nano-MnO_2–biochar composites may be effective catalysts for various types of advanced oxidation processes in water and wastewater treatment.

3.04.P-Th163 Biotransformation of Metronidazole, Sulfamethoxazole, and Trimethoprim by The Green Microalga Chlorella sorokiniana: Removal Efficiency, Mechanism, and Pathways

Ornrumpha Sethanunt[1]*, James PJ Chong*[1]*, Thierry Tonon*[1] *and Brett Sallach*[2]*, (1)Department of Biology, University of York, United Kingdom, (2)Department of Environment and Geography, University of York, United Kingdom*
Assessing the efficiency of wastewater treatment in eliminating pharmaceutical contaminants from water is important and also reduces the effect on the environment when effluent is released. It is crucial not only to monitor the percentage of total removal of pharmaceutical pollutants but also to examine the transformation products (TPs) that formed during the process. TPs are normally more inconstant than their parent molecules and may also be more durable and more toxic.

We have used, *C. sorokiniana* to assess the biotransformation of three antibiotics (metronidazole: MTZ, sulfamethoxazole: SMX, and trimethoprim: TMP) both individually and in a mixture. In the single antibiotic experiments, removal efficiency for each antibiotic was higher when compared to mixed antibiotic cultures. The antibiotic removal mechanisms involved were biodegradation > photodegradation > bioadsorption > bioaccumulation. More efficient antibiotic removal was observed for MTZ > TMP > SMX > mixed antibiotics. Higher algal growth at the end of the experiment was shown in the presence of MTZ > mixed antibiotics > SMX > TMP.

The analysis of the transformation products from the supernatant samples of individual antibiotic experiments was carried out by ultra-high-performance liquid chromatography coupled with mass spectrometry. The degradation of MTZ, TMP, and SMX resulted in six, four, and ten TPs, respectively. Based on these observations TPs, three transformation pathways are suggested, with total transformation products in the MTZ, TMP, and SMX pathways showing 18, 19, and 41 TPs, respectively.

These findings suggest that *C. sorokiniana* represent an interesting microalga for antibiotic removal in wastewater.

Keywords: Chlorella sorokiniana, Microalga, Transformation products, Transformation pathways, Antibiotics

3.04.P-Th164 Occurrence of Illicit Drug Residues and New Psychoactive Substances in Wastewater Influents in the Region of Sfax, Middle East of Tunisia.

Bilel Moslah[1]*, Omar Samoui*[2]*, Thomas Néfau*[3]*, Dorra Amira*[2] *and Abderrazek Hedhili*[2]*, (1)University of Tunis El Manar, Tunisia, (2)Research Laboratory of Toxicology and Environment, Tunisia, (3)European Monitoring Centre for Drugs and Drug Addiction*

Numerous studies confirm the contamination of wastewater with organic compounds, including residues of drug of abuse (DAs) and novel psychoactive substances (NPS) at minute concentrations. This research investigated the presence of these emerging micropollutants in influent wastewaters (IWW) from five Tunisian Wastewater Treatment Plants (WWTPs). Composite samples of influent wastewater (collected over 24 hours) were gathered continuously for 7 days in November 2021. A well-optimized multi-residue liquid chromatography tandem mass spectrometry (LC–MS/MS) method was employed to identify and quantify 11 drug of abuse compounds or their metabolites. Among the sewage plants studied, cannabis and ecstasy (MDMA) were the most frequently detected substances. In this study, a novel wastewater-based epidemiology (WBE) approach was introduced to estimate illicit drug usage, enabling the calculation and assessment of collective illicit drug consumption at a community level. This approach relied on the concentrations of specific illicit substances and their primary metabolites in influent wastewater. The average cannabis consumption in the examined cities ranged from 1.6 to 31.93 g/day/1000 inhabitants and exhibited an increase on weekends. MDMA consumption ranged from 0.1 to 7.26 g/day/1000 inhabitants. Additionally, a qualitative investigation of new psychoactive substances (NPS) was conducted for the first time in an African nation, evaluating the presence of 33 NPS in wastewater samples. Out of these 33 NPS screened across all sampling sites, 17 were provisionally identified through this methodology. These 17 detected NPS encompassed a wide range of representative molecules from various NPS categories, including synthetic opioids, synthetic cathinones, derivatives of amphetamines, and synthetic cannabinoids. The highest detection frequency was recorded in the weekend particularly for synthetic cathinones and amphetamines derivatives (alpha-PHPP, mephedrone, pentedrone, pentylone, ethylone, MDA, MDEA), although synthetic cannabinoids (JWH-250, JWH-073, CP47497, HU-210) were much higher across the sampling week than other detected NPS in this study. This seems consistent that mainly stimulant drugs have been found, as music festivals and nightlife venues are more prone to the use of this category of NPS during weekend.

3.04.P-Th165 Rapid Multi-analyte Quantification of Disrupting Contaminants in Surface Water Through the Use of Deep Eutectic Solvents and Tandem Mass Spectrometry

Sara Cunha *and Jose O. Fernandes, LAQV-REQUIMTE, Portugal*

There is a wide range of anthropogenic contaminants targeted in water resources. Among these are the "disrupting contaminants" including pharmaceutical and personal care products, bisphenols, and pesticides, used in a growing scale. These contaminants pose environmental challenges due to their persistence and the ability to cause specific physiological effects even at low concentrations. Despite wastewater effluents represent just one potential source, they are considered the primary pathway for these compounds to enter the aquatic environment, mainly because most wastewater treatment plants are not prepared to eliminate them. The impact on the quality of river water is crucial for environmental risk assessment and often leads to unpredictable effects on wildlife and human health. The aim of the present work is the development of a rapid and environmental friendly analytical procedure for determination of 31 disrupting contaminants in surface waters. Several personal care products, namely fragrances and UV-filters, bisphenols, and pesticides were subject to dispersive liquid-liquid microextraction (DLLME) using a deep eutectic solvent (DES) as extractive solvent. Gas chromatography - tandem mass spectrometry analysis was performed with electroionization by using multi reaction monitoring (MRM). During method development, a comparison of different types of DES, extractive and dispersive volumes, and extraction times was performed using a chemometric approach. The developed method was validated according to European guidelines criteria by determining linearity, precision, recovery, limits of quantification and limits of detection.

3.04.P-Th166 Antimicrobial exposure with Eisenia fetida earthworms: multitarget analysis, by-products identification and biological effects elucidation

Irantzu Vergara[1]*, Camila Fatima Rutkoski*[2]*, Erik Urionabarrenetxea*[3]*, Eduardo Alves Almeida*[2]*, Eneritz Anakabe*[4]*, Maitane Olivares*[5]*,* ***Manuel Soto***[6] *and Ailette Prieto*[1]*, (1)Analytical Chemistry, University of the Basque Country (UPV/EHU), Spain, (2)Universidade Regional de Blumenau, Brazil, (3)Zoology and Animal Cell Biology, University of the Basque Country (UPV/EHU), Spain, (4)Organic and Inorganic Chemistry, University of the Basque Country (UPV/EHU), Spain, (5)Analtytical Chemistry, Research Center for Experimental Marine Biology Biotechnology "Plentziako Itsas Estazioa", University of the Basque Country (PiE-UPV/EHU), Spain, (6)Research Center for Experimental Marine Biology Biotechnology "Plentziako Itsas Estazioa", University of the Basque Country (PiE-UPV/EHU), Spain*

The overuse of antimicrobials (AMs) has led to their presence in different untargeted environmental matrices, which is of global concern due to the emergence of AM-resistant strains. Earthworms are sensitive to contaminants in soil, therefore, they are considered adequate model organisms in terrestrial ecotoxicology to evaluate the introduction of contaminants, such as AMs, into the food chain. The determination of AMs in earthworms is still a field to be further investigated since the complex biological matrix together with the different physicochemical properties of the different AM families make the simultaneous analysis difficult. In addition, little is known about the degradation of AMs in the organism and their effects. In that context, in this work an analytical method has been validated, which showed adequate accuracy (apparent recoveries in the range of 80-120 % and procedural limits of quantification of 1.4 $\mu g \cdot kg^{-1}$ - 9.6 $\mu g \cdot kg^{-1}$) for the simultaneous determination of ten AM families in earthworms. Moreover, OECD-207 toxicity test was performed, exposing *Eisenia fetida* organisms to soils spiked with 10 $mg \cdot kg^{-1}$, 100 $mg \cdot kg^{-1}$ or 1000 $mg \cdot kg^{-1}$ of sulfamethazine (SMZ) and tetracycline (TC), individually. The results confirmed the bioaccumulation of both AMs in the organisms, showing a greater tendency for the accumulation of SMZ since higher bioconcentration factor values were obtained for this compound at the different exposure concentrations tested. Moreover, degradation of both AMs has been detected in both matrices; successfully identifying thirteen transformation products (TPs) in soil and eight of them in earthworms too and their trend over time have been studied. Regarding the biological effects, only SMZ caused changes in earthworm growth, evidenced by weight loss in earthworms exposed to concentrations of 100 $mg \cdot kg^{-1}$ and 1000 $mg \cdot kg^{-1}$. The riboflavin content decreased in all concentrations of SMZ, as well as in the highest concentration of TC, suggesting that these AMs have the potential to disturb the immune system of *Eisenia fetida*. This works supposed a step forward in broadening the understanding of AM contamination and the effects at the lower end of the food chain, both chemically and biologically.

3.04.P-Th167 A Comprehensive Pollutant Profile Characterization of Sewage Sludge: The effect of different polarity fractions on compound recovery and toxicological profile using Accelerated Solvent Extraction

Rhayn Werz[1]*, Maria Larsson*[2]*, Anna Maria Rotander*[3]*, Kevin Rocco*[4]*, Magnus Engwall*[3] *and Anna Kärrman*[3]*, (1)Oerebro University, Sweden, (2)MTM Research Centre, Orebro University, Sweden, (3)Orebro University, MTM Research Centre, Sweden, (4)Orebro University, Sweden*

Sewage sludge is commonly applied as fertilizer on agricultural fields due to its favorable levels of phosphorus and organic matter, thereby increasing soil fertility and contributing to closing nutrient loops. However, the presence of a diverse range of emerging micropollutants has raised concern around this practice. While optimized extraction and chemical analysis methods exist for individual pollutant groups, there is a pressing need for a more comprehensive method.

This study aims to fill this gap by adapting and combining an Accelerated Solvent Extraction (ASE) with different sludge pre-treatments, resulting in different polarity fractions. The aim is to evaluate the impact on the extraction and recoveries of target compounds as well as the toxicological profiles.

Using a spike-addition approach, extraction efficiencies of apolar contaminant groups such as polychlorinated biphenyls, dioxins and furans, polybrominated diphenyl ethers, polycyclic aromatic hydrocarbons, and siloxanes were tested. Polar contaminant groups, like the 22 per- and polyfluoroalkyl substances (PFAS) specified in Denmark's recent sludge directive, and a mix representing widely used pharmaceutical classes, were also included. Sewage sludge samples were obtained from an urban wastewater treatment plant (Uppsala,Sweden).

Extractions were conducted with two different solvents (*n*-hexane and methanol) as well as different pre-treatments of the sludge (acidic digestion, alkaline digestion, no digestion) prior. Chemical analysis was performed with GC and LC-HRMS instruments for the hexane and methanol extracts respectively. Additionally, unspiked extracts were analyzed using an aryl hydrocarbon receptor (AhR) responsive DR CALUX® bioassay.

Recoveries of spiked compounds in the apolar extracts differed with pre-treatments and for this fraction, highest recoveries were achieved with no prior digestion. The bio-TEQ values derived from the DR CALUX® assay differed with pre-treatment and were also highest for the undigested fraction, reflecting different extraction efficiencies of AhR-activating compounds.

ASE combined with HRMS-GC and LC analysis seems to be promising to extract and characterize a wide range of pollutants present in sewage sludge and different pre-treatments should be considered as the resulting polarity affects extraction efficiency of pollutants to be monitored. Bioassays like DR CALUX® can give further insights into extraction efficiencies of bioactive compound classes.

3.04.P-Th168 Investigation of pesticides, pharmaceuticals and personal care products in small water bodies using polar organic chemical integrative samplers (POCIS) and non-target screening

Ivo Havranek*, Marit Almvik, Roger Holten and Marianne Stenrød, Norwegian Institute of Bioeconomy Research (NIBIO), Norway*

Pharmaceuticals and personal care products (PPCPs) as well as pesticides are classes of organic pollutants that pose a growing concern in the context of circular economy strategies due to their potential adverse impacts on both biota and human health. This study focuses on the occurrence of PPCPs and pesticides in three small water bodies located in Norway. To assess the presence of these contaminants over an extended period, polar organic chemical integrative samplers (POCIS) were employed as sampling devices.

Over the course of one year, water samples were collected at three-week intervals and subsequently analyzed using non-target screening on HRAM Orbitrap LC-MS. Confirmation of identified compounds was achieved through the utilization of reference standards. The aim of this study was to comprehensively investigate the distribution and concentration levels of PPCPs and pesticides in the selected water bodies, shedding light on their potential impact on the surrounding ecosystem and human health.

The results of this study will contribute to a better understanding of the prevalence and persistence of PPCPs and pesticides in aquatic environments. Additionally, the utilization of POCIS in combination with advanced analytical techniques offers a valuable approach for comprehensive and time-resolved monitoring of these contaminants. The findings underscore the importance of implementing effective strategies to mitigate the release and accumulation of PPCPs and pesticides in water bodies, thereby promoting sustainable practices within the circular economy framework.

3.04.P-Th169 Assessing the Ecotoxicity of Thymol and Carvacrol Isomers on Aquatic and Terrestrial Organisms

Cristina Gan-Oria, *Antonio Valenzuela, Elisa Langa, Diego Ballestero and María Rosa Pino Otín, Universidad San Jorge, Spain*

Thymol and carvacrol, natural monoterpenic isomeric phenols, possess diverse bioactivities, notably as potent antimicrobial agents against *Escherichia coli*, *Staphylococcus aureus*, *Salmonella thymimurium*, and *Pseudomonas aeruginosa*. Despite their benefits, their environmental impact on aquatic and terrestrial organisms remains poorly understood, necessitating a comprehensive assessment for environmental toxicity

This study seeks to compare the ecotoxicological effects of thymol and carvacrol on aquatic and terrestrial organisms, employing *Daphnia magna*, *Vibrio fischeri*, *Allium cepa*, and *Eisenia fetida* as test subjects.

D.magna and *V. fischeri* served as biological indicators for aquatic environments. The acute toxicity of thymol and carvacrol on *D. magna* was examined with concentrations of 2, 4, 6, 8, and 12 mg/L. Mobility effects were assessed 24 hours post-exposure, yielding Thymol EC_{50}(24h) = 8.131 (7.298–9.203) mg/L, EC_{10} (24h) = 12.494 (10.655–17.113) mg/L, Carvacrol EC_{50}(24h) = 4.751 (3.936–5.523) mg/L, and EC_{10}(24h) = 9.529 (7.802–13.755) mg/L. The dose-response curves for both compounds exhibited similar shapes, indicating a steep dose response, with carvacrol proving more toxic. *V. fischeri* fluorescence inhibition results after 30 minutes revealed thymol EC_{50} = 6.20 (5.150-6.945) mg/L and carvacrol EC_{50} = 0.585 (0.487 -0.701) mg/L.

A. cepa and *E. fetida* were used as indicators for terrestrial environments. *A. cepa* exposed to concentrations of 0.03, 0.3, 3, 30, and 300 mg/L of both compounds exhibited root inhibition impact after 72 hours, resulting in phytotoxicity EC_{50} values of 4.048 mg/L (3.449–4.756 mg/L) for thymol and 6.466 mg/L (5.679–7.370 mg/L) for carvacrol. Thymol demonstrated greater toxicity at low to medium doses, while carvacrol inhibited root growth more significantly at high doses. *E. fetida*, after 14 days of exposure, showed high toxicity, with an EC_{50} of 7.520 (6.097 - 9.109) mg/Kg for thymol and 0.967 (0.818 - 1.565) mg/Kg for carvacrol. Carvacrol exhibited greater toxicity against both aquatic organisms and *E. fetida*, while for *A. cepa*, thymol presented greater toxicity.

This study underscores the potential toxicity of thymol and carvacrol on environmental organisms. Despite their promise as alternatives to aggressive antimicrobial products, careful consideration of their environmental impacts is crucial.

3.04.P-Th170 Contamination of agricultural soils by micropollutants in irrigated areas of the Czech Republic

Roman Grabic[1], ***Radka Kodesova***[2], *Vít Kodeš*[3], *Miroslav Fér*[4], *Helena Švecová*[5], *Alina Sadchenko*[5], *Antonín Nikodem*[4] *and Ales Klement*[6], *(1)University of South Bohemia in Ceske Budejovice, Faculty of Fisheries and Protection of Waters, Czech Republic, (2)Soil Science and Soil Protection, Czech University of Life Sciences Prague, Czech Republic, (3)Czech Hydrometeorological Institute, Czech Republic, (4)Dept. of Soil Science and Soil Protection, Czech University of Life Sciences, Czech Republic, (5)University of South Bohemia in České Budějovice, Faculty of Fisheries and Protection of Waters, Czech Republic, (6)Soil Science and Soil Protection, Czech University of Life Sciences, Czech Republic*

Agricultural soil can be contaminated by various micropollutants. One of the sources of these contaminants is agricultural practice, where a variety of pesticides are used for plant protection. The spectrum of the pesticide depends on the cultivated crops. Another source of contamination can be river water that is often used for irrigation. This water may contain various micropollutant including pesticides, pharmaceuticals, and personal care products. River contamination depends on the sources of the compounds, that can be, for example, discharged wastewater, surface water runoff from agricultural or urban land, etc. Therefore, contamination can vary both between individual rivers and along one river. Our study focused on soil contamination in areas irrigated with water from three rivers in the Czech Republic. These were mainly plots on which vegetables were grown (lettuce, onions, celery, parsley, carrots, beets, or potatoes), but also plots on which corn or buckwheat was grown. Targeted LC-MS^2 methods were used to measure concentrations of selected pesticides, pharmaceuticals, and their metabolites. In total 73 pesticides and their metabolites were found in the entire set of soil samples. The concentrations of 10 pesticides and their metabolites were > 20 ng/g of dry soils. The number of pesticides and their metabolites quantified in one soil sample varied between 28 and 52. The maximal sum of their concentrations in one soil sample was around 1500 ng/g of dry soil. The number of pharmaceuticals and their metabolites quantified in one soil sample varied between 1 and 7. The maximal sum of their concentrations in one soil sample was around 6 ng/g of dry soil. In addition, nontargeted LC-HRMS full scan/DIA methods were deployed to identify other pollutants in soils. By this approach, 49 additional pesticide related compounds were identified at Schymanski level 2. Semiquantitative comparison of peak areas revealed the gap of seven highly abundant compounds between the first and second quantified pesticide. This fact documents the importance of a nontargeted approach for local monitoring setting and pesticide management. Principal component analysis did not reveal the dependence of pesticide occurrence on sampling site, i.e., on crop or source of irrigation water. The work was supported by the Ministry of Agriculture of the Czech Republic, project No. QK23020018.

3.04.P-Th171 Groundwater vulnerability maps of the Czech Republic specified for selected micropollutants

Vít Kodeš[1], *Radka Kodesova*[2], *Ganna Fedorova*[3], *Martin Kočárek*[4], *Miroslav Fér*[4], *Helena Švecová*[3], *Ales Klement*[5], *Antonín Nikodem*[4] *and Roman Grabic*[6], *(1)Czech Hydrometeorological Institute, Czech Republic, (2)Soil Science and Soil Protection, Czech University of Life Sciences Prague, Czech Republic, (3)University of South Bohemia in České Budějovice, Faculty of Fisheries and Protection of Waters, Czech Republic, (4)Dept. of Soil Science and Soil Protection, Czech University of Life Sciences, Czech Republic, (5)Soil Science and Soil Protection, Czech University of Life Sciences, Czech Republic, (6)University of South Bohemia in Ceske Budejovice, Faculty of Fisheries and Protection of Waters, Czech Republic*

Soil can be contaminated by various micropollutants if treated wastewater or surface water that has been contaminated by this source are used for irrigation. Another source of contamination can be sewage sludge from wastewater treatment plants that is frequently used for soil enrichment. These contaminants can be taken up by plants or migrate through the soil environment and subsequently contaminate groundwater. Their leaching from soils and migration towards groundwater depends on the climatic conditions, properties of the vadose zone environment and behavior of a particular compound, i.e., its sorption onto soils and sediments, and stability in the environment. The Freundlich sorption isotherms were evaluated for twenty-one micropollutants (mainly pharmaceuticals) and representative soils of the Czech Republic. Multiple linear regressions were used to derive equations for predicting the Freundlich sorption coefficient (K_F) using the properties of tested soils. These equations, the soil map, and the database of soil properties were used to predict the K_F value distributions within the Czech agricultural soils and subsequently to delineate classes of compounds' mobility in the soil environment (i.e., mobility index). The dissipation and half-lives of all micropollutants were also evaluated for the representative Czech soils. This information was used to define compound's stability index. General groundwater vulnerability map (i.e., distribution of the DRASTIC vulnerability index) was derived using the DRASTIC method based on the climatic conditions and properties of the vadose zone. Next, specific groundwater vulnerability maps for each compound were obtained by combining the DRASTIC vulnerability index, mobility index and stability index. The resulting maps of specific groundwater vulnerability were confronted with the results of groundwater monitoring that is carried out by the Czech Hydrometeorological Institute. This information will be used to improve the monitoring of groundwater quality within the Czech Republic. The work was supported by the Ministry of Agriculture of the Czech Republic, project No. QK23020018 and QK21020080.

3.04.P-Th172 Optimisation of SPE and LC-MS for the Determination of Antibiotic Concentrations in Liquid Environmental Samples

Kalina Dobrowolska[1], *Chloe Martin*[2], *Chloe Richards*[3], *Belinda Huerta*[4], *Krystina Mrstna*[2], *Dylan O'Flynn*[5], *Xinmin Zhan*[6], *Shohei Yasuda*[7] *and Fiona Regan*[5], *(1)Dublin City University (DCU), Ireland, (2)Dublin City University (DCU) School of Chemical Sciences, DCU Water Institute, Ireland, (3)School of Chemical Sciences, Dublin City University (DCU) School of Chemical Sciences, DCU Water Institute, Ireland, (4)Glasnevin, Dublin City University (DCU) School of Chemical Sciences, DCU Water Institute, Ireland, (5)Water Institute, Dublin City University (DCU) School of Chemical Sciences, DCU Water Institute, Ireland, (6)College of Science and Engineering, University of Galway, Ireland, (7)Collge of Science and Engineering, University of Galway, Ireland*

In 2015, an estimated 11,134.97 tonnes of antibiotics were consumed by humans in 59 countries. This figure is projected to increase to 128 billion doses by 2030. Antibiotics that are not fully metabolised by the organism end up in wastewater treatment plants. Conventional wastewater treatment plants cannot completely remove antibiotics, which remain in anaerobic treated effluents (ATEs). ATEs themselves lead to the occurrence of antibiotic resistance genes due to their interaction with microbes in treatment facilities. This establishes a clear link between antibiotic use and antibiotic resistance, which causes over 700,000 deaths per year. Thus, it is necessary to accurately measure antibiotic levels in the environment, but the precision of existing methods is limited by the occurrence of matrix effects. Matrix effects are an increase (ion enhancement) or decrease (ion suppression) in the response of the target analyte. Due to this, matrix effects can dramatically alter the performance of a method.

The aim of this work was to determine and measure the presence and concentration of antibiotics in water using Solid Phase Liquid Extraction (SPE) and Liquid Chromatography-Mass Spectrometry (LC-MS). SPE was performed using Oasis HLB 200 µg cartridges, and the retained analyte was eluted with acetonitrile and reconstituted in a 10:10:80 methanol:acetonitrile:water solution. LC-MS/MS analysis was completed using an Agilent HPLC instrument with a 1290 Infinity II LC multi-sampler and temperature-regulated sample tray and column compartment. The columns used were a Zorbax eclipse plus C18 2.1 x 50 mm 1.8 µm LC column and a Zorbax eclipse plus C18, 2.1 x 5 mm, 1.8 µm UHPLC guard column at 30℃. A 6470A triple-quadrupole mass spectrometer with electrospray ionisation (Agilent Technologies) was used for detection. Helium was used as a collision gas and N_2 as a nebulising and desolvation gas. Data was collected using MassHunter software. The antibiotic sulfamethoxazole (SMX) was detected in each of the investigated surface water bodies in Ireland. The highest detected concentration was 3.2 ng/L showing a matrix effect of 321% (6.33% matrix effect SD).

At present, there is no method developed for the detection of antibiotics that is not subjected to inaccuracies due to matrix effects. The developed optimised method allows for the precise and accurate detection of antibiotics in water samples, by decreasing the occurrence of matrix effects to improve sensitivity.

3.04.P-Th174 Identification of Chlorinated Paraffin Biotransformation Products in Sediment Cores of a Polluted Lake: Insights into Oxidative Degradation

Xiaodi Shi[1]*, Anna M. Castaldi*[2]*, Håkon A. Langberg*[3]*, Anna Sobek*[4] *and Jonathan P. Benskin*[5]*, (1)Stockholm University, Stockholm, Sweden, (2)Stockholm University, Sweden, (3)Norwegian Geotechnical Institute (NGI), Norway, (4)Environmental Science, Stockholm University, Sweden, (5)Department of Environmental Science (ACES), Stockholm University, Sweden*

Due to their inherent persistence and bioaccumulative potential, the widespread application of organohalogens in our society poses threats to public health and ecosystems. However, our capacity is inadequate to assess these risks, considering innumerable unknown organohalogens, including undocumented chemicals, byproducts, and transformation products. Therefore, disclosing unknown organohalogens is an everlasting challenge for environmental analytical chemists. Leveraging relatively smaller molecular sizes of organohalogens, ion mobility spectrometry-derived collision cross section (CCS) is a promising dimension to flag unknown organohalogens in massive nontarget data. Herein, ion mobility-high-resolution mass spectrometry coupled to high performance liquid chromatography was used to depict depth profiles of substances in sediment cores from Lake Tyrifjorden, Norway. This lake has been reported to be heavily polluted by emissions from a factory producing paper products. After peakpicking, alignment, and cleanup, 218 features were prioritized as potential emerging organohalogens with smaller sizes (CCS<100+0.2 x mass) and significantly increasing trends with the year of deposition (p <0.05). Among those features, 113 showed a typical chlorine isotopic distribution, comprising 44% of the total intensity of potential emerging organohalogens in the uppermost layer of the cores, suggesting a large volume of use in the catchment. Based on isotopic patterns, exact masses, and fragment ions, element compositions of 34 unknown compounds were derived and grouped as potential oxidized chlorinated paraffins ($C_{24\text{-}26}H_{37\text{-}43}Cl_{9\text{-}11}O_3$) and sulfated chlorinated paraffins ($C_{24\text{-}26}H_{36\text{-}47}Cl_{7\text{-}12}SO_5$, $C_{24\text{-}26}H_{36\text{-}43}Cl_{9\text{-}11}SO_6$, and $C_{26}H_{43}Cl_9SO_7$). To validate our deduction and further investigate their formation mechanism, biodegradation experiments were conducted using clean upstream sediments. Functions of CCS vs. mass were established to predict CCS of all potential chlorinated paraffin biotransformation products. *In situ* increasing ratios of oxidized products over potential precursors with the depth indicated that even in the deeper layer of sediment (~10 cm), oxidative degradation still prevailed over reductive dechlorination. This study reports a CCS-oriented method to readily acquire profiles of chlorinated paraffin biotransformation products, and empirical evidence of the dominance of oxidative elimination of chlorinated paraffins in typical lake sediments.

3.04.P-Th175 Analytical Method Validation, Residue and Health Risk Assessment for Clopidol in Egg Using Liquid Chromatography-Tandem Mass Spectrometry

Min-Chul Shin*, Seung-Min Lee, Ji-Young An, Jong-Su Seo and Jong-Hwan Kim, Environmental Safety-Assessment Center, Korea Institute of Toxicology (KIT), Korea, Republic of (South)*

Clopidol is extensively used in livestock farming and residues of this antibiotic can persist in animal tissues, posing a risk to humans and the environment. The analytical method was validated with respect to parameters such as specificity, limit of detection (LOD), limit of quantification (LOQ), linearity, accuracy, and precision. Additionally, the accuracy and precision were assessed based on three replicate samples at four different spiking concentrations. As a result, no interference peak was observed to affect the quantification of clopidol in the pretreatment methods, and the LOD and LOQ values were 0.0005 and 0.001 µg/g, respectively. The concentrations of calibration standards in the method ranged from 0.1 to 20 ng/mL (r > 0.99). The accuracy of the pretreatment method was assessed through recovery results, and precision was estimated using the coefficient of variation (CV). The mean accuracies ranged from 71.74% to 89.85%, while the CV ranged from 0.2% to 7.1%, respectively. Consequently, these results are within the acceptable ranges specified in the guidelines for analytical method validation. In this study, following 14 days of exposure (after administering a clopidol-contaminated diet), clopidol concentrations were highest in eggs (median: 9.83 mg/kg) compared to other tissues (liver, fat, kidney, and muscle). A cumulative risk assessment for clopidol in eggs using the hazard quotient (HQ) method was conducted. The HQ values exceeded 1 for all age groups, especially for young children (<18 years).

This research was supported by a grant (22192MFDS356-3) from Ministry of Food and Drug Safety in 2023.

3.04.P-Th176 Analytical Method Validation and Residue Kinetic of Fumagillin in Rainbow Trout Using Radiolabeled Compound

Seung-Min Lee*, Min-Chul Shin, Ji-Young An, Jung-Hoon Jung, Seong-Hoon Jeong, Hyeong-Jin Youn and Jong-Hwan Kim, Environmental Safety-Assessment Center, Korea Institute of Toxicology (KIT), Korea, Republic of (South)*

Fumagillin is a compound isolated from the fungus *Aspergillus fumigatus* and is widely employed as an antimicrobial agent for honeybees and fish. It shows promise as both an anti-infective and antiangiogenic agent. In this study, we investigated the magnitude, dissipation, and metabolism of fumagillin, radiolabeled as [3H]fumagillin, in rainbow trout (fillet). Prior to analyzing the tissues collected from the test animals, specificity, linearity, system suitability, and recovery (accuracy and precision) tests were conducted. All results are within the acceptable ranges specified in the guidelines for analytical method validation. Fumagillin was administered orally, and the average dose administered, based on the body weight of the rainbow trout, was approximately 50.1 mg/kg after acclimation for Day 7. Ten rainbow trout were sacrificed at 6, 12 hours, Day 1, 2, and 7 after dosing, and fillet tissues were collected. The total radioactivity residue (TRR) in the extract of each tissue was determined by LSC analysis, followed by Radio-HPLC to separate fumagillin and its metabolite. Radio-HPLC analysis showed that no metabolites other than the parent compound were detected in the fillet tissue extract. The concentration of fumagillin increased from 1.2 mg/kg to 2.3 mg/kg at 12 hours following dosing and then declined to 0.2 mg/kg on Day 7. The unextractable residues remained within the range of 1.2 to 1.7 mg/kg but significantly declined to 0.4 mg/kg by Day 7.

This research was supported by a grant (22192MFDS356-3) from Ministry of Food and Drug Safety in 2023.

3.04.P-Th177 Analysis and Occurrence of UV Filters, Parabens and Benzotriazoles in Cadiz Bay (Andalusia, SW Spain)
Lillie Jeal Elizabeth Freemantle[1]*, Rubén Ríos Quintero*[2]*, Pablo Antonio Lara Martín*[2] *and Marina G. Pintado Herrera*[2]*, (1)Phyisical Chemistry, Cádiz University, Spain, (2)Universidad de Cadiz*
The present study provides new insights into the environmental distribution of two families of personal care products (PCPs) in estuarine systems in Cadiz Bay (southwest Spain): ultraviolet radiation filters (UV-Fs) widely used in sunscreens, and parabens (PBs) which are mainly used as preservatives in cosmetic products. Additionally, benzotriazoles, a group of high production volume compounds (HPVCs) that are used daily in various applications, were studied in this work. Despite being present in relatively low concentrations (parts per billion, ppb to parts per trillion, ppt) in the aquatic environment, these selected compounds of emerging concern (CECs) are capable of generating imbalances in the environment and producing toxic effects in organisms.

For this purpose, first, ultra-high performance liquid chromatography coupled to tandem mass spectrometry (UPLC-MS/MS) analysis method was optimised to determine the selected PCPs. Then, solid phase extraction (SPE) and pressurised liquid extraction (PLE) techniques were optimised for the extraction of these compounds in liquid and solid samples, respectively. Environmental samples from both wastewater and aquatic systems of the Cadiz Bay (Guadalete River Estuary and San Pedro River Tidal Creek) were analysed to determine the presence and distribution of PCPs using the previously optimised analytical method. To assess the environmental risk in the study area, hazard quotients (HQs) were evaluated.

The multi-residue analytical method developed obtained acceptable results for 15 PCPs, of which 15 were detected in aqueous samples and 9 in solid samples.

The wastewater analysis provided removal rates of these compounds, which were higher for UV-Fs, parabens and 1H-Benzotriazole (BTA) when considering not only the dissolved fraction, but also the particulate fraction in the wastewater samples (2.84 % for UV-Fs, 34.10 % for parabens and 48.11 % for 1H-Benzotriazole). Also, in the Guadalete River Estuary a higher incidence of UV-Fs and PBs in summer was observed. Selected compounds such as BTA showed conservative behaviour along the Estuary, serving as an indicator for sewage contamination. Concentrations of UV-Fs and PBs in the sediment of the Guadalete River (202.78 and 37.3 ng·g $^{-1}$ respectively), were higher than those registered in the sediment of the San Pedro River Tidal Creek (78.66 and 13.49 ng·g $^{-1}$).

Finally, BTA and EthylPABA were the two compounds with the highest risk coefficients (HQ higher than 1).

3.04.P-Th178 Degradation of the Herbicide Profoxydim by Ozone Water Treatment. Theoretical DFT Study to Elucidate the Reaction Mechanism
Maria Cobos-Escudero[1]*, Alberto Cruz-Alcalde*[2]*, Al Mokhtar Lamsabhi*[3]*, Manuel Alcami*[3]*, Juan Carlos Nieto-Carmona*[1]*, José Alonso-Prados*[1] *and* ***Pilar Sandin-España***[1]*, (1)Institute for Agricultural and Food Research and Technology, Spanish National Research Council (INIA-CSIC), Spain, (2)Department of Chemical Engineering and Analytical Chemistry, University of Barcelona, Spain, (3)Departamento de Quimica, Universidad Autónoma de Madrid, Spain*

Drinking water sources are subjected to disinfection processes in order to achieve an adequate control of pathogenic microorganisms in the final drinking water. In this sense, ozone is one of the most innovative treatments in drinking water treatments due to its oxidizing and bacteriological power against waste. Ozone is also capable of reacting with organic pollutants such as pesticides present in water. Profoxydim is an herbicide used on rice crops that can reach natural water reservoirs intended for human consumption or reuse for agricultural purposes. Therefore, the objectives of this work were to study the behavior of this herbicide in the presence of ozone and to identify the possible degradation products (DPs). Furthermore, a theoretical study will be carried out to identify the main reaction mechanism, in order to explain the data obtained experimentally.

The kinetic evolution of aqueous solutions of profoxydim in the presence of ozone generated by a lab ozonizer was followed by HPLC-DAD. The assays were carried out at different ratios of Profoxydim: ozone (1:1/1:5/1:10). The identification of the main DP formed was performed by HPLC-ESI-QToF. The results showed that the herbicide was fast degraded by ozone under the conditions studied. A main and more stable DP was detected which tentatively identified as a by-product resulting from the oxidation of the sulfide moiety of the herbicide, leading to the corresponding sulfoxide. This byproduct has also been detected in other water disinfection treatments studied, such as chlorination.

The reaction mechanism for the formation of these oxidation by-products is not clear and there is no consensus in the literature. Therefore, a theoretical-computational study was carried out by means of DFT calculations using the basis set (B3LYP/6-311G+ (d, p)) to elucidate which oxidation pathway of Profoxydim sulfide (ionic or radical) is the most likely. The results may be useful to know how other pesticides might evolve under these conditions.

3.04.P-Th179 Migration of Organic Compounds from Rubber Materials in Contact with Water and their Safety Evaluation as Water Contact Materials

Andreia Videira Dra.[1]*, Cristina CM Almeida Prof*[2]*, Ana Isabel Penetra Dra.*[1]*, Vitor Vale Cardoso Dr.*[1] *and Rui N Carneiro Eng.*[1]*, (1)Laboratory, Empresa Portuguesa das Águas Livres, S.A. – EPAL, Portugal, (2)iMed.UL, Faculdade de Farmácia da Universidade de Lisboa, Portugal*

Water for human consumption comes into contact with different construction materials used in the collection, treatment, storage, and supply systems, and in the building networks up to the consumer's tap.

All the materials used in water supply structures have the potential to change water quality by leaching into the water, due to electrochemical mechanisms, biological phenomena, oxidation, corrosion, among others.

The nature of the leached compounds and the potential chemical interactions depend on the type of material used, namely, cementitious (cement, aggregates, water, additives, adjuvants, and fibers), organic (polymer matrix composites and elastomers, namely high-density polyethylene and epoxy resins) and metallic (especially stainless steel, copper, ductile iron, and metal alloys). These compounds can be harmful to human health.

The connection between the different pipework sections can be made through metal compression fittings, with the sealing being achieved by rubber sealing rings, through fittings of the same material connected by polyfusion welding.

In this work, six series of specific migrations studies from rubber materials intended for water contact have been studied. The amount of material used for each test depends on the surface-to-volume ratio (S/V) of each material and, the tests take place with a ratio S/V of 3 and 6. The experiments were carried out with ultrapure water under suitable conditions of time and temperature (1,2). The liquid-liquid extraction of 500 mL of migration water in acid and basic conditions was used for the extraction of all potential organic compounds with 200 mL of dichloromethane. The organic extract was concentrated to 0.5 mL in a Turbovap system and analyzed by gas chromatography coupled to mass spectrometry (3). A semi-quantitative method with ten deuterated standards was used for the quantification of all the compounds identified in migration waters. The electric conductivity, redox potential, color, pH, and the turbidity of migration waters were also performed.

More than 50 organic compounds were quantified in migration waters with a total concentration of up to 2608 µg/L. Most of the organic compounds showed concentrations lower than 10 µg/L, but some of them showed concentrations of up 200 µg/L. The number of organic compounds and their concentrations decrease with the number of migration periods.

3.04.P-Th180 Optimisation of Solid Phase Extraction for the Determination of Bifenthrin, Estrone, and Diclofenac in Marine Environments

Jodie Bermingham[1]*, Caroline Murphy*[1]*, Enrique Jacobo Díaz-Montaña*[2]*, Chloe Richards*[3]*, Kalina Dobrowolska*[4]*, Ciprian Briciu-Burghina Dr.*[5]*, Krystina Mrstna*[1]*, Dylan O'Flynn*[5]*, Belinda Huerta*[6] *and Fiona Regan*[5]*, (1)Dublin City University (DCU) School of Chemical Sciences, DCU Water Institute, Ireland, (2)DCU Water Institute, School of Chemical Sciences, Dublin City University, Ireland, (3)School of Chemical Sciences, Dublin City University (DCU) School of Chemical Sciences, DCU Water Institute, Ireland, (4)Dublin City University (DCU), Ireland, (5)Water Institute, Dublin City University (DCU) School of Chemical Sciences, DCU Water Institute, Ireland, (6)Glasnevin, Dublin City University (DCU) School of Chemical Sciences, DCU Water Institute, Ireland*

Pesticides, hormones, and pharmaceuticals are contaminants of emerging concern that can be found in many environmental samples, such as marine water. Bifenthrin (BF) is one such contaminant, which easily binds to soil particles, causing residues to be carried into the environment. The toxicity of BF to non-target organisms is of most concern, highly toxic to fin-fish and crustaceans. Low concentrations of BF have also been shown to cause behavioural effects in fish, raising concerns of neurotoxic properties in fish species, impacting the ability to forage and escape from predators. Other contaminants that are found in aquatic environments are synthetic hormones and pharmaceuticals, such as estrone and diclofenac, respectively, that do not easily breakdown in the environment.

Due to this, it is necessary to find and improve methods to extract and detect these chemicals. This research focuses on the optimisation of solid phase extraction (SPE) coupled with liquid chromatography-mass spectrometry (LC-MS). Due to the low concentrations at which these are found in marine environments, the analytes must be pre-concentrated and extracted before they can be detected using LC-MS. This project focuses on the optimisation of the pre-concentration and extraction of contaminants.

The sample is spiked with a standard solution of the analyte. Oasis HLB 6cc 200 mg extraction cartridges were used for the SPE process. During SPE the analyte is eluted using 5 mL of acetonitrile. This is then dried and reconstituted in 20/80 (% v/v) methanol/water. An Agilent HPLC instrument was used for LC-MS/MS analysis. The columns used were a Zorbax eclipse plus C18 2.1x50 mm 1.8 μm LC column and a Zorbax eclipse plus C18, 2.1x5 mm, 1.8 μm UHPLC guard column at 30℃. A 6470A triple-quadrupole mass spectrometer with electrospray ionisation (Agilent Technologies) was used for detection.

BF was detected at a concentration range of 0.065-0.079 ng/L among water samples. Estrone and diclofenac were not measured in these samples, further investigations will be carried out for these analytes. The concentrations detected may not be fatal, but an increase in concentration or repeated (chronic) exposure could have long-term damaging effects for aquatic wildlife.

To preserve marine environments it is necessary to monitor the levels of pollution in marine waters. The proposed method will enable the extraction and detection of contaminants of emerging concern.

3.04.P-Th181 Analysis of Pesticides, Pharmaceuticals and Personal Care Products in Drinking and Environmental Water by Direct Injection Using UPLC-MS/MS

*Hannah Willmer[1] and **Cecile Pinto**[2], (1)Waters Corporation, United Kingdom, (2)Waters Corporation, France*

The monitoring of harmful substances in drinking and environmental water is essential for protecting human health and maintaining environmental quality standards. Accurate measurements at ultra- low levels is an essential part of any trace monitoring program. As more and more pesticides, pharmaceuticals and personal care products (PPPCPs) are released into the environment, there is a growing demand for analytical methods with multiple compound groups, where one major analytical challenge for analysis lies in the wide chemical diversity of compound classes and structures.

The purpose of this work was to demonstrate a direct injection UPLC-MS/MS method for the ultra-low level determination of pesticides, pharmaceuticals and personal care products in drinking and environmental waters. The method performance study was completed on an ACQUITY Premier™ LC System with a Xevo TQ Absolute™ MS system.

A method validation study was carried out on drinking and surface water matrices. The method performance was assessed using 3 spike levels at 10, 25, and 125 ng/L for all analytes, with 6 replicates at each level. Average method performance for trueness, repeatability, linearity, and sensitivity was assessed through inter and intra-laboratory studies.

The sensitivity of the Xevo TQ Absolute™ MS system allows for the use of a direct injection approach which removes complex sample preparation and enables the simple, high-throughput analysis of pesticides, pharmaceuticals, and personal care products in drinking and environmental water.

3.04.P-Th182 Anthropogenic substances on Mar Menor beaches: occurrence, environmental risk, and usefulness as markers of anthropogenic contaminant sources.

*Yolanda Valcarcel Rivera[1], Sandra Mozas Blanco[1], **Judit Kalman**[1], Andreu Rico[2], Isabel López[3] and Jose Luis Rodriguez Gil[4], (1)Rey Juan Carlos University, Spain, (2)Cavanilles Institute of Biodiversity and Evolutionary Biology, University of Valencia, Spain, (3)IMDEA Water Institute, Spain, (4)Experimental Lakes Area (IISD-ELA), Canada*

The Mar Menor lagoon (Murcia, Spain) is one of the largest in Europe and is protected by national and international environmental legislation due to its great ecological value. However, anthropogenic contaminants such as pharmaceuticals, which are not treated efficiently in Wastewater Treatment Plants (WWTPs), could pose a risk to this ecosystem. The objective of this study was to determine the occurrence, concentrations and environmental risk of different anthropogenic contaminants on 6 representative beaches in the lagoon. Sampling was carried out in spring and summer to evaluate how seasonality influence in the measured environmental concentrations. 41 substances from 8 therapeutic groups, including parenteral compounds and metabolites were analyzed by liquid chromatography coupled to mass spectrometry with triple quadrupole analyzer. Methodological Detection Levels (MDL) are between 0.04 – 0.9 ng/L. Seasonal variation were evaluated with non-parametric test for paired samples (Wilcoxon). Risk Quotient (HQ) was used to assess the environmental risk of the substances. Laboratory chronic toxicity data were used where possible, and QSAR models were used when not available. 37 of the 41 substances were detected in at least one of the two samples, 4 of them included in the 4th Watch List of European Union. Concentrations were greatly varied between beaches and also samplings. In general, concentrations were higher in summer, but only 7 compounds were statistically significant ($p<0.5$), 4 of them were stimulants. All substances in this group were detected in 100% of the samples. The average total concentration of compounds was higher in August in all beaches except Rambla del Albujón. In May, this beach had the highest total average, while in August Santiago de la Ribera did so (984.7 ng/L), much higher than Villananitos and Urrutias (639 and 626.6 ng/L respectively). All beaches present substances posing, at least, a moderate risk. High risk ($HQ > 10$) was detected for 4 compounds. Eight substances reached, at least, moderate risk ($1 \leq HQ < 10$) in, at least, one of the seasons. Sixteen reached low risk ($1 \leq HQ < 10$) levels in at least one location in at least one season. Caffeine, paraxanthine and carbamazepine most frequently posed a risk in the studied beaches. . This is the first study that analyzes wide variety of anthropogenic contaminants on Mar Menor beaches, as well as the influence of seasonality in their occurrence and environmental risk. It also points out the importance of including not only parent compounds but also metabolites in risk assessment as well as determine possible sources.

3.04.P-Th183 Chemical and Biological Transformations of ZnO Engineered Nanoparticles in Aquatic Environments: Implications for Toxicity and Environmental Risk Assessment

Mikołaj Edward Feculak[1], *Susana Loureiro*[2], *Patricia V. Silva*[3], *Monika Stefania Raczkiewicz*[4], *Patryk Oleszczuk*[4] *and Izabela Jośko*[5], *(1)Institute of Plant Genetics, Breeding and Biotechnology, University of Life Sciences, Poland, (2)CESAM - Centre for Environmental and Marine Studies & Department of Biology, University of Aveiro, Portugal, (3)Department of Biology, University of Aveiro, Campus Universitário de Santiago, Portugal, (4)Department of Radiochemistry and Environmental Chemistry, Maria Curie-Skłodowska University, Poland, (5)Institute of Plant Genetics, Breeding and Biotechnology, University of Life Sciences in Lublin, Poland*

The increasing global production and use of engineered nanoparticles (ENPs) resulted in their release into the aquatic environment. In light of the potential hazard posed by emerging contaminants, extensive investigations have been conducted to elucidate their toxicity on living organisms. Notably, these studies have predominantly focused on pristine engineered nanoparticles (*p*ENPs). However, it is imperative to acknowledge that ENPs released into the environment undergo rapid and intricate physical, chemical, and biological transformations. These transformations may pivotally alter the properties of ENPs and further their fate in the environment, including toxicity. Our study aimed to assess whether chemical and biological transformations mitigate or exacerbate the toxicity of ZnO ENPs to the freshwater crustacean *Daphnia magna*. For chemical transformation, *p*ZnO ENPs were aged in solutions containing S^{-} or PO_4^{3+} ions, while to obtain the biocorona of the ENPs *p*ZnO ENPs underwent the physisorption with protein and polysaccharide. Additionally, the obtained ZnS ENPs were subsequently covered with a protein layer. The transformed ZnO ENPs (*trans*ZnO ENPs) were physiochemically characterized and evaluated in terms of acute toxicity towards *D. magna*, according to OECD Guidelines 202. Both chemical and biological transformations significantly reduced the toxicity of ZnO ENPs. Among the chemical transformations, sulphidation was the most effective in mitigating the toxic effects on *D. magna*, and in addition, the protein corona formed on previously sulphidised ZnO ENPs enhanced this effect. In conclusion, the transformations that ENPs may undergo in the aquatic environment have the potential to mitigate toxicity on living organisms. A potential mechanism for toxicity reduction may be the decreased dissolution of *trans*ENPs compared to *p*ENPs, but further studies are needed to confirm this. The results obtained may also provide a basis for the risk analysis of increasing environmental pollution by ENPs and contribute to the development of effective methods to reduce their harmful effects on the biosphere.

3.04.P-Th184 Improving the sensitivity of additive detection in environmental matrices using SPE and selected reaction monitoring

Michaela Reay[1], *Maddy Murphy*[1], *Charlie Monkley*[2], *Helen Whelton*[1], *Martine Graf*[3], *Richard P Evershed*[1], *David R Chadwick*[4], *Davey L Jones*[4] *and Charlotte E M Lloyd*[1], *(1)Organic Geochemistry Unit, School of Chemistry, University of Bristol, United Kingdom, (2)University of Bristol, United Kingdom, (3)School of Natural & Environmental Sciences, Bangor University, United Kingdom, (4)School of Environmental & Natural Sciences, Bangor University, United Kingdom*

Plastic mulch film supports improved food security, particularly in regions of marginal productivity. Organic additives included within these films are not chemically bound and thus susceptible to loss to the wider soil environment prior to the breakdown of the polymer. This includes additives with potential human health impacts (e.g., phthalates), under assessment for bioaccumulation (e.g., organophosphites), and those with unknown potential hazards (e.g., oligoesters derived from biodegradable plastics). It is essential to quantify the abundance of such additives in soil, and potential uptake into plants. Testing published methods for plant matrices revealed significant interference from the plant matrix, which prohibited the detection of low-level additives. We propose that the concentration difference of soil and plant-derived compounds relative to additives currently prohibits the reliable detection of these emerging compounds of concern, particularly in settings that have recently employed plastic mulch. Resolving this is essential to determine the fate of leached additives in the early stages of plastic mulch use.

In this study we have optimised the extraction and solid phase extraction (SPE) work-up of additives from plastic mulch films. We targeted known compounds and degradation products of two commercially available mulches, a LDPE and a biodegradable (PLA/PBAT) mulch, so to better reflect the complexity of additive inputs into the environment. Fractions were subsequently analysed by GC-QTOF-MS, with increased sensitivity and exclusion of potential interference from the plant or soil matrix using selected reaction monitoring. Quantification was achieved by external calibration. This was then applied to soil, spiked with additives extracted from the film, and from a field experiment where the mulches had been used for three sequential growing seasons.

The sequential aminopropyl-silica SPE following microwave extraction yielded two to three fractions of interest per mulch type, and reduced the interference of the soil/plant matrices, to allow reliable detection of additives in spiked soils with high recovery (>90%). This approach will then be applied to soils that have been exposed to plastic mulch films for three growing seasons, where theoretical loading from the plastic mulch use over three years is in the nanogram range per gram of soil, excluding the degradation of additives.

3.04.P-Th185 Occurrence of pharmaceuticals in surface water from rural areas located in the Northwest of Spain

Gabriela Castro[1], *Victoria Fernandez-Fernandez*[2], *María Ramil*[1], *Rafael Cela*[3] *and Isaac Rodriguez Pereiro*[4], *(1)University of Santiago de Compostela, Spain, (2)Analytical Chemistry. Institute for Research on Chemical and Biological Analysis, Universidade de Santiago de Compostela, Spain, (3)Mestrelab Research Center (CIM), Spain, (4)Analytical Chemistry. Institute for Research on Chemical and Biological Analysis, University of Santiago de Compostela, Spain*

Urban wastewater constitutes a relevant vector of pharmaceuticals in the aquatic environment. Many of these compounds are incompletely removed in the sewage treatment plants (STPs), and thus reaching surface watercourses and reservoirs, and even groundwater. In remote and rural areas, domestic wastewater receives limited treatment and attention, which added to leaks from sewers and septic tanks, may contribute to the contamination of surface and groundwater with anthropogenic substances. Galicia, in the Northwest of Spain, is characterized by a very dispersed population all over the territory. Thus, monitoring the presence of pharmaceuticals in surface and groundwater is required to understand their distribution in the environment, to identify markers of anthropogenic pollution, and to assess their potential eco-toxicological risks.

The aim of this presentation encompasses i) to develop and validate a fully automated methodology based on SPE online connected to LC-MS/MS for a set of pharmaceuticals commonly reported in urban wastewater; ii) to investigate the temporal fluctuations of the selected compounds in rural dispersed population areas of Galicia through four sampling campaigns, performed in two main rivers in the area.

SPE online system, based on a reusable and reversed-phase sorbent, tailored to liquid chromatography mass spectrometry (LC-MS/MS) provided a sensitive and accurate determination of a wide selection of pharmaceuticals in water samples through easy sample processing. Pharmaceutical residues were ubiquitous in the investigated samples. Tramadol, o-desmethyl venlafaxine, irbesartan, valsartan acid and olmesartan are proposed markers of municipal wastewater discharges. Among them, olmesartan is highlighted as potentially hazardous in the aquatic environment attending to currently available PNEC values with risk quotients of 4.4 and 254 in reservoir and river water, respectively.

3.04.P-Th187 Marine ecotoxicity of amines used as solvents in carbon capture processes: Species sensitivity distributions and additive toxicity aspects.

***Bjørn Henrik Hansen**[1], Ewa Wielogórska[1], Dag Altin[2], Anna Korre[3], Julia Farkas[4], Eirik Falck da Silva[5], Karl Anders Hoff[6], Hanne Kvamsdal[5], Lisbet Sorensen[4] and Odd Gunnar Brakstad[1], (1)SINTEF, Norway, (2)Research Infrastructure SeaLab, Norwegian University of Science & Technology (NTNU), Norway, (3)Imperial College, United Kingdom, (4)SINTEF Ocean, Norway, (5)SINTEF Industry, Norway, (6)Process Technology, SINTEF Industry, Norway*

2-Amino-2-methyl-1-propanol (AMP) and piperazine (PZ) are amines used as solvents in carbon capture (CC) technologies, and during this process some of the utilized amines will be emitted to the atmosphere. With rapid development and implementation of amine-based technologies with the purpose to decarbonize industries and meet climate goals, there is a concern for potential environmental impacts of these emitted amines. To assess their environmental risk, information is needed about their environmental fate and ecotoxicity, however, surprisingly little is known about the ecotoxicity of AMP and PZ. As the ocean represents the sink for most anthropogenic emissions, we investigated ecotoxicity thresholds for AMP and PZ in three marine species representing three trophic levels, namely the marine algae *Skeletonema pseudocostatum*, the copepod *Calanus finmarchicus* and fish Atlantic cod (*Gadus morhua*). Acute toxicity thresholds (72 h-EC_{50}, algae, and 96h-LC_{50}, copepod) were in the range 159-522 mg/L and 147-381 mg/L for AMP and PZ, respectively. For Atlantic cod, which were exposed as developing embryos in the egg, observations up to 8 days post exposure did not provide evidence for delayed mortality or larvae deformations. We also tested binary mixtures of the amines on the copepod, which was the most sensitive species, and found that the amines displayed a pattern of additive toxicity. Furthermore, we collected literature data for both amines and a range of degradation products to assess species sensitivity distributions. Our data are important for regulatory agencies and policy makers involved in environmental risk assessment processes relating to amine-based CC technologies highlighting the needs for testing towards organisms at different trophic levels.

3.04.P-Th188 Spatial variability of microplastic concentration in benthic sediments from coastal aquaculture region of Korea using a new device for extracting microplastics from sediments

***Dong-Hoon Im**[1], Minkyu Choi[1], Won Chan Lee[1], Sunggyu Lee[1] and Tae-Hoon Kim[2], (1)National Institute of Fisheries Science, Korea, Republic of (South), (2)Faculty of Earth and Environmental Sciences, Chonnam National University, Korea, Republic of (South)*

To date, methods for extrating microplastics from marine sediments have some limitations such as complexity, low extraction efficiencies and incompatibility with very fine sediments. Here, we developed an imporved method to extract microplastics from benthic sediments using the principle of density floatation in a single step with a mean efficiency of 99.5% (±SE 2.25%; min 90%; max 100%). We used the method to analyze the spatial distribution of microplastics in benthic sediments from 7 coastal aquaculture regions of Korea. The abundance of microplastics in benthic sediments ranged from 578 to 3,228 particles/kg, and the fragment was the most dominant shape. Polypropylene and polyethylene, and polystyrene accounted from 20~69%, 14~34%, and 0~29% of total microplastics. respectively. The distribution of microplastics in benthic sediments peaked in the 100~200 ㎛ size range.

3.04.P-Th189 A study of chemical toxic effects on juvenile Rockfish (Sebastes schlegeli) exposed to hull cleaning discharge using brain and liver transcriptome analysis

***Seong Hee Mun**[1], Kwang-Min Choi[2], Dongju Shin[2], Moonkoo Kim[2], Taekhyun Kim[2,3] and Jee hyun Jung[2,3], (1)Korea Institute of Ocean Science and Technology (KIOST), Yeongdo-gu, Korea, Republic of, (2)Korea Institute of Ocean Science and Technology (KIOST), Korea, Republic of (South), (3)University of Science and Technology (UST), Korea, Republic of (South)*

Antifouling paints serve as protective coatings on vessels, preventing the attachment of marine organisms. Chemical constituents of antifouling paints can be released into the marine environment during vessel cleaning processes, including in-water cleaning (IWC). During the hull IWC process, a mixture of antifouling paint particles is produced and directly discharged into the coastal environment, yet few studies have investigated their toxic effects on resident marine species. Environmental IWC discharges serve as a source of toxic substances, including metals and biocides that may leach from them, potentially causing harmful effects on non-target organisms residing in the area. In this study, the toxic effects of IWC discharge on juvenile rockfish (*Sebastes schlegeli)* which is one of the major fishery resources was investigated. Chemical analysis revealed that zinc (8.05 ± 0.96 to 189.96 ± 47.76 μg/L), followed by copper (0.87 ± 0.19 to 1.97 ± 0.60 μg/L), was the most abundant compound found in the IWC discharge. No mortality was observed in any of the experimental groups at 7 days after exposure. However, variation in reactive oxygen species (ROS) and acetylcholinesterase (AChE) activity was noted in juvenile rockfish exposed to a 10-times dilution of IWC discharge. Genes associated with oxidative stress, detoxification, and the immune response exhibited significant alterations after exposure to the 10-times dilution-IWC discharge. Transcriptomic variations in the brain and hepatic of juvenile rockfish exposed to IWC discharge also revealed changes in genes related to the immune system and detoxification. Furthermore, significant alterations in the nervous system development and homeostatic processes were also observed in the brain-transcriptomic network analysis. The findings of this study contribute to an enhanced understanding of the effects of zinc-abundant in-IWC discharge on the neuronal and immune toxicity of commercially important fishery species.

3.04.P-Th190 Acute toxic effects of hull in-water cleaning discharge on embryonic flounder (Paralichthys olivaceus)
Seong Hee Mun[1]*, Kwang-Min Choi*[2]*, Dongju Shin*[2]*, Moonkoo Kim*[2]*, Taekhyun Kim*[2] *and Jee hyun Jung*[2]*, (1)Korea Institute of Ocean Science and Technology (KIOST), Yeongdo-gu, Korea, Republic of, (2)Korea Institute of Ocean Science and Technology (KIOST), Korea, Republic of (South)*
Antifouling paints, consisting of biocidal compounds, are applied to boat and ship hulls to prevent or minimize the attachment of fouling organisms. Despite the potential toxicity risk associated with these pollutants, there is a limited number of studies investigating and monitoring the toxic effects on embryonic fish using IWC discharge collected from multiple ships. In this study, hull IWC discharge from four ships were collected in 2022 and 2023 and toxic effect assessments were conducted on flatfish fertilized embryos. After dividing the IWC discharge into untreated discharge and filtered wastewater, fertilized embryos were exposed based on various dilution factors (5-, 10-, 100-, and 1000-fold dilutions). As a result of chemical analysis of IWC discharge, Fe, Cu, and Zn were confirmed in high proportions. The experimental groups exposed to hull IWC discharges exhibited higher mortality rates at lower dilution folds compared to those at higher dilution folds. Moreover, the mortality rate was high in embryonic fish exposed to untreated discharge compared to filtered discharge. Malformations in morphogenesis, including pericardial edema, dorsal curvature, tail fin fold defects, and developmental delays, were observed in fertilized embryos following exposure to IWC from all four different ships. To understand the molecular biology of malformation, eight genes ((heart formation (*nkx2.5*, NK2 transcription factor–related 5; *SOX6*, SRY-box–containing gene 6; *robo1*, roundabout receptor1), bone malformation (*bmp4*, bone morphogenetic protein 4), fin malformation (*plod2*, procollagen-lysine 2-oxo-glutarate 5-dioxygenase 2, *furin*, furin; *wnt3a*, Wnt family member 3a), and tumors (*TP73*, Tumor protein p73) related to morphogenesis were evaluated using qRT-PCR. To clarify the potential toxic effects of IWC discharge, we also conducted RNA-seq (high-throughput sequencing) on embryonic flounder exposed to hull IWC wastewater. This study provided crucial evidence of the risks associated with IWC discharge when exposed to marine organisms. Taken together, these results may inform strategies to improve hull-cleaning wastewater pollution management to better protect coastal ecosystems.

3.04.P-Th191 Occurrence and seasonal variations of 160 current-use pesticides in surface seawater of Korean coastal waters
Sunggyu Lee*, Minkyu Choi, Dong-Hoon Im and Won Chan Lee, National Institute of Fisheries Science, Korea, Republic of (South)*
With the frequent used of chemical pesticides, the current-use pesticides (CUPs) emerge and concentrate in the sea. However, there is little research on this topic. The present study, 160 CUPs were screened in 66 seawater samples collected from two coastal bays, with high agricultural activities. The number and total concentration of detected CUPs were much higher in summer than in winter season, which was due to their large application in the local agriculture activities. In studied two bays, higher detection and concentration of CUPs were found in Gunsan Bay than Jinhae Bay, indicating intense human activities and riverine input. In summer, 73 pesticides in seawater samples were detected and total concentration of the pesticides ranged from 5,140 to 287,000 ng/L. Higher levels showed in herbicides than in insecticides and germicides, and mean concentrations of metazosulfuron, imazosulfuron, mefenacet and benxulfuron-mehty were higher than 1,000 ng/L. The germicides with relative high levels were isoprothiolane, tebuconazole, tricyclonazole, hexaconazole, and azoxystrobin. Diuron (herbicide and antifouling paint biocide) and DEET (mozzie repellent) showed 100% detection frequency and high concentration. These detected pesticides in seawater were all much lower values than the toxicological endpoints, presenting low toxic effects to aquatic organisms.

3.04.P-Th192 Comprehensive monitoring of emerging contaminants following “Daniel” and “Elias” storm events at Pagasitikos Gulf, Eastern Mediterranean Sea, Greece, utilizing the technique of LC-VIP-HESI-TIMS-HRMS
Rallis Lougkovois[1]*, Georgios Gkotsis*[2]*, Maria-Christina Nika*[3]*, Constantinos Parinos*[4]*, Ioannis Hatzianestis*[4]*, Nikolaos S. Thomaidis*[3] *and Alexandra Pavlidou*[4]*, (1)Hellenic Center for Marine Research (HCMR), Greece, (2)Chemistry, National and Kapodistrian University of Athens, Greece, (3)National and Kapodistrian University of Athens, Greece, (4)Hellenic Centre of Marine Research*

Comprehensive monitoring of emerging contaminants provides insights on the quality of ecosystems. Chemicals such as plant protection products, pharmaceuticals and per- and polyfluoroalkyl substances (PFAS) often end up in the environment and are distributed in different compartments. Their presence may be attributed to human related activities and wastewater treatment plants' (WWTP) inability to remove them from wastewater stream. Upon reaching the sea, biotic and abiotic processes take place, that produce transformation products (TPs), suspected to cause more potent effects than parent compounds towards the environment and human health. Thessaly, Greece, was severely struck by sequential major storm events "Daniel" and "Elias" during the fall of 2023. Approximately 1.5 million tons of water per square kilometer rained down the surrounding area during the phenomena. Such events caused by natural induced environmental change may increase the number of chemicals ending up in the marine ecosystem. Aiming to extract as many contaminants as possible, generic sample preparation protocols were applied using multilayer mixed-mode SPE cartridges to enrich final extracts with thousands of non-volatile, thermally unstable, semi-polar to polar organic pollutants. The analytes were separated using a Liquid Chromatography system linked to a hybrid Trapped Ion Mobility Spectrometer coupled to High Resolution Mass Spectrometer (LC-TIMS-HRMS). The occurrence of more than 2,500 chemicals from different chemical classes was investigated via wide-scope target analysis. TIMS provides an additional dimension of separation, adding increased value of confidence to the identification criteria, minimizing false positive selection, further optimizing target screening methodology. Preliminary results indicate the presence of numerous plant protection products in seawater samples, such as Azoxystrobin and Atrazine along with their TPs: Azoxystrobin acid, 2-hydroxy-atrazine, desethyl-atrazine and desisopropyl-atrazine, pharmaceuticals, in areas close to WWTPs, such as Carbamazepine and its' TPs: 10,11-epoxy-carbamazepine and 10-hydroxy-carbamazepine, possibly due to overflowing of said facilities. The presence of PFAS like Perfluorooctanesulfonic acid (PFOS) and Perfluorooctanoic acid (PFOA) is also confirmed, linked to the destruction of port infrastructure.This work was funded by the Ministry of Development & Investment of Greece, National Strategic Reference Framework.

3.04.P-Th193 Assessing the Removal and Risks of Micropollutants and Transformation Products in PAC-AGS Treatment

Heewon Jang[1]*, Junho Jeon*[2]*, Hanna Choi*[3]*, Jaewoo Lee*[4]*, Woojong Mo*[3]*, Kwangsoon Choi*[3] *and Minsu Kim*[4]*, (1)Department of Environment engineering, Changwon National University, Korea, Republic of (South), (2)Department of Environmental Engineering, Changwon National University, Korea, Republic of (South), (3)Taeyoung E&C, (4)University of Korea*

The removal of micropollutants poses a challenge in conventional biological reactors (BR), leading to the formation of transformation products (TPs) and potential risks to ecosystems. Addressing these challenges requires new technologies. In this study, we applied powdered activated carbon-aerobic granular sludge (PAC-AGS) technology to a conventional BR to treat micropollutants and their TPs. Extensive LC-HRMS screening was conducted to identify and quantify substances occurring in wastewaters before and after the treatments. Samples were collected from the influent and effluent (retention time: 15hr) of the BR at a domestic sewage treatment plant. The effluent was collected after treating stage 1 (AGS) for 4 hours and stage 2 (PAC-AGS) for either 3 or 6 hours. Target screening quantified 72 substances (pharmaceuticals: 34, pesticides: 18, industrial: 5, TPs: 15) among 219. Of these, 61 were confirmed in the influent, and 47 (including 10 TPs) were confirmed in the effluent. When only the first stage (AGS) was applied to the influent, 57 substances (including 13 TPs) were confirmed. In contrast, when the second stage (PAC-AGS) was applied, 16 substances (including 1 TP) were confirmed. The number of substances detected in PAC-AGS decreased threefold compared to the conventional BR, with the total concentration decreasing sevenfold in PAC-AGS (1,400 ng/L) compared to the conventional BR (9,500 ng/L). In the effluent, the highest concentrations were found in the following order: valsartan acid (2,500 ng/L), irbesartan (780 ng/L), olmesartan (640 ng/L), Tris(2-butoxyethyl) phosphate (TBEP) (600 ng/L), and lidocaine (550 ng/L). Compared to the removal rates of the conventional BR, valsartan acid decreased by 81%, irbesartan by 100%, olmesartan by 54%, and both TBEP and lidocaine by 95%. The risk quotient (RQ) values of four substances (n-desmethyl tramadol, diclofenac, carbamazepine, venlafaxine), originally posing potential environmental risks with an RQ value of 1 or higher, were reduced to 0. Overall, the RQ estimate decreased from 190 (conventional BR) to 77 (PAC-AGS), confirming that the risk of residual substances during PAC-AGS treatment is reduced by more than two times compared to conventional BR treatment. These results affirm that PAC-AGS technology is more effective in removing micropollutants and reducing TP formation compared to conventional BR, ultimately decreasing the risk to aquatic organisms.

3.04.P-Th194 RHE-MEDiation Lighthouse: Responsive hub for long term governance to destress the Mediterranean Sea from chemical pollution

Rallis Lougkovois[1]*, Constantinos Parinos*[2]*, Georgios Gkotsis*[3]*, Maria-Christina Nika*[4]*, Alexandra Pavlidou*[2]*, Nikolaos S. Thomaidis*[4]*, Ioannis Hatzianestis*[2]*, Stylianos Samios*[5] *and Georgios Katsouras*[5]*, (1)Hellenic Center for Marine Research (HCMR), Greece, (2)Hellenic Centre of Marine Research, (3)Chemistry, National and Kapodistrian University of Athens, Greece, (4)National and Kapodistrian University of Athens, Greece, (5)Athens Water Supply and Sewerage Company S.A.*

Restoring and protecting the Mediterranean Sea from chemical pollution is one of the most urgent challenges of our time. That is because today, every stage of 'source to sea' applies heavy pressure to the entire water cycle. Decades of pollution and unsustainable energy use have severely degraded the quality of marine ecosystems. Major pressures include discharge, loss and leakage of chemicals. Plant protection products, pharmaceuticals, heavy metals and radioactive substances primarily originate from land-based sources, while marine transport and sea-based activities also contribute. Contamination is highest in coastal waters and toxic substances accumulating in seafood affect humans through the food chain. Ocean restoration is pivotal to the implementation of the United Nations' 2030 agenda for sustainable development, while the EU's implementation plan to restore waters by 2030 has paved the way for the International Ocean Governance 2022 agenda, a milestone for ocean governance. The new Horizon Europe project "RHE-MEDiation" supports the work of policy makers by providing advanced, ready-to-use remediation solutions for Mediterranean hotspots and a toolkit for monitoring and control, enabling the engagement of civil society at the same time. To characterize and prioritize emerging contaminants, additional research concerning major sources, transport pathways in open or deep-sea settings, determination techniques and adverse effects is required. Upon reaching the marine environment, many compounds are subjected to biochemical processes that produce transformation products, often more potent in terms of adverse impact to the environment and to human health than the parent compounds. Comprehensive monitoring of emerging contaminants demands wide-scope screening analytical techniques, which in turn provide better understanding about the chemical imprint of related anthropogenic activities. Scientists and scientific groups that take part in organizing strategies for the preservation of the Eastern Mediterranean aquatic ecosystem are also heralds of disseminating information resulting from related research. The RHE-MEDiation project also aims to enable knowledge transfer at national and international level by making holistic approaches in the field of organic geochemistry. This work has received funding from the European Union’s HORIZON EUROPE Research and Innovation Programme under the Grant Agreement No. 101113045.

3.04.P-Th195 Exploring the Potential of Vacuum-Assisted Evaporation Concentration for Improved Analysis of Very Polar Compounds: Comparing Analysis Platforms, Method Development and Method Validation

Lisa Marina Reinhardt, *Jan Christensen, Selina Tisler and Thomas Molnár Karlsson, University of Copenhagen, Denmark*

Studies reviewing the efficiency of current water analysis have pointed out a severe lag in analytical techniques covering very polar compounds. Especially persistent and mobile organic chemicals (PMOCs) which are known to be toxic to the environment and to humans. Therefore, there is a pressing need for the development of analytical methods able to analyse very polar compounds. This study developed and validated a vacuum-assisted evaporation concentration (VEC) as a water sample preparation method, with a particular focus on very polar compounds, such as PMOCs. The efficiency of the VEC method was subsequently compared to multiple-layer solid-phase extraction (SPE). Moreover, its compatibility with different chromatographic techniques was evaluated, including supercritical fluid chromatography (SFC) and reversed-phase liquid chromatography (RPLC). The developed VEC method, allowed the rapid evaporation of 100 mL samples. Of two tested evaporation endpoints, dryness and a residual volume of 0.3, evaporation to dryness was regarded as the preferred method due to the potential variability induced by salt deposition in residual volume evaporation. The high salt contents were also suspected to cause strong signal suppression in the applied RPLC-MS/MS analysis. The VEC recovery assessment resulted in recoveries spanning 40% to 60% for almost all compounds. In comparison to SPE, VEC resulted in overall lower recovery, but achieved higher VEC recovery for targeted very polar compounds. In conclusion, VEC has the potential to analyse very polar compounds including PMOCs. Further research is needed to determine the best analysis strategy for VEC concentrated samples, in order to further optimise and fully understand its capabilities.

3.04.P-Th196 Exploring the Absorption Dynamics of Benzophenone-3 and Octocrylene in Polyethylene and Polypropylene in Pure and Sea Water

Albert Contreras Llin[1], *Mariana Palape Oxa*[2], *Jose Manuel Diaz Cruz*[2] *and Silvia Diaz-Cruz*[3], *(1)Agencia Estatal Consejo Superior de Investigaciones Científicas, Spain, (2)Department of Chemical Engineering and Analytical Chemistry, Universitat de Barcelona, Spain, (3)Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain*

Benzophenone-3 (BP-3) and octocrylene (OC), commonly present in skincare products for UV protection, pose environmental risks when entering the ocean through activities like swimming or sewage discharge. Detected in marine environments, these compounds, known to bioaccumulate in aquatic organisms, contribute to issues like coral bleaching and tissue necrosis. Additionally, they could adsorb onto microplastics (MPs) which are likewise prevalent in marine environments. This study investigates the absorption capacity of polyethylene (PE) and polypropylene (PP) when exposed to BP-3 and OC, using a fractional factorial design for efficient resource utilization in experimentation.

The controlled experiments exposed the materials to both pure and seawater. The synthetic seawater serves as a simulation of a natural environment, providing a more realistic assessment of the absorption process. The experiments were performed by analysing the exposure solution over time, using both High-Performance Liquid Chromatography-Tandem Mass Spectrometry (HPLC-MS/MS) and Voltammetric determination (VD) using commercial screen-printed electrodes. HPLC-MS/MS is a powerful tool for the detection and quantification of analytes, providing high sensitivity, selectivity, and accuracy, while VD offers a straightforward working protocol and ease of miniaturization, making it an appealing tool for measuring contaminants of emerging concern even with the capability to perform on-site analysis.

The primary focus of this work is to assess the absorption capacity of PE and PP, providing valuable insights into their potential as both vectors of transport and mediums for the removal of these contaminants from water systems. A fractional factorial design was employed considering variables including temperature, salinity, exposure time, and pH. These selected variables encompass a diverse range of factors critical for assessing real-scale variations in the environment and understanding the absorption capacity of BP-3 and OC onto MP surfaces. The results of this study could have significant implications for the development of more effective and sustainable methods for water treatment and pollution control, as well as real-time on-site analysis with voltammetry. This research contributes to the broader understanding of the interactions between synthetic polymers and organic contaminants and could inform future strategies for environmental protection and waste management.

3.04.P-Th197 The Occurrence of Poly- and Perfluoroalkyl Substances (PFASs) and Potential Sources in the River Liffey, Ireland

*Leila Bowe[1], Belinda Huerta[2], Enrique Jacobo Díaz-Montaña[3], **Helen Burke**[4] and Fiona Regan[5], (1)DCU Water Institute, Dublin City University (DCU), Ireland, (2)Glasnevin, Dublin City University (DCU) School of Chemical Sciences, DCU Water Institute, Ireland, (3)DCU Water Institute, School of Chemical Sciences, Dublin City University, Ireland, (4)Dublin City University (DCU), Ireland, (5)Water Institute, Dublin City University (DCU) School of Chemical Sciences, DCU Water Institute, Ireland*

Decades of widespread use of poly- and perfluoroalkyl substances (PFAS) globally and in Ireland has raised concerns about potential legacy environmental contamination and their impact on human health. PFAS can enter the environment during manufacturing of substances, use of the substances themselves and through disposal. The persistence, bioaccumulation, toxicity and long-range transportation of PFAS compounds has meant that they are ubiquitous in the environment and have been detected globally in several sample types (soil, air, biota and water).

Recent research in Ireland has indicated the presence of PFAS in a variety of media, including surface water. Therefore, the main objective of this work was to characterise exposure risks to the environment and human health. 20 surface water samples were taken from sites along the river Liffey, between a tributary in Kildare to the sea. It was found that concentrations of up to 2 µg/L of individual PFAS compounds were detected along the river, with highest concentrations towards the sea.

To interpolate the nature and distribution of PFAS compounds along the river and identify potential links to upgradient sources, a 4-step hierarchical process was used.

1. Geographical proximity - The river Liffey flows through the centre of Dublin and is known to have legacy contamination. Known primary and secondary sources of PFAS in the catchment include civil (airports and fire stations), anthropogenic (wastewater treatment facilities and waste facilities) and industrial pressures (chemical manufacturing plants, paper and wood processing facilities and other industries with emissions licences).
2. Chemical footprint - Nowadays, there are 4700 identifiable PFAS compounds. Individual compounds have unique properties and different combinations are used by industries for specific purposes. By identifying unique compounds and distinguishable compound rations, a specific diffuse PFAS source can be inferred.
3. Dimensional calculation – A solute transport model was employed to predict the spatio-temporal fate of PFAS and infer proximity to industrial sources.
4. Dimensional modelling and cluster analysis was employed to refine the source identification.

In conclusion, with the data obtained the occurrence of different PFAS substances were linked to potential civil, anthropogenic and industrial sources in the River Liffey catchment, remarking the effect of the emission not only in the near environment but also in a further one.

3.04.P-Th198 An approach to the presence of the recent emerging organic contaminants adsorbed onto microplastics in the Canary Islands.

***Ludovit Schreiber**[1], José Juan Santana-Rodríguez[1], Maria Zoraida Sosa[2] and Sergio Santana-Viera[3], (1)University of Las Palmas de Gran Canaria (ULPGC), Spain, (2)Chemistry Department, Universidad Las Palmas de Gran Canaria, Spain, (3)Institute of Environmental Assessment and Water Research - Spanish National Research Council (IDAEA-CSIC), Barcelona, Spain*

Microplastics have traditionally been recognized as significant pollutants in marine environments. Their capacity to adsorb different organic substances, thereby serving as vectors of contamination, has been extensively researched. Numerous studies support this assertion. In our investigation, an approach to the occurrence of the most recent organic compounds from the Watch List compounds, in accordance with the criteria set by the European Union, adsorbed on microplastics was studied at the coastal areas of The Canary Islands.

For that, an ultrasound-assisted extraction method was optimized and employed as extraction process. The influence of the various factors affecting the extraction process was investigated through an experimental design with Minitab® software. This approach allowed us to evaluate the individual impact of each variable on the extraction process and the identification of potential correlations among these variables.

Following the extraction process, an ultrahigh-performance liquid chromatography system coupled with a triple quadrupole mass spectrometer (UHPLC-MS/MS) was used for the separation and detection of analytes. Several validation parameters were tested to determine the suitability of the proposed method for the compounds of interest.

Finally, the novel methodology was applied to analyze samples of microplastic fragments and plastic pellets gathered from various tourist and secluded beaches of Tenerife in the Canary Islands archipelago (Spain). The objective of this assessment is to ascertain the presence of these emerging contaminants adsorbed on the microplastic residues.

Acknowledgements**:** Ludovit Schreiber thanks the European Union his post-doc grant agreement No.101090291.

3.04.P-Th199 In-Depth Investigation of Organic Micropollutant Burden in the Dnieper River Basin Using HRMS-Based Workflows

Nikolaos Boinis[1], *Georgios Gkotsis*[1], *Konstantina Diamanti*[1], *Maria-Christina Nika*[1], *Nikiforos Alygizakis*[2], *Jaroslav Slobodnik*[2] *and Nikolaos S. Thomaidis*[3], *(1)Chemistry, National and Kapodistrian University of Athens, Greece, (2)Environmental Institute, Slovakia, (3)National and Kapodistrian University of Athens, Greece*

Organic micropollutants are constantly released into the environment due to various anthropogenic activities. The final receiver of these pollutants is usually the freshwater ecosystem, thus degrading the water quality and harming the organisms that live in these habitats. The occurrence of organic micropollutants has been globally reported in freshwater bodies, including sorption in sediments based on their physicochemical properties, findings that highlight their potentially harmful effects on environmental and human health. Consequently, monitoring studies on surface water and sediment samples are crucial for assessing the environmental quality standards and identifying the river basin specific organic micropollutants and their concentration levels.

The aim of this study is the in-depth investigation of organic micropollutant burden in the Dnieper River basin which belongs to the fourth longest river in Europe. In this framework, 12 surface water samples and 8 sediment samples were gathered from the Dnieper River in Ukraine during 2023. The sample analysis utilized complementary chromatographic techniques and ionization modes, coupled with high-resolution mass spectrometry (LC-ESI-QToF MS and GC-APCI-QToF MS). The data treatment consisted of wide-scope target screening protocols investigating the presence of more than 2,500 organic micropollutants from various categories, such as pharmaceuticals, per-and polyfluoroalkyl substances (PFAS), industrial chemicals and plant protection products, and their transformation products (TPs), as well as the suspect screening for 65,000 environmentally relevant organic micropollutants following suspect screening methodologies.

Preliminary results highlight the occurrence of industrial chemicals (benzotriazole, tolytriazole), pharmaceuticals (aceclidine, carbamazepine) stimulants (caffeine, nicotine, and the TP cotinine), and plant protection products (atrazine and the TP atrazine-desethyl, metolachlor). In addition, the results of this study were compared with the data gathered from the previous sampling campaign on the Dnieper River in 2020.

3.04.P-Th200 A comparative study of the presence of organic contaminants of emerging concern in two urban wastewater treatment plants from Canary Islands (Spain) and Tunisia.

Ludovit Schreiber[1], *Maria Zoraida Sosa*[2], *José Juan Santana-Rodríguez*[1] *and Hedi Ben Mansour*[1], *(1)University of Las Palmas de Gran Canaria (ULPGC), Spain, (2)Chemistry Department, Universidad Las Palmas de Gran Canaria, Spain*

The role of quality monitoring in municipal wastewater is pivotal for sustainable development. Wastewater treatment plants (WWTPs) play a crucial role as the primary source of emerging pollutants released into the environment and their persistence is often a challenge for conventional treatments. These emerging pollutants pose significant issues to water management due to their potential and definite environmental impact as well as potential risks to human health. To better understand their fate in the environment, monitoring systems must be established to ensure the acquisition of representative data regarding their presence.

This study focuses on the comprehensive analysis of wastewater samples obtained from two municipal WWTPs located in Las Palmas de Gran Canaria (Spain) and Mahdia (Tunisia), to identify and quantify emerging contaminants included in the lasted listed in the European Union (EU) Watch List.

In this way, an optimized solid phase extraction method was employed for the extraction process. Afterward, an ultrahigh-performance liquid chromatography system coupled with a quadrupole Time of Flight mass spectrometer (UHPLC-QToF) was utilized to detect and determine the analytes. Validation parameters were assessed to ascertain the appropriateness of the proposed method for the compounds of interest.

Water samples from both the influent and effluent of the two WWTPs studied were analyzed, and the obtained results were subsequently compared. This research contributes valuable insights into the presence of emerging contaminants in municipal wastewater systems.

Acknowledgements**:** Ludovit Schreiber thanks the European Union his post-doc grant agreement No.101090291.
Dr. Hedi Ben Mansour thanks the Spanish government his Maria Zambrano grant.

3.04.P-Th201 Determination of Glyphosate, Aminomethylphosphonic Acid (AMPA), and Glufosinate in Drinking Water Using Direct Analysis by Liquid Chromatography Tandem Mass Spectrometry

Stuart Adams[1], *Simon Hird*[1], *Benjamin Wuyts*[2] *and* ***Cecile Pinto***[3], *(1)Waters Corporation, United Kingdom, (2)Waters Corporation, Belgium, (3)Waters Corporation, France*

Reliable analytical methods are needed for detection, quantification, and identification of glyphosate, aminomethylphosphonic acid (AMPA), and glufosinate in drinking water. Accurate and reliable methods are required to monitor these widely used pesticides in drinking water from different sources. This work describes a simple direct analysis method, based on liquid chromatography coupled to tandem mass spectrometry (LC–MS/MS), which avoids the need for lengthy and laborious derivatization and solid-phase extraction (SPE). Samples of water were injected directly into the LC-MS/MS system (ACQUITY™ Premier UPLC™ System with Xevo™ TQ Absolute Tandem Mass Spectrometer) using the Anionic Polar Pesticide Column. The performance of the method was successfully evaluated in three different types of drinking water. The extremely high sensitivity of the Xevo TQ Absolute System was demonstrated with reliable detection for all three analytes at concentrations as low as 10 ng/L (0.01 µg/L). The performance of the method was evaluated in-house and by an inter-laboratory study using spiked water samples. Results from both studies showed that the trueness of the method was between 82 and 110%. Close agreement was observed with the repeatability, within laboratory reproducibility, and between laboratory reproducibility, all being <16% RSD. The method is considered sensitive, specific, accurate, and suitable for the determination of these challenging analytes in a range of different types of drinking water, for checking compliance with regulatory limits, and to support studies focusing on human exposure.

3.04.P-Th202 Improved compound identification in GC-MS analysis using an EI&CI-TOFMS

Marleen Vetter*, Steffen Braekling and Sonja Klee, TOFWERK AG, Switzerland*

A time of flight (TOF) mass spectrometer simultaneously operating an electron ionization (EI) and a chemical ionization (CI) source is presented for non-target analysis. By coupling both ionization sources directly to one single gas chromatograph (GC), structural as well as accurate mass molecular ion information is generated simultaneously from each analyte. Hence, target and suspect screening analysis as well as effective non-target analysis using GC-MS is improved considerably. In this poster, various experiments will be discussed, illustrating the potential of the GC-EI&CI TOFMS especially for non-targeted approaches, including applications in fields such as environmental contaminants, material emissions, food and flavor analysis and metabolomic research.

An Agilent 6890A GC was coupled to an EI&CI TOFMS (ecTOF, TOFWERK, Thun, Switzerland), using a 70 eV EI source and the newly developed Tofwerk HRP CI source. Various GC methods and sampling procedures were employed depending on the analytical need of the study, including liquid injection of extracted samples, headspace sampling including SPME and thermal desorption using Tenax tubes. To generate the ideal molecular ion information different reactant ions (e.g., $[NH_4]^+$, $[N_2H]^+$, $[H_3O]^+$) were used for the chemical ionization process.

Standard procedures employed by routine laboratories, e.g., target screening for (material) emissions or detection of unknown volatile constituents in consumer products and within the environment, are shown to be feasible using the GC-EI&CI TOFMS. Whilst standard methods mainly focus on target analysis, suspect screening is improved and non-target analysis enabled using the GC-EI&CI TOFMS. Especially when EI library hits are fair with low corresponding probability, chromatographic and CI information can be used to increase compound identification confidence. False positives from an EI only approach can easily be identified and often correctly annotated using the additional information from the GC-EI&CI TOFMS. Furthermore, compounds that are not listed in libraries have a high uncertainty for identification using an EI only approach. Using the accurate mass information generated by CI, molecular sum formula for these unknowns can be derived. Combining this with the structural information generated by EI, tentative structure elucidation becomes feasible in many cases. Hence, non-target approaches become viable using the GC-EI&CI TOFMS.

3.04.P-Th203 Tidal influence on the distribution and partitioning of pharmaceuticals in estuarine environments

Ruben Rios-Quintero[1]*, Pablo Antonio Lara Martín*[2] *and Marina G. Pintado Herrera*[2]*, (1)University of Cadiz, Cadiz, Spain, (2)Universidad de Cadiz*

Coasts are the interface between land and the ocean, the vastest ecosystem on Earth. They are undergoing tremendous socioeconomic and environmental changes due to increasing utilization and development. Pharmaceutically active compounds (PhACs) have been described as “pseudo-persistent” pollutants due to their continuous release and may present a threat to marine ecosystems. Estuaries are very dynamic environments, concentrations of contaminants are strongly affected environmental factors. This works focuses on the study of spatio-temporal variations in the concentrations of a wide range of PhACs and other sewage-derived contaminants during tidal events in several estuaries from SW Spain. Different economic activities take place at these sites (Guadalquivir, Guadalete, and Barbate estuaries), including aquaculture, maritime traffic, and wastewater discharges from industries and urban areas.

Water (n = 120) and surface sediment samples (n = 50) were collected including sampling of tidal events. Sediment samples and suspended solids resulting from filtering of aqueuos samples underwent pressurized liquid extraction (PLE). Those extract and water samples were collected to use a multiresidue method based on solid-phase extraction (SPE), followed by ultra-performance liquid chromatography-triple quadrupole spectrometry (UPLC-MS/MS).

Thirty-seven out of 109 compounds were detected in our samples, with Sucralose, Fenoprofen, Gemfibrozil, and Caffeine accounting for the highest frequency of detection (>80%) and concentration (>10 ng mL^{-1}). Concentrations of PhACs were usually higher in upstream stations with respect to the stations located closer to the mouth of the river. A conservative behavior was observed for many of them, such as a carbamazepine, which showed a linear decrease in relation with salinity changes along the estuaries and within tidal cycles. Those concentrations were clearly influenced by tidal events, with values rising during low tides and decreasing during high tides due to the dillution with cleaner ocean water.

PhACs were also detected in suspended solids and surface sediments at higher concentrations (ng g^{-1}) than in the aqueous samples. Partitioning was established by determination of water/sediment and water/suspended solids ratios. Such ratios were directly related with the hydrophobicity of the different target compounds (log K_{ow}), but no significant changes were detected along the estuary and within tidal cycles.

3.04.P-Th204 Factorial Design Optimization of a Bioanalytical Method Using Low-Temperature Purification Extraction (LTPE) and LC-MS/MS to Determine Levamisole in Fish Meat

Lucas Victor Pereira de Freitas[1]*, Ana Luísa Bigliassi Alponti*[1]*, Sarah Chagas Campanharo*[1]*, Marina Alves Damaceno*[1]*, Agnaldo Fernando Baldo da Silva*[1]*, James Jacob Sasanya*[2]*, Susanne Rath*[3] *and Jonas Augusto Rizzato Paschoal*[1]*, (1)Department of Biomolecular Sciences, School of Pharmaceutical Sciences of Ribeirão Preto, University of São Paulo (USP), Brazil, (2)International Atomic Energy Agency, Austria, (3)Department of Analytical Chemistry, Institute of Chemistry, University of Campinas, Brazil*

Aquaculture has been the fastest-growing food production sector in the world. However, the spread of diseases is one of the biggest limitations of this system, mainly due to the reduced number of regulated drugs. In this scenario, levamisole, an anthelmintic and immunostimulant drug, has been studied as a promising alternative for fish farming. Investigations of drug residue depletion in the target animals are demanded for medicines aimed at food-producing animals. For so, the availability of high-sensitivity and selectivity analytical methods for the determination of drug residues at trace concentrations in fish meat (muscle plus skin in natural proportion) is underlying, which is highly critical when considering complex matrix such as fish fillet. For so, this study aimed to optimize a novel bioanalytical method following a sample preparation involving a low-temperature purification extraction (LTPE) procedure associated with analysis by high-performance liquid chromatography-tandem mass spectrometry (LC-MS/MS) for determination of levamisole residues in fish meat. A fractional factorial design was employed to select the variables which affected the sample preparation procedure. The results showed that the addition of ammonium hydroxide (NH_4OH) in the extraction phase, amount of primary secondary amine (PSA) in the clean-up, centrifugation temperature, and centrifugation time were statistically significant at the tested levels. To determine the best extraction conditions, a final optimization of these significant parameters was performed by using a central composite design (CCD). The optimum conditions for levamisole extraction by LTPE were achieved by using 1.0 g of sample, 2.0 mL of acetonitrile containing 1% NH_4OH, freezing time of 30 min, centrifugation at 2,900 xg for 2 min at -5° C, and clean up step with 100 mg of PSA. The LC-MS-MS analysis was conducted with a mobile phase composed of methanol and water, both with 0.5% formic acid under isocratic elution (85:15 v/v). The electrospray interface source was set to operate in positive mode. Therefore, multivariate optimization allowed us to obtain a bioanalytical method with high efficiency (extraction efficiency > 90%), adequate selectivity and detectability (LOQ = 1 ng g^{-1}) for levamisole quantification at residual concentrations (1-100 ng g^{-1}) in fish meat.

3.04.P-Th205 Occurrence and Trophodynamics of Organic UV Filters, Benzotriazole UV Stabilizers and Aromatic Secondary Amines in the Food Web of the St. Lawrence Estuary Beluga Population.

Alexis Eric Adrien Trinquet[1]*, Mathieu Babin*[2]*, Jonathan Verreault*[3]*, Véronique Lesage*[4]*, Jory Cabrol*[4]*, Stephane Lair*[5]*, Gerald Tetreault*[6] *and Zhe Lu*[7]*, (1)Institut des Sciences de la Mer de Rimouski, Canada, (2)CIRAD - Centre de coopération internationale en recherche agronomique pour le développement, Canada, (3)University of Quebec at Montréal, Canada, (4)Maurice Lamontagne Institute, Fisheries and Oceans Canada, Canada, (5)University of Montréal, Canada, (6)Environment and Climate Change Canada (ECCC), Canada, (7)Institut des Sciences de la Mer de Rimouski (ISMER), University of Quebec at Rimouski (UQAR), Canada*

Organic UV filters (UVFs), benzotriazole UV stabilizers (BTZ-UVs), and aromatic secondary amines (Ar-SAs) are contaminants of emerging concern in the environment that may cause adverse health effects in organisms. A previous study detected some of these contaminants in the blubber and liver beluga (*Delphinapterus leucas*) from the St. Lawrence Estuary (SLE), a population that is considered endangered in Canada. However, the trophodynamics of these contaminants in the food web of SLE beluga is currently unknown. To fill this knowledge gap, tissues were collected from 17 known and potential prey (n=183 including 15 fish species and 2 invertebrates) of SLE beluga in 2019 and 2020 to investigate the biomagnification patterns of selected UVFs, BZT-UVs and Ar-SAs in the SLE beluga's food web. Carbon sources and trophic position of all beluga preys items were determined using stable carbon ($\delta^{13}C$) and nitrogen ($\delta^{15}N$) isotope ratios, respectively, and used to identify most probable dietary sources based on their respective contaminant loads. Contaminant levels, which were determined using gas chromatography and mass spectrometry (GC-MS/MS), showed decreasing concentrations from UVFs, to BZT-UVs and Ar-SAs. Except for BP, all UVFs were frequently detected (>50%) in the 17 prey species. The most common compounds detected were five UVFs (BP3, EHMC, EHS, HMS, OC) and four BZT-UVs (UV326, UV320, UV328 and UV327). Of the target contaminants with 100% detection in the 17 prey species, UVP, UV328, total BZT-UVs, HMS, BP3, and total UVFs were positively associated with $\delta^{15}N$, indicating that these contaminants were biomagnified in the SLE food web. Although mean levels of EHS and OC that were analyzed were not associated with $\delta^{15}N$, positive correlations were identified when considering all individuals in the analysis, suggesting that EHS and OC may also biomagnify in the SLE food web. UV327 and EHMC were found in all prey samples but were uncorrelated with $\delta^{15}N$. This study provides a baseline for monitoring these contaminants in the SLE beluga food web and contribute to a better understanding of the environmental fate of these contaminants in the estuarine environment.

3.04.P-Th206 Atmospheric Pressure Ionization GC/MS/MS of Multi-Class Semivolatile Organic Compounds: Reducing Environmental Impact Without Compromise

*Douglas Michael Stevens[1], Frank Dorman[1] and **Cecile Pinto**[2], (1)Waters Corporation, (2)Waters Corporation, France*
The analysis of multi-class, semivolatile organic compounds (SVOCs) in environmental matrices is a common analysis in labs around the world. Therefore, modernizing SVOC analytical methods has the potential to reduce the environmental impact that labs themselves have on the environment. An important aspect of reducing the environmental impact of SVOC methods is reducing solvent consumption associated with sample preparation. Gas chromatography atmospheric pressure chemical ionization (GC-APCI) produces intense molecular ions for most analytes. When combined with tandem quadrupole MS/MS then, the sensitivity of GC-APCI combined with MS/MS directly contributes to the improved environmental sustainability of SVOC analytical methods. Furthermore, GC-APCI is readily adaptable to the use of nitrogen as an alternative carrier gas to helium. In this work we will determine if the same benefits are achievable for SVOCs on a new generation of mass spectrometer with reduced electric consumption and heat output.

A previously developed helium carrier gas based SVOC method was adapted for the use of nitrogen carrier gas by scaling the column dimensions to achieve equivalent chromatographic separation and runtime. Following method development on the latest model tandem quadrupole the dry source method was transferred to a previous generation tandem quadrupole. That system was operated with helium carrier gas and argon CID gas using the same MRM transitions as the all nitrogen system in order to generate comparative data.

Both the all-nitrogen system and the one using helium carrier achieved equivalent chromatographic separations and sensitivity. The equivalency of the data across the two configurations demonstrates the feasibility of both for performing quantification of multi-class SVOCs extracted from environmental matrices at sensitivity levels compatible with the scaling of sample preparation to reduce solvent consumption while also using a split injection to reduce matrix loading on the column.

3.04.P-Th207 A Water Quality Stocktake: Identification of Priority Emerging Pollutants in Waters of England and Northern Ireland

***Ed Stutt**[1], Iain Wilson[1], Hazel Vallack[2] and Vera Jones[2], (1)wca environment Ltd., United Kingdom, (2)AtkinsRéalis, United Kingdom*
An investigation was undertaken for the Office for Environmental Protection (OEP) with the aim of bringing together the latest scientific understanding on chemicals in the water environment in England and Northern Ireland. The primary focus was on ‘emerging pollutants’ and 'pollutants with significant new insights’ because of the need for early identification of chemicals of concern, so that effective intervention can be undertaken prior to damage being caused to the environment, wildlife or human health. This review considered broad use categories for chemicals that included biocides, pharmaceuticals, industrial chemicals, personal care products, veterinary medicines, and endocrine disrupting chemicals.

A stepped approach was followed to identify relevant pollutants of greatest concern. An initial literature review identified 194 chemicals of most interest, which were then narrowed down to a shortlist of 74 classed as ‘emerging’ or with ‘significant new insights’. Many of the substances could be grouped together, resulting in a total of 25 pollutants/categories of interest (9 individual substances and 16 groups) that were the subject of factsheets that compiled information on their primary sources, ecological & human health impacts and relevant legislation. The aim of the factsheets was to provide an accessible and objective summary of the key pollutants and support prioritisation for further work.

Focussed risk assessment was undertaken for an initial set of 7 priority substances selected to ensure that there was a representative for each use category and on the basis of specific concerns highlighted in the factsheets. Risk assessment focused on the spatial extent of pollution as indicated by mapping of monitoring data, the magnitude of risk currently posed to the natural environment and human health & how this may evolve over time. Of the pollutants considered 1,4-dioxane (an industrial solvent) and fipronil (an insecticide used in flea treatments for pets) were considered to present the highest risk to the aquatic environment. Galaxolide (fragrance used in household products) and bisphenol A (utilised in plastics and polymers) were also found to pose a relatively a high risk. The pharmaceutical diclofenac appeared to present a high risk in England, but a low risk in Northern Ireland. Climbazole (a fungicide used in personal care products) and the pharmaceutical substance carbamazepine present a moderate level of risk.

3.04.P-Th208 Environmental Assessment of Tire-Road Wear Particles and Tire Rubber Additives in Water and Biota Samples from Llobregat River Delta

***Francesca De Angelis**[1], Merce Gari[1] and Nicola Montemurro[2], (1)Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain, (2)Department of Environmental Chemistry, Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain*
Tire-Road Wear Particles (TRWPs) originate from the abrasion caused by the interaction between vehicle tires and road surfaces. Recent studies highlighted the significant role of TRWPs in contamination of environmental compartments such as soil, water, air and, biota. These particles, which include synthetic rubber, fillers, softeners, vulcanizing agents, and additives, pose ecological and health concerns. Specifically, Tire Rubber Additives (TRAs) and their Transformation Products (TPs) have raised interest due to their possible toxicity. The compound N-(1,3-dimethylbutyl)-N′-phenyl-p-phenylenediamine (6PPD), finds wide use in tire manufacturing and research proved the lethal effects of his TP, 6PPD-quinone on coho salmon.

Other common TRAs include Hexamethoxymethyl melamine (HMMM), 1,3-diphenyl guanidine (DPG), 1,3-dicyclohexylurea (DCU), N,N-dicyclohexylmethylamine (M-DCA), and benzothiazole (BT).

This study explores the presence of TRAs and TPs in the Llobregat River Delta (Catalonia, Spain), an area comprising the second-biggest Spanish airport surrounded by urban, agricultural, industrial, and natural protected spaces. Water and biota (fish and macroinvertebrates) samples were collected in a sampling campaign covering 6 different sites. A preliminary analysis focuses on the quantification of six common TRAs and 6PPD-quinone. Sample preparation for water (n=14) required solid phase extraction (SPE) with Oasis HLB, whereas a more complex protein and lipid clean-up was implemented for biota samples (n=21). Different extraction solvents and SPE cartridges have been evaluated and compared based on analyte recovery and matrix effect. The instrumental analysis was performed by Liquid Chromatography coupled to High-Resolution Mass Spectrometry (LC-HRMS).

To date, the potential environmental and health impacts of TRWPs are unknown, mainly due to the lack of reliable data, the limited number of samples studied, the diversity of compounds, and the methodological challenges. The application of this method, and its extension to a larger number of compounds can help monitor the environmental fate of tire rubber additives and risk assessment.

Acknowledgments - The authors acknowledge the support of the Economy and Knowledge Department of the Catalan Government through Consolidated Research Group (SGR01150 and SGR00986). This work falls under the TRANSIT national project (PID2022-138623OA-100) funded by the Spanish Ministry of Science and Innovation.

3.04.P-Th209 A Novel approach in addressing the challenges of monitoring multi-classes of POPs in a single run by GC-Ion Moblity-HRMS

Carsten Baessmann[1]*, Noud van der Borg*[2]*, Arnd Ingendoh*[3]*, Javier Lopez*[4] *and Miguel Angel Perez*[4]*, (1)Bruker Daltonics GmbH, Germany, (2)Bruker Nederland B.V., Netherlands, (3)Bruker Daltonics GmbH & Co. KG, Bremen, Germany, (4)Bruker, Spain*

Polychlorinated dioxins and furans are bio-accumulative molecules largely formed during combustion and industrial manufacturing processes. Their analysis is complex due to low level regulatory exposure limits and difficult sample matrices. Both are considered as persistent organic pollutant (POP) and could be widely found in environmental samples. Principal consequences derived from dioxins and furans exposure, even at low concentrations, are cancer, reproduction and growth issues, immune system diseases and endocrine effects. This is similar for another POP family, the polychlorinated biphenyls. It consists of 209 congeners, 12 of them known as “Dioxin-like PCBs”. Applications for these compounds are heat transfer fluids, dielectric components and coolant fluids for electrical components. Even though their manufacturing was drastically decreased in the 1960’s due to the proved toxicity, their chemical stability and lipophilicity cause some congeners to still be found today in environmental samples, like soils and sediments. Most reported health effects are dermal and ocular lesions, lowered immune responses, mutagenic effects, breast cancer and poor cognitive development in and motor control problems.

These species are mainly analyzed by high-resolution sector field mass spectrometry. We propose here a novel workflow involving ion mobility as an orthogonal criterion for identification and quantification, coupled to a high-resolution QTOF mass spectrometer. The benefit is a high flexibility for analyzing various classes of compounds in the same GC run with high sensitivity.

1 uL samples were separated by GC (35 min run time, Restek 60 m 0.25 mm id 0.25 um column, HxCDD and HxCDF separation). A GC-APCI source was coupled to the timsTOF Pro 2 (Bruker) which enables fast and sensitive analysis of Dioxins, Furans and PCBs in the very same run. Criteria for validation and quantification of compounds were high mass accuracy, retention time, isotope pattern matching, MS/MS qualifiers and collision cross sections (CCS) from ion mobility filtering. Kendrick mass defect plots were applied for the extraction of the specific area of compounds containing Cl or Br from the complete GC/MS chromatogram.

All PCBs have been detected at an LOD of ≤10-20 ppt. The dioxins were detected down to levels of 25-125 ppt, depending on the individual compound. Examples of the analysis of real-life samples like rapeseed oil, milk fat, sludge extract and ash are presented.

3.04.P-Th210 Analysis of rubber-derived contaminants in surface water by liquid chromatography coupled with a hybrid linear ion-trap-Orbitrap high-resolution mass spectrometry.

Julie Anquetin[1]*, Mathieu Babin*[2]*, Rachid Amara*[3] *and Zhe Lu*[2]*, (1)University of Quebec at Rimouski (UQAR), Canada, (2)Institut des Sciences de la Mer de Rimouski (ISMER), University of Quebec at Rimouski (UQAR), Canada, (3)UMR 8187 - LOG – Laboratoire d'Océanologie et de Géosciences, Univ. Littoral Côte d'Opale, CNRS, IRD, Univ. Lille, France*

Rubber-derived organic contaminants are of emerging environmental concern because of their potential risks to aquatic organisms. For example, N-(1,3-dimethylbutyl)-N′-phenyl-p-phenylenediamine-quinone (6PPD-Q), which is a transformation product of the antioxidant 6PPD used in tires, has been identified to induce acute mortality in spawning coho salmon. However, the occurrence and fate of these contaminants in the aquatic environment are largely unknown, in part due to the limited analytical methods available. Therefore, the objective of this study is to develop a method to analyze five PPD-Qs and four amine and urea-type rubber additives in the dissolved phase and suspended particulate matter of riverine and estuarine surface waters. The developed method extracts the dissolved phase using solid phase extraction (SPE) by hydrophilic-lipophilic balance cartridges. The suspended particulate matter was extracted using ultrasonic-assisted extraction followed by SPE cleanup. The separation and quantification were achieved by reversed-phase C8 chromatography coupled with positive electrospray ionization linear ion-trap-Orbitrap high-resolution mass spectrometry. Linearity for all compounds throughout the 12-points calibration range was >0.99. The instrument detection limit was from 0.098 to 12.5 ng/mL. The absolute recovery range was 5 to 90 % for HPLC water, 2 to 85% for environmental water, and 22 to 99% for suspended particulate matter. The surface water samples collected from the Rimouski River and the St. Lawrence River and Estuary (Canada) will be used to determine the limits of detection and quantification and validate the method. To our knowledge, this is the first research to use a hybrid linear ion-trap-Orbitrap mass spectrometry to analyze the four amine and urea-based rubber additives and five PPD-Qs in the dissolved phase as well as the suspended particulate matter of riverine and estuarine surface waters. The developed method will contribute to a better understanding of the occurrence and partitioning of these contaminants in water, which are key environmental processes affecting exposure risks.

3.04.P-Th211 Monitoring and Risk Assessment of Contaminants of Emerging Concern in the Middle Tagus River Basin (Central Spain)

***Cristina de los Reyes Ramos**[1], Alfonso Fernández García[2], María Jiménez Moreno[3], Nuria Rodríguez Fariñas[3], Francisco Javier Guzmán Bernardo[3], David Moreno González[2], Beatriz Larraz Iribas[4], Susana Seseña Prieto[3] and Rosa C. Rodríguez Martín-Doimeadios[3], (1)Analytical Chemistry and Food Technology, University of Castilla-La Mancha (UCLM), Spain, (2)Physical and Analytical Chemistry, Jaén University, Spain, (3)Analytical Chemistry and Food Technology, Castilla La Mancha University (UCLM), Spain, (4)Applied Economics, Castilla La Mancha University (UCLM), Spain*

The Tagus River and its tributaries in Central Spain are crucial for over six million inhabitants (more than five million of them concentrated in the Madrid area). Unfortunately, overpopulation and related wastewater treatment plants, many different industries, and agricultural and livestock activities are also concentrated in the central area where tributaries from the Madrid region discharge. In this context, the environmental risk by contaminants of emerging concern (CECs) is very serious and the information about the pollution state of the river is very scarce. Therefore, the aim of this project has been the monitoring of the pollution state and risk assessment in the Tagus River before and after the Jarama River confluence (Madrid city input) in a downstream cross section of one hundred kilometers.

Waters were sampled from 19 sites, specially selected considering the presence of livestock and agricultural farms, pharmaceutical industries, and wastewater treatment plants. Six sampling campaigns were carried out seasonally along 2022 and 2023. To have a general picture of the area, the samples were analyzed for more than 50 parameters, including those of physicochemical nature, and those reporting the pollution caused by both metals and organic matter. However, the focus was the study of CECs (primarily pharmaceuticals). To undertake this study, a sensitive and selective liquid chromatography tandem mass spectrometry (UHPLC-MS/MS) method has been developed for the determination of over CECs. The separation was performed by using a reversed phase C18 column Zorbax Eclipse Plus RRHD (2.1 mm × 100 mm, 1.8 μm). Mobile phase was water and acetonitrile both them with 0.1% of formic acid. The mass spectrometer was a TSQ Quantiva triple quadrupole analyzer (QqQ) (Thermo Scientific, USA) operating in selected reaction monitoring. To isolate the analytes from the sample, a solid phase extraction (SPE) using the HLB sorbent was employed.

Preliminary results showed a serious degradation state in this area. The pharmaceutical industries and the highly populated areas cause a significant input of CECs, being a hotspot for antibiotics and antimicrobial resistance (AMR). In general, the concentration of those compounds decreases downstream, but not for all the CECs. A huge number of samples and analytes are still under data treatment, and more focused and detailed conclusions are expected.

3.04.P-Th212 Development of an Analytical Method based on micro-Matrix Solid Phase Dispersion Combined with Gas Chromatography -Mass Spectrometry for the Determination of Bisphenols in Mussel Samples

*Rebeca Fernandez[1], Isabel Garcia[1], Maria Ignacio[1], Sergio Soñora[1], Ana Mouteira[1] and **Nieves Carro**[2], (1)Chemical pollution, INTECMAR, Spain, (2)Chemical pollution, INTECMAR (Techonological Institute for the Control of the Marine Environment of Galicia), Spain*

Bisphenols (BPs) are widely used in manufacture of different products as paints, adhesives and plastics. They are added to plastics during production in order to improve their properties for industrial and domestic applications. As BPs are weakly bound to the polymer matrix, are susceptible to migration from plastics to marine environment. In environmental samples, BPA and its analogues have been found in marine water, sediment and biota in high concentrations.

The main aim of this paper is to develop a cheap, easy and fast method based on a miniaturized matrix solid phase dispersion (*micro*-MSPD) combined with GC-MS (mode SIM) by using a factorial design which is capable of determination of nine BPs in mussel samples. The bisphenols analysed are BPAF (2,2-Bis (4-hydroxylphenyl) hexafluoropropane), BPF (bis (4-hydroxyphenyl) methane), BPE (4,4’-ethylidenebisphenol), BPA (2,2-bis (4-hydroxyphenyl) propane), BPG (2,2-Bis(4-hydroxyl-3-isopropylphenyl) propan), BPC2 (1,1-dichloro-2,2-bis(4-hydroxyphenyl) ethylene), BPZ (1,1-Bis(4-hydroxyphenyl) cyclohexane), BPS (4,4’-sulfonyldiphenol) and BPM (4,4’-(1,3-phenylenediisopropylidene) bisphenol). The sample preparation was made using Agilent Captiva EMR-lipid as dispersant and cleanup agent. To increase volatility, enhance chemical and thermal stability and reduce polarity of analytes, derivatization with 99% N,O-Bis-(trimethylsilyl)trifluoroacetamide+1% trimethylchlorosilane (BSTFA+1% TMCS) was necessary. Validation has been successfully achieved for linearity, LOQ, recovery and precision. The validated method has been applied to five mussel samples coming from Galician Rías.

This method has several advantages when compared with other conventional extraction techniques as it is less time consuming and cheaper and it uses less solvent volumes.

Acknowledgments**:** This resear**c**h was funded by the Spanish *Agencia Estatal de Investigación* MCIN/AEI/10.13039/501100011033 through the project PID2020-117686RB-C32.

3.04.P-Th213 Multicompound method for the ultra-sensitive quantification of non-polar pesticides in Swiss rivers and effluents

Vera Ganz[1]*, Kim Luong*[2] *and Heinz Singer*[1]*, (1)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (2)Environmental Chemistry, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland*

Studies have shown that pyrethroids pose a major risk to aquatic organisms in small and medium-sized watercourses in Switzerland. These substances are toxic even in the low pg/L range. They tend to sorb to particles and accumulate in non-target organisms due to their high hydrophobicity and are the major contributors to ecotoxicological risk. However, detailed information on the occurrence, sources and input pathways of pyrethroids and other non-polar pesticides is missing. A sensitive multi-method is essential to investigate their occurrence in selected wastewater treatment plants and small watercourses, enabling the quantification of both dissolved and particle-bound concentrations. Obtaining the total concentration is indispensable for a proper risk analysis of non-polar compounds.

For this purpose, an existing liquid-liquid extraction (LLE) followed by gas chromatography atmospheric pressure chemical ionization (GC-APCI) coupled to a triple quadrupole (QqQ) mass spectrometer (MS) method for pyrethroids and organophosphate insecticides was further developed in order to facilitate the quantification of non-polar pesticides in the dissolved and particle-bound fraction (Rösch et al. 2018).

The compound list was expanded by about 70 PPPs and biocides with logP>4, notably, carbamates, diazines, coumarin rodenticides, etc. along with additional isotopically labelled internal standards. To quantify the widest possible range of substances, the extract was split and analyzed using complementary chromatography and ionization methods, namely GC-APCI and liquid chromatography electrospray ionization (LC-ESI), both coupled to a QqQ-MS. Hexane and cyclohexane as well as a combination of both, were tested as extraction solvents. Absolute recoveries were determined for each substance across the individual steps of the sample preparation, including the extraction from the water phase, addition of Na_2SO_4 to dry the extract, evaporation by nitrogen and the dissolution. The limits of quantification (LOQs) for 60% of the compounds in the final method range from 10 to 500 pg/L, 37% have LOQs even under 100 pg/L.

The performance of the developed method will be demonstrated through the initial findings obtained from wastewater and river samples collected during a field campaign in Switzerland.

3.04.P-Th214 DIRECT AQUEOUS ANALYSIS OF PESTICIDES AND PPCPS IN DRINKING AND BOTTLED WATER AT PARTS PER TRILLION LEVELS

Daniel McMillan[1]*, Bertram Nieland*[2]*, Jianru Stahl-Zeng*[3]*, Jack Steed*[1] *and Ian Moore*[4]*, (1)SCIEX, United Kingdom, (2)SCIEX, Netherlands, (3)AB Sciex Germany GmbH, Germany, (4)SCIEX, Canada*

Drinking water analysis is subjected to extremely low and rigid prescribed consent values (PCV) for determinands. Water suppliers and utility companies need to ensure that the final water product they send out for bottling or into supply networks is safe and complies with state and country regulations. Water can be a challenging matrix, in particular if it is sourced from a river, lake or reservoir before entering the water treatment process.

Here, a series of experiments was conducted in collaboration with Vitens Water Company, to test several types of water samples spiked with a mixed standard of 431 determinands, including pesticides, pharmaceuticals and personal care products.

Direct aqueous injection was performed of spiked water samples - MilliQ water, tap water, Evian bottled water and Fiji bottled water. The samples were spiked with a custom mix standard, containing 431 analytes. A series of 11 standards were made in the respective matrices at sequential concentrations from 0.1 to 500 ng/L. A collection of unknown blank samples was also included in this study. The analysis was performed using a SCIEX 7500 system, operated in both positive and negative electrospray ionization with fast polarity switching.

The analytical method presented shows ultra-high levels of sensitivity with LOD values of 0.1 ng/L reported. All data was acquired through direct aqueous injection with no SPE needed. Good chromatographic peak-to peak separation was achieved with a total run time of 25 minutes. Even at low level concentrations, excellent levels of precision and accuracy were achieved (e.g. %CV ≤6.76 at 0.1 ng/L). There is scope to expand the number of analytes tested and apply this system to other individual workflows which demand very low limits of quantification. This method provides solutions for drinking water analysis and problematic determinands such as dicamba.

3.04.P-Th215 Exploring the impacts of primary and secondary aerosols from emerging sources on human health

Aristeidis Voliotis[1], *Cyrill Bussy*[2], *Olivia Jackson*[1], *Gordon McFiggans*[1], *Andrew Trafford*[1] *and Hugh Coe*[1], *(1)University of Manchester, United Kingdom, (2)Division of Immunology, Immunity to Infection and Respiratory Medicine, School of Biological Sciences, University of Manchester, United Kingdom*

Atmospheric fine aerosols was the fifth mortality risk factor in 2015, causing 7 million deaths and 203.1 million disability adjusted life years (DALY). Sources of air pollution in the indoor and outdoor environment include vehicle emissions, biomass burning, cleaning products, and many other anthropogenic and natural sources. More recently, the emissions from the usage of volatile chemical products, such as pesticides, coatings, flame-retardants, adhesives, cleaning agents, and personal care products are rising. Despite some success in mitigating air pollution in certain countries, 90% of the world's population still live in areas exceeding the guidelines of the World Health Organisation. The hazard quantification of the human exposure to atmospheric aerosols is largely derived based on epidemiological studies however, to date, little is known for the mechanisms that underpin the exposure and can induce biological responses.

Recently, in-vitro toxicological studies have revealed the inflammatory responses of cell lines from the exposure to aerosol particles from a number of sources. However, the majority of the studies on VCPs are focused on the quantification of primary emissions from indoor or outdoor sources. An increasing number of studies have showed that VCPs can react efficiently with atmospheric oxidants, such as the hydroxyl radicals, leading to the formation of a plethora of currently unknown secondary species, known as secondary organic aerosols (SOA). Exposure to SOA has been strongly associated with cardiorespiratory disease mortality, while laboratory studies have showed that SOA exhibit increased toxicity with atmospheric transformation processes. Despite this evidence, the environmental persistence and health impacts of the VCP-SOA remain unknown.

This work aims to provide novel chemical and biological descriptions of the atmospheric behaviour and impacts of pesticides as representative VCPs. By developing novel experimental multidisciplinary techniques, this work investigates the atmospheric fate, the SOA formation potential, and physicochemical characteristics of selected pesticides atmospherically relevant conditions. Further, standardised sampling protocols have been developed to demonstrate the capability for accurate biological assessment of their health hazards. This will be the first study of its kind to systematically investigate such complex systems.

3.04.P-Th216 Towards Standardization of the Biomimetic Extraction using Solid-Phase Microextraction (BE-SPME) Analytical Method

Tara Reddington[1], *Asfaw Bekele*[2], *Aaron Redman*[3], *Abraham Smith*[3], *Alexander M. Cancelli*[4], *Linso Varghese*[5], *Lingling Yang*[6], *Tim Leshuk*[7], *Christoph Aeppli*[8], *Kieran Armstrong*[9], *Magdalena Rakowska*[10] *and* ***Barry C Kelly***[4], *(1)Exxon Mobil, (2)Imperial Oil, Canada, (3)ExxonMobil Biomedical Sciences, Inc., (4)Simon Fraser University, Canada, (5)ExxonMobil Research Qatar, Qatar, (6)University of Alberta, Canada, (7)H2nanO Inc., Canada, (8)Bigelow Laboratory for Ocean Sciences, (9)H2Nano, Canada, (10)Texas Tech University*

Biomimetic extraction using solid-phase microextraction (BE-SPME) is a passive sampling analytical method that can predict the aquatic toxicity of complex petroleum substances. The method provides a non-animal biomonitoring alternative to traditional bioassays that can reduce both vertebrate and invertebrate aquatic toxicity testing. The technique uses commercially available polydimethylsiloxane-coated fibers that, following non-depletive extraction of water samples, are injected into a gas chromatograph with flame ionization detection. During BE-SPME analysis, the solid-phase microextraction step can be conducted either manually or using an autosampler. Recent round robin research program comparing results from 10 laboratories reported that the results from the automated BE-SPME method yielded much lower inter- and intra-laboratory variability relative to the results obtained using the manual method. While the source of the variability in results from the round robin was suspected to be caused by the mixing rate and type during the SPME fiber–sample equilibration, additional data from analyses of duplicate water samples at multiple laboratories using only the automated method showed significant interlaboratory variability (50-100% relative percent difference). This high interlaboratory variability hampers comparisons across studies and pooling of data to allow reproducible hazard assessments of waters containing complex petroleum substances. Additional research involving multiple laboratories has been initiated to identify other potential sources of interlaboratory variability of BE-SPME with the aim of standardizing the method. This presentation will discuss the main causes of identified interlaboratory variability and potential solutions.

3.05 Analytical Developments and Challenges in Detection and Monitoring of the Growing Universe of Per- And Polyfluoroalkyl Substances (PFAS)

3.05.T-01 Unravelling the Combination of Atmospheric Pressure Ionization Sources to Extend the PFAS Coverage

Juan Francisco Ayala Cabrera[1,2]*, Naroa Lopez*[2,3]*, Belen Gonzalez-Gaya*[2,3]*, Anne San Román*[2,3,4,5]*, Amaia Irizar*[4,5,6,7]*, Eunate Abilleira*[4,5] *and Nestor Etxebarria*[3,8]*, (1)Analytical Chemistry, University of the Basque Country (UPV/EHU), Spain, (2)Research Centre for Experimental Marine Biology and Biotechnology (PiE-UPV/EHU), Spain, (3)Department of Analytical Chemistry, University of the Basque Country (UPV/EHU), Spain, (4)Department of Analytical Chemistry, Epidemiology and public health, BioGipuzkoa Health Research Institute, Spain, (5)Department of Public Health, Basque Goverment (Gipuzkoa), Spain, (6)Department of Preventive Medicine and Public Health, University of the Basque Country (UPV/EHU), Spain, (7)Spanish Consortium for Research on Epidemiology and Public Health (CIBERESP), Instituto de Salud Carlos III, Spain, (8)Research Centre for Experimental Marine Biology and Biotechnology (Plentzia Marine Station; PiE-UPV/EHU), University of the Basque Country (UPV/EHU), Spain*

Per- and polyfluoroalkyl substances (PFAS) involves a large group of compounds (more than 6,300) covering a vast variety of chemical structures going from ionic to neutral PFAS that are classified as contaminants of emerging concern. Although they are usually analyzed by liquid chromatography coupled to high-resolution mass spectrometry (LC-HRMS) using electrospray ionization (ESI) for both targeted and non-targeted screening (NTS) approaches, the upgrade of analytical strategies to fulfill the monitoring requirements for a wide-scope determination of PFAS, especially PFAS with low/null ionization efficiency by ESI is still limited. Thus, this work aims to propose high-throughput cutting-edge methodologies based on HRMS combining atmospheric pressure ionization sources such as ESI and atmospheric pressure chemical ionization (APCI) to sort out the complexity on the analysis of PFAS by extending the analyte coverage of the LC-HRMS methodologies.

Although ESI provides an efficient ionization for most of ionic PFAS, the ionization of less polar fluorotelomers (FTs) is less favored due to their higher difficulty to generate the $[M-H]^-$. Thus, it was observed that ESI provided slightly better instrumental limits of detection (iLODs) around 16-fold lower than those achieved by APCI for ionic PFAS, while for FTs, APCI showed iLODs up to 3-fold lower than ESI. This is specially relevant for low-polar PFAS such as fluorotelomer alcohols that were only ionized by APCI through characteristic series of in-source fragment ions differing in 20 Da (HF losses). Using this approach, the use of orthogonal ion sources not only allows to extend the range of PFAS but also helps to increase the confidence on the annotations ionized with both sources. Besides, this approach allows the stablishment of new NTS strategies using either the observed ion/s or ESI/APCI correlations under fix conditions. Thus, the neutral losses of HF due to the in-source fragmentation observed for FT-based PFAS by APCI were used as data mining strategy to prioritize features. This was easily visualized in Kendrick mass defect plots (HF scale) which group series of in-source fragment ions belonging to the same FT compound. Finally, a model for the estimation of the concentration of tentatively identified PFAS (when no standard is available) was set based on the normalized relation between ESI and APCI responses showing the great potential of this analytical approach to dive deeper in the NTS of PFAS.

3.05.T-02 Quantitative Assessment of Poly- and Perfluoroalkyl Substances (PFASs) in Aqueous Film Forming Foam (AFFF) Impacted Soils: A Comparison of Analytical Methodologies

Christopher Higgins[1]*, Nicholas Gonda*[1] *and Chuhui Zhang*[2]*, (1)Colorado School of Mines, (2)North Carolina State University*

Poly- and perfluoroalkyl substances (PFASs), particularly perfluoroalkyl acids (PFAAs) like perfluorooctanoic acid (PFOA) and perfluorooctane sulfonic acid (PFOS), have received significant attention due to their widespread contamination, environmental persistence, bioaccumulation, and toxicity. Aqueous film forming foams (AFFFs) are an important source of PFAS releases to both groundwaters and soils. While AFFF formulations are known to contain fluorinated surfactants, their exact compositions are proprietary and manufacturer-dependent. The diversity of PFAS chemistries at AFFF-impacted sites is not only due to fluorochemical manufacturing processes, but also the fact that the wide-range of polyfluoroalkyl chemistries used in AFFF can transform into an even wider range of PFASs upon release into the environment, particularly in soils. Many of these PFASs are likely significant sources of PFAAs due to *in situ* transformations. Accurately quantifying the full suite of PFASs at AFFF-impacted sites, particularly in soils, is essential in understanding the potential risk an AFFF impacted site poses to surrounding humans and biota. The objective of this study was to assess the performance of various analytical approaches for extracting and quantifying ΣPFASs in AFFF-impacted soils, with a particular focus on analytical approaches that enable both liquid chromatography high resolution mass spectrometry (LC-HRMS) analyses and total organic fluorine measurements in the same extract. Draft EPA Method 1633 was evaluated, as were modifications to 1633 to ensure that a comprehensive list of anionic, cations, and zwitterionic PFASs could be analyzed for AFFF-impacted sites. Three AFFF impacted soil composites were analyzed using the modified 1633 methodology, 1633 as currently proposed, and a previously published comprehensive extraction and cleanup method. Targeted and suspect screening analyses were performed in both electrospray negative (ESI-) and positive (ESI+) modes. In addition, spike experiments using clean matrices, native PFASs, and mass labeled PFASs were conducted to determine absolute compound recoveries of the three methodologies. The results suggest that with minimal modifications, this modified 1633-like methodology is capable of quantifying a wide range of PFASs in AFFF-impacted soils while maintaining compatability with total organic fluorine-type analyses.

3.05.T-03 Analysis of Per- and Polyfluoroalkyl Substances (PFASs) in Consumer Food Packaging by Different Analytical Approaches

Yelena Sapozhnikova[1]*, Kevin Stroski*[2] *and Raegyn B Taylor*[1]*, (1)U.S. Department of Agriculture, (2)Baylor University*

Diet is considered one of the major routes of human exposure to PFASs which can be present in both the food itself but also the food contact materials (FCM) and migrate into food. In this study, we tested 88 consumer food packaging samples from different geographical locations for PFASs. Thousands of PFAS chemicals are used in commerce, however, information on their identity and use is lacking, plus limited amount of PFAS analytical standards are commercially available for method development and routine testing. To address these challenges and to expand the analytical scope, this study utilized various sample preparation and instrumental analysis approaches. Sample extraction and controlled migration experiments were utilized to determine PFAS occurrence and levels in food packaging samples. In addition, total oxidizable precursor (TOP) assay was utilized to capture PFAS precursors. Both targeted and non-targeted analyses using liquid chromatography tandem mass spectrometry and Orbitrap high resolution mass spectrometry (HRMS) were employed. Targeted analysis for 34 PFASs resulted in 19 analytes detected in the tested samples after extraction. Overall, 84% of the samples had detectable levels of at least one PFAS, with 6:2 fluorotelomer phosphate diester (6:2 diPAP) found most frequently and at the highest levels (up to 224 ng/g). Other frequently detected substances were PFHxS, PFHpA and PFDA. PFHpA, PFPeA and PFHxS were present at levels up to 51.3, 24.1 and 18.2 ng/g, respectively. The TOP assay results revealed that average ΣPFAS levels increased over 10 times after oxidation, suggesting the presence of undetected PFAS precursors. Four PFAS were found migrating into food simulants during controlled migration tests: PFHxS, PFHpA, 6:2 diPAP and PFHxA. Based on the highest migrated measured levels, weekly intake values were calculated and were below the established EFSA maximum total weekly intake of 4.4 ng/kg body weight/week. Finally, non-targeted analysis was utilized to discover and identify PFAS not covered by the limited scope of our targeted approach. Multiple HRMS workflows were developed and validated utilizing signatures unique to PFAS compounds. Results from the non-targeted analysis of food packaging samples showed 41 potential PFAS features with 8 being found in all four food and material types. Five tentatively identified compounds were confirmed with analytical standards, and quantified using retrospective data analysis.

3.05.T-04 Characterization of Fluoropolymers for Residual PFAS: Implications for Munitions, Thermal Degradation, and Human Exposure

Mitchell Lee Kim-Fu[1], *Esteban Eustacio Hernandez*[1], *Willie Rochefort*[1], *Thierry Fouquet*[2], *Amergin McDavid*[1], *Johanna Peeters Weem*[1], *Ansel Moll*[1], *Gerrad Jones*[1], *Alexandra Pidwerbecki*[1], *Jennifer Field*[1] *and Jesse Sanchez*[1], *(1)Oregon State University, (2)National Institute of Advanced Industrial Science and Technology (AIST), Japan*

To dispose of unserviceable explosives and munitions, open burns are conducted by the United States Department of Defense as part of demilitarization programs. However, there is growing concern over possible air emissions and associated risk to humans and the environment produced during open burns of munitions containing fluoropolymers. While fluoropolymers themselves do not appear to pose a significant risk, there is evidence that at high temperatures fluoropolymers thermally degrade to non-polymeric PFAS of toxicological significance as well as hydrofluorocarbons, a class of greenhouse gases. Additional fluorinated compounds are found as residuals used in the synthesis of fluoropolymers. Prior to thermal degradation, a thorough characterization of pure and cross linked fluoropolymers is needed to understand the range of gas-phase thermal degradation byproducts that can potentially form. The total fluorine content of pure and cross-linked fluoropolymers was determined using instrumental neutron activation analysis and characterized by pyrolysis gas chromatography mass spectrometry (GC-MS). A simple method was developed to extract fluorinated residuals from fluoropolymers. A novel, in-tube ^{19}F and ^{1}H nuclear magnetic resonance spectroscopy (NMR) method was then used to identify the organic solvent most effective for extracting fluorinated residuals. Extracts also underwent analysis by liquid chromatography quadrupole time-of-flight mass spectrometry (LC-QTOF) for target, suspect, and non-target analysis via Kendrick mass defect for nonvolatile PFAS and by GC-MS for target volatile PFAS. Thermogravimetric analysis with an evolved gas analyzer was performed to understand the range and quantity of thermal degradation products that form when fluoropolymers and their fluorinated residual thermally degrade. Acetone was selected as the most effective solvent for swelling and extracting residuals. Individual PFAS contributed to <1% of total fluorine in fluoropolymers. By LC-QTOF, polytetrafluoroethylene consisted of 0.43 ng/g to 2.8 ng/g of a series of C4 to C16 perfluoroalkyl carboxylic acids (PFCAs). Additionally, NMR was used to identify the presence of bisphenol AF and non-targeted unknown PFAS in crosslinked Viton A. With the presence of PFCAs, during thermal degradation there exists the potential for fluoroethenes to form, which are neurotoxins, that creates an exposure risk for those conducting open burns.

3.05.P Analytical Developments and Challenges in Detection and Monitoring of the Growing Universe of Per- And Polyfluoroalkyl Substances (PFAS)

3.05.P-Th217 Quantification of ultrashort per- and polyfluoroalkyl substances (PFAS) in water samples via headspace gas chromatography-mass spectrometry (GC-MS) - a method development

Peter Leube[1], *Christian Vogel*[2] *and Franz-Georg Simon*[2], *(1)Division 4.3 Contaminant Transfer and Environment Technologies, Federal Institute Materials Research and Testing (BAM), Berlin, Germany, (2)Division 4.3 Contaminant Transfer and Environment Technologies, Bundesanstalt für Materialforschung und -prüfung (BAM), Germany*

Per- and polyfluoroalkyl substances (PFAS) were classified as a group of highly concerning chemicals over the last decades. Because of the high persistence of PFAS, their previous use led to contamination of the environment and human population. Due to ongoing use and incomplete remediation or destruction methods, the PFAS background in the environment is growing continuously.

The presence of ultrashort PFAS (with ≤3 carbon atoms) in the environment is often overlooked despite their contributions to PFAS levels. These compounds may directly contaminate the environment and arise from degradation of polyfluorinated compounds as well as incomplete PFAS destruction in certain industrial processes. Nonetheless, few approaches for targeted analysis of ultrashort PFASs have been developed, except for trifluoroacetic acid (TFA). Beside liquid (LC-MS/MS), supercritical fluid (SFC-MS/MS), and ion chromatography (IC-MS)-based systems, gas chromatography coupled with mass spectrometry (GC-MS) is a promising method for detection and quantification of ultrashort PFAS.

The goal of this study was to develop a simple headspace GC-MS method for the quantification of ultrashort perfluorocarboxylic acids (PFCAs) and polyfluorinated alcohols (PFOHs) in water samples. In contrast to PFOHs, functionalization of PFCAs was required for quantification. This was done by esterification with methanol at 80 °C, which can be carried out directly in the headspace GC-MS system.

Moreover, several parameters were optimized to achieve a low limit of quantification for the analytes used: i) The ratio of the aqueous solution, methanol, and available gas phase within the analysis vessel, ii) the concentration of additional acid in esterification mixtures of PFCAs, iii) shaking frequency and iv) shaking time before analysis. After optimizing the procedure, we were able to quantify ultrashort PFCAs and PFOHs. Thus, our developed headspace GC-MS method has the potential to be used as an alternative target analysis for ultrashort-chain PFCAs and PFOHs in various water samples (groundwater, wastewater).

3.05.P-Th218 Per- and Polyfluoroalkyl Substances (PFAS) Precursors in Dutch Surface Waters

D. Liwara[1]*, Pim Leonards*[1]*, Sicco Brandsma*[1]*, Huiling Liu*[2]*, Jon Eigill Johansen*[2] *and Jacob de Boer*[1]*, (1)Vrije University Amsterdam, Netherlands, (2)Chiron AS, Norway*

PFAS are a huge group of chemicals with unique properties used in aqueous film-forming-foams (AFFFs) or in manufactured products such as fabrics or food packaging materials. However, after their use, they end up in the environment and can contaminate water, soil and air. Surface waters are important to monitor because humans and wildfile depend on them to live. Legacy PFAS like for example PFOS (perfluorooctanesulfonic acid) or PFOA (perfluorooctanoic acid) are usually monitored because they are bioaccumulative and negatively affect human health. PFAS precursors can be an important source of contamination because they can be degraded into parent compounds which accumulate in the environment or the human body. This work focuses on the identification of PFAS precursors and legacy PFAS in Dutch surface water samples using reference standards synthesized beforehand. Synthesized compounds include *N*-sulfo propyl perfluorohexane sulfonamide, short-chain perfluoroalkane sulfonamide derivatives (C4 and C6) namely *N*-alkyl perfluoroalkane sulfonamide and *N*-alkyl perfluoroalkane sulfonamidoacetic acid, *N*-trimethylammoniopropyl perfluoroalkane sulfonamide (C4, C6 and C8), 6:2 fluoroteomersulfonyl propanoic acid, 6:2 fluorotelomerthia propanoic acid, *N*-dimethyl ammonio propyl perfluoroalkane sulfonamide (C4, C6 and C8) and *N*-sulfopropyl dimethylammoniopropyl perfluorohexane sulfonamido propyl sulfonate. Twenty surface water samples from the Netherlands were extracted by solid phase extraction (SPE) then analysed by liquid chromatography – tandem mass spectrometry (LC-MS/MS). The sum of the analysed PFAS was on average 25-30 ng/L, for every sample except three that showed a concentration higher than 60 ng/L. PFOS, PFOA, PFBS, PFBA, PFHxA and PFHxS were the legacy PFAS with the highest concentrations (5-17 ng/L). Targeted precursors were detected in almost all samples, especially *N*-methyl perfluorobutane sulfonamidoacetic acid (MeFBSAA) (around 0.2 ng/L) and SPr-FHxSA. A source of SPr-FHxSA might be the use of AFFFs since this compound was mainly identified in these foams. MeFBSAA was five times higher (1.1 ng/L) in one sample close to Tilburg. The reason is still unknown but it may be related to the textile industrial past in this region. Other samples will be analysed in this region to follow up this elevated concentration.

3.05.P-Th219 PFAS in Sub-Antarctic Seabirds: Evidence for Long-Range Transport and Bioaccumulation of Emerging Contaminants

Imogen Bailes[1]*, Jonathan Barber*[2]*, Sara Losada Dr.*[2]*, Richard Phillips*[3]*, Lloyd Peck*[3] *and Andrew Sweetman*[4]*, (1)Lancaster Environment Centre, Lancaster University, United Kingdom, (2)Centre for Environment Fisheries and Aquaculture Sciences (Cefas), United Kingdom, (3)British Antarctic Survey, United Kingdom, (4)Lancaster University, United Kingdom*

Poly- and perfluoroalkyl substances (PFAS) are a large group of chemicals that are characterised by a hydrophilic moiety (e.g., SO_3^- or COO^-) and a hydrophobic perfluorocarbon chain that varies in length. PFAS display unique properties due to combined oil and water repellence, extreme stability, and hence are used in a wide range of industrial processes and consumer products. These chemicals can be problematic in the environment due to their potential to undergo long-range transport, persistence and toxicity. Some longer-chain PFAS have already been listed in the Annexes of the Stockholm Convention and included in other international regulations, but replacements have started to emerge. Furthermore, the European Chemicals Agency (ECHA) is seeking to ban the use and production of PFAS (defined as chemicals containing CF_2) completely in Europe. As such, it is important to document current levels of both legacy and emerging PFAS in the environment prior to this proposed ban so that any resulting decline in concentrations can be assessed accurately. Here, we employ an ultra-performance liquid chromatography coupled to a high-resolution mass spectrometer (Orbitrap) to analyse a range of both legacy and emerging PFAS including 11 PFCAs (C4-C14), 9 PFSAs (C4-C10), 3 FASAs, 3 PFPiAs and 6 fluorotelomer acids, among others. We have analysed liver tissues of black-browed albatrosses, white-chinned petrels and common diving petrels collected from the Falkland Islands and South Georgia from the early 2000s to the mid-2010s. The data show varying spatial and temporal trends between different species and but similar profiles for individual compounds; we draw comparisons between trophic levels by employing stable isotope analysis. Trends in these data reveal various pathways e.g., atmospheric and hydrospheric, for PFAS into the Southern Ocean before bioaccumulating through food chains. Our research addresses the need to understand exposure levels in wildlife to PFAS compounds in areas close to and remote from sources.

3.05.P-Th220 Potential Impacts of COVID-19 on Per- and Polyfluoroalkyl Substances (PFASs) in Air in the Great Lakes Basin

*Wen-Long Li[1], **Hayley Hung**[2], Chubashini Shunthirasingham[1], Alexander Kasperkiewicz[1], Fiona Wong[1], Richard Park[1], Patrick Lee[1] and Helena Dryfhout-Clark[1], (1)Environment and Climate Change Canada, Canada, (2)Air Quality Processes Research Section, Environment and Climate Change Canada, Canada*

Under Canada's Great Lakes Basin (GLB) Monitoring and Surveillance Program per- and polyfluoroalkyl substances (PFASs), are being monitored in air at two regionally representative background stations, namely Point Petre located on the north shore of Lake Ontario and Evansville located on Lake Huron. At Point Petre, air samples were collected from October 2018 to December 2022. At Evansville, samples were collected from May 2019 to December 2022. Air samples were taken once every 36 days using a high volume air sampler with a glass fiber filter (GFF) and a polyurethane foam-XAD sandwich (PUF/XAD/PUF). Air samples were analyzed for 19 ionic PFASs and 7 neutral PFASs. Most PFASs were detectable in greater than 50% of all air samples. Perfluorobutanoic acid (PFBA), perfluorooctanoic acid (PFOA) and perfluorooctane sulfonic acid (PFOS) were the dominant ionic PFASs while 6:2 and 8:2 fluorotelomer alcohol (FTOH) were the dominant neutral PFASs found in air. Generally higher air concentrations were found at Point Petre compared to Evansville as the Point Petre location is closer to urban centers, industrial activities and waste streams. During the COVID-19 pandemic, a significant decline in ∑PFASs concentrations in air was observed before and after 2020 reflecting the decrease in human and industrial activities in the region during COVID-shutdown. Multimedia environmental modelling revealed that the main in flow of PFOA and PFOS to Lake Ontario is via wastewater treatment plant effluents and tributary input; while water outflow from the lake, rather than sediment burial, is the main removal process.

3.05.P-Th221 Detection of Legacy and Emerging PFAS in Wastewater from a Fluoropolymer Production Facility in Italy

***Sara Valsecchi**[1], Marianna Rusconi[1], Stefano Polesello[1], Claudio Roscioli[1], Maria Teresa Palumbo[1], Marco Parolini[2], Igor Fochi[3], Laetitia Six[4], Lutz Ahrens[5], Georgios Niarchos[5], Katrin Vorkamp[6] and Valeria Dulio[7], (1)Water Research Institute - Italian National Research Council (IRSA-CNR), Italy, (2)University of Milan, Italy, (3)Thermo Fisher Scientific SpA, Italy, (4)OVAM, Belgium, (5)Department of Aquatic Sciences and Assessment, Swedish University of Agricultural Sciences (SLU), Sweden, (6)Department of Environmental Science, Aarhus University, Denmark, (7)Institut National de l'Environnement Industriel et des Risques (INERIS), France*

Studying the environment near manufacturing sites of per- and polyfluoroalkyl substances (PFAS) enables us to evaluate current, but also former PFAS releases and potential forthcoming PFAS concerns.

Employing suspect screening (SS) and non-targeted analysis (NTA) using high-resolution mass spectrometry (HRMS) has shown to be a suitable method for detecting a wide spectrum of PFAS, including new and potentially less-studied contaminants.

This study has been chosen as a case study for the European Partnership for the Assessment of Risks from Chemicals (PARC) and is being conducted in collaboration with the USEPA. Waste water samples of a fluoropolymer manufacturing site located in Northern Italy were analyzed by liquid chromatography coupled to HRMS (Orbitrap) and were processed with Compound Discoverer (Thermo Fisher). State-of-the-art methodologies designed for NTA of environmental samples, such as mass defect filtering, and identification of compound series by Kendrick plots, were employed to identify unknown or suspected PFAS.

The investigation showed the ongoing discharge of legacy PFAS (e.g. PFOA), despite their discontinuation in the fluoropolymer production a decade ago. Furthermore, alternative fluorosurfactants, fluorinated monomers and byproducts were identified. The findings show a chronological progression of fluorinated surfactants at this manufacturing site, i.e. a transition from C8-PFAS to short-chain PFAS, and ultimately to non-fluorosurfactant applications in the fluoropolymer production. However, the results also demonstrated the continued production or utilization of long-chain PFAS, despite increasing concerns regarding their bioaccumulative potential in aquatic and terrestrial food chains. Additionally, the investigation provides insight into environmental emissions resulting from the production of novel fluorinated polymers within the context of developing new materials for energy transition.

3.05.P-Th222 Comprehensive Screening for Per-and Polyfluoroalkyl Substances (PFAS) in Fish From More Than 100 Water Bodies in Southern Germany

***Jessica Fischer**, Bavarian Environment Agency (LfU), Augsburg, Germany*

This project explores the bioaccumulation potential of per-and polyfluoroalkyl substances (PFAS), a profoundly concerning group of substances, in fish. Analyses for up to 42 PFAS were conducted on pooled muscle samples (filet of 3 - 15 individuals) from more than 90 Bavarian inland water bodies, with focus on smaller rivers and streams. Sites were selected based on prior water analyses that triggered fishing actives preferably during the same year, when perfluorooctane sulfonate (PFOS) concentrations exceeded . This threshold, equivalent to three times the environmental quality standards (AA-EQS) for PFOS in inland surface water, was chosen anticipating no exceedance of the biota-EQS below this level.

Furthermore, larger rivers were sampled over three consecutive years to uncover potential short-term trends. The seven Bavarian trend monitoring sites under the water framework directive (WFD) were selected for these annual investigations, considering previous data and an abundant availability of fish of the same species (*Squalius cephalus* or *Rutilus rutilus*). These analyses extended beyond pooled muscle samples and included the filet of every individuum captured per site (usually 15 - 25).

PFOS was detected in every sample and mostly as the predominating compound. Significant variation within individuals of the annually sampled sites, in some cases spanning an order of magnitude, Perfluorooctanoic acid (PFOA) was only found in fish of two nearby water bodies, linked to pre-2008 industrial use (fluoropolymer production). Other targeted perfluorocarboxylic (C4 - C18) and perfluorosulfonic acids (C4 - C13) were detected in a limited number of cases, with PFSAs being barely found, while PFCAs were more frequently identified. Among them, perfluorononanoic acid (PFNA) dominated in both number of occurrences and concentrations, followed by longer-chain compounds (C > 10). None of the targeted replacement chemicals, including components of F-53B (9Cl-. PF3ONS and 11Cl-PF3OUdS), DONA and Gen-X / HFPO-DA were detected. The same applied to precursors (10:2-, 8:2-, 6:2- and 4:2-FTSA, EtFOSA, N-EtFOSAA, N-EtFOSE, MeFOSA, N-MeFOSAA, N-MeFOSE, PFOSA) as well as to degradation products and other PFASs (H_4PFUnA, H_2PFDA, HPFHpA, PF-3,7-DMOA). This ongoing five-year project provides a unique opportunity to gain insights into bioaccumulation as it provides a vast set of fish and corresponding water data.

3.05.P-Th223 Environmental and multisource monitoring of PFAS in a pan-European perspective
Stefano Polesello[1], *Sara Valsecchi*[1], *Laetitia Six*[2], *Lutz Ahrens*[3], *Georgios Niarchos*[3], *Anja Duffek*[4], *Nicole Bandow*[4], *Katrin Vorkamp*[5] *and Valeria Dulio*[6], *(1)Water Research Institute - Italian National Research Council (IRSA-CNR), Italy, (2)OVAM, Belgium, (3)Department of Aquatic Sciences and Assessment, Swedish University of Agricultural Sciences (SLU), Sweden, (4)German Environment Agency (UBA), Germany, (5)Department of Environmental Science, Aarhus University, Denmark, (6)Institut National de l'Environnement Industriel et des Risques (INERIS), France*
Establishing a process for environmental and multisource monitoring is a key component in the Horizon Europe Partnership for the Assessment of Risks from Chemicals (PARC), with the purpose of supporting the chemical risk assessment of the European Union (EU). A pilot project was launched in this task to develop and validate a workflow which could become the model for future monitoring campaigns in PARC. Per- and polyfluoroalkyl substances (PFAS) are one of the compound groups selected for this pilot project. It intends to establish a PFAS baseline for Europe to reflect the current environmental levels of PFAS resulting from decades of PFAS production and use. Using available monitoring data, PFAS baseline levels will be derived for different regions, matrices and land uses which can serve as a benchmark for future comparisons. Besides this baseline, a set of case studies will address PFAS pathways from source to aquatic recipients. The case studies will focus on European sites with a confirmed PFAS contamination (e.g., firefighting training sites, wastewater-impacted areas, fluoropolymer production facilities). Using a combination of advanced methodological approaches (target analysis, suspect and non-target screening, and sum parameters such as TOF and TOP assays), the case studies will determine the role of PFAS precursors in the environmental fate of PFAS (transport and transformation pathways), and explore the possibility of using PFAS fingerprinting to improve the understanding of PFAS pathways and source identification. Following the actual monitoring work, the pilot study will be concluded with an analysis of lessons learned and potential adjustments in future environmental monitoring projects under PARC.

3.05.P-Th224 Per- and Polyfluoroalkyl Substances (PFAS): Validation of Methodology for the Determination of Residues in Surface Water and Plasma
Stephen Brewin, *Chloe Wilson, Simon Tate and Victoria Remnant, Environmental Sciences, Labcorp, United Kingdom*
Per- and polyfluoroalkyl substances (PFAS) are a class of synthetic organofluorine compounds that have become a concern due to their persistence in the environment following extensive use over the last few decades. Due to their high degree of chemical stability, as well as their widespread use, PFAS chemicals now are increasingly being detected in the environment and appear to persist for extended periods of time. Furthermore, exposure to these chemicals in everyday objects, such as packaging and cookware, as well as within certain areas of industry, has led to the apparent bioaccumulation in certain areas of the population. Because of the concerns over health and environmental issues associated with PFAS chemicals, there has been a need to be able to monitor the occurrence of these materials in humans and the environment.

There are numerous approaches to analysing a range of these chemicals in a number of different matrix types, and this area of analytical chemistry is constantly evolving as new PFAS chemicals are identified and added to the list of those where methods already exist.

The work described in this poster was a project to develop and validate an LC-MS/MS method for the analysis of a “typical” suite of PFAS chemicals in the environment (surface water) as well as in body fluids (plasma). A simple and robust method was required, that could be easily applied to routine analysis at low concentrations, using commonly available equipment and approaches. There was also a requirement to be able to add additional PFAS analytes to expand the method as the need arises.

The resulting method of analysis of PFAS chemicals in plasma involves extraction/precipitation with methanol, followed by dilution with aqueous ammonium acetate. Surface water samples were prepared by the addition of ammonium acetate and methanol. Quantitation was performed by LC-MS/MS.

The method was successfully validated for 22 PFAS analytes in plasma and 21 in surface water at limits of quantitation (LOQ) of 10 ppb and 0.1 ppb respectively. Detection limits were equivalent to 2 ppb and 0.02 ppb for plasma and surface water. The validations were performed in accordance with the SANTE/2020/12830 guidelines to ensure that current and future performance requirements were met. Further work will include additional analytes to the PFASs already validated, as well as to investigate approaches to reduce the LOQ of the method to increase its sensitivity.

3.05.P-Th225 PFAS Reference Materials: From Industrial Precursors and Technical Grade to High Purity n-Isomers
Huiling Liu[1]*, Anton Pavlov*[1]*, D. Liwara*[2]*, Ana R. L. Araujo*[3]*, Craig McKenzie*[1] *and Jon Eigill Johansen*[1]*, (1)Chiron AS, Norway, (2)Vrije University Amsterdam, Netherlands, (3)University of Amsterdam (UVA), Netherlands*
Per- and polyfluoroalkyl substances (PFAS) are a class of synthetic chemicals with widespread industrial and commercial applications. Their persistence and potential health effects raise significant environmental concerns. Accurate measurement of PFAS in environmental and biological samples is crucial for assessing exposure and risk. High-quality reference materials (RMs) and certified reference materials (CRMs) are essential for this purpose.

Since 1950, PFAS compounds have been widely used in various industrial and commercial applications. The global manufacturing has employed two processes to produce perfluoroalkyl chain compounds. Electrochemical fluorination produces a mixture of linear and branched isomers; telomerization typically yields an isometrically pure (or enriched) linear product. These techniques have resulted in PFAS with varying isomeric purities and also other organic impurities, water, solvent, and inorganic residues. These contaminants affect chromatographic and net purity, influencing analytical detector response and compromising the reliability of quantitative analysis. PFAS homologues, linear and branched PFAS isomers may exhibit distinct environmental and toxicological properties and metabolic profiles. Therefore, reference material producers must provide a range of fully characterized reference standards and labeled internal standards.

Numerous environmental samples contain both branched and linear isomers of PFASs. This mixture poses challenges in accurately quantifying many PFASs in environmental matrices, quantitative analysis of PFASs often involves eluting all isomers together and integrating them as a single peak. Isomer-specific PFAS analysis is hindered by limitations in analytical instrument development and methods. Additionally, the lack of high-quality, fully characterized analytical reference standards for isomer-specific identification and purity further impedes accurate PFAS analysis.

This study focuses on synthesizing, purifying, and characterizing isometrically pure PFAS reference materials, primarily n-isomers of different PFAS compounds. The development of PFAS reference materials from technical grade materials to pure isomer RM and CRMs will be addressed. The synthesis and purification process, and the differences in analytical approaches for bulk reference standard characterization and environmental analysis at trace levels will also be discussed.

3.05.P-Th226 Laboratory Considerations when Analysing PFAS Containing Samples
Matt James *and Anthony Edge, R&D, Avantor Sciences, United Kingdom*
The LC-MS determination of PFAS in environmental matrices is challenging due to the increasingly low-level quantification required by regulatory authorities. This challenge is exacerbated by the use of PFAS containing materials within the laboratory environment, which can result in inadvertent contamination of analytical samples and invalidation of analytical data. To avoid quantification issues, it is essential to characterise potential sources of contamination and to apply rigorous working practices to eliminate them. This work summarises experiences from within our laboratory when establishing a PFAS LC-MS method within a working “non-PFAS” laboratory and is intended to serve as guidance for analysts new to the field of PFAS analysis.

Initially, common laboratory consumables used during sample preparation were screened by LC-MS to identify materials that could potentially contaminate samples. Several consumables were found to contain extractable PFAS. This data was used to eliminate/control sample handling and preparation steps that could potentially contaminate samples. The LC-MS system and consumables were also thoroughly assessed; background PFAS components (PFHxA, PFHpA, PFOA, PFNA and PFDA) were found to originate from LC-MS solvent line tubing and the use of a PFAS delay column was shown to resolve the problem. Additionally, the importance of testing consumables, including sample vials was demonstrated. In one case, a vial cap material recommended for PFAS analysis was found to leach 4,8-dioxa-3H-perfluorononanoic acid (ADONA) into methanolic diluent.

Many PFAS workflows utilise sample pre-concentration by solid phase extraction (SPE). This step was anticipated to be potentially problematic, indeed persistent contamination of PFHxA from the nitrogen blowdown step was found to originate from compressed air and nitrogen line tubing. Various tubing materials were assessed, with several found to contain extractable PFAS. An additional concern with sample preparation was the potential for high PFAS load water samples to cross-contaminate other samples when undergoing parallel or subsequent processing. A novel rapid pre-screening method was developed, which allows a small 200µL aliquot of sample to be screened in under two minutes using a 10 mm column and one minute gradient. By applying this approach, laboratories may quickly pre-classify incoming samples and divert high PFAS samples to alternative work streams to safeguard against cross contamination.

3.05.P-Th227 Overcoming Solvent Effects at High Injection Volumes in PFAS Analysis

***Marcus James Chadha, PhD**, Agilent Technologies, Inc., United Kingdom*

The challenge of low PFAS detection and quantification limits: The analysis of PFAS (per- and polyfluorinated alkyl substances) often requires sample preparation techniques like solid phase extraction (SPE), especially in case of drinking water analysis with low detection limit requirements. The final samples ready for LC/MS/MS analysis are therefore usually dissolved in 80-100% organic solvents.[1] Additionally, recommended drinking water concentration limits are getting even lower, lately.[2] Injecting high sample volumes could improve sensitivity and therefore allow lower detection limits but this is limited by undesirable solvent effects caused by the high elution strength of the sample solvent in case of common reversed phase liquid chromatography.

Overcoming solvent effects in a convenient way: Here we present how the use of feed injection, as an alternative injection principle to the common flow through injection allows much higher injection volumes without negative impact on the peak shape, even when the sample is dissolved in 100% organic solvents. This is achieved by infusing the sample into the mobile phase stream with a special valve resulting in a dilution.[3] The use of a novel C18 reversed phase column designed to be compatible with a 100% aqueous mobile phase helps to maximize the improvement.

3.05.P-Th228 PFAS Analysis to Address the EU Regulations for 24 Compounds

***Day Powell**, Agilent Technologies, Inc.*

Poster to highlight the latest analytical techniques to test for PFAS (Per & polyfluoroalkyl substances) in various Matrices including Drinking water and Raw waters. Data and results to be included using the latest analytical techniques used to analyse for over 24 PFAS including the latest 24 PFAS in the EU regulations, including Liquid-Chromatography/Mass-Spectrometry and Gas-Chromatography/Mass-Spectrometry, with the latest developments in liquid-chromatography hybrid sampling techniques and online-Solid Phase Extraction. These developments have allowed for the analysis to overcome many challenges associated with PFAS analysis reaching lower levels of detection across wide ranges of challenging matrices and compounds. The new methodologies can also be applied to other PFAS compounds such as in the UK regulatory compounds, now containing 48 PFAS compounds, and allow analysts to reach the new parts per quadrillion levels set in the USA by the EPA for water analysis. New injection/preparation techniques described include online-Solid Phase extraction which allows the analysis of complex matrices such as foods or biological samples with less interferences and more reproducibility in results. This improved analysis will allow for accurate research and environmental modeling of PFAS.

3.05.P-Th229 Occurrence of Poly- and Perfluoroalkyl Substances (PFAS) in Transitional and Marine Water along the Dublin Coast

***Helen Burke**[1], Belinda Huerta[2], Enrique Jacobo Díaz-Montaña[3] and Fiona Regan[4], (1)Dublin City University (DCU), Ireland, (2)Glasnevin, Dublin City University (DCU) School of Chemical Sciences, DCU Water Institute, Ireland, (3)DCU Water Institute, School of Chemical Sciences, Dublin City University, Ireland, (4)Water Institute, Dublin City University (DCU) School of Chemical Sciences, DCU Water Institute, Ireland*

Poly- and perfluoroalkyl substances (PFAS) are a large group of compounds consisting of a partially or fully fluorinated carbon chain. Due to their physio-chemical properties these substances are widely used across a range of industries including electronic and pharmaceutical manufacturing as well as use in firefighting foams. As a result of growing use and their stable nature, PFAS are now ubiquitous in the environment showing bioaccumulation and adverse health effects in wildlife and humans. Although PFAS are currently being studied worldwide, little information on PFAS concentration in Ireland's marine environment exist.The main objective of this study was to determine PFAS concentration in transitional and marine waters along Dublin Bay and pinpoint areas where the existing concentration of these compounds, or slight increases could pose an environmental problem.Marine samples were treated with sodium thiosulfate to reduce free chlorine prior to analysis. Water samples were extracted by solid phase extraction (SPE) using Oasis WAX (500 mg). The extract was analysed by High performance liquid chromatography (HPLC) using an Agilent Zorbax Eclipse Plue C18 column (3.0 x 50 mm; 18µm) and an identical guard column. For detection, HPLC was coupled with a triple quadrupole mass spectrometer.Results confirm the presence of both legacy and novel PFAS in transitional waters entering Dublin Bay, with fluctuations in concentrations observed in upper and lower estuary sites along the river Liffey.

The highest concentrations detected were 1393.7 and 1217.9 ng/l at upper estuary sites for perfluorooctanoate (PFOA) and perfluoroundecanoate (PFUdA) respectively. Levels of PFOA, a legacy PFAS, decreased from upper to lower stream sites with a concentration of 57.7 ng/l at the final sampling site in Dublin Bay. The novel PFAS perfluoropropoxypropanoic acid (GenX) was detected at upper estuary sites with the highest concentration of 37.8 ng/l, this decreased downstream at lower estuary sites to <25ng/l.

The two final sampling sites were located upstream and downstream of Ringsend wastewater treatment plant (WWTP). Five of the seven analytes detected at these two sites were found to increase downstream of the WWTP, these analytes include GenX which increased from 18.8 to 23.9 ng/l, and perfluorohexanoic acid (PFHxA) which increased from 95.8 to 157.9 ng/l downstream of the WWTP. PFUdA concentration was found to decrease from 1066.3 to 582.7 ng/l between these two sites

3.05.P-Th230 An Investigation into Apolar Extractable Organofluorine

***Melanie Lauria**[1], Merle M. Plassmann[2] and Jonathan P. Benskin[3], (1)Department of Environmental Science, Stockholm*

University, Sweden, (2)Stockholm University, Sweden, (3)Department of Environmental Science (ACES), Stockholm University, Sweden

Current fluorine mass balance (FMB) studies employ extraction procedures designed to extract polar and semi-polar per- and polyfluoroalkyl substances (PFAS), such as perfluoroalkyl acids. However, organofluorine substances encompass a wide range of structures with equally diverse properties. Non-polar PFAS, such as bromotetrafluoro biphenyl, fluorinated liquid crystal monomers and fluorinated polycyclic aromatic hydrocarbons, are known to exist, but are rarely considered in FMB experiments. Moreover, the recent discovery of unidentified extractable organofluorine (EOF) in the blubber of a Greenland killer whale suggests that unknown lipophilic fluorinated substances are already accumulating in wildlife. Therefore, to obtain a complete picture of the organofluorine burden in the environment, alternative extraction procedures must be considered.

The current work aimed to investigate the prevalence of apolar EOF in a diverse range of environmental samples. We started by performing spike/recovery experiments in fish muscle and/or diatomaceous earth using PFAS with a diverse range of physical-chemical properties, namely: 1) perfluorooctane sulfonic acid (PFOS), 2) 1H,1H,2H,2H-perfluorodecyltriethoxisilane (a fluorinated silane used in cosmetics), 3) Scotchgard™ (a side chain fluorinated polymer, SFP), and 4) a textile treated with a C_8F_{17}-SFP. Sample extraction was carried out with polar solvents typically used for EOF determination, followed in series by a re-extraction with hexane to measure apolar EOF. Total fluorine (TF) was measured for neat samples and for extracted ("spent") samples. Combustion ion chromatography was employed for all analyses. Following the spike/recovery experiments, the procedure was repeated on liver and blubber from marine mammals, as well as dust and municipal wastewater treatment plant sludge.

Overall, spike/recovery experiments demonstrated that SFPs are only partially extractable using both polar and non-polar solvents, which might be the case for several PFAS subclasses. In unfortified samples, significant quantities of both polar and apolar EOF were observed. Moreover, notable levels of fluorine were still present in samples after the two consecutive extractions, attributable to either inorganic fluorine and/or unextractable organofluorine. This study highlights the need to characterize unknown apolar EOF and develop novel extraction and analytical methods for the identification of neutral organofluorines.

3.05.P-Th231 Expanding Per- and Polyfluoroalkyl Substances Coverage in Nontargeted Analysis Using Data-Independent Analysis and IonDecon

*Jeremy Koelmel[1], Michael Kummer[2], Kathy Hunt[3], **Stephan Baumann**[4], Emma Rennie[4], Marcus James Chadha, PhD[5], John A Bowden[6] and Krystal Pollitt[1], (1)Yale University, (2)Innovative Omics, (3)Vogon Labs, Canada, (4)Agilent Technologies, Inc., (5)Agilent Technologies, Inc., United Kingdom, (6)University of Florida*

The FluoroMatch suite of open-source software tools simplifies suspect and nontargeted screening of PFAS compounds. It automates file conversion, chromatographic peak picking, blank feature filtering, PFAS annotation based on precursor and fragment masses, and annotation ranking. The software library currently contains 15,643 PFAS fragmentation patterns based on rules derived from standards and literature, and the software automates a process to add more compounds to the PFAS library. FluoroMatch Flow directly processes vendor files and includes a systematic scoring framework to communicate confidence for every feature, alongside reporting confidence levels via the Schymanski schema.

IonDecon is the latest FluoroMatch software tool, it deconvolutes All Ions Data Independent Analysis (DIA) data files to correlate fragment ions with precursor ions. It takes DIA data to generate an open source Data Dependent Acquisition (DDA) formatted file, which can be used in any downstream nontargeted analysis workflow. The deconvoluted All Ions spectra retained the most abundant peaks also observed in DDA, while filtering out much of the artifact peaks. In a neat solution, annotation of PFAS standards using IonDecon and All Ions DIA had the same false positive rate as DDA. However, IonDecon can retain some false fragments in complex samples, moderately increasing the false discovery rate. Overall, incorporating DIA All Ions fragmentation (AIF) and IonDecon can enhance the MS/MS coverage of PFAS (more than tripling the number of annotations in domestic sewage) without resorting to a time-consuming DDA workflow.

3.05.P-Th233 Investigating The Extent of Legacy Per- and Polyfluoroalkyl Substances Contamination in English Surface Waters: An Environment Agency Water Quality Archive Investigation

***Rafael Georgiou**[1], Crispin Halsall[1], Alun James[2], Jonathan Barber[3] and Reza Ahmadian[4], (1)Lancaster University, United Kingdom, (2)Environment and Business, Environment Agency United Kingdom, United Kingdom, (3)Centre for Environment Fisheries and Aquaculture Sciences (Cefas), United Kingdom, (4)Cardiff University, United Kingdom*

Poly- and Perfluoroalkyl Substances (PFAS) are a large group of persistent and bioaccumulative chemicals found in many consumer products. Their unique physicochemical properties of thermal and chemical inertness and water and grease-repellency grant them applicability in many products including non-stick cookware, food packaging, fire-fighting foams, electrical products and others. Subsequently, PFAS enter wastewater and runoff streams and eventually end up in rivers and estuaries. Perfluorooctanoic (PFOA) and Perfluorooctanesulfonic acid (PFOS) also known as legacy PFAS have been widely monitored since the early 2000s as they are present in humans and wildlife, and are associated with an array of toxic effects. They are also listed in the UNEP Stockholm Convention as POPs: PFOA under Annex A, 'elimination', and PFOS under Annex B 'restriction'. However, little is known about their use, lifecycle, sources and occurrence in UK surface waters. Using surface water monitoring data focusing on PFOS and PFOA from the Environment Agency's Water Quality Archive, collected over the period 2019-2022, the aim was to investigate the spatial distribution of these chemicals in the English aquatic environment and identify patterns of their occurrence related to land use.

Given the large number of monitoring sites, the Water Quality Archive provides a foundation for detailed insights into the spatial differences in chemical concentrations. Moreover, clustering analysis for mixed data (k-prototypes) in conjunction with a GIS approach was applied to link land use (Rural and Urban Areas, Non-irrigated Arable Land and Coasts and Estuaries), PFAS occurrence and suspected PFAS-rich nearby sources.

The clustering output successfully separated sites with relatively higher signals from sites with lower concentrations. Most of the higher signal samples were taken from urban areas which were isolated in one cluster. This confirmed that densely populated areas drive higher PFAS emissions. Sites in the vicinity of suspected PFAS point sources of pollution were isolated (airports, firefighting stations, wastewater treatment plants). Overall, this study is useful for chemical risk assessments to effectively predict PFAS hotspots and develop appropriate ways to mitigate PFAS pollution in heavily contaminated areas. Lastly, the results of this study provide the basis for more specific catchment-based monitoring to understand PFAS occurrence and sources in English surface waters.

3.05.P-Th234 Monitoring Produced Gases From PFAS Removal Technologies Using Thermal Desorption Coupled To Gas Chromatography/Mass Spectrometry

*Hannah Calder[1], **Chris Llewellyn**[1] and Jose Juan Rivero Marabé Mr.[2], (1)Markes International, United Kingdom, (2)Agilent Technologies, Inc., Spain*

Many per and polyfluoroalkyl substance (PFAS) removal technologies seek to breakdown the compounds into small components which can be captured or neutralized. Incineration of PFAS, and PFAS containing products like aqueous film forming foams (AFFF), is a common disposal method and aims to degrade PFAS species into HF, CO_2 and water. However if this process does not happen under the correct conditions products of incomplete destruction (PIDs) are created. This is also true of other novel techniques which are now being researched and used to try and managed PFAS. Often PIDs are smaller fluorinated species and have their own detrimental effect upon the environment such as acting as greenhouse gases or ozone depleting substances. This means that PFAS destruction must be monitored in a meaningful way.

Thermal desorption coupled to gas chromatography and mass spectrometry (TD-GC-MS) is commonly applied to monitoring of hazardous organic compounds in ambient air. The technique is well suited to monitoring ultra-volatile species and enables detection of compounds at low ppt levels from canister or online samples.

In this study we will share data generated using a Markes UNITY-CIA Advantage-xr preconcentrator system and the 8890/5977 for GC/MS analysis. The matrix from incineration based sources can be challenging due to high levels of CO2 and water which is a challenge for sample injection, separation and compound detection. The data will show that canister sampling offers a robust approach to performing monitoring of ultra-volatile perfluorocarbon species which are expected to be produced at destruction sites and enable detection limits as low as 1 pptv.

3.05.P-Th235 Quantitation of different compound classes in drinking water to comply with EU regulations by LC-MS/MS workflow and direct injection

***Josep Lliberia**[1], Jianru Stahl-Zeng[2], Oscar Quintela[3], Carlos Bueno[3] and Daniel McMillan[4], (1)Sciex Spain, Spain, (2)AB Sciex Germany GmbH, Germany, (3)Sciex, Spain, (4)Sciex, United Kingdom*

Drinking water analysis is important and all water supply companies need to ensure that the final water product they send out into supply networks is safe and complies with state and country regulations, for example, EU directive 2020/2184. This directive establishes detection limits for a whole series of compound classes that are considering harmful for human healthy and restricted. This work demonstrates the performance of both the SCIEX QTRAP 6500+ and SCIEX QTRAP 7500 systems, to be able to answer the challenge. High sensitivity and robustness of the methods achieve levels for all legislated compounds without need of extensive sample preparation and sample preconcentration step, simply by direct injection.

Standard SOPs will be provided with the necessary information for the analysis of following compound classes:

- Haloacetic acids (HAA) where the sum of 6 selected HAAs must not exceed a concentration of 60mg/L.
- Pharmaceuticals and personal care compounds (PPCPs), including azithromycin and diclofenac where each compound must not exceed a concentration of 100ng/L.
- Polyfluoroalkylated compounds (PFAS) where each PFA must not exceed a concentration of 100ng/L.
- Polar pesticides where each compound (Glyphosate, Gluphosinate and AMPA) where each PFA must not exceed a concentration of 100ng/L.
- Acrylamide where must not exceed a concentration of 100ng/L
- b-Estradiol where must not exceed a concentration of 1ng/L
- 4-nonylphenol where must not exceed a concentration of 300ng/L
- Bisphenol A where must not exceed a concentration of 2.5mg/L

All methods demonstrated high sensitivity and robustness. Most important, possible combination of different compound classes to one HPLC method and easy of change between different methods.

3.05.P-Th236 Utilizing Ion Mobility to Enhance Targeted and Non-Targeted Analysis of Per- and polyfluoroalkyl substances (PFAS) from a Landfill Leachate Sample

*Kari Organtini[1], Sarah E. Dowd[1] and **Cecile Pinto**[2], (1)Waters Corporation, (2)Waters Corporation, France*

Per- and polyfluoroalkyl substances (PFAS) are a group of industrial compounds that have been identified as a class of environmental contaminants of high concern due to their negative health effects and widespread presence in the environment. As new regulations on the use and manufacture of legacy PFAS are imposed, alternative replacement PFAS compounds have emerged. Current targeted methods focus on a short list of legacy and emerging PFAS and are therefore not comprehensive enough for measuring the potential PFAS contamination in environmental samples. Non-targeted analyses (NTA) with high-resolution mass spectrometry (HRMS) is a promising technique for the discovery and identification of new PFAS. Here, HRMS was coupled with liquid chromatography and ion mobility separation on the SELECT SERIES™ Cyclic™ IMS QTOF mass spectrometer (Waters Corporation) to improve the number of detected features in a complex environmental sample: landfill leachate. As PFAS may be present at low levels in complex samples, a data independent acquisition was utilized to get as much information as possible in a single injection. Detected peaks were first compared to an internal HRMS PFAS library for identification. Identifications were filtered based on metrics like accurate mass, retention time error, diagnostic fragments and measured collision cross section (CCS). In the sample, several legacy PFAS including perfluoroalkyl sulfonates, perfluoroalkyl carboxylic acids, and fluorotelomer sulfonates were identified. For the discovery of PFAS not in the suspect library, IMS adds an additional advantage as this class of compounds have lower CCS values compared to other compound classes of similar *m/z*. In this study, filtering peaks based on their observed drift time and *m/z* revealed polyhalogenated species that were in the leachate sample even at low intensity levels. A series of PFAS previously unreported were tentatively identified in the leachate samples. As authentic standards for new PFAS are difficult to find, the certainty of proposed structures benefit greatly from the data generated with LC-IMS-HRMS.

3.05.P-Th237 Extending PFAS coverage and sensitivity in a direct injection UPLC-MS/MS method for water matrices based on EU and UK Drinking Water regulations

*Jenny Louise Davies[1] and **Cecile Pinto**[2], (1)Waters Corporation, United Kingdom, (2)Waters Corporation, France*

Per- and Polyfluoroalkyl Substances (PFAS), are extremely persistent in the environment. Their production and use have resulted in severe contamination of soil, water and food. To protect public health, advisory and regulatory limits continue to be created and updated. Consequently, routine PFAS analysis has become challenging as not only low detection limits are required, but extensive compound coverage is a prerequisite nowadays.

The purpose of this work was to demonstrate a direct injection method to fulfil the requirements of a list of 47 per-and polyfluoroalkyl substances (PFASs) by the UK Drinking Water Inspectorate (DWI) and the 20 PFAS contained in the 2020 EU Drinking Water Directive (DWD) totaling 48 analytes. The work was carried out using an ACQUITY™ Premier UPLC system coupled to the XEVO™ TQ Absolute tandem quadrupole mass spectrometer using a UniSpray™ ion source. Sub-ng/L Method Detection Limits (MDLs) were achieved for all 48 analytes using a 50 µL injection volume. Method robustness was shown with validation batches analyzed over three days in drinking water, surface water and river water.

Improvements in both the analytical and isolator column technologies demonstrated in this work, as well as enhancements in negative ion sensitivity from the Xevo TQ Absolute Mass Spectrometer are helping to support ongoing efforts in PFAS analysis. This allows for easier, more robust, and accurate options as PFAS analysis continues into the future.

3.05.P-Th238 Screening of Legacy Precursor Per- and Polyfluoroalkyl Substances (PFAS) and Potential Precursors in Curtains, Sofas and Carpets Fabric Samples

***D. Liwara**[1], Pim Leonards[1], Sicco Brandsma[1], Huiling Liu[2], Jon Eigill Johansen[2] and Jacob de Boer[1], (1)Vrije University Amsterdam, Netherlands, (2)Chiron AS, Norway*

Per- and polufluoroalkyl subtances (PFAS) are a huge group of manmade compounds used for example as water and oil repellents to protect textiles and fabrics. Due to a growing concern around these compounds, industries introduced new PFAS varieties. Various PFAS are therefore found in fabric samples, for example, due to contamination with dust, other manufactured products, storage or transport. Possible restrictions concern only legacy PFAS, and not suspected or recently identified compounds, meaning that the environment and the population are still potentially exposed to unknown chemicals. This study focusses on the synthesis of newly synthezised PFAS precursors and screen them together with conventional PFAS in 32 curtains, sofas and carpets fabric samples. Synthesized compounds include *N*-sulfo propyl perfluorohexane sulfonamide, short-chain perfluoroalkane sulfonamide derivatives (C4 and C6), namely *N*-alkyl perfluoroalkane sulfonamide and *N*-alkyl perfluoroalkane sulfonamidoacetic acid, *N*-trimethylammoniopropyl perfluoroalkane sulfonamide (C4, C6 and C8), 6:2 fluoroteomersulfonyl propanoic acid, 6:2 fluorotelomerthia propanoic acid, *N*-dimethyl ammonio propyl perfluoroalkane sulfonamide (C4, C6 and C8) and *N*-sulfopropyl dimethylammoniopropyl perfluorohexane sulfonamido propyl sulfonate. Samples were extracted two times with methanol before clean-up using Envi-carb. Samples were analysed by LC-MS/MS. Legacy PFAS were observed in low concentrations for most of the samples but in some of them, particularly in fabrics based on recycled materials, concentrations were much higher. For instance, PFOS was identified in two samples with a concentration of 56 ng/g (22335 ng/m^2) and 0.87 ng/g (1660 ng/m^2), considerably higher than EU limit of 1 µg/m^2. Various newly synthesized precursors were also identified, especially in the carpet samples. For instance, 2:2 FTS (4.3 ng/g – 8223 ng/m^2) and MeFBSAA (0.18 ng/g – 783 ng/m^2) were detected. These preliminary results suggest that PFAS not usually screened can also be present in carpets. Thesamples will also be analysed for the volatile PFAS by gas chromatography.

3.05.P-Th239 Per- And Polyfluorinated Alkyl Substances (PFAS) in Car Interior Materials

Ulrika Eriksson[1] *and Maria Larsson*[2]*, (1)Örebro UniversitySchool of Science and Technology, Oerebro University, Sweden, (2)MTM Research Centre, Orebro University, Sweden*

Per- and polyfluorinated alkyl substances (PFAS) is a chemical family with several thousands different compounds that have been used in numerous different applications due to their water- and grease repellent properties. The usage of PFAS includes a vast number of consumer product applications, such as in cosmetics, textiles, leather, paperboard, waxes, and electronic. Increasing knowledge and awareness about the toxic and bioaccumulative properties of PFAS has led to increasingly stricter regulations and voluntary phase-out not only of single PFAS compounds but also of the PFAS family as a whole. Though a number of recent studies address PFAS in consumer products, there is still only a few studies about PFAS in car interior materials. PFAS in car interior materials implicates an environmental risk at end-of-life when destinated to landfills, and also pose a risk for human health considering the large number of hours many drivers spend in cars. Sources for PFAS in car interior materials may be intentionally added PFAS for grease-and water repellent performance, PFAS present in the original feedstock of materials, or stem from recycled materials used in the production. Investigations of PFAS contamination patterns in car interior material can provide increased understanding of contribution from both intentionally added PFAS as well as the role of recirculation and background contamination.

In this study, samples from car interior materials including foam, artificial leather, car seat textile, and plastic components from 2022-2023 were extracted and analyzed for a broad range of PFAS compounds (persistent PFAS, intermediates, and precursors). Extraction was performed using ultrasonication with hexane:isopropanol and acetonitrile:methanol. Analysis was performed using liquid chromatography tandem mass spectrometry (LC-MS/MS).

3.05.P-Th240 Fate of PFAS in dune infiltration systems

Elvio D Amato*, KWR Water Research Institute, Netherlands*

Per- and polyfluoroalkyl substances (PFAS) are a very broad and diverse group of chemicals that pose a risk to human end environmental health. Several processes contribute to the spreading of PFAS in the environemnt, including atmospheric transport via sea-spray aerosols (SSA), which are known to contain elevated levels of PFAS. Due to their amphiphilic properties, PFAS are impervious to conventional treatment processes used for drinking water production, including dune infiltration. Furthermore, deposition of SSA may potentially introduce additional PFAS in coastal dunes, and pose a risk to drinking water sources. In this study, we investigated the occurrence of PFAS in SSA, soil, and groundwater in a dune infiltration area. The presence of additional PFAS that are not included in targeted methods was also investigated using complementary suspect and non-targeted screening (SNTS) analysis performed on SSA samples. Strong relationships were found between PFAS and Na measured in air samples, indicating that SSA was likely a major source of atmospheric PFAS. The general trend indicated increasing concentrations of carboxylic acids from C5 to C8 followed by decreasing concentrations from C8 to C11. Sulfonic acids included PFOS, PFHxS, PFBS and PFHpS. PFOS and PFOA were by a significant margin the most abundant compounds in SSA. Precursors such as 6:2 FTS and FOSA were also detected in SSA, however, no correlations with Na were observed. SNTS analysis performed on SSA samples identified several compounds (confidence level 2-3 according to Charbonnet et al. (2022)) that were not included in the targeted method, such as MeFBSAA and fluorotelomers, which may contribute to undetected contamination in the dunes, and formation of more stable PFAS upon degradation of precursors. Incresing PFAS levels were measured in groundwater upon infiltration in coastal dunes. Contamination in soil and groundwater appeared to be consistent with potential contributions from SSA deposition, however, further research is needed to quantify the input of PFAS from SSA deposition, and understand transport mechanisms of PFAS in the saturated and unsaturated zones. SNTS analyses tentatively annotated several unmonitored PFAS in SSA, including precursors. Complementary analyses aiming at quantifying the total PFAS burden should be performed to investigate the potential role of PFAS precursors in coastal dunes.

3.05.P-Th241 To Isolation and Beyond: A New Mixed Mode Column Approach for PFAS Chromatography

Kari Organtini[1] *and* ***Cecile Pinto***[2]*, (1)Waters Corporation, (2)Waters Corporation, France*

Per- and polyfluorinated alkyl substances (PFAS) are one of the most commonly discussed and researched environmental contaminants. This is due in part to how widespread and impactful PFAS contamination has become, but also from increasing media awareness. Initially, most focus was on monitoring PFAS in water, mainly drinking water, but the prominence of these compounds in everyday items have expanded analysis to other matrices such as food, cosmetics, and human biofluids. As more research is focused on PFAS exposure and impacts, analytical techniques have been advancing as well to help progress research and monitoring efforts.

One of the constantly changing areas in PFAS analysis is the list of PFAS compounds that are being targeted for. One trend impacting this is the movement of manufacturers from using long chain PFAS to short chain and ultra-short chain PFAS. As the chain length shortens, chromatography can become more complicated, not only from a perspective of the analytical column the sample is separated on, but also regarding the functionality of the isolator column that is crucial to delaying PFAS interference from the LC system. These compounds require advancements in chromatographic techniques to properly detect and quantify in samples.

Faced with this challenge, a new mixed mode column (XBridge™ Premier BEH™ C18 AX Column) was evaluated as both an isolator column and an analytical column to provide better retention of short chain and ultra-short chain PFAS. This presentation will demonstrate how this column was applied in both cases to not only delay chromatographic interference, providing accurate sample quantitation, but also to extend the possible list of PFAS analyzed in a single injection to include PFAS chain lengths.

3.05.P-Th242 Uncovering the PFAS Complexity: A powerful IMS-QTOF Workflow for Biota Analysis combining Targeted and Non-target Approaches

Noud van der Borg[1]*, Georgios Gkotsis*[2]*, Carsten Baessmann*[3]*, Dimitrios E. Damalas*[4] *and Nikolaos S. Thomaidis*[4]*, (1)Bruker Nederland B.V., Netherlands, (2)Chemistry, National and Kapodistrian University of Athens, Greece, (3)Bruker Daltonics GmbH, Germany, (4)National and Kapodistrian University of Athens, Greece*

With their widespread presence in the environment and organisms, and their persistent, bioaccumulative, and toxic (PBT) properties, Per- and Polyfluoroalkyl Substances (PFAS) pose a significant challenge as organic micropollutants. The vast array of commercially available PFAS compounds and their transformation products necessitate tight monitoring within environmental compartments. This study aims to the development of a combined targeted and non-target workflow for the thorough characterization of PFAS in complex environmental matrices, particularly biota, by incorporating trapped ion mobility spectrometry (TIMS) into LC-HRMS.

Biota extracts were prepared by a generic protocol for the simultaneous extraction of 56 PFAS compounds from various sub-groups. RPLC was coupled to a novel heated electrospray source (HESI) for analyzing the extracts in negative ion mode on a timsTOF Pro 2 (Bruker). The targeted workflow utilized bbCID (broadband collision-induced dissociation) in data-independent acquisition (DIA), while the non-target workflow employed PASEF (parallel accumulation and serial fragmentation) in efficient data-dependent acquisition (DDA). The CCS-aware target analysis incorporated information for a list of 60 PFAS compounds, including elemental composition, retention time, MS1 and MS2 qualifier ions, and ion mobility-derived collision cross section (CCS) values.

The results of the targeted screening demonstrated improved sensitivity and lower PFAS detection limits due to HESI, along with higher quality for the full-scan MS and bbCID MS/MS spectra supported by the ion mobility filtering. Adding CCS values enhanced the identification confidence.In the non-target workflow, raw data was transformed into a comprehensive feature table, and the detected features were filtered by Kendrick mass analysis. A PFAS suspect list with 5,000 compounds was employed for further annotation. *In-silico* prediction of MS/MS spectra and CCS prediction aided the identification of suspected compounds. Notable examples highlight the identification of suspected features as PFAS-related compounds, supported by the extensive MS2 coverage provided by PASEF.

This combined approach contributes to a better understanding of the chemical universe of PFAS in the environment and plays a crucial role in safeguarding the environment, wildlife, and human health in a One Health approach.

3.05.P-Th243 Fate of Per- and Polyfluoroalkyl Substances in a Waste-to-Energy (WtE) Plant – Transport and Distribution in WtE Residues

Sofie Eleonora Björklund[1,2]*, Eva Weidemann*[3]*, Åsa Beckert*[4] *and Stina Jansson*[3]*, (1)Department of chemistry, University of Umea, Sweden, (2)Industrial Doctoral School, Umea university, Sweden, (3)Department of chemistry, Umea University, Sweden, (4)Umea Energi, Sweden*

Per- and polyfluoroalkyl substances (PFAS) are a ubiquitous group of man-made chemicals used in various consumer products. Given their widespread use, some products containing PFAS will eventually end up in waste streams which in many European countries are processed in Waste-to-Energy (WtE) facilities. The fate of PFAS in full-scale incineration is largely uncertain, and there is a divergence between lab-scale and full-scale studies, highlighting the need for a comprehensive investigation of the fate of PFAS in WtE.

The present work is the first study assessing the fate of PFAS in a WtE plant and investigating the distribution of PFAS in solid, gaseous, and liquid residual fractions. Bottom ash, filter ash, boiler ash, air pollution control residue, gypsum, flue gas (before wet flue gas treatment and in the stack), condensate and treated process water from the in-house water treatment plant was sampled at an operating WtE plant. The plant was incinerating a mixture of household waste (60%) and industrial waste (40%). All samples were analyzed for 18 individual PFAS by LC-qTOF/MS.

PFAS was detected in filter ash and bottom ash, but not in boiler ash, air pollution control residue or gypsum. PFAS was observed in both condensate and treated process water. Interestingly, the total concentration of PFAS in treated process water was 25-100% higher than that in condensate, indicating that there are additional sources of PFAS from the wet flue gas treatment to the treated process water.

PFAS was detected in both untreated flue gas and in the stack. A reduction of the total concentration of PFAS was observed when comparing concentrations before and after the wet flue gas treatment, on average -35% ±10%. This suggests that the wet flue gas treatment can transfer some PFAS from the flue gas into other residual streams.

The total annual release of PFAS via WtE residues from this plant was estimated to be between 7 and 20 g, equally distributed between bottom ash, treated process water and stack flue gas. In comparison, the annual release via leachate from the temporary waste stockpile at the same plant was estimated to be 33 g per year.

This study provides the first insights into the transport and distribution of PFASs in a WtE plant. Moreover, these results demonstrate that some PFAS are not fully degraded by the high temperatures during WtE processes and can be emitted from the plant via bottom ash, treated process water, and flue gas.

3.05.P-Th244 Electrochemical Degradation of Perfluorinated Organic Compounds (PFAS) in pH-Controlled media using Boron-Doped Diamond (BDD) Flow Cell

Dua'a M. F. Tahboub[1]*, Klaus Kerpen Dr*[2] *and Ursula Telgheder Dr*[2]*, (1)Instrumental Analytical Chemistry, University Duisburg-Essen (Uni DUE), Duisburg, Germany, (2)Instrumental Analytical Chemistry, University of Duisburg-Essen (Uni DUE), Germany*

Water contamination by Per- and polyfluoroalkyl substances (PFAS) presents a pressing environmental concern, given their persistent and bioaccumulative nature, posing threats to ecosystems and human health. PFAS, integral to numerous industries, consequently, PFAS experiences substantial release into water sources. Conventional treatment methods challenge incomplete remediation, by-product accumulation and high energy and chemical consumption. The utilization of the BDD-flow-cell promises a safe, efficient, and cost-effective method for PFAS removal emphasizing the importance of minimizing auxiliary substances and by-products to prevent secondary water pollution. This research investigates a promising electrochemical degradation (ED) technique employing a Boron-Doped Diamond (BDD) flow-cell under varying pH conditions. BDD is utilized to overcome these challenges due to its high chemical and electrochemical stability, especially the electrochemical resistance even under severe conditions.

Our aim is to investigate the PFAS-ED method, targeting various PFAS chain lengths and moieties. Employing LC-MS/MS analysis, we elucidate the electrochemical degradation (ED) process, providing comprehensive mass balances for degradation products. Model water experiments, comprising Perfluorooctanoic acid (PFOA), Perfluorooctanesulfonic acid (PFOS), and Perfluorobutanesulfonic acid (PFBS), will be conducted using a BDD electrode flow-cell system. The flow-cell, with a BDD working electrode and a stainless-steel counter electrode, circulates electrolyte-PFAS solution, optimizing the current density for maximum PFAS degradation. Exploring different pH media, including acidic, basic, and neutral electrolyte-PFAS solutions, will help to determine the optimum conditions for ED efficiency.

Preliminary results reveal higher degradation efficiency in basic media, followed by neutral, while acidic media exhibits the least ED efficiency. Our research investigates the role of pH in the ED process, elucidating the impact of OH- and H+ ions for optimal selectivity and efficiency. This study not only advances ED methods for PFAS remediation but also provides insights into reaction mechanisms for sustainable water purification. Future work will implement the optimized ED method for real water treatment.

Acknowledgment: Greatly thankful for the financial support from the German Academic Exchange Service (DAAD).

3.05.P-Th245 Solving the PFAS Challenge: Comprehensive Screening of Environmental Samples against 1000s of Compounds in a Single Run

Arnd Ingendoh[1]*, Carsten Baessmann*[2]*, Eva-Maria Niehaus*[3] *and Andrea Kiehne*[3]*, (1)Bruker Daltonics GmbH & Co. KG, Bremen, Germany, (2)Bruker Daltonics GmbH, Germany, (3)Bruker Daltonics, Germany*

PFAS are known as “forever chemicals” due to their persistent, bio-accumulative, toxic (PBT) properties and ubiquitous presence in the environment and organisms. Ca. 5000 PFAS are marketed worldwide, making their systematic environmental monitoring an extremely challenging task. On top, there is a lack of reference standards or spectral libraries, and there are plenty of isomers. Adding trapped ion mobility spectrometry (TIMS) to UHPLC-HRMS allows for comprehensive monitoring of organic micropollutants in environmental matrices such as water and soil.

Water samples were spiked with sets of PFAS compounds or taken from common household and environmental water resources. Data independent acquisition was performed on a high-resolution mass spectrometer equipped with ion mobility. Kendrick mass defect (KMD) analysis filtered potential PFAS from the matrix background, based on the fluorine content (repeating CF_2 units). Spectra were compared with either a spectral library of available PFAS standards in a targeted workflow or with the Norman network and NIST suspect lists of 5000 entries for non-targeted analysis. The Norman and NIST suspect lists contain information about the elemental composition and the InChI structures for PFAS which were compared with the exact mass, MS/MS fragmentation and CCS values of the experimental data for an automated and untargeted identification of all PFAS present in the sample.

The ion mobility feature of the system was utilized for several purposes. First, it can separate coeluting isobars and isomers. Second, the TIMS filter results in higher sensitivity and lower detection limits of the targeted PFAS as well as significantly higher quality of full-scan MS and bbCID MS/MS spectra. Finally, collisional cross sections (CCS) as additional identification criteria enhanced the identification confidence with is based on the exact mass, diagnostic fragmentation ions and the isotope pattern fit. The wide-scope suspect screening of real-life samples against the suspect lists proved to be a comprehensive approach for a fast and efficient identification and quantification of PFAS against the total set of 5000 compounds in complex environmental matrices. Therefore, it will assist in understanding the chemical universe of PFAS in the environment and protecting environment, wildlife, and human health.

3.05.P-Th246 Ion Mobility Filtering for Non-Targeted Analysis of PFAS from Environmental Samples Collected at a Ski Resort

*Kari Organtini[1], Sarah E. Dowd[1], Frank Dorman[1], Marian Twohig[1], Jean Carlan[2] and **Cecile Pinto**[3], (1)Waters Corporation, (2)Department of Chemistry,, Dartmouth College, Germany, (3)Waters Corporation, France*

Perfluoroalkyl substances (PFAS) are a group of commonly used compounds, known particularly for their hydrophobic, non-stick properties. Their unique chemistry led to their use in ski waxes. While competition rules have recently banned the use of PFAS-containing ski wax, the persistence of PFAS means they could still be detected for years. Given the hazards and concern about PFAS contamination, we investigated if PFAS could be detected at a ski area that supports a high-level race program. While previous studies have looked at targeted analysis for known PFAS, this study used high-resolution mass spectrometry (HRMS) and ion mobility to look for new and unexpected PFAS. Samples were collected from a variety of locations within a ski area in New Hampshire to investigate the trends of PFAS in this type of environment. Data collection was done with ion mobility enabled data-independent acquisition on a SELECT SERIES™ Cyclic™ IMS (Waters Corporation). The added dimension of ion mobility can be used for spectral clean-up, which aids in the elucidation of unknown compounds as well as confirmation of known target compounds. Detected peaks were first compared to an internal HRMS PFAS library for identification. In the extracts, several legacy PFAS including perfluoroalkyl sulfonates, perfluoroalkyl carboxylic acids, and fluorotelomer sulfonates were detected. Unknown peaks were selected for further scrutiny based on their detected drift time in the ion mobility dimension. Previous studies have shown that the CCS values of per- and poly-fluorinated compounds are lower than compounds of similar *m/z*. An ion mobility filter was created based on this knowledge and applied to a list of detected peaks to select for possible PFAS. Using this filter, a series (C9-C24) of polyfluorinated carboxylic acid compounds with one hydrogen substitution in the carbon chain was tentatively identified. The distribution for this series of compounds was not consistent, with longer chains found in samples from the base of the ski slopes and the shorter chains in the snowmaking retention pond. While authentic standards were not available for many of the tentative identifications, two standards were purchased and compared with experimental data to confirm proposed structures.

3.05.P-Th247 Pushing PFAS Possibilities: The hunt for Ultra Sensitivity to Reach ppq EPA Health Advisory Levels

*Kari Organtini[1] and **Cecile Pinto**[2], (1)Waters Corporation, (2)Waters Corporation, France*

PFAS are well known chemicals with a variety of commercial and consumer uses, characterized by their extreme stability and structural diversity. PFAS are highly persistent and toxic contaminants that accumulate in humans, animals, and the environment. Detection requirements for PFAS have been getting more challenging as advisory and regulatory limits continue to be created and updated. In June 2022, the US EPA tightened its health advisory levels (HALs) in drinking water from 70 ng/L to 0.004 ng/L for PFOA and 0.02 ng/L for PFOS. Additionally, final HALs were set for PFBS at 2000 ng/L and HFPO-DA (commonly referred to as GenX) at 10 ng/L. The near zero PFOA and PFOS levels pose analytical challenges regarding instrument sensitivity and sample preparation conditions to limit contamination. This goal of this work was to show with proper care during sample preparation and analysis using a highly sensitive mass spectrometer, these near zero limits are possible to detect.

All samples were prepared in a typical shared laboratory environment, taking extreme care to screen all consumables and reagents for PFAS contamination before use. 250 mL water samples were extracted using Oasis™ WAX SPE Cartridges, followed by analysis using a highly sensitive mass spectrometer.

This presentation will discuss best practices for sample preparation to reduce contamination as well as the minimum level of contamination achieved during these experiments. Additionally, information on the Limit of Quantitation (LOQ) for each compound and method recovery values will be shared.

3.05.P-Th248 Performance of Different Sorbents on the Removal of Per- and Polyfluoroalkyl Substances from Aqueous Firefighting Foam Impacted Ground- and Wastewater

***Joost Dalmijn**, Department of Environmental Science (ACES), Stockholm University, Sweden*

PFAS containing firefighting foams are typically applied on sites with increased risk of flammable liquid (Class B) fires, such as air bases or refineries. In fire fighting training activities as well as fire emergencies PFAS-containing Aqueous Film Forming Foams (AFFF) have been and are used. The PFAS fluorosurfactants in these foams create a thermally stable film that covers the flammable liquid. Although AFFF mitigates Class B fires, the remnants of these fires and training activities poses an environmental risk as large volumes of PFAS containing wastewater is produced, which can possibly contaminate soil, groundwater and surface water. The aim of this research is to assess the typical PFAS constituents of AFFF impacted waste and groundwater and to study the intrinsic removal of these molecules from these field derived water matrices by various sorbents in a batch setup.

3.05.P-Th249 Developing Targeted and Untargeted Liquid Chromatography-Tandem Mass Spectrometry Methods for Analyzing PFAS in Potable and Wastewater Samples

***Emir Nazdrajić**[1], Arthur E Lee[1], Shannon C Lemmens[1], Anish Arjuna[1], Larry Campbell[1,2] and W Scott Hopkins[1,3,4], (1)Department of Chemistry, University of Waterloo, Canada, (2)Bedrock Scientific Incorporated, Canada, (3)Watermine*

Innovation, Canada, (4)Centre for Eye and Vision Research, Hong Kong
Per- and polyfluoroalkyl substances (PFAS) are a group of man-made compounds with a wide range of applications from industry to everyday life (*e.g.*, coatings to enhance corrosion resistance, emulsion polymerization, cookware, food packaging, etc.). Although the use of some PFAS has been restricted, their ubiquity has resulted in significant accumulation within the environment. Many drinking (potable) water and wastewater plants have been employing methods intending to reduce PFAS concentrations in environmental media. However, little research has been devoted to studying PFAS degradation products and their potentially adverse impact on the environment.

Our work focuses on developing the sample preparation, as well as both targeted and non-targeted liquid chromatography-tandem mass spectrometry method. The targeted method is improved from the 4th Draft EPA method and employed on Agilent 1100 liquid chromatography coupled to a SCIEX 6500 triple quadrupole mass spectrometer, while the non-targeted method is developed on a Waters Acquity liquid chromatography coupled to a Waters Synapt G2-Si quadrupole time of flight mass spectrometer equipped with a ion mobility spectrometry.

Preliminary results of the targeted method include the assessment of the instrumental minimum detection limits, extraction recoveries, and instrumental carryover. The instrumental minimum detection limits for a set of 40 PFAS compounds ranged between 0.05 and 2.0 ng L^{-1}. At the same time, the recoveries from aqueous and solid samples met the requirements of the 4th Draft EPA method for detected PFAS. Preliminary results of the non-targeted method yield less than 5 ppm mass accuracy of the standards and isotopically-labeled standards.

This study is relevant to the worldwide community because it focuses on developing a method for analyzing PFAS present in aqueous and (bio)solid samples. The non-targeted method will provide higher degrees of confidence when assigning annotations to unknown features from environmental samples by combining retention time, mass accuracy, and collision cross sections from the ion mobility spectrometry. This project is also directed towards developing machine learning algorithms that will aid the identification of unknown features in non-targeted spectra.

3.05.P-Th251 An ultra-high sensitivity and robust analysis of PFAS compounds in multiple water sources.

***Jianru Stahl-Zeng**[1], Kay Hup[2], Abdessamad Chahbouni[2] and Josep Lliberia[3], (1)AB Sciex Germany GmbH, Germany, (2)Het Waterlaboratorium, Netherlands, (3)Sciex Spain, Spain*
PFAS compounds are becoming increasingly ubiquitous in our environment due to overuse and their lack of breakdown, ensuring that this will be a challenge for decades to come. Therefore, it is imperative to provide rigorous and sensitive analytical testing to regulate these compounds and try to limit their possible effects on human health

As the limits for PFAS compounds continue to be reassessed and reduced it becomes increasingly important to provide methods which achieve limits of detection which are as low as is reasonably possible

It has been well documented that when performing PFAS analysis contamination and interference can be large challenges of a successful analysis due to the numerous sources of these compounds and the interferences which can be observed. Here, we detail the steps which we recommend being taken to ensure the analysis of PFAS compounds is as simple and challenge free as possible:

Overall, it is possible to achieve ultra-high levels of sensitivity for PFAS compounds down to 0.2 ng/L when using the SCIEX 7500 System. Excellent levels of precision, accuracy and linearity have been achieved for all compounds analyzed. Detection limits down to 0.06 ng/L in three different water matrices. The importance of reducing interferences and contamination is paramount to a successful PFAS analysis. And long term stability of the method will be demonstrated in this poster.

3.06 Application of Biomonitoring Approaches to Support Surveillance of Chemical Exposure in the Environment

3.06.T-01 On-site Application of Biological Early Warning Systems in combination with high resolution Online-Chemical Monitoring

***Ali Kizgin**[1], Danina Schmidt[1], Julian Bosshard[2], Heinz Singer[3], Juliane Hollender[4], Eberhard Morgenroth[5], Cornelia Kienle[6] and Miriam Langer[7], (1)Ecotox Center Eawag-EPFL, Switzerland, (2)Environmental Chemistry, Eawag, Switzerland, (3)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (4)Environmental Chemistry, Environmental Chemistry, Eawag, Swiss Federal Institute of Aquatic Science and Technology, Switzerland, (5)ETH Zurich, Switzerland, (6)Ecotox Centre, Switzerland, (7)University of Applied Sciences and Arts Northwestern Switzerland (FHNW), Switzerland*
Detection of problematic substances in wastewater effluents by using traditional toxicity testing approaches including ecotoxicological bioassays or chemical analysis with discrete effluent samples, poses a difficult and costly task for environmental researchers. A continuous monitoring approach using biological early warning systems (BEWS) coupled with online chemical analysis to indicate micropollutant dynamics in the effluent could be an interesting combination to address this challenge. In this study, three selected BEWS with *Chlorella vulgaris*, *Daphnia magna* and *Gammarus pulex* as test organisms, were operated in a full-scale municipal wastewater treatment plant (WWTP) in parallel with an automated online HPLC high resolution mass spectrometric system (MS2Field) to monitor wastewater effluent. During the five weeks of operation, the

BEWS showed alarms and deviations from normal behavior, while target and non-target screening indicated micropollutants at elevated concentrations in the treated wastewater. In the second week, increased *Gammarus* activity was registered during a rainfall event, which could be related to the change in abiotic parameters. In the third week, the presence of several suspect compounds was correlated with behavioral responses that led to alarms. In addition to the suspect compounds, a pesticide not authorized in Switzerland was identified by non-target analysis. This pesticide occurred in concentrations close to literature EC50 concentrations. In subsequent verification tests, test organisms in the BEWS were exposed to this pesticide in the same concentration range as measured in the effluent. This provided evidence that the measured concentration of the pesticide in the WWTP effluent most likely induced the organisms' response. Overall, the integration of biological and chemical monitoring with continuous and high temporal resolution provided a promising approach to identify critical contamination hotspots in WWTP effluent with relatively low cost and maintenance.

3.06.T-02 Development of a Holistic Approach for River Health Assessment: from Bioindicators to the Ecosystem
Isabella Calattini[1], *Claudio Leonzio*[2], *Dario Giani*[3], *Stefania Ancora*[2], *Tiberio Fiaschi*[4], *Pietro Centorrino*[5], *Letizia Marsili*[3], *Maria Cristina Fossi*[6], *Claudia Angiolini*[4], *Silvia Casini*[3] *and Tommaso Campani*[3], *(1)University of Siena, Siena, Italy, (2)Department of Physical, Earth and Environmental Sciences, University of Siena, Italy, (3)University of Siena, Italy, (4)Department of Life Sciences, University of Siena, Italy, (5)Associazione LaGorà, Italy, (6)Department of Physical Sciences, Earth and Environment, University of Siena, Italy*
Freshwater ecosystems are essential for the planet. Despite the importance of the freshwater ecosystems, the anthropogenic pressures decrease water quality and affect the ecological health of river basins. The Water Framework Directive has the key goal of protecting the aquatic environment in its entirety, and establishes the importance of defining the ecological status of rivers with an interdisciplinary e multiparametric approach (2000/60/CE). In this study, we propose an integrated and holistic methodology to evaluate the river's health status taking into account chemical, ecological and ecotoxicological parameters. We used the Elsa River as a case study. It is a tributary of the Arno River, in Tuscany (Italy). The area is characterised by agricultural and industrial activities, by the presence of some cities and a river park. Chemical parameters of water (concentrations of nitrates, phosphates, ammonium and pH) were measured thanks to a citizen science project, inscribed to "Fresh Water Watch", carried on by the population and high schools of the area. For the ecological analysis, the EBI (Extended Biotic Index) and the FFI (Fluvial Functionally Index) were evaluated. The freshwater fish Italian chubs (*Squalius squalus*) were used as bioindicators, for the chemical and ecotoxicological analyses. We evaluated the microplastics ingestion, heavy metals and OCs concentration and a battery of biomarkers (AChE, EROD, PAHs metabolites, LPO, GST, LDH, IDH and ENA Assay). The results showed a general negative trend going from upstream to downstream, with some sources of macronutrients and contaminants, mainly in correspondence with the presence of inhabited centres. The ecotoxicological analysis showed a genotoxic effect correlated to Hg, PCBs and B(a)P metabolites in bile. The contamination is probably due to agricultural and industrial activities, vehicular traffic, polluted tributaries and inappropriate disposal of waste. The greatest abundance of microplastics was found in chubs caught in the river park, due to the presence of the urban area, the regular release of wastes along the river in the past, and the increase of tourism in the last years. This holistic approach has permitted us to define the health status of the river and identify the contamination and the sources of contaminants. This tool is helpful in promoting mitigation actions to block the sources of impact and bring the river to a good ecological state.

3.06.T-03 Temporal and Spatial patterns of Xenobiotics in German fish
Belen Gonzalez-Gaya[1], *Maitane Olivares*[2], *Nestor Etxebarria*[3], *Jan Koschorreck*[4] *and Olatz Zuloaga*[5], *(1)ESTACI”N MARINA DE PLENTZIA. UPV/EHU, Spain, (2)Analtytical Chemistry, Research Center for Experimental Marine Biology Biotechnology “Plentziako Itsas Estazioa”, University of the Basque Country (PiE-UPV/EHU), Spain, (3)Department of Analytical Chemistry, University of the Basque Country (UPV/EHU), Spain, (4)German Environment Agency (UBA), Germany, (5)Analytical Chemistry, University of the Basque Country (UPV/EHU), Spain*
The complexity of the occurrence of emerging contaminants in aquatic environments is remarkable. The different physicochemical properties of the compounds and thus, their degradation and bioaccumulation processes affecting aquatic organisms are often missing due to a lack of analytical procedures to measure emerging compounds in biota. Moreover, the temporal trends in the occurrence of compounds that have been overlooked in the monitoring programs since decades are a scientific gap that could be tackled thanks to the sample repositories stored in the specimen banks across Europe.

The objective of this study is to apply the recently optimized protocol in the Plentzia Marine Station (EHU/UPV) to analyze xenobiotics in a biological tissue (fish filet) from a non-target point of view in historical and present biota samples.[1] A collection provided by the German Specimen Bank of 24 samples of bream from the Saale and Mulde rivers gathered biannually from 1996 to 2018, plus 25 samples from other rivers in Germany, including Rhine, Elba, Danube, and Saar among others, taken in 2018 was analyzed. The assessment was performed on a Thermo Scientific Dionex UltiMate 3000 UHPLC coupled to a Thermo Scientific™ Q Exactive™ Focus quadrupole-Orbitrap equipped with a heated ESI source (Thermo, CA, USA). Analysis of the extracts was performed in positive and negative mode in the Full scan data-dependent MS2 discovery acquisition. A selection of circa 250 compounds, including personal care products and pharmaceuticals, consumption products, industrial compounds (PFAS, plasticizers), and pesticides was used for the target analysis. Finally, a full suspect analysis with a database of more than 40,000 compounds from the NORMAN list will be presented.

Preliminary results in the targeted analysis revealed that 87 out of 304 emerging pollutants were present in the fish. Pesticides, parabens and phthalates were the families found at higher concentrations, but there were changes in relative presence through the years and locations. For that, the assessment of archived biological samples is of great interest to perform retrospective analysis with new high-throughput analytical techniques.

Focused Ultrasound-Based Extraction for Target Analysis and Suspect Screening of Organic Xenobiotics in Fish Muscle. *STOTEN* **2020**, *740*, 139894. https://doi.org/10.1016/j.scitotenv.2020.139894.

3.06.T-04 Exploring Plant Protection Product Dynamics in Terrestrial Ecosystems: Insights from Bee Pollen
Sergio Cirelli[1], *Emmanuel Schaad*[1], *Christina Kast*[2], *Thomas D. Bucheli*[3] *and Aurea C. Hernández*[1], *(1)University of Bern, Switzerland, (2)AgroSwiss Bee Research Centre, Agroscope, Switzerland, (3)Environmental Analytics, Agroscope, Switzerland*
Plant protection product (PPP) interactions with the environment are still challenging to assess because of their multiple input sources and intricate ecosystem dynamics. Biomonitoring techniques have emerged as a promising tool, offering valuable insights into the processes and factors influencing PPP fate and transport. In this study, we utilize bee pollen from *Apis mellifera* as a tool for terrestrial PPP monitoring in an area covering 39 fields cultivated according to standard agricultural practices. Our research integrates chemical analysis of pollen collected during cultivation season with an extensive dataset on PPP applications. This dataset includes details on applied substances, quantities, application timing, and weather conditions, forming a robust foundation for our analysis. It offers valuable insights into the terrestrial exposure of pollinators, enabling a more detailed evaluation of PPP dynamics.

In brief, we collected weekly pollen samples from April to early October from five beehives strategically placed adjacent to a meteorological station. We pooled the hive samples each week to represent the bee population comprehensively. Additionally, we isolated specific fractions through targeted pollen fractionation, enhancing our ability to discern contamination patterns and identify sources. The pollen analysis was performed by target and non-target analysis using liquid chromatography coupled with mass spectrometry (LC-MS/MS) and high-resolution mass spectrometry (HRMS) to explore unknown substances by tracking their presence based on concentration trends.

Our results reveal a substantial presence of PPP contamination in pollen samples, with 50% of identified compounds aligning with those applied in our controlled area. Further interpretation of the detailed PPP application allowed us to pinpoint the specific pathways and factors influencing PPP contamination in the pollen. Moreover, our analysis of pollen fractions shows that wildflowers are the primary source of PPP in pollen. This result highlights a significant non-target species pathway through which these contaminants enter the pollinator ecosystem.

In summary, this study presents a comprehensive exploration of PPP contamination in bee pollen, providing unique insights into environmental dynamics and highlighting the suitability of this matrix as a biomonitoring tool for terrestrial ecosystems.

3.06.T-05 Polyhalogenated Carbazoles in the Food Web of the St. Lawrence Estuary Beluga Population.
Alexis Eric Adrien Trinquet[1], *Mathieu Babin*[2], *Jonathan Verreault*[3], *Véronique Lesage*[4], *Jory Cabrol*[4], *Stephane Lair*[5], *Gerald Tetreault*[6] *and Zhe Lu*[7], *(1)Institut des Sciences de la Mer de Rimouski, Canada, (2)CIRAD - Centre de coopération internationale en recherche agronomique pour le développement, Canada, (3)University of Quebec at Montréal, Canada, (4)Maurice Lamontagne Institute, Fisheries and Oceans Canada, Canada, (5)University of Montréal, Canada, (6)Environment and Climate Change Canada (ECCC), Canada, (7)Institut des Sciences de la Mer de Rimouski (ISMER), University of Quebec at Rimouski (UQAR), Canada*
Contaminants represent a major stressor that may adversely affect the health and recovery of the endangered St. Lawrence Estuary (SLE) beluga (*Delphinapterus leucas*) population (Canada). However, the exposure of SLE belugas to many emerging contaminants remains unknown. Such emerging contaminants of concern are the Polyhalogenated Carbazoles (PHCZs), which are impurities in halogenated indigo dye formulations or carbazole-containing polymers that are used in electronic devices. PHCZs are structurally similar to halogenated dibenzofurans, and can pose dioxin-like toxicities to organisms, and are known to bioaccumulate and biomagnify in food webs. Some PHCZs have previously been reported in sediments and fish of the Great Lakes of North America, but their levels in the SLE, which is located downstream of the Great Lakes and home to SLE beluga, are unknown. To fill this knowledge gap, tissues were collected from SLE beluga (n=7 including liver and blubber) and 17 known and potential prey (n=183 including 15 fish species and 2 invertebrates) of SLE beluga in 2019 and 2020 to investigate the occurrence and trophodynamics of 11 PHCZs in the SLE beluga's food web. Tissue samples were analyzed for nitrogen isotopes ratios (δ^{15}N) to assess trophic position. All target PHCZs were detected in prey samples except for 1,3,6,8-tetrabromocarbazole (BCZ-1368). Concentrations of total PHCZs in prey samples were in the range of 2.3 ± 0.3 to 50.7 ± 19.1 ng/g (mean ± SE) (lipid weight (lw)), thus lower than previously reported concentrations in fish from the Great Lakes (66.1 ± 20.3-181 ± 141 ng/g (lw)). The trophodynamics of target contaminants with 100% detection indicate that 36-dichlorocarbazole (CCZ-36) was positively correlated to δ^{15}N, indicating biomagnification in the SLE food web. The estimated toxic equivalent (TEQ) concentration of total PHCZs for the analyzed species (mean range: 0.20-1.62 pg/g lw) was lower than for fish from the Great Lakes (8.7-25.7 pg/g lw) and San Francisco Bay (2.5-34.8 pg/g lw), and harbor seals from San Francisco Bay (7.6-174 pg/g lw). This study provides a baseline for monitoring PHCZs in the SLE beluga food web, and enhance our understanding of the mechanisms underlying the biomagnification of PHCZs in aquatic food webs.

3.06.P Application of Biomonitoring Approaches to Support Surveillance of Chemical Exposure in the Environment

3.06.P-Mo114 Exposure contribution and integrated exposure assessment of methyl paraben and propyl paraben

Inhye Lee[1]*, Sunmi Kim*[2] *and Kyunghee Ji*[3]*, (1)Occupational and Environmental Health, Seoul National University, Seoul, Korea, Republic of, (2)Chemical Analysis Center, Korea Research Institute of Chemical Technology (KRICT), Korea, Republic of (South), (3)Yong In University, Korea, Republic of (South)*

Parabens, including methyl paraben (MP), ethyl paraben, and propyl paraben (PP), are widely used as preservatives in cosmetics, stored foods, beverages, and personal care products to inhibit the growth of microogranisms. Previous studies mainly focused on one exposure source and specific exposure route to evaluate external exposure, and limited information is available on various exposure sources and routes of parabens. In this study, a library of exposure sources and contamination data for MP and PP was collected through a literature review, and the contribution of paraben exposure was evaluated across different life stages, including infants, preschool children, school-age children, adolescents, and adults. In addition to the conventional sources of exposure, pharmaceutical intake scenarios were established for the infants and children population. Although data on PP contamination levels are limited compared to MP, both parabens contribute significantly to exposure through oral and dermal routes. The oral exposure contribution rate was high in the order of fruits, vegetables, and paste in children, adolescents, and adults, however, infants had a higher exposure contribution through breast milk in both parabens. For dermal exposure route, body/hair products, cleansing products, skin care products and color cosmetics were identified as major sources of MP. The dermal exposure source of PP shows comparable results, with the exposure levels from oral care products being higher than those of methyl paraben. The contribution rate of PP was found to be high from consuming sources, inhaling indoor air, and using cleansing products. The results of this study can be used for integrated exposure assessments of other parabens, and emphasize the need for ongoing monitoring of MP and PP in various products.

Keywords: Exposure assessment, Alternative phthalates, Intervention study

3.06.P-Mo115 Legacy and Emerging POPs in a Rare Greenland Shark Stranding

Imogen Bailes[1]*, Rosie Williams*[2]*, Jonathan Barber*[3]*, Sara Losada Dr.*[3]*, Rob Deaville*[4]*, James Barnett*[5] *and Andrew Sweetman*[6]*, (1)Lancaster Environment Centre, Lancaster University, United Kingdom, (2)Zoological Society of London, United Kingdom, (3)Centre for Environment Fisheries and Aquaculture Sciences (Cefas), United Kingdom, (4)Institute of Zoology, Zoological Society of London, United Kingdom, (5)Cornwall Marine Pathology Team, (6)Lancaster University, United Kingdom*

Greenland sharks (*Somniosus microcephalus*) inhabit cold, deep Arctic and North Atlantic waters and they are thought to be the longest-lived vertebrate on Earth; potentially living for 400 years. Growing only one cm/year up to five metres in length, this species is considered vulnerable due to a combination of its long maturation period and low fecundity, as well as facing pressure from pollution and overfishing. Further, this species is considered an apex predator in Arctic food webs, feeding on a variety of dead and live fish, squid and mammals. Sightings/strandings of this shark in the UK are extremely rare, however a recent stranding on the coast of Cornwall in 2022 presents a unique opportunity to learn more and monitor this species. By studying the contaminant load of this shark, we can seek to understand how anthropogenic pollutants impact marine biota. This is particularly pertinent given previous declines in biodiversity linked to the input of organic chemicals into the oceans. Here, we present data on the organic contaminant loading measured in a Greenland shark sample, including PCBs and PFAS compounds. We used liver tissue to study these contaminants and followed established extraction and clean-up procedures for each pollutant group, using GC-MS and LC-HRMS to analyse the samples. Several PCB congeners, DDTs and PFAS compounds were detected in the shark at measurable concentrations. Pollutant burdens were dominated by PFAS compounds, which mainly consisted of long-chain PFCAs, similar to other shark species. DDTs were the second most dominant pollutant, followed by PCBs with hexa- and hepta- congeners accounting for >50% of the PCB burden. Levels of PCBs were generally lower than those reported for other large-bodied elasmobranchs and for Greenland sharks stranded in their typical home range, whereas PFAS concentrations were found to be comparable or even higher. Our research addresses the need to understand exposure levels in a lesser studied species to both legacy and emerging contaminants.

3.06.P-Mo116 Development of biomarkers for immunotoxicity in mussels: an in situ experiment

Elina Kvist[1]*, Joachim Sturve*[2] *and Sunna Hrund Sverrisdóttir*[3]*, (1)University of Gothenburg, Sweden, (2)Biological and Environmental Sciences, University of Gothenburg, Sweden, (3)Marine science, University of Gothenburg, Sweden*

The European Union has adopted the Marine Strategy Framework Directive (MSFD) to protect and restore the marine environment and achieve a good environmental status (GES). The MSFD defines 11 descriptors of GES regarding biodiversity, food webs, seafloor integrity and *contaminants*. Biomonitoring is a crucial tool to preserve good environmental status in the marine environment. New chemicals are entering the market every day and our consumption of chemicals is still increasing. The receiving end of this is the water systems that will eventually lead to the marine environment. In our toolbox for biomonitoring there are several biological effects markers (biomarkers) that can help in assessing the exposure of pollutants. These biomarkers can report on disturbances in several physiological systems, such as reproduction and toxicant metabolism. But there is still a lack of biological effects markers that can be used to indicate immunotoxic effects in marine organisms. This is due to the complexity of the immune system, lack of information provided in papers and difficulties in linking chemical mode of action to immunological effects in organisms.

In order to suggest new such biomarkers the current project has the aim to optimize and develop biomarkers for immunotoxicity in fish and mussel that can be used in annual biomonitoring in Sweden and the rest of the European Union.

Fish and mussel were sampled from a known polluted marine site and from a reference site with pristine waters. Zoarces viviparous and Mytilus edulis were chosen since they are stationary organisms and can thus reflect the effects in the local environment. In the laboratory the two species were exposed to bacterial LPS for three days to trigger the immune system. After the three days they are euthanised and candidate biological effect markers were analysed. The markers were selected through literature search and previous research in our laboratory. Several of these markers has shown promising results and will be further developed in this novel experimental setup. The biomarkers that were analysed are cytokines, complement system activity, lysozyme activity, IgM concentration, c-reactive protein, white blood cells/haemocyte count, leukocyte viability, phagocytic capacity, and gene expression of relevant genes such as Diablo. Results on how the capacity of these parameters respond to a pathogen insult is affected by long time exposure to toxicants will be presented.

3.06.P-Mo117 Using the Otter and Buzzard as Sentinels for the Assessment of Spatial and Temporal Trends in Synthetic Chemical Pollution between Contiguous Aquatic and Terrestrial Environments

Holly Elizabeth Hulme[1]*, Elizabeth Chadwick*[2]*, M. Gloria Pereira*[3]*, Lee Walker*[3] *and Frank Hailer*[2]*, (1)University of Cardiff, United Kingdom, (2)Cardiff University, United Kingdom, (3)UK Centre for Ecology & Hydrology (UKCEH), United Kingdom*

Synthetic chemicals are pervasive in our environment, and the exposure of terrestrial and freshwater biota to these compounds presents a growing concern. Conventional monitoring primarily relies on targeted screening of abiotic samples, potentially missing toxicologically relevant chemicals that exist at concentrations below detection limits in such samples. Some chemicals may accumulate in biota, making their detection achievable even when undetectable in abiotic samples. Additionally, wide-ranging biota can serve as integrators of temporally and spatially heterogeneous chemical inputs, offering a more comprehensive perspective.

The study explored differences in chemical occurrence, concentration, and temporal trends, between otters (*Lutra lutra*) and buzzards (*Buteo buteo*) in the UK. We aimed to evaluate whether differences in chemical pollution between the two top predator species might indicate differences between aquatic and terrestrial environments.

Otter and buzzard carcasses were collected from a common geographical zone within the UK between 2002 and 2019. Liver samples from both species were analysed through the LIFE APEX programme in LC-QToF-MS wide-scope target analysis of over 2,200 contaminants, which spread over a broad spectrum of applications and uses. Statistical analysis and modelling were conducted to provide quantitative results.

We highlight the efficacy of the chosen sentinels for monitoring chemical pollution and describe the wide range of synthetic chemicals in both the terrestrial and freshwater environment. Comparisons highlight the differences in both occurrence and concentration between the two compartments, which confirms that the inclusion of both sentinel species is beneficial in understanding environmental chemical pathways, and thus shows the species to be a valuable resource for pollution surveillance over both space and time. The insights gained from this study therefore contribute to the development of more robust biomonitoring strategies, which are more effective for evaluating the risks associated with synthetic chemicals to both wildlife and human health.

3.06.P-Mo118 Active Biomonitoring of River Pollution Using an Ex-Situ Exposure System With Model Species.

Sarah Bancel[1]*, Jérôme Cachot*[2]*, Christelle Clérandeau*[2]*, Alexandra Coynel*[3]*, Oliver Geffard*[4]*, Nicolas Mazzella*[5]*, Rémi Recoura-Massaquant*[6] *and Éric Rochard*[1]*, (1)EABX, Institut national de recherche pour l'agriculture, l'alimentation et l'environnement (INRAE), France, (2)EPOC CNRS, University of Bordeaux, France, (3)UMR EPOC 5805, Equipe TGM, University of Bordeaux, France, (4)RiverLy, Institut national de recherche pour l'agriculture, l'alimentation et l'environnement (INRAE), France, (5)INRAE BORDEAUX, France, (6)Institut national de recherche pour l'agriculture, l'alimentation et l'environnement (INRAE), France*

In the last two decades, the evaluation of environmental quality has grown in importance, leading to the necessity to develop new methods to better integrate contamination and its impact on aquatic organisms. Sensitivity of early life stages of fish to contamination makes them especially valuable for monitoring applications. However, their development is highly influenced by water parameters (such as temperature) which poses a challenge to their use in active biomonitoring.

The *ex-situ* exposure method involves a direct and continuous exposure to river water flow but in controlled temperature, oxygen and photoperiod conditions. The control of environmental parameters allows to eliminate the potential influence of these confounding factors on the results interpretation. This method has been used in spring 2023 on the Garonne river (France) to conduct Fish Early-Life Stage Toxicity Tests (OECD TG 210) using Japanese medaka (*Oryzias latipes*) embryos. They were exposed to river water throughout their development from 24h post-fertilization up to 2 days after hatching, while temperature and oxygen saturation were controlled. Mortality during embryonic development was significantly higher for those exposed to the Garonne water compared to control in the two exposure series conducted, with the highest rate of mortality occurring during organogenesis..

In parallel, experiments on the freshwater amphipod *Gammarus fossarum* have been conducted also by using the *ex-situ* exposure. This species is widely used in active biomonitoring and standardized tests exist in France for this purpose. Reprotoxicity and feeding rate were assessed while controlling water parameters. The results did not reveal a significant reproductive toxicity on the organisms. However, an induction of feeding rate was observed in gammarids exposed to the Garonne water compared to control in certain batches.

Water contamination was also assessed. Passive samplers were deployed to monitor pesticides and samples of water were taken to quantify metal concentrations in water. Results will be available and presented in May 2024.

These results highlight the significance of the exposure method, particularly in controlling water parameters to expose more sensitive organisms and reveal substantial variations in the toxicity of the Garonne River's water depending on the exposed taxon.

3.06.P-Mo119 Method development and application for simultaneous determination of hydroxy derivatives of PAHs in wastewater for using in wastewater-based epidemiology

Katarzyna Styszko[1]*, Karolina Cwynar*[2]*, Laura Frydel*[2]*, Zuzanna Prus*[2]*, Agnieszka Pac*[3] *and Elżbieta Sochacka-Tatara*[3]*, (1)University of Science and Technology (AGH), Poland, (2)AGH University of Science and Technology, (3)Jagiellonian University, Poland*

It is important to assess the exposure of PAHs, especially in urban areas. Exposure to PAHs causes a number of negative health effects, including: reproductive defects, DNA mutations, leukemia and cancer of the lung, bladder, bone, brain and scrotum. There is a lack of knowledge and understanding of the local exposure to organic air pollutants, especially in highly urbanized regions of Eastern Europe. PAHs entering the body in a certain part are removed in unchanged form, but usually undergo several steps of biotransformation and detoxication process and are excreted as hydroxymetabolites through urine and feces.

The aim of the study was the determination of the hydroxyl PAH metabolites profile in wastewater. The 24 composite samples of wastewater influent were collected at the “Plaszow” wastewater treatment plant (WWTP) in Krakow, in winter and summer. This plant is the biggest one in the city and the third in the country, treating over a 70% of Krakow wastewater with an average capacity of 165.000 m^3/day.

Studies were carried out using SPE-GC-MS/MS method for the determination of selected OH-PAH (1-hydroxy and 2-hydroxynaphthalene (1-OH-NAP, 2-OH-NAP), 2-hydroxy and 9-hydroxyfluorene (2-OH-FLU, 9-OH-FLU), 9-hydroxyphenathrene (9-OH-PHEN), 1-hydroxypyrene (1-OH-PYR), 3-hydroxybenzo(a)pyrene (3-OH-BaP)) in samples collected in WWTP. Analysis was carried out by means of a Thermo Scientific GC TRACE 1300 (GC-(IT)MS/MS) and a TriPlus RSH Autosampler.

The average concentrations of compounds ranged from 5 ng/L to more than 400 ng/L. The highest concentrations of OH-PAH were detected in the influents, for 2-OH-NAP and 9-OH-FLU in winter and summer. However, their concentrations were twice lower in summer. A similar trend was observed for other compounds. 1-OH-PYR was observed for influent and effluent samples only in winter at average concentrations of 8 ng/L and 5 ng/L, respectively.

3.06.P-Mo120 Methods Enabling Accurate Data on Microplastics Abundance and Distribution: Applicability for Biomonitoring Programs

Nagore Blasco[1]*, Uxue Uribe Martínez*[2]*, Tomas Maupas*[3]*, Alberto De Diego*[3]*, Olivia Gomez-Laserna*[3]*, Urtzi Izagirre*[1]*, Manuel Soto*[4] *and Nerea García-Velasco*[1]*, (1)Zoology and Animal Cell Biology, University of the Basque Country (UPV/EHU), Spain, (2)University of the Basque Country (UPV/EHU), Spain, (3)Analytical Chemistry, University of the Basque Country (UPV/EHU), Spain, (4)Research Center for Experimental Marine Biology Biotechnology “Plentziako Itsas Estazioa”, University of the Basque Country (PiE-UPV/EHU), Spain*

The presence of microplastics (MPs) in marine ecosystems is of considerable concern. In recent years, many effort has been made to quantify MPs pollution in marine biota using a wide variety of approaches. One of the main problems in the visual quantification of MPs is the overestimation. For a realistic assessment of MPs in the environment chemical analysis such as Raman spectroscopy are needed which allow to accurately identify the nature of the particles observed under the stereoscope in monitoring programs. Thus, the aim of the study was (1) to define the most accurate methodology for the identification/quantification of MPs in environmental samples and (2) to provide precise data of MPs abundances in mussels from the Urdaibai Biosphere Reserve (case study). Mussels *Mytilus galloprovincialis* were collected seasonally during a one-year monitoring program in two sampling points (TXA and TE) along the Urdaibai estuary. Samples were alkaline digested with 10% KOH (40º C during 48 h) and filtrated through a vacum filtration system using 30 µm metal filters. Filters were first analysed visually by stereoscope and then with the aid of Raman. For the identification of MPs in Raman, a grid overlay system has been developed to localise visually detected MPs. After visual observation the amount of MPs was much higher than after Raman confirmation, with an overestimation of 88% of MPs. Confirmed fibers and fragments were detected in mussels from both sites, being fibers predominant. The MPs accumulated by the mussels from TXA were PET, PE, PP and PS; while in TE PET and PE were identified. Blue was the predominant color observed in MPs ingested by mussels in Urdaibai.

The results show differences in the abundance of MPs between seasons for TE, with a significant decrease and increase in February and April, respectively. Moreover, significant differences were observed between sampling points in February and April. Based on these results, Raman spectroscopy is crucial to recognice environmnetal MPs with high reliability, which enable a reliable diagnostic and assessment on MPs occurrence and fate in marine ecosytems. Funded: Basque Government (IT1743-22, IT- 1446-22) and MICINN (PID2020-118685RB-I00).

3.06.P-Mo121 Concentrations of Mercury in Water, Sediment and Blood of Grass Carp and Their Associations with Oxidative Stress Biomarkers

Anton Kovacik*, Marek Helczman, Lubos Harangozo, Eva Tvrda, Marian Tomka, Tomas Jambor, Martin Fik, Jaroslav Andreji and Peter Massanyi, Slovak University of Agriculture in Nitra, Slovakia*

Mercury (Hg) is a toxic metal that can accumulate in aquatic ecosystems and pose a risk to human and wildlife health. Mercury in fish blood can cause oxidative stress, which is a condition where the production of reactive oxygen species (ROS) exceeds the capacity of the antioxidant system to neutralize them. ROS can damage cellular components such as lipids, proteins, and DNA, and impair the normal functioning of cells and tissues. The aim of this study was to investigate the concentrations of Hg in water, sediment, and whole blood of grass carp from a university experimental freshwater fishpond in Slovakia, and to examine their associations with biomarkers of oxidative stress. Mercury in fish blood and oxidative stress are closely related and can be used as indicators of mercury toxicity in fish. 20 samples were obtained from each matrix. Total Hg was measured by cold vapor atomic absorption spectrometry. Biomarkers of oxidative stress (reactive oxygen species, glutathione peroxidase, and lipid peroxidation) were assessed in grass carp blood samples. The highest concentrations were observed in sediment samples, followed by whole blood samples, and the lowest concentrations were in water samples. Hg concentrations in carp blood were positively correlated with biomarkers of oxidative stress (ROS, GPx and MDA), but without significant differences. Hg levels in water were statistically significantly negatively correlated with GPx and total weight of fish. Analysis of biomarkers indicated a negative association between GPx and ROS, and GPx and MDA. These findings suggest that carp fish from the lake are exposed to low levels of Hg, but slightly show signs of Hg-induced effect in their blood and provide insight into oxidative stress defences in grass carp. Further studies are needed to evaluate the potential health effects of Hg exposure on carp fish and other aquatic organisms in the lake. This work was supported by the Slovak Research and Development Agency under the contract No. APVV-21-0168. This publication was also supported by The Ministry of Education, Science, Research and Sport of the Slovak Republic under the project VEGA 1/0571/23.

3.06.P-Mo122 Wastewater Micropollutant Surveillance Using Effect-based Biomonitoring

George Ruck[1]*, Arnaud Chaumot*[2]*, Jean-Baptiste Aubin*[3]*, Hervé Quéau*[4]*, Laura Garnero*[5] *and Didier Neuzeret*[6]*, (1)UR RiverLy - Ecotox, National Research Institute for Agriculture, Food and Environment (INRAE), France, (2)INRAE (Institut National de la Recherche Agronomique), France, (3)INSA de Lyon, France, (4)INRAE, France, (5)UR RiverLy - ECOTOX, Laboratoire d'écotoxicologie INRAE, France, (6)ViewPoint, France*

As availability of water resources decreases, the apparition of new contaminants of concern (CEC) identified in water networks continues to increase. Current wastewater monitoring in treatment plants relies on interval based grab sampling measurements for a select few chemicals or for punctual effluent toxicity assessment using a restricted choice of bio-assays. As this strategy is known to omit at portion of micro-pollutants and contaminants of emerging concern (CECs), innovative approaches to wastewater management are essential to attemp to avoid potentially detrimental impact of largely unknown CEC discharge in aquatic ecosystems and improve efficiency of urban water re-use.

In previous work using the biomonitoring apparatus ToxMate, whereby the video-tracking of locomotor behaviour of bio-indicator invertebrates (*Gammarus*, *Radix*, and *Erpobdella*) generates positional data in the on-line wastewater multi-species monitoring device, we showed the biomonitoring method is an effective in non-targeted effect-based screening of micro pollutant presence (including little known emerging contaminants). Our current research illustrates results from lab studies and long term surveillance in WWTPs, where the characterization of the effluents in real-time for the multispecies approach alerts operators and allows strategic sampling, giving a better understanding of effluent composition. Laboratory testing has led to the accumulation of behavioural reaction analysis for over 80 micropollutants, allowing the definition of multi-species behavioural fingerprints to characterise causes for temporal variability in CEC discharge, presented using functional data analysis (FDA) and artificial intelligence. Fingerprints are then used to link alerts to their potential chemical nature.

Continuous surveillance not-only identifies critical moments but has incorporated timely sampling techniques to validate reactions. Couple with behavioural fingerprinting, these moments may help adapt wastewater management strategy in real-time. Thus, the potential is not only limited to the improvement of aquatic environmental quality through wastewater management, but could also provide concrete indicators of the suitability of re-use in various domains such as urban, agricultural and leisure use.

3.06.P-Mo123 Assessment of Temporal Trends in Quality of European Surface Waters: Towards a New Biological Indicator

Jannicke Moe*, Jan-Erik Thrane, Sophie Mentzel and Anne Lyche Solheim, Norwegian Institute for Water Research (NIVA), Norway*

The European Topic Centre Biodiversity and Ecosystems (https://www.eionet.europa.eu/etcs/etc-be) is a Consortium of 24 organisations led by the Norwegian Institute for Water Reseach (NIVA). The consortium is working in partnership with with

the European Environment Agency (EEA) under a Framework Partnership Agreement for the period 2023-2026. The ETC BE contributes to EEA's integrated systemic assessments of terrestrial, freshwater and marine ecosystems. These assessments include effects of climate change and how to mitigate climate change, cumulative drivers and pressures on these ecosystems, as well as socio-economic implications of solutions. Assessments of spatial and temporal trends in the aquatic environments across Europe are fundamental for these assessments and are based on a set of indicators such as «Industrial pollutants released to water», «Pesticides in rivers, lakes and groundwater», «Nitrate in groundwater and rivers», and «Nutrients in transitional, coastal and marine waters in Europe». EEA indicators are designed to answer key policy questions and to support environmental policy making from policy monitoring and evaluation to communicating to policymakers and the public.

Here we focus on a new candidate indicator, «Biology in rivers, lakes, transitional and coastal waters». This indicator is based on ecological quality ratios (EQR), which are normalised in a continuous scale 0-1, and therefore more informative than the 5-level ecological status class data reported to the Water Framework Directive. EQR values have been reported to EEA from more than 20 European countries through the WISE-2 Biology data flow within WISE-SoE (Water Information System for Europe – State of the Environment); mostly from river and lakes, but also from transitional and coastal waters. The EQR values represent the impacts of specific pressures such as nutrient enrichment and organic pollution, hydromorphological pressures or acidification, and can therefore provide a link to physical and chemical stressors affecting the ecological status of water bodies. The use of normalised EQR values enables both analysis of geographical and temporal patterns, statistical trend analysis, and quantitative relationship with physical/chemical stressors. However, the reported WISE-2 Biology data still show variations in the number of water bodies and years among countries, which represent challenges concerning its representativity as a European-scale indicator.

3.06.P-Mo124 Challenges and Opportunities of Building a Collaborative Chemicals Biomonitoring Framework Today, for the Chemicals of Tomorrow

Suzane Qassim, PhD[1]*, Lee Walker*[2]*, Jonathan Barber*[3]*, Libby Barnett*[4]*, Jacky Chaplow*[2]*, Sophie Common*[5]*, Rosie J Lennon*[1]*, Shinji Ozaki, PhD*[6]*, M. Gloria Pereira*[2]*, Lindsey Sturdy*[7]*, Julia Louise Sussams*[8] *and Claus Svendsen*[2]*, (1)Natural England, United Kingdom, (2)UK Centre for Ecology & Hydrology (UKCEH), United Kingdom, (3)Centre for Environment Fisheries and Aquaculture Sciences (Cefas), United Kingdom, (4)Fera Science Ltd., United Kingdom, (5)Institute of Zoology (ZSL), (6)United Kingdom Centre for Ecology & Hydrology (UKCEH), Wallingford, United Kingdom, (7)Chief Scientist's Group, Environment Agency (England), United Kingdom, (8)Department for Environment Food & Rural Affairs (DEFRA), United Kingdom*

A proposed collaborative terrestrial chemicals biomonitoring framework for England will be presented. The aim of the framework is to produce impactful 'fit for purpose' data and evidence for use in environmental, chemical and agrochemicals, regulation and policy, and conservation delivery. An overview of the terrestrial chemicals monitoring in England will be presented alongside, developmental terrestrial indicators of exposure and effects on wildlife, reported on against available toxicity thresholds over time.

The key components of the terrestrial biomonitoring framework will be shared. This will include the process and scientific investigations undertaken, in selecting sentinel species and analysis of new and archived samples for contaminant residues, as well as the application of systems thinking to develop sample and data platforms and protocols. Technical challenges will be discussed with a focus on development of tissue sample and data archives, sampling design, and decision-making tools used to deliver the data needs of today while also being future proof. Attention will be drawn to the need for monitoring data to improve chemical prioritisation and early warning systems in the terrestrial environment. In addition to the need to build a data architecture with clear and robust data ethics principles and guidance, that enable the delivery, housing, use, and sharing of non-targeted screening data.

3.06.P-Mo125 Temporal Trends of Dietary Patterns and Mercury in Norwegian Killer Whales (Orcinus orca) from Contrasting Ecosystem States

Stephanie J Milne[1]*, Clare Andvik*[1]*, Eve Jourdain*[2]*, Dag Vongraven*[3]*, Nils Øien*[4]*, Anders Ruus*[5] *and Katrine Borga*[1]*, (1)University of Oslo (UiO), Norway, (2)Norwegian Orca Survey, Norway, (3)Norwegian Polar Institute, Norway, (4)Institute of Marine Research in Norway, Norway, (5)Norwegian Institute for Water Research (NIVA), Norway*

Killer whales are long-lived, occupy a high trophic position, and are valuable bioindicators to assess marine ecosystem health and exposure to persistent contaminants. Norwegian killer whales were formerly categorized as fish specialists strongly associated with Norwegian Spring Spawning Herring (*Clupea harengus*) (NSSH), but are now known to incorporate other prey, including marine mammals, into their diet. The NSSH stock collapsed in 1970 due to overfishing but have since recovered. This study aimed to evaluate historic and contemporary dietary variations possibly correlated to changes in preferred prey availability, and to assess changes in mercury (Hg) concentrations between and within individuals over time by (1) investigating annual patterns of inter and intraindividual dietary trends and Hg accumulation over both time periods, (2) evaluating whether shifts in preferred prey resources caused by fishing pressures played a role in killer whales integrating more marine mammals in their diet, (3) determining if feeding on higher trophic prey resulted in a greater body burden of Hg, and (4) to identify temporal trends of Hg intake in response to changes in emissions.

Bulk stable isotopes of carbon ($\delta^{13}C$) and nitrogen ($\delta^{15}N$), and Hg concentrations were analysed from annual growth layers of killer whale teeth (n=21) from two groups living in contrasting ecosystem states. Teeth were sectioned longitudinally with a diamond saw and two slices (circa. 1 mm width) were cut from each half. The left slice was ground into a powder mixing all GLGs, and the right piece was decalcified in a 0.25 M HCl solution. Each growth layer was extracted and minced using a scalpel. Samples were prepared for $\delta^{13}C$ and $\delta^{15}N$ analysis performed by the Institute for Energy Technology (Kjeller, Norway). Mercury analysis is scheduled for December 2023 at the University of Oslo.

Preliminary results show the contemporary group exhibits higher $\delta^{15}N$ values and a greater range than the historical set. This could indicate a higher variability in dietary patterns and a larger consumption of marine mammal prey. $\delta^{15}N$ values for powdered tooth samples representing all combined GLGs were greater for the contemporary set ($\delta^{15}N$: Max=15.59 ‰, Min=11.82 ‰) than the historical samples ($\delta^{15}N$: Max=13.14 ‰, $\delta^{15}N$ Min=11.40 ‰). This project offers six decades of insight on how Hg has been accumulating in wildlife pre- and post-emission reductions brought forth by the Minamata Convention.

3.06.P-Mo126 Occupational (fishermen and recycler workers) exposure assessment to organophosphate esters, phthalate esters, and alternative plasticizers through human hair analysis

***Boris Johnson-Restrepo**[1], Fredys Sanchez-Catalán[1], Jessica Paola Mercado-Paez[1], Aleix Balasch Garcia[2] and Ethel Eljarrat[2], (1)Environmental Chemistry Research Group, University of Cartagena, Colombia, (2)Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain*

Due to their widespread use in consumer products, organophosphate esters (OPEs) and phthalate esters (PAEs) are ubiquitous in the environment, leading to potential human exposure through ingestion, inhalation, and dermal absorption . Both OPEs and PAEs are used as plasticizers, and some specific OPEs are also used as flame retardants (FR). They are mainly used in plastic materials, such as household appliances, furniture, textiles and personal care products. OPEs consumption was increased to be used as alternatives to polybrominated diphenyl ethers (PBDEs), which were FRs banned in the Stockholm Convention on Persistent Organic Pollutants. Hair samples were collected from volunteers of two occupational groups: a) recycler workers (n=32) at industrial recycling park in Cartagena city (Colombia) and b) fishermen (n=36) in local communities across of Bolivar state (Colombia) as well as their families. Extraction was done by pressurized liquid extraction (PLE) using an ASE 350 system (Dionex, Sunnywale, CA, USA), with hexane:acetone (1:1) as solvent extraction and working at 1600 psi and 50 °C. After PLE, extracts were concentrated to incipient dryness and re dissolved with methanol for a final volume of 500 µL. The extracts were injected in an online sample purification and analysis method based on turbulent flow chromatography (TFC) (Thermo Scientific TurboFlow ™ system) coupled to a triple quadrupole (QqQ) tandem mass spectrometry (MS MS) and a heated electrospray ionization source (H ESI) was used. The most intense transition was used for quantification, while the second provided confirmation. Concentration levels of 16 OPEs, 11 PAEs and 4 alternative plasticizers have been measured in hair samples from recyclers and fishermans in Colombia, which shows the occupational exposure to these compounds. In the case of OPEs, it has been seen that recyclers presented higher concentration levels in hair than the fishermans, while for PAEs and their alternatives there were not found differences in concentrations. This study demonstrates the potential of using human hair as a biomarker for assessing exposure to PAEs and OPEs, particularly in occupational settings, with a non invasive sample collection and a rapid analysis. The findings highlight the need for improved safety measures and regulations to reduce PAE and OPE exposures in high risk occupations

3.06.P-Mo127 Environmental Exposure to Anticoagulant Rodenticides and α-Chloralose in the Liver of Domestic Cats (Felis catus) in Slovenia

***Vesna Cerkvenik-Flajs**[1], Detlef Schenke[2], Simona Korenjak-Černe[3], Marko Cvetko[1], Tanja Švara[1] and Mitja Gombač[1], (1)Institute of Pathology, Wild Animals, Fish and Bees, University of Ljubljana, Veterinary Faculty, Slovenia, (2)Julius Kühn-Institute Federal Research Centre for Cultivated Plants (JKI), Germany, (3)University of Ljubljana, School of Economics and Business, Slovenia*

Due to their mass and continuous use, rodenticides pose a significant environmental problem as they can have harmful effects on non-target wildlife and domestic animals. For this reason, the residues of anticoagulant rodenticides (ARs) and an alternative rodenticide α-chloralose were monitored in domestic cats (*Felis catus*) in Slovenia. In the period from 2021 to 2022, 99 free-roaming or partially free-roaming cats were collected from veterinary clinics in all geographical regions of Slovenia. Their livers were extracted with methanol/water (2:1, v/v), cleaned-up using a solid supported liquid-liquid extraction and measured by liquid chromatography-electrospray tandem mass spectrometry (LC-ESI-MS/MS) with reporting limits in the range of 0.2 – 10.0 ng/g. Residues of at least one substance investigated were detected in 64.7% of the analyzed livers. Concentrations of pooled ARs ranged from 0.8 to 1,819.7 ng/g with a mean and median value of 110.8 and 22.9 ng/g, respectively. The second generation ARs (SGARs) brodifacoum, bromadiolone, difenacoum and difethialone were found in 53.5, 25.3, 8.1 and 2.0% of the samples, respectively. Flocoumafen was not detected. We determined brodifacoum at concentrations of ≥800 ng/g in 3 of 99 cat livers (3.0%) and one of these (1%) contained residues of >1,800 ng/g. Coumatetralyl was mainly found in the first generation of ARs (FGARs) and was determined in 21.2% of the samples, all of which were below 4.1 ng/g, while warfarin was found in one sample (1.0%) with a concentration of 14.1 ng/g and chlorophacinone was not detected. α-chloralose was found in one sample (1.0%) with a concentration of 561.7 ng/g. Two older animals living outdoors contained hepatic residues of as many as 4 substances (three SGARs and one FGAR). As the results of the study indicate a potential toxicological risk for domestic cats in Slovenia, asymptomatic poisoning related to rodenticides in this species should be continuously monitored in the future. The relevance of the study lies in its complementarity to the assessment of the environmental risk of rodenticides to non-target animals in the Western Balkans. The results highlight a potential environmental problem related to the persistence, bioaccumulation, secondary poisoning and toxicity of rodenticides in this region and will contribute to the knowledge of the protection of European ecosystems.

3.06.P-Mo128 Determination of the presence of endocrine disruptors in breast milk samples from the municipality of Malambo/ Atlántico (Colombia)

***Julia Gonzalez Puertas*[1]**, *Lesly Patricia Tejeda[2], Roberto García-Alzate[3] and Juan Pablo Satizabal[4], (1)Enviromental Toxicology, University of Atlantico, Colombia, (2)University of Cartagena, Chemical Engineering Department. Biomedical, Toxicological and Environmental Sciences Research Group, Cartagena de Indias, Colombia., Colombia, (3)universidad del Atlántico, Colombia, (4)Universidad del Atlántico, Colombia*

Background: Breast milk has an important role in the first month of life, because in this phase there are a series of changes in the neonatal organism and important adaptive mechanisms are developed in the child's relationship.Breast milk has been used as a biological marker of environmental pollution due to bioaccumulation processes in fatty tissue; many chemical compounds reach easily measurable concentrations.Endocrine disrupting chemicals (EDcs) are compounds capable of affecting the normal balance of hormonal functions in animals and their progeny and can pass into breast milk, becoming a possible threat to newborns. OBJECTIVE: determine levels of EDcs in breast milk samples from the municipality of Malambo/Atlantico. METHODOLOGY: The levels of EDcs in breast milk were measured by IR spectroscopy. RESULTS: breast milk samples from 25 donors were analyzed, mainly finding products that are used in industrial applications, specifically in the field of plastics and polymer such as: acrylamides, pentaerythritol, aminocarbonylethene, 2-Butene 1,4-Diol CONCLUSION**:** it is necessary to identify the substances that may be affecting the quality of breast milk in the different stages of maturation and in this way evaluate the consequences on the health of breastfeeding children.

3.06.P-Mo129 Plane tree leaves: An integrative bioindicator for monitoring air concentrations of Semi Volatile Organic Compounds

***Fabrice Alliot*[1]** *and Elodie Guigon[2], (1)METIS - UMR 7619, France, (2)EPHE*

The use of plant species to assess air contamination is now well reported. Indices of overall air quality have been established, for example, with lichens that can accumulate certain contaminants, in particular, metallic trace elements.Higher plant species also show an accumulation of some organic compounds (PCBs, PAHs) in the leaves via absorption in the waxes of these contaminants present in the gaseous phase of the air. Here, the studied model is the plane tree leaf for its ubiquitous presence in contrasting environments and its long leaf period allowing a greater accumulation. A global procedure, from sampling to analysis, was validated with leaves of plane trees to quantify 6 families of semi-volatile organic compounds (SVOCs): Phthalates, PAHs, PCBs, Organochlorine Pesticides, PBDEs, and Parabens. The leaves are harvested at the end of the autumn and then washed, dried, crushed and extracted by an Accelerated Solvent Extraction system (ASE). The extract is split into 3 on a cartridge of Florisil. The fractions are then purified prior to analysis in GC/MS, GC-MS/MS or LC-MS/MS. The quantification limits are in the order of ng/g except for the phthalates (tens of ng/g). Plane tree leaves were sampled in the region of Paris (France) and during 2 periods (2002 and 2012-14).

- The contents in the leaves and the concentrations in the gaseous phase of the air (active sampling) show a good correlation.
- At the spatial level: differences are observed between several contrasting sites: forest, rural, urban, dense urban, traffic.
- At a finer spatial scale, two contrasting urban sites (distance < 1.3 km) also show an influence of traffic on PAHs levels in the leaves.
- At the temporal level: at the same urban site, Paris center, the harvested leaves with a 10-year difference show a variation of air contamination. A significant decrease in leaf levels is observed: from 5 to 10 times, depending on the families studied, except for parabens where a slight increase is obtained. These concentrations are related to the practices and uses of the contaminants studied.

These results show:
- there is an accumulation of SVOCs in plane tree leaves in relation to the sources and uses of these contaminants.
- this tool is relevant to be used for the biomonitoring of the gaseous phase of the air.

3.06.P-Mo130 Urinary Chromium as Biomarker Among Lung Adenocarcinoma Patients in Vojvodina

***Nataša Milošević*[1]**, *Maja Milanović[1], Danica Sazdanić Velikić[2], Mirjana Ševo[3], Mirka Lukić Šarkanović[4] and Nataša Milić[1], (1)Department of Pharmacy, University of Novi Sad, Faculty of Medicine, Serbia, (2)Institute for pulmonary diseases of Vojvodina, Clinic for pulmonary oncology, University of Novi Sad, Faculty of Medicine, Serbia, (3)University of Novi Sad, Faculty of Medicine, Serbia, (4)University Clinical Center of Vojvodina, Clinic for anesthesiology, intensive therapy and pain therapy, University of Novi Sad, Faculty of Medicine, Serbia*

Introduction: The occupational exposure to chromium is associated not only to increased incidence of lung and nasal cancers, the buccal cavity and the pharynx cancers but also to enhanced risk of overall mortality due to lung, larynx, bladder, kidney, testicular, bone, and thyroid cancer. Mechanisms of chromium toxicity and carcinogenicity are not completely understood since chromium (VI) is unreactive towards most biomolecules, the impact of Cr (VI) on the cellular stress response might had a central role in its adverse effects. Moreover, due to chromium intracellular reduction chemically versatile species are generated and may attribute to its carcinogenicity. In this study, the urinary chromium levels among advanced lung adenocarcinoma male patients were determined.

Methodology: A total of 36 male patients (39-84 years old) with inoperable IIIB and IV stadium of lung adenocarcinoma, diagnosed in the Institute for Pulmonary Diseases of Vojvodina, Serbia were enrolled in the study. All participants provided their first morning urine samples in which chromium concentrations were determined by ICP-MS.

Results: In 38.99% (14/36) urine samples Cr was detected above the limit of quantification. The measured chromium levels were above urinary mean levels 0.22 μg/L for healthy adults defined by the ToxGuide of the US Agency for Toxic Substances and Disease Registry. The chromium urinary concentrations varied between 5.585 and 117.544 μg/L. The maximum urinary chromium level when dilution factor was taken into account was as high as 555.067 μg/g creatinine.

Conclusion: Almost 40% of lung adenocarcinoma patients (with inoperable IIIB and IV stadium) from Vojvodina were detected with high urinary chromium levels which are above mean urinary levels for healthy adults.

Acknowledgement: This work was supported by the Provincial Secretariat for Higher Education and Scientific Research, AP Vojvodina, Republic of Serbia [grant number 142-451- 3120/2022-01]

3.06.P-Mo131 Heavy Metals as Risk Factors for Neuroendocrine Lung Cancer - Preliminary Results of Biomonitoring Study

*Danica Sazdanić Velikić[1], **Nataša Milošević**[2], Maja Milanović[2], Mirjana Ševo[3], Mirka Lukić Šarkanović[4] and Nataša Milić[2], (1)Institute for pulmonary diseases of Vojvodina, Clinic for pulmonary oncology, University of Novi Sad, Faculty of Medicine, Serbia, (2)Department of Pharmacy, University of Novi Sad, Faculty of Medicine, Serbia, (3)University of Novi Sad, Faculty of Medicine, Serbia, (4)University Clinical Center of Vojvodina, Clinic for anesthesiology, intensive therapy and pain therapy, University of Novi Sad, Faculty of Medicine, Serbia*

Heavy metals such as Hg, Cd, Ni, Cr and Pb are ranked as the first class of hazard due to their high toxicity. The continuous exposure to heavy metals, even at trace levels, is associated with various biochemical and physiological alterations and serious health problems. Although the lung cancer incidence and mortality rates significantly differ among countries, this type of cancer is still the major cause of cancer associated death worldwide. Neuroendocrine cancer is reported in 2% of all lung tumors cases in adults as less-frequent and -invasive lung cancer. However, the role of environmental risk factors, such as heavy metals in onset and progression of neuroendocrine lung cancer is still unclear. Hence, the aim of this biomonitoring study was to investigated the load of heavy metals in patients with neuroendocrine lung cancer. In this preliminary study four men and six women (aged 57-76) with inoperable IIIB and IV stage lung neuroendocrine cancer were enrolled. The levels of heavy metals (Hg, Cd, Ni, Cr and Pb) were estimated in morning urine samples after mineral digestion using inductively coupled plasma mass spectrometry analysis (ICP-MS spectrometer 7700x, Agilent Technology, Germany). At least one heavy metal was quantified in urine above limit of quantification (LOQ) in both women and men. More than half (60%, 6/10) of neuroendocrine lung cancer patients were exposed to Cd and Hg. Although, nickel and chromium were measured above LOQ in smaller number of collected samples, the quantified levels (24.2-114 μg/L for nickel and 18.1-29.3 μg/L for chromium) were much above the recommended concentrations (1-3 μg/L for Ni and 0.22 μg/L for Cr). In addition to Cd and Hg, Pb was quantified at concentration 13.4 μg/L in one female sample. Despite the small sample size, the obtained results suggest that lung neuroendocrine cancer patients were exposed to mixture of heavy metals. Further studies are needed in order to better elucidate if high exposure to heavy metals might lead to the poor prognosis in lung cancer patients.

3.06.P-Mo132 Evaluation of biomarkers of effect due to exposure to environmental fine particulate matter (PM 2.5) in a population neighboring an industrial park in Cartagena, Colombia

***Belkis Palacio**[1], Maria Cecilia Garcia-Espineira[2], Barbara Julia Arroyo[2] and Lesly Patricia Tejeda[3], (1)Bolivar, Universidad De Cartagena, Colombia, (2)Bolivar, University of Cartagena. Faculty of Medicine; Biomedical, Toxicological and Environmental Sciences Research Group (BIOTOXAM), Cartagena de Indias, Colombia., Colombia, (3)University of Cartagena, Chemical Engineering Department. Biomedical, Toxicological and Environmental Sciences Research Group, Cartagena de Indias, Colombia., Colombia*

Introduction: Air pollution is the main environmental risk for human health. The World Health Organization (WHO) estimated that air pollution caused 4.2 million premature deaths in 2019 worldwide. Air pollution consists of a variable mixture of components such as fine particulate matter (PM), organic compounds such as polycyclic aromatic hydrocarbons (PAHs), gases and heavy metals. The main route of exposure to air pollution is through inhalation. PM can be divided into particles of 10 microns (PM 10) and 2.5 microns or smaller (PM 2.5), which are even more harmful to health. PM 2.5 can cross the lung barrier and enter the blood system. Chronic exposure to PM contributes to the risk of developing cardiovascular, respiratory diseases and lung cancer.

Objective: To evaluate the presence of metals and PAHs in urban dust samples and their impact on people's health through the evaluation of the response of immune cells and determination of DNA damage in people residing in an area neighboring the park. industrial of the city of Cartagena, Colombia.

Methodology: The sampling location was located near the industrial zone. 12 urban dust samples were collected. Environmental contaminants were quantified by atomic absorption spectrometry for metals and GC-MS analysis for PAHs. Biomonitoring was carried out in a cohort of thirty adult inhabitants of the region who freely agreed to participate. The contaminants were quantified and an automated count of immune cells was performed in peripheral blood to determine the leukocyte formula as a biomarker of immunotoxicity; Genotoxicity was determined with comet assay and micronucleus identification. Data were expressed as means ± SEM. ANOVA was performed for statistical analysis. GraphPad Prism was used, $p < 0.05$ was considered statistically significant.

Results: The data obtained provided evidence of the presence of substances toxic to human health in variable concentrations. Biomonitoring showed different responses to evaluated contaminants.

Conclusion: Biomonitoring contributes to the understanding of the mechanisms underlying adverse health impacts due to exposure to environmental contaminants.

Keywords: Air pollution, fine particulate matter, genotoxicity, immunotoxicity.

3.07 Beyond Microplastics: Analytics, Environmental Fate and Impacts of (Water-Soluble) Polymers and Biodegradable Polymers

3.07.T-01 Application of standardized methods to evaluate the environmental safety of polyvinyl alcohol disposed of down the drain

***Jennifer Menzies**[1], Ashley Wilcox[2], Jessica Brill[2], Brian Morris[2], Kristin Connors[2], Maura Hall[2] and Kathleen McDonough[2], (1)Procter & Gamble, Mason, United States, (2)Procter & Gamble*

PVOH 18-88 is a water soluble form of PVOH. It was used as a case study to evaluate the environmental fate, ecotoxicity, and overall safety profile of polyvinyl alcohol homopolymers used in detergent films. An OECD 303A Wastewater Treatment Plant Simulation Study was conducted with dissolved organic carbon (DOC) as the analytical endpoint. During the plateau phase high levels of removal due to biodegradation were observed (avg 97.4 ± 7.1, range 88-116%). The OECD 303A simulation study quantitatively verified that freshwater is the dominant receiving compartment for PVOH 18-88 post treatment. River water screening respirometry was performed to confirm the ability to surface water microbes to degrade PVOH. A suite of standard acute algae, invertebrate, and fish embryo (FET) ecotoxicity studies were performed. Due to the potential for the chorion to impact PVOH 18-88 bioavailability, both chorionated and dechorionated FET tests were conducted. L/EC_{50} >1000 mg/L for FET (chorionated and dechorionated), invertebrate, and algae were observed. The REACH framework was used to evaluate EU environmental risk. EUSES was used to predict local and regional exposure concentrations and compared to the predicted no effect concentration (1 mg/L). The predicted exposure concentrations were >2 OM below the effects concentration, indicating negligible risk from PVOH homopolymer used in detergent films. This talk will also include an update our efforts to conduct additional simulation tests (OECD 314B and OECD 309) using tritiated PVOH 18-88.

3.07.T-02 Biodegradation of Water-Soluble Polymers by Wastewater Microbiomes: Adapting Laboratory Testing Protocols

***Michael Zumstein**[1] and Aaron Kintzi[2], (1)University of Vienna, Austria, (2)Environemental Geoscience, University of Vienna, Austria*

Biodegradability is an important functionality of water-soluble polymers (WSPs) that enter environmental systems at the end of their lifecycle. To enable the development and regulation of biodegradable WSPs, there is a need for testing methods that are scientifically valid and economically practicable. In our research, we have employed respirometric laboratory tests, based on the OECD 301 testing guideline, to investigate the biodegradation of a set of water-soluble polymers – with a focus on the poly(amino acids) poly(lysine) and poly(aspartic acid), and further including poly(ethylene glycol) and poly(vinyl alcohol). As the use of WSPs in many applications (e.g., home and personal care) results in the release of WSPs into wastewater systems, we conducted our study with microbial inocula derived from the aeration tanks of two municipal wastewater treatment plants.

Given that the OECD 301 guideline, and the majority of commonly applied biodegradation testing methods, were developed for small molecules, our main goal was to examine the effects of protocol variations on the resulting biodegradation dynamics for WSPs. Our tests revealed that avoiding aeration of the microbial inocula before introducing WSPs, subjecting WSPs to incubation with extracellular extracts from untreated wastewater prior to biodegradation testing, and reducing the concentration of WSPs all can have a positive impact on WSP biodegradation rates. While individual protocol variations resulted in modest effects, we observed a remarkable effect when combining the afore-mentioned protocol variations. Importantly, the tested protocol variations had no substantial effect on the biodegradation dynamics of low-molecular-weight reference substrates tested in parallel, suggesting that the effects are indeed specific for the WSPs. Complementary to respirometric tests, we applied enzyme activity assays and conducted microbial community analyses to further investigate effects of protocol variations on enzymes and microbiomes used for testing.

This contribution sheds light on the relevance, strengths, and limitations of respirometric laboratory methods for biodegradation testing of water-soluble, reveals promising biodegradation dynamics of poly(amino acids), and provides an initial step in the process of adapting biodegradation testing protocols from small molecules to polymers.

3.07.T-03 A Systematic Approach for a Holistic Ecotoxicological Assessment Strategy of Polymers from the Laboratory to Field Scale

Marie Winter[1]*, Gabriele Broll*[2]*, Bodo Philipp*[3,4] *and Karsten Schlich*[5]*, (1)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (2)Institute of Geography, University of Osnabrueck, Germany, (3)Environmental Microbiology, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (4)Institute of Molecular Microbiology and Biotechnology, University of Münster, Germany, (5)Ecotoxicology, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany*

To enhance crop growing conditions and a secure yield, commercial agricultural practice resorts to e.g. seed coatings or mulch films. Those products often contain polymers favoured by their physico-chemical properties. However, the substance group is not regulated except for intentionally added microplastics, which were recently banned from the European market. Evaluation concepts for polymers, e.g. PLC-Concept, do not include ecotoxicity as indicator for environmental concern. As a result, the environmental behaviour of polymers remains unknown. Our main aim of the study is therefore to develop a systematic ecotoxicological hazard assessment including terrestrial and aquatic toxicity screening for (bio-)polymers.

To determine suitable test methods, model organisms and test systems were chosen based on REACH and Plant Protection regulation (EC 1907/2006, EC 1107/2009) considered as regulatory required standard tests contrasted to potentially more sensitive alternative tests.

For the terrestrial compartment the regulatory required tests OECD 216 (Nitrogen transformation), OECD 232 and OECD 222 (Collembola and earthworm reproduction) are compared to ISO 15685 (Potential nitrification), ISO 20130 (Extracellular enzymatic activities), molecularbiological testing (ARISA and qPCR with targets: amoA, amoB), as well as ISO 17512-1/-2 behaviour studies (Collembola and earthworm avoidance). For the aquatic compartment OECD 201 (Alga growth inhibition) and OECD 202 (Daphnia acute immobilisation) tests will be miniaturised to enhance substance throughput efficiency.

The tests will be performed with different types of polymers, i.e. biopolymers (cellulose fibres, chitosan, alginate, xanthan), synthetically modified polymers (starch, carboxymethylcellulose, hard/ charcoal), bioplastics (polylactic acid) and microplastics (polyethylene, polycaprolactam).

First results are available for modified polymers and biopolymers. A differentiation of test suitability for certain polymeric groups (biopolymers, modified polymers) is not possible yet. Terrestrial test methods indicated highest sensitivity for microbial function as well as earthworm behaviour testing. Comparing aquatic ecotoxicity tests, alga growth is the most suitable indicator for aquatic ecotoxicity as daphnia immobility was no sensitive endpoint. For final test method sensitivity comparison, the data set will be completed and presented at the conference.

3.07.T-04 Analytical Characterisation of Polymers for EU Regulatory Purposes

Laszlo Majoros[1]*, Pertti Elo*[1]*, Ronan Nicolas*[1] *and Ewa Skowron*[2]*, (1)European Chemicals Agency (ECHA), Finland, (2)ECHA, Hazard assessment unit, European Chemicals Agency (ECHA), Finland*

In 2020, the European Commission started developing a proposal for polymer registration based on Article 138(2) of the REACH Regulation. The proposal defines certain physico-chemical parameters and information on structure and composition that need to be assessed by the registrants in detail to determine if a polymer requires registration. To achieve a meaningful implementation of the potential Regulation of polymers, the identity of these complex substances needs to be established in a way that comparability of the analytical results obtained by the manufacturers and importers of the polymers is ensured. It needs for instance to be ensured that companies dealing with the exact same polymer do not end up with different conclusions on its identity. Analytical characterisation of certain polymers is anticipated to be challenging due to their chemical complexity.

Comparable analytical characterisation of the polymers to be registered is a prerequisite for their proper hazard assessment and the assessment of closely related analogues. It should be stressed that information on chemical composition, structure and physico-chemical parameters are also important features that can influence the environmental fate, bioavailability and toxicity of polymer. Therefore, correct identification and characterisation of polymers will allow to select the best representative(s) for testing under the future regulatory scheme.

Many analytical techniques exist to characterise polymers. However, if different techniques are used the comparability of the obtained results and consequently the identification of polymers might be difficult. Even if the same technique is used, certain standardisations of the methods are needed to minimise differences in the outcomes. Finally, for such complex substances as polymers the manufacturing process description adds a significant part to the identification and characterisation.

ECHA intends to gather statistical data on the registered No Longer Polymers. The aim of the work is to assess the relation between the reported compositions and the type of the analytical techniques submitted in the dossiers, and to measure the concerns that companies rely on different analytical methods, which may be a source for inconsistencies. The work will additionally provide further insight on the strategy considered so far for characterising the low molecular weight polymerised constituents. Part of the results of this work will be shared at the conference.

3.07.P Beyond Microplastics: Analytics, Environmental Fate and Impacts of (Water-Soluble) Polymers and Biodegradable Polymers

3.07.P-Th280 Bioavailability of Polymers: Factors Governing Bioaccumulation and Toxicity

Fola Ogungbemi[1]*, Lena Benner*[1,2]*, Jan Wolff*[1] *and Thomas Sadler*[1]*, (1)Product Compliance, Currenta GmbH & Co. OHG, Germany, (2)Hochschule Niederrhein, Germany*

Polymers, integral components of numerous modern materials, lack the same comprehensive environmental safety assessments afforded to non-polymeric substances. Despite their widespread use, limited knowledge exists regarding their behavior in the environment, prompting the need for further exploration of properties such as bioavailability and bioaccumulation, pivotal in determining toxicity. Presently, the European Commission is actively developing a proposal to instigate the registration of polymers under the European Union's REACH chemicals legislation, reflecting a contemporary effort to enhance understanding and regulation of these versatile materials. Some sources suggest the concept of “polymers of low concern”, categorized based on a set of structural and physico-chemical criteria, that would receive exemptions from notification requirements. Suggested criteria include parameters such as molecular weight, electrical charge, reactive functional groups, partition coefficients or water solubility. Are all these criteria equally relevant for predicting bioaccumulation of a polymer, or is it possible to identify a small number of key parameters? Therefore, to support this effort to develop a risk assessment methodology for polymers, the factors affecting bioaccumulation of polymers will be investigated via an initial literature search. Results to these two questions would be presented: 1) What are the influential parameters for the hazard assessment of polymers and 2) What is the correlation of the identified key parameters to bioaccumulation.

3.07.P-Th281 Overcoming Analytical Challenges in Size Exclusion Chromatography for Accurate Characterization of Molecular Weight Distribution of Polymers

Timo Florian Beskers[1]*, Bastiaan Staal*[1]*, Claude Arreyngang Tabe*[1]*, David Schaffert*[1]*, Renata Gerhardt*[1]*, Sabine Keune*[2] *and Alexander Eifert*[3]*, (1)BASF SE, Germany, (2)Evonik Operations GmbH, (3)Wacker Chemie AG*

Polymers, composed of repeating monomer units, exhibit distributions in many properties, with molecular weight being the most prominent. Accurate determination of the molecular weight distribution (MWD) and oligomer content (percentage below 1000 g/mol and 500 g/mol) is essential in the regulatory framework of polymer risk assessment. Within any regulatory framework for polymers standardized, rapid, universally applicable, and validated methods for MWD determination are required. Size exclusion chromatography (SEC) or gel permeation chromatography (GPC) is the state-of-the-art technique for MWD characterization. However, SEC poses several analytical challenges in accurate determination of MWD and oligomer content.

Limitations of SEC arise for example from insolubility, crosslinking, and ultra-high molecular weight. Additionally, the interference with signals from side components such as solvents cause problems. SEC is a relative technique and thus requires suitable calibration standards, which are not always available. This limits comparability of results. For MWD determination and especially for oligomer content determination, alternatives to SEC are practically non-existant.

This presentation highlights the need for innovative methods and strategies, as well as the development of comprehensive guidelines, to facilitate the registration of polymers effectively and efficiently. Several approaches have been proposed to handle the challenges, including the use of new sample preparation techniques, data interpretation and the development of standardized methods and calibration techniques.

In summary, SEC is a well-established technique for MWD determination, but several challenges must be addressed to ensure its general applicability in a regulatory framework. Addressing the challenges associated with SEC is important for successful implementation of the upcoming REACH revision and the development of an efficient and effective polymer notification and registration process.

3.07.P-Th282 A PROPOSAL FOR A THREE-TIERED APPROACH FOR TARGETED INFORMATION REQUIREMENTS FOR POLYMERS

Jens C. Otte[1]*, Heli Hollnagel*[2]*, Christiane Nagel*[1]*, Renata Gerhardt*[1]*, Wendel Wohlleben, Dr.*[1]*,* ***Nathalie Vallotton***[2]*, Diederik Schowanek*[3]*, Gordon Sanders*[4]*, Joe Frasca*[5]*, Tushar Mahale*[6]*, Mark Pemberton*[7]*, Bjoern Hidding*[1] *and Robert Landsiedel*[1]*, (1)BASF SE, Germany, (2)Dow Europe GmbH, Switzerland, (3)Brussels Innovation Centre, Procter & Gamble, Belgium, (4)Givaudan International SA, Switzerland, (5)ExxonMobil, (6)Lubrizol, India, (7)Systox Ltd, United Kingdom*

Polymers are a diverse set of chemistries, part of our daily life and provide a multitude of technical functionalities. Usually, polymers cover a broad spectrum of molecules with medium to very high molecular size such as celluloses, waxes and resins. By their nature, polymers are different to small and discrete molecules and conventional risk assessment approaches are not necessarily equally suitable for polymers.

Therefore, the European Centre for Ecotoxicology and Toxicology of Chemicals (ECETOC) Polymers Task Force has developed a conceptual three-tiered proposal to generate data to assess individual and groups of polymers requiring registration (PRR). A prerequisite is the grouping of polymers according to three criteria: chemistry, physico-chemical properties and hazard similarity. The proposed approach considers the limited bioavailability of polymers as a prominent difference to many small molecules and takes this into account as a central element, in particular for human health. Among others, methods for assessing a potential for systemic bioavailability are integral to Tier 1. Within Tier 1, basic data will be generated on a single polymer or polymer group making use of non-vertebrate testing methodologies. Decisions for further studies at higher tiers are based on considerations of properties and effects, combined with systemic bioavailability, and use and exposure considerations. For many PRRs, Tier 1 data on hazard, use and exposure will likely be sufficient for achieving the protection goals under chemical legislation such as REACH. Vertebrate animal studies and higher-tier fate testing in Tiers 2 and 3 can be focussed on testing needs according to the combined factors above.

The ECETOC Polymers Task Force is of the opinion that the principle of a tiered approach with no vertebrate animal testing at Tier 1, followed by justified, limited and targeted vertebrate testing in higher tiers considering systemic bioavailability estimates, use and exposure considerations and material properties first, provides a basis for modern and considerate data generation for the next decade to ensure the selection of polymers for safe production and use. The Task Force welcomes comments and encourages scientific discussion on the proposal.

3.07.P-Th283 Biodegradation of Water-Soluble Polymers – Reviewing In-Silico Methods
***Dimitrios Alexander Skodras**[1], Michael Huben[2] and Judith Klein[1], (1)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (2)Ecological Chemistry, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany*
In light of the increasing prevalence of polymers across diverse industries, evaluating their environmental impact becomes imperative, particularly within the framework of the European Green Deal and the Chemicals Strategy for Sustainability. Historically, there was no mandated scrutiny of the environmental fate of polymers, as they were exempt from REACH (EC 1107/2009). However, this exemption is anticipated to undergo changes in the coming years. A crucial aspect of this evaluation is the assessment of degradability and persistence of functional polymers such as for applications in cosmetic formulations.

Degradation processes are fundamentally describable through chemical formulations and can be mathematically modeled. These models can then be implemented in computer programs to calculate degradation pathways for any substance based on its chemical profile. In instances where degradation processes lack an analytically closed-form, statistical procedures, such as Quantitative Structure-Activity Relationship (QSAR) and Quantitative Structure-Property Relationship (QSPR) models, can be employed to establish relationships between the structure of a polymer and its degradation characteristics.

This poster presents the current state of in silico methods for assessing polymer degradation, shedding light on their limitations in handling polymers and in accurately calculating biodegradation. The shortcomings are examined, emphasizing the need for improvement in these methodologies. Potential avenues for enhancement are outlined, underscoring the importance of refining in silico methods to ensure a comprehensive understanding of the environmental fate of polymers, especially those used in water-soluble cosmetic formulation applications.

3.07.P-Th284 A Novel Approach for Determining Oligomer Content in Partially Insoluble Polymers Using Size Exclusion Chromatography and OECD 118/119
***Timo Florian Beskers**, Bastiaan Staal and Bianca Czarny, BASF SE, Germany*
Size exclusion chromatography (SEC) is a widely used method for determining the molecular weight distribution (MWD) of polymers and polymeric products. However, the analysis of high-molecular weight or cross-linked samples using SEC presents challenges, particularly in accurately determining the oligomer content. This content of lower molecular weight fractions below 1000 g/mol and 500 g/mol is vital for regulatory purposes. The method for SEC and oligomer content determination is outlined in OECD guidelines 118 and 119, as well as similar DIN and ISO norms.

The upper limit of SEC separation is determined by the pore sizes in the column material. Larger molecules or species, such as ultra-high molecular weight or cross-linked samples (gel), do not dissolve completely or only swell, impeding their passage through the SEC column. Consequently, only the soluble fraction is analyzed, resulting in underestimated mean values of the MWD (Mn, Mw), and an overestimation of the oligomer content.

Determining the proportion of the analyzed sample from the total sample proves challenging, with weighing the filter often yielding inaccurate results. It is recommended in OECD 119 to calibrate the detector response to determine the amount of the analyzed sample. However, this approach requires either known dn/dc values or a completely soluble, SEC-compatible reference substance with identical chemical composition to the sample. Both is usually not available.

In summary, the analysis of ultra-high-molecular weight or cross-linked samples - such as dispersions used in paint for example - by SEC poses difficulties, hindering the accurate determination of the oligomer content. This presents a challenge for proper classification in the risk assessment process of polymers, as an alternative, equivalent method for determining oligomer content does not currently exist.

Here, we present a novel approach for determining the detector response and, consequently, dn/dc for partially insoluble polymers such as cross-linked or high molecular weight polymers. This new method uses ultrasound to break down the crosslinking and makes the sample fully soluble, thus enabling the precise determination of the oligomer content (amounts <1000 g/mol and <500 g/mol) with only two simple SEC measurements following OECD 118/119. Importantly, this approach can be applied even when the product is a mixture or dispersion of unknown concentration, which is often the case for real-life polymeric products.

3.07.P-Th285 Assessing the Applicability of Eco-Toxicological OECD Guidelines 202 and 487 for Testing of Polymers
*Denis Botin[1], **Simon Lüderwald**[2] and Nora Hartner[1], (1)Analytical and Material Science, BASF SE, Germany, (2)Experimental Toxicology and Ecology, BASF SE, Germany*
In line with the recent developments for the transitions into circular and sustainable economy, the Chemical Strategy for Sustainability aims at the extension of registration requirements for chemicals. A major consideration concerns the planned end of the exemption of polymers from registration in REACh.

The generation of robust, meaningful and consistent data as well as from analytical and from toxicological testing is paramount for this purpose. OECD guidelines exist for such purpose, but were developed for small, well-defined molecules and their applicability to much larger polymeric species is questionable. The main problem is the high molar mass that is intrinsic to many polymers. Additionally, polymers are characterized by a distribution of molecular weights, potentially also a distribution of composition.

Such nature differentiates them from the small molecules, resulting in different behaviour in test media (e.g., solubility, stability, reactivity), all whilst the sample preparation procedure becomes even more important. In general, several cases can be identified:

- polymers are soluble in test media, but may still interfere with assays e.g. due to light scattering
- polymers are insoluble in media, but forming a stable dispersion of particles, resulting in a constant exposure during eco-toxicological tests
- insoluble polymers, unstable in test media
- and polymers reacting with water and/or test media.

Here we demonstrate results obtained for a set of polymers that represent each of the above categories with different properties (molecular weights, chemistry) when one applies the test media, concentrations and procedures prescribed in OECD guidelines for aquatic toxicity (OECD 202) and genotoxicity (OECD 487). We applied different sample preparation procedures and tested the colloidal stability and homogeneity to get insight into polymer behaviour during actual testing. These results are compared to the observations during toxicity testing and evaluation of water solubility of polymers according to the OECD Guideline 120.

3.07.P-Th286 Influence of Gel Permeation Chromatography Set-up on Results
***Sebastian Schmiedt** and Paul Bendig, Eurofins Agroscience Services EAG Laboratories GmbH, Germany*
For registration of Polymers under REACh characterization of polymers with gel permeation chromatography (GPC) will be a prerequisite. The technique appears well established to determine molecular weight distributions of polymers itself. However, complexity increases when looking at different chromatographic conditions and low molecular weight fractions.

It has been reported that the separation of analytes and the results obtained using gel permeation chromatography is not solely depending on the molecular weight, but also other attributes. Hence, results are highly dependent on the combination of column material, elution solvent and calibration substances and naturally on the polymer itself.

The influence on results of selected column-solvent system combinations is presented and applied to different example polymers. Challenges and opportunities in the low molecular weight fraction will be investigated and discussed. The low molecular weight fraction may comprise monomeric and oligomeric constituents/impurities as well as intentionally added chemicals. Combination of different detectors could help enhance comprehensibility of the elugram in the low molecular weight fraction.

3.07.P-Th287 Challenges and Recommendations for Addressing Side Components in SEC Chromatograms of Polymers for Regulatory Purposes
*Bastiaan Staal[1], **Timo Florian Beskers**[1], Yvonne Matheis[1], Paul-Albert Schneide[1] and Gabriel Vivo Truyols[2], (1)BASF SE, Germany, (2)Tecnometrix*
Size Exclusion Chromatography (SEC) is a widely used technique for analyzing the molecular weight distribution (MWD) and

oligomer content of polymers. Accurate determination of oligomer content is important within regulatory risk assesment frameworks for polymers. It's part of the basic data requirement for polymer substance registration in many countries, including the anticipated REACh revision in the EU. SEC separates molecules based on their size in solution, specifically their hydrodynamic volume, making it an entropic process that is not specific to any particular chemical characteristic.

However, the presence of side components in the sample poses a significant challenge in SEC analysis. SEC measurement conditions must be optimized for the polymer species, striking a balance in polarity between the sample, solvent, and stationary phase to prevent enthalpic interactions that could impede the SEC separation mechanism. Side components can be of different chemical natures and potentially different polarities. If these side components have similar polarity, they elute within the calibrated SEC range, overlapping with the polymer signals and hindering accurate determination of oligomer content and molecular weight distribution. However, if side components have different polarity, they either elute after the SEC chromatogram and the void peak (similar to other forms of liquid chromatography) or may not be detected at all if they are insoluble in the solvent for example. Consequently, oligomer content determined using SEC cannot serve as a comprehensive parameter for all low molecular weight species present. Neither does SEC always measure the oligomer content of the polymer alone, as it lacks specifity. Analyzing real-life polymer products, where the contained polymer is often not available in pure form, presents challenges due to overlapping peaks. In some cases, polymer purification or careful selection of the LC method parameters can induce interactions with side components, causing their peaks to fall outside the SEC separation range. Alternatively, if the concentration of the side component is known and can be measured as a reference, peak subtraction can be employed as a viable solution.

In this presentation, we will discuss the challenges, provide examples, and offer recommendations for effectively addressing side components in SEC analysis.

3.07.P-Th288 Polyvinylpyrrolidone in aquatic organisms: Development of an aqueous GPC method for water-soluble polymer analysis

***Eve Tarring*[1]*, Charlotte Robison-Smith[2], Joanne Cable[3], Isabelle Durance[3], Michael Harbottle[3] and Ben Ward[3], (1)Chemistry, Cardiff University, United Kingdom, (2)Biosciences, Cardiff University, United Kingdom, (3)Cardiff University, United Kingdom*

Water-soluble polymers (WSPs) are additives that are widespread in both domestic and industrial products due to their plethora of uses and characteristics in formulation. These include personal-care products (PCPs) as well as wastewater treatment flocculants, soil conditioning additives and as an ingredient in aquaculture products. These polymers are widely used and therefore predicted to enter the environment, with polymers such as polyethylene oxides (PEOs) quantified in freshwater. However, there is a limited understanding of their environmental effects, partially due to the lack of regulation surrounding their use but also due to their complex and vast range of chemical structures and behaviour in environmental matrices. Polyvinylpyrrolidone (PVP) represents a particular concern due to its lack of biodegradation, which implies it may have the ability to persist in the environment and has already been shown to have sub-lethal toxic effects at environmentally relevant concentrations on multiple species during lab-based studies. Despite the increased interest in PVP, there is still a lack of quantitative information to inform on ecotoxicological persistence, due to the lack of analytical methods to detect PVP. This is relevant for environmental protection and regulation, but its prevalence within aquaculture practises to prevent disease outbreak raises direct concern for food security and human ingestion of polymers. Multiple methods have begun to be developed for WSP analysis, however this is still with a focus on lower-molecular weight polymers. Polymer specific methods are only very recently being explored as an alternative, combining traditional polymer analysis methods such as gel-permeation chromatography (GPC) with ecotoxicology. In this study, we explore the use of GPC as a method to detect and quantify PVP in exposed aquatic organisms to determine whether bioaccumulation of this chemical is possible in aquatic food webs. This ongoing work aims to investigate both the analytical capabilities of GPC in environmental analysis but also explain the sub-lethal toxicity of PVP to aquatic species.

3.07.P-Th289 A comprehensive study of polymer – lipid membrane interactions with in-chemico NAMs.

*Coralie Sophie Schneider[1], **Wendel Wohlleben, Dr.**[2] and Lan Ma-Hock[2], (1)BASF, United States, (2)BASF SE, Germany*

To minimize the need for in-vivo testing with animals, new approach methods (NAM) and integrated assessment strategies are needed for potential hazard and/or bioaccumulation. One such strategy could include the testing for interactions between polymers and model bio membranes (ECHA, Key Areas of Regulatory Challenge, November 2023). Our test set included both solid polymers (i.e. nano- and microplastics) and soluble polymers with many different chemical functionalities.

We present a comprehensive study of polymer – lipid membrane interactions and quantification thereof consisting of three different in-chemico NAMs: Firstly, with the quartz-crystal microbalance with dissipation monitoring (QCM-D), where we have prepared a supported lipid bilayer (SLB) at the solid/water interface. Secondly, with interfacial rheology, where a lipid layer is prepared at the water/air interface of a drop. And lastly, with analytical ultracentrifugation we test the interaction between unilamellar lipid vesicles and polymers by detecting the disruption, insertion, or bridging of vesicles. Additionally, electron spin resonance with CPH spin trap (EPR) experiments were performed to detect radical generation as a potential initiating event of cellular toxicity (Lehman et al, Environ. Sci.: Nano, 2016, 3, 55-56).

Since the four methods test for different interactions via different mechanisms or at different interfaces, a comprehensive data set was generated. To assess the relevance of the different descriptors for prediction of toxicity, data sets of selected polymers were compared to and correlated with existing in-vivo inhalation data.

3.07.P-Th290 Polyethylene Terephthalate (PET) Biodegradation Using Isothermal Titration Calorimetry: A Path to Circular Economy

***Noelia Fernandez Merayo**[1] and Thomas Maskow[2], (1)Environmental Microbiology, University of Leipzig, Germany, (2)Environmental Microbiology, Helmholtz Centre for Environmental Research (UFZ), Germany*

The increasing plastic production has been a concern for the last decades, reaching a production of 390.7 million metric tons in 2021, excluding polymers that are not used in the conversion of plastic parts and products (i.e. for paints, cosmetics, textiles, adhesives, etc.). As a consequence, the current plastic waste management system has been put on the spotlight, since according to the OECD only 9% of the plastic waste is being recycled. Subsequently a large fraction of the plastic enters the environment, which afterwards will most likely be fragmented and turned into microplastics (<5 mm) and nanoplastics (NP, <100 nm). In addition, NP are of higher concern as they can permeate into animal and human tissues.

Polyethylene therephtalate (PET) is of particular interest, since it is mainly used for packaging and disposable items and therefore often ends up in the environment instead of being recycled. It has been reported that PET-NP can be degraded by different microorganisms or enzymes (e.g. *Ideonella sakaiensis,* TfCut2 from *Thermobifida fusca*) to obtain intermediate oligomers or the original monomers, i.e. terephthalic acid and ethylene glycol. The technical exploitation of these potentials would open up options for efficient recycling and approaching to a circular economy. This requires information about kinetic and thermodynamic parameters of the depolymerization, hard to obtain with conventional analytical techniques.

Using isothermal titration calorimetry, it has been possible to monitor and characterize the biodegradation process. A model was developed for the degradation of PET nanoparticles size 180 nm, using a plant-metagenome-derived cutinase, the LCC^{ICCG}. This provides a new method, along with insight into the kinetic cleavage of ester bonds, opening the door to implementing this at a bigger scale and a possibility of expanding this models to different hydrolysable polymers.

3.07.P-Th291 Polymer risk assessment: Consideration from the ECETOC Polymer Task Force

***Nathalie Vallotton**[1], Christiane Nagel[2], Renata Gerhardt[2], Wendel Wohlleben, Dr.[2], Diederik Schowanek[3], Gordon Sanders[4], Joe Frasca[5], Tushar Mahale[6], Mark Pemberton[7], Bjoern Hidding[2], Robert Landsiedel[2] and Heli Hollnagel[1], (1)Dow Europe GmbH, Switzerland, (2)BASF SE, Germany, (3)Brussels Innovation Centre, Procter & Gamble, Belgium, (4)Givaudan International SA, Switzerland, (5)ExxonMobil, (6)Lubrizol, India, (7)Systox Ltd, United Kingdom*

Polymers represent a large and broad aspect of the chemical space and provide a multitude of technical functionalities. An ECETOC Task Force has summarized the state-of-the-art polymer regulation and testing. Importantly, the Task Force has proposed the ECETOC Conceptual Framework for Polymer Risk Assessment (CF4Polymers) that includes eight steps for aspects to consider in risk assessment and intelligent testing of polymers. Case studies confirmed that due to the wide range of polymer types and properties, no 'one size fits all' set of rules is applicable to this diverse set of materials, leaving regulators and industry to apply rules on a case-by-case basis. The scope of the risk assessment of polymer products may vary depending on a combination of deciding factors, among which the assessor considers the type of polymer chemistry, the application during use and relevant routes of exposures. Depending on scope, the focus may be on the polymeric substance should the polymeric substance have reactive functional group suggesting specific hazards. Alternatively, emphasis may be on IAS (intentionally added substances) and NIAS (non-intentionally added substances). Indeed, many polymer types are complex mixtures where IAS and NIAS contribute to, and in some cases are responsible for, the expressed hazard properties. Currently in the EU, product regulations such food contact materials and cosmetics focus on the product as placed on the market and prioritize constituents of polymeric products relevant to potential exposure. The objective of expanding the registration of polymers, for example in the REACH regulation, raises questions on the type of information required to support the purpose of the safety assessment of polymers requiring registration (PRR), as produced. This results in a shift of paradigm from a focus on a targeted scoping of assessment on polymer products aligned to the end use applications, to standard information requirement for PRR. This challenging landscape led the ECETOC Task Force to develop a tiered approach to support the assessment of PRR, considering elements of bioavailability to biota and the objective of minimizing vertebrate testing. Challenges in informing quantitative risk assessment will be discussed, acknowledging the lack of agreement among stakeholders on the domain of applicability of test methods, as well on the suitability of testing information to support the safety assessment of polymers.

3.07.P-Th292 Environmental Persistency Assessment for Synthetically Modified Biopolymers

***Harald Streicher**[1], Diego Robles[1] and Alistair Boxall[2], (1)Beiersdorf, Germany, (2)University of York, United Kingdom*

Synthetic polymers are used in a very broad range of products and applications. In the area of cosmetic products, they enable important functionalities of e.g., rheology modifying and film forming. However, established materials are often known to be persistent in the environment. In contrast, natural biopolymers e.g. Cellulose, Starch, Guar are biodegradable but both their performance as well as their variety of resulting sensorial profiles are limited and not up to par to conventional technologies.

Synthetically modified biopolymers are an interesting and promising alternative for cosmetic product formulations as they combine several aspects: Their natural polymer backbone is biodegradable and their functional hydroxyl groups allow a wide range of synthetic modifications and functionalities. The current screening tests to rule out persistency (e.g., OECD 301 and OECD 302) were not developed for polymers. As polymers are exempt from registration e.g. via REACH in the EU, data gaps are frequent.

To ensure essential biodegradability a weight of evidence persistency assessment is proposed which takes into account OECD screening results, structural analysis of the respective synthetically modified biopolymer and higher tier testing results.

Biodegradation data of different synthetically modified celluloses with different functional groups and molecular weights has been generated to compare OECD screening results with higher tier testing data.

3.07.P-Th293 Safer by design approach to support innovation : a practical case study with microplastics

Mickael Cregut*, Laura Gallorini, Torres Anaelle and James Wilson, Rhone, Solvay - Biomattech RIC-Lyon, France*

Solvay aims to develop different activities to assess the potential impact of the substances during their manufacturing, their use or their degradation/release. A safer-by-design approach allows the selection of the best candidates from application performance tests, (eco-)toxicological assays and biodegradability results, and is employed during the development of a new range of safe and sustainable products by our research and innovation function.

One of the safer by design approaches for which we gather information at an early stage of development is biodegradability evaluation. According to the application, the substances (coating of seeds, additives in shampoo…) can be released in the environment or in wastewater treatment plants. In this context, the research lab aims to investigate the biodegradability of the product, by following the degradation *via* respirometric analyses from micro-organisms.

Among the substances which have gone through this process during the past years, some microplastics case studies are presented here. Polymers are used in a wide range of applications such as packaging and coating, consumer goods, medical equipment or agriculture. Polymers with a low solubility below 2g.L-1 can be suspected to be microplastics according to the new incoming regulation in Europe. To answer to the needs of their registration and classification several factors such as their ready and/ultimate biodegradability can be highlighted in conventional OECD tests to ensure their environmental safety and to confirm that they can be considered or not as microplastics. Among those tests, our internal facilities allow Solvay to screen both ready biodegradability traits with or without BIMs (bioavailability improvement methods) and notably (emulsion) to highlight the potential of biodegradability of the substance. If these first tests are not conclusive, OECD & regulations propose to investigate both compartmental biodegradability and potential of persistence of these substances.

Associating to these biodegradation results, the impact of the native substance and of its biodegradation byproducts in terms of toxicity and ecotoxicity, will allow in the future to secure our safer by design approach.

3.07.P-Th294 Modelling Techniques for the Prediction of Polymer Properties

*Jessica Bean[1], Glauco Battagliarin[2], **Averina Nicolae**[3], Andreas Künkel[2], Sonja Schmidt[3] and Volker Settels[3], (1)BASF Plc, (2)Research Biopolymers, BASF SE, Germany, (3)BASF SE, Germany*

The development and use of in silico tools for the modelling and prediction of polymer properties has evolved rapidly over the past decade, mainly based on evolution of machine-learning (ML) techniques. These techniques allow fast and accurate prediction of factors of interest, which has already been well documented. The use of predictive models for environmental fate in the regulatory context is already well established, with the use of BIOWIN, EPISUITE and OPERA already commonly used for the assessment of environmental fate and pathways. So far, however, these tools are only available for the evaluation of small molecules, as polymer structure is frequently too complex to accurately use for ML. Techniques used for small molecules – such as SMILES or InChI codes - cannot convey the information on polydispersity, branching, crystallinity or macroscopic structure which polymer modelling requires for accurate understanding. The lack of comprehensive datasets containing this information has additionally hindered development of models for polymers. As the environmental fate of polymers is receiving growing attention, it is increasingly important and relevant to develop tools which apply to this class.

A number of new methods are now being proposed which show promise in offering a description which can be used by ML. BigSMILEs is one of the most popular, as its logic and notation extend from the already widely used SMILES. There is however still much development still needed on an overarching method to describe polydispersity, for example. Here, new applications of ML will be presented which can be used to predict environmental fate of polymer structures. More importantly, a framework will be given on what is still needed in order to develop ML for polymer environmental fate applications into tools for regulatory purposes.

By developing new methods to accurately describe polymer structure *in silico*, it will open the door to development of new ML based tools for prediction of environmental fate for complex structures. Such tools will greatly increase the amount of data available for fate of new structures in different environments, and critically, will offer fast, low-cost tools which aid understanding before higher cost lab tests.

3.07.P-Th295 Applying a High-Throughput Biodegradation Test to Assess Factors Affecting the Biodegradability of Polymers

Edward Mitchell[1], *Russell Davenport Prof*[2], *Jennifer Menzies*[3] *and Kathleen McDonough*[4], *(1)Environmental Engineering, Newcastle University, United Kingdom, (2)Newcastle University, United Kingdom, (3)Procter & Gamble, Mason, United States, (4)Procter & Gamble*

Polymers are found in a wide variety of everyday products from pharmaceuticals to detergents, this results in a high environmental exposure upon their disposal. Despite this, little is known about the fate of these polymers in the environment and there is only a limited range of tools available to assess their biodegradability. To address these two problems, we have developed a new high-throughput biodegradation test for glucose-based biopolymers. This method detects and quantifies glucose as the analytical endpoint of the polymer's biodegradation and can be conducted in a 96-well plate format. It exposes the polymer to an enzyme-mixture specific to its backbone, and under ideal conditions for the enzymes, to see how much degradation can be achieved in 48 hours. To optimise this for eventual use on complex modified polymers, the test was applied first to unmodified polymer backbones, in particular Pullulan and Dextran. The aim was to detect approximately 100% degradation in these unmodified polymers to be confident that the method was reliable enough to test modified counterparts. Thus far, this has been achieved in Pullulan but not Dextran which is hypothesised to reach ~100% with adjustments to the choice of secondary enzymes. Once optimised, this test could then be utilised to study the effects of different characteristics on the biodegradability of polymers. A set of modified Pullulan and Dextran samples with differences in degree of substitution and molecular weight have been selected for testing, to investigate the effects these characteristics have on their biodegradation. It is further hypothesised that degree of substitution will have a greater effect with greater levels of substitution lowering biodegradability. Once completed, this method could be a simple, high-throughput tool for providing an insight into biodegradability in novel polymers, before committing to more expensive and laborious biodegradation testing. Applying this test could also advance knowledge of factors affecting biodegradability of these polymers to help better understand their fate in the environment.

3.07.P-Th296 Investigating Biodegradation of Polymers: A Bibliometric Analysis of Research Trends and Proposed Informative Framework for Water-Soluble Polymers

Prabodhi Preethika Dehiwalage Dona[1], ***Russell Davenport Prof***[2], *Kathleen McDonough*[3] *and Jennifer Menzies*[4], *(1)Newcastle University, Newcastle, United Kingdom, (2)Newcastle University, United Kingdom, (3)Procter & Gamble, (4)Procter & Gamble, Mason, United States*

There is a growing global concern around chemicals in consumer products, given the associated demand and the potential risks they pose to the environment and human health. Many of these chemicals originate from petrochemical feedstocks. In the pursuit of sustainable alternatives, attention is turning to polymers. While plastic polymers have extensive information, there is a research gap in bio-based polymers, which present a promising substitute for fossil-fuel-based chemicals in consumer products.

This study investigates the research and grey literature to better understand polymer characterization analysis, particularly in the context of biodegradation. The overall goal is to develop an information-based framework for making decisions about developing appropriate biodegradation tests for polymers. The bibliographic analysis involved extracting literature from SCOPUS using VOS viewer software and EndNote. This analysis narrowed down the initial 9593 publications to 157 papers, which were thoroughly reviewed to identify research trends and critical knowledge gaps.

The quantitative analysis showed a deficiency in research focus, particularly regarding biodegradation tests, polymer fate, distribution of potential polymer-degrading microorganisms, and methods for quantifying and handling degradation products. Furthermore, critical knowledge gaps were identified, emphasizing the absence of standardized testing methods for biodegradable polymers (BP), and the lack of persistence assessments, hindering accurate evaluation.

We have proposed an informative framework to understand crucial polymer characteristics and biodegradation, enabling decisions based on accurate test information, analytical endpoints, and diverse testing strategies. This proposal encompasses various stages: 1) Polymer selection; 2) Information collection; 3) Evaluation of methodology and applicability; 4) Identification of test limitations; 5) Analysis of fragments and transformed derivatives; 6) Investigation of long-term fate and test modifications. We intend to further develop and evaluate this framework, utilizing the case study of water-soluble polymers and validating it through laboratory experiments, which can be used in down-the-drain consumer products.

This research significantly contributes to the field by offering a roadmap for future investigations on biodegradable polymers. Ultimately, it addresses a crucial aspect of environmental sustainability for future generations.

3.07.P-Th297 Fragrance encapsulates: impact of the polymeric shell purification method on the accuracy of the OECD 301F biodegradability assessment

Katerina Karagianni[1], ***Karen Jenner***[2], *Fatimata Dembele-Kuntzmann*[1], *Antoine Charbonnier*[1], *Vladica Bocokic*[1], *Ian Harrison*[1], *Georg Kreutzer*[3] *and Arturo Mendoza*[3], *(1)Givaudan France SAS, France, (2)Givaudan UK Ltd, United Kingdom, (3)Givaudan Suisse SA, Switzerland*

Fragrance encapsulates are widely used in consumer care applications such as fabric softeners or other liquid laundry care products since they provide multiple benefits, from fragrance protection in the commercial product to a controlled release and improved sensorial experience for the consumers. Polymeric fragrance encapsulates are in scope of the EU regulation restricting the use of intentionally added microplastics particles and industry is actively working on innovation programs to find biodegradable alternatives. However, particular attention needs to be paid to claims that a fragrance encapsulation system is biodegradable because biodegradation test results can vary considerably depending on how a test material is prepared, which can even lead to false positive biodegradation test results. In this study we demonstrate the importance of the sample preparation phase of the process. We show how the biodegradation level can fluctuate from 0 to 91%, depending on how the test material is isolated from a given microcapsule slurry system and present a method that can be used in order to obtain trustworthy biodegradation results.

3.07.P-Th298 (Bio)degradation of Model Polymers with Varying Physico-Chemicals Properties & Structures

Guillaume Cottin[1]*, Elsa Païva*[2]*, Xavier Schultze*[2]*, Jérôme Loriot*[2]*, Sean Ellacott*[2]*, Alaa Bensetra*[3] *and Cyril Sweetlove*[1]*, (1)L'Oréal, France, (2)L'Oreal Research & Innovation, France, (3)Analytical chemistry, L'Oréal, France*

The life cycle of polymers most commonly found in the environment has been estimated at several decades, even hundreds of years. Alongside these polymers, which are mainly used in packaging, polymers that are soluble or dispersed in water or application solvents are commonly used in a wide range of industries. Considering this, chemical product regulations (including polymers) are evolving. The European Commission has notably adopted its sustainable strategy, which constitutes a key commitment of the Green Deal. In addition, the REACH and CLP regulations will be revised in the coming years and will include polymers. In this context, polymers contained in rinsed-off products require an appropriate assessment. Only polymers whose biodegradability in the environment can be demonstrated will ultimately be authorized.

In this context, the aim of this study is to establish structure-property relationships among different molecular structures (different backbones & end groups), their physico-chemical properties (Tg, molecular weight, solubility, etc.) and biodegradation measured using biotic and abiotic tests. Three families of model polymers were selected (PVA (Polyvinylalcohols) / Polyalkylglycols (i.e. PEG) / PCL (Poly(caprolactone)).

These results show the importance of taking into account the physicochemical parameters of polymers (solubility, Mw, particle size, end groups, …) in the context of the biodegradability assessment and generally in their envrionmental impacts assessment. These parameters generate additional variability on top of the existing biological variability.

For this, it's essential to ensure a good bioavailability of a polymer under the test condition (grinding, BiM) and include a positive polymer reference indicating an equivalent response of the activated sludge from one biodegradability test to another.

Understanding the (bio)degradation mechanisms of polymers is essential in order to optimize existing guidelines for polymers, particularly in view to regulatory evolutions.

3.07.P-Th299 Interactions of cosmetic polyacrylic-based water-soluble polymers with activated sludge: Biodegradability, adsorption, and effects

Gabriela Kalcikova[1]*, Ula Rozman*[1] *and Janja Novak*[2]*, (1)Faculty of Chemistry and Chemical Technology, University of Ljubljana, Slovenia, (2)University of Ljubljana, Slovenia*

Water-soluble polymers (WSPs) are used in a variety of applications, including as an essential ingredient in personal care products and cosmetics. After use, they are flushed down the drain and treated in wastewater treatment plants. However, their interactions and fate in wastewater treatment plants are still unclear. In this context, the aim of this study was to investigate the adsorption potential of two polyacrylic acid (PAA)-based WSPs (homopolymer and copolymer) on activated sludge, their effects on settling and respiration, and their biodegradability.

The results showed that both the homopolymer and the copolymer were rapidly adsorbed on activated sludge after the first minute of contact. They were not desorbed in the following six hours of the experiment. The adsorption led to an increased settling behaviour (expressed as sludge volume index, SVI) in the case of the copolymer, while the SVI of the homopolymer was comparable to that of the blank. Neither PAAs had an effect on the respiration of the activated sludge. However, both PAAs showed limited biodegradability and did not even exceed 10 % in 28 days in the biodegradability tests.

The results showed that the selected PAAs had no acute significant effects on the activated sludge, but both showed a very high affinity to the activated sludge and were not biodegradable. The long-term effects on the activated sludge and the efficiency of the wastewater treatment plant should be investigated in future research. Due to the high adhesiveness of both PAAs, there is a possibility that PAAs can be transported together with activated sludge into the terrestrial environment if activated sludge is used as soil fertilizer or stabilized by composting.

3.07.P-Th300 Prolonged test duration for testing the biodegradability of polymers in OECD 301 improves reproducibility of test results

Marlies Bergheim Sr M*, Christian Kastner Sr M and Johannes Tolls Dir, Corporate Scientific Services, Henkel AG & Co. KGaA, Germany*

Polymers are currently receiving increasing regulatory attention in the EU. Examples are the planned inclusion of polymers into the scope of REACH and the restriction on intentionally added microplastics. The results of biodegradation tests are of great relevance for derogating polymers from restrictions. They also might become relevant when polymers has to be tested under REACH. Screening tests to evaluate biodegradability were developed for water-soluble, low molecular weight substances. Here, the applicability of such screening tests to polymers is explored. Recently published biodegradability test data (Mc Donough et al. 2023) are investigated in view of factors influencing the test outcome. In this study, different water-soluble polymers were tested by independent test institutes in the classic screening tests according to the OECD 301 series. Particular attention was paid to the test duration. The mean degree of degradation increased with the duration of the test. Above all, the variability of the results (variance) after 60 test days is significantly lower than after a test duration of 28 days. These findings are discussed in view of adapting the current screening tests to enhance their applicability for the assessment of polymers.

3.07.P-Th301 Biodegradability of Water-Soluble and Water-Dispersible Polymers in Respirometric Laboratory Methods

***Glauco Battagliarin**[1], Kathleen McDonough[2], Marlies Bergheim Sr M[3], Jared Bozich[4], Katie Endersby[5], Dave Gore[5], Bjoern Hidding[6], Christian Kastner Sr M[3], Jan Robinson[7], Georg Kreutzer[8], Hans Leijs[9], Jennifer Menzies[10], Meera Raghuram[11] and Nathalie Vallotton[12], (1)Research Biopolymers, BASF SE, Germany, (2)Procter & Gamble, (3)Corporate Scientific Services, Henkel AG & Co. KGaA, Germany, (4)International Flavors and Fragrances, (5)Safety and Environmental Assurance Centre (SEAC), Unilever, United Kingdom, (6)BASF SE, Germany, (7)International Association for Soaps, Detergents and Maintenance Products (A.I.S.E.), Belgium, (8)Givaudan Suisse SA, Switzerland, (9)IFF, Netherlands, (10)Procter & Gamble, Mason, United States, (11)Lubrizol, (12)Dow Europe GmbH, Switzerland*

Water-soluble and water-dispersible polymers can be found in a large range of applications in our everyday life, from cosmetics to detergents, from paints to agricultural formulations. For polymeric materials regulations world-wide are rapidly developing with greater focus on the assessment of the degradability of polymers in application leading to environmental exposure. This has put an increasing emphasis on the need to identify, and critically evaluate testing guidelines for assessing biodegradability of for polymeric materials.

Multiple biodegradation testing methods are available. While developed for discrete substances, these may in principal be used to assess biodegradability of soluble and poorly soluble polymeric materials. These methods range from screening tests such as the OECD test guidelines (e.g., 301/310) for biodegradation, or media-specific methods such as ISO (e.g., 14852) and ASTM test guidelines (e.g., 5988). These methods have some commonalities such as reliance on non-specific analyses (i.e., O_2 consumption, DOC and CO_2) and offer some level of flexibility regarding inoculum type and concentration and test substance dose level. Unfortunately, systematic investigations about their applicability to different types of polymers are lacking and limited publicly data are currently available. In view of the extremely dynamic regulatory atmosphere, these knowledge gaps need to be urgently filled.

In this study we present a series of experiments performed in different laboratories across the globe according to OECD, ISO and ASTM methods to study biodegradability of representative water-soluble and water-dispersible polymers. A set of synthetic polymers and modified polysaccharides have been used as case studies. Standard methods and modifications thereof to improve method deficiencies, ranging from polymer, inoculum ratio, microbial concentration and effect of temperature   will be presented.

3.07.P-Th302 From Proteome to Behaviour: Evaluating the Ecological Impacts of Water-Soluble Polymers on Daphnia Magna

***Lara Nigro**[1], Stefano Magni[1], Marco Aldo Ortenzi[2], Stefano Gazzotti[2], Silvia Giorgia Signorini[1], Riccardo Sbarberi[1] and Andrea Binelli[1], (1)Biosciences, University of Milan, Italy, (2)Chemistry, University of Milan, Italy*

Nowadays, water-soluble polymers (WSPs) are considered almost ubiquitous in the aquatic environment due to their widespread use in various industrial and consumer applications. For this reason, the presence of these polymers in the aquatic ecosystem raises concerns about their impact on the health of freshwater organisms, including keystone species such as *Daphnia magna*. This study evaluates for the first time the effects of the most used WSPs, as the polyvinil-alcohol (PVA), polyvinilpirrolidone (PVP), poliacrilic acid (PAA) and polyetilen glycole (PEG), on different levels of biological organization within this freshwater model organism.

An integrated approach was conducted to assess the impacts of three concentrations (0.001, 0.5 and 1 mg/L) of these WSPs at molecular, cellular, physiological, and organisms’ level of *D. magna* specimens. Both acute (mortality) and chronic (heart rate and some swimming performances) effects were evaluated on the exposed organisms. In addition, the activity of monoamine oxidase (MAO) and acetylcholinesterase (AChE) were investigated to evaluate potential neurotoxic effects, while the content of glycogen (GLY) was measured to assess the potential alteration in energetic metabolism. Furthermore, a *high-throughput* methodology based on gel-free proteomics was applied on specimens exposed to the highest concentration (1 mg/L) of all the WSPs.

Our findings reveal that exposure to different WSPs induces specific responses at each biological level of *D. magna*. PEG was the only WSP inducing lethal effects at 0.5 mg/L and altered AChE activity. At the physiological level, all WSPs affected the behavioural performance and the heartbeats of the specimens, with PAA as the most impacting polymer on behavioural parameters analysed. Otherwise, proteomic analyses revealed altered protein profiles following the exposure of all the WSPs, highlighting PVA as the most effective in modulating protein expression. This study underscores the complexity of the risk assessment of these WSPs and highlights the need for a better understanding of their impact on aquatic organisms. This knowledge is crucial for the preservation of freshwater ecosystems by an informed environmental management.

3.07.P-Th303 Assessing the biodegradability of water-soluble polymer flocculants and their impact on microbial communities

Eve Tarring[1]*, Alexandra Howard*[2]*, Richard Cross, PhD*[3] *and Daniel Read*[2]*, (1)Chemistry, Cardiff University, United Kingdom, (2)Centre for Ecology and Hydrology, United Kingdom, (3)UK Centre for Ecology & Hydrology (UKCEH), United Kingdom*

Water-soluble polymers (WSPs) are chemicals ubiquitous within society. Their use in household products, such as personal-care products (PCPs), raises concerns about their entry into freshwater environments. However, their use in industry is on a much greater scale, particularly in wastewater treatment, where a large volume of WSP flocculant is used to dewater sludge before, in some cases, it is applied to agricultural land. Little is known about the chemical composition, behaviour and fate of these flocculants. Furthermore, it is not known whether they are biodegradable, either during wastewater treatment or in the environment however, their large molecular size indicates this may not be possible. To investigate this, we propose both a short and long-term biodegradation assay using biological oxygen demand (BOD) to monitor the biodegradation of multiple WSPs from microbial communities isolated from activated sludge. This includes two commonly used wastewater treatment flocculants. Using a short-term assay enables the rapid testing of readily biodegradable polymers, while a longer 28-day OECD biodegradation test continues the monitoring of more recalcitrant polymers. Alongside this, high-throughput sequencing allows the change in these microbial communities to be monitored, thus indicating the impact of WSPs on the behaviour of these communities and their ability to function. Gel-permeation chromatography (GPC) will also be used to confirm the molecular weight of the original polymer and identify any molecular weight changes throughout the study. This ongoing work aims to couple the chemical analysis of WSP biodegradation with the wider impact on microbial community composition. By identifying if wastewater flocculants are able to be biodegraded within wastewater treatment plants, we can determine if they end up in the environment and any potential concern this poses for aquatic organisms.

3.07.P-Th304 Fate of water-soluble and water-dispersible polymers used in agricultural formulations

Michael Sander[1]*,* ***Kevin Kleemann***[2] *and Patrick Bolduan*[3]*, (1)Department of Environmental Systems Science, ETH Zürich, Switzerland, (2)ETH Zurich, Switzerland, (3)BASF SE, Germany*

Modern agriculture faces the challenge of ensuring a stable food supply amid climate change and freshwater scarcity, necessitating the adoption of innovative technologies in crop production. This contribution reports on the environmental fate of biodegradable water-soluble polymers (WSPs) and water-dispersible polymers (WDPs) used in agricultural formulations. WSPs and WDPs stabilize active ingredients such as pesticides and fertilizers in agricultural formulations. The environmental fate of WSPs and WDPs remains poorly studied and understood. We explored the adsorption behavior, transport dynamics, and biodegradation dynamics of conventional and candidate biodegradable WSPs and WDPs in soil. Studying the interplay between biodegradation and adsorption is critical, as adsorption to soil particles affects biodegradation rates: on the one hand, adsorption may impede biodegradation by protecting the polymers from enzymatic and microbial breakdown in soil pore waters. On the other hand, adsorption may increase the polymer concentrating in microbially active, upper soil layers and prevents transport towards less-active deeper soil horizons. Utilizing a combination of solution-depletion measurements, surface adsorption techniques, and column transport experiments, complemented by respirometric testing in soil incubations, we characterized the influence of polymer properties on their fate in soil. Our findings demonstrate that electrostatic interactions and hydrogen bonding govern adsorption of these polymers to mineral surfaces, which in turn affects their biodegradability. For polyethylene glycols (PEGs) – with seemingly contrasting biodegradation properties reported in the literature – we found decreasing biodegradation rates with increasing molecular weight suggesting that biodegradation is controlled by decreasing cellular uptake with increasing size. The contribution highlights the need to consider WSPs and WDPs chemical structure and conformation in assessing their fate in soils. A detailed understanding of adsorption and biodegradation is key to design and use sustainable WSPs and WDPs in agricultural formulations and to mitigate environmental impact.

3.07.P-Th305 Can we Spectroscopically Trace Deuterium from Labeled Biodegradable (Micro)Plastics into Microbial Biomolecules?

Kara Müller, Martin Elsner and ***Natalia P. Ivleva****, School of Natural Sciences (Dep. Chemistry), Technical University of Munich, Chair of Analytical Chemistry and Water Chemistry, Institute of Water Chemistry, Germany*

Complete biodegradation of plastics which cannot be retrieved from environment is essential since nano- and microplastics can have biological, physical, and chemical effects. The plastic's final utilization must be understood to study its final fate in different environments. While mineralization into CO_2 has been reported several times with ^{13}C-labels for reliable quantification, Zumstein et al. additionally traced the label into fungal biomass with nanoscale secondary ion mass spectrometry. We chose cost-reduced D-labels instead and monitored their uptake from deuterated polylactic acid (dPLA) into single bacterial cells with stable isotope Raman microspectroscopy. This technique was previously used to trace stable isotopes from other carbon substrates or D_2O into microbial biomass. C-H vibrations of biomolecules like lipids and proteins are extensively red-shifted into the Raman-silent region if hydrogen is replaced by its heavier isotope. Incubation experiments of an environmental bacterium with dPLA showed undeuterated biomass spectra, dPLA particles and after three weeks, additional signatures were assigned to deuterated biomass. Compared to reference spectra of bacteria labeled with glucose-d_{12} or D_2O, it has a larger D-lipid to D-protein ratio, which suggests an adapted metabolism. The cells were deuterated to up to 22 % after incubation with dPLA, and their distribution resembled that one of labeling with 50 % deuterated glucose. The next step is to extend our approach to realistic conditions of terrestrial environments. Therefore, soil microcosm experiments will be conducted with dPLA in environmental soil, which was previously exposed to PLA to allow bacteria adaptation and shorten incubation times. Until now, the isolation of cells from soil was completed to gain Raman spectra with satisfyingly small backgrounds and high signal-to-noise ratios.

3.07.P-Th306 Development of a Modified Screening Method for Degradation of Polymers and Validation with 14C-radiolabelled Alginate

Julia Marie Peters[1]*, Michael Huben*[2]*, Dieter Hennecke*[2]*, Annika Jahnke*[3] *and Andreas Schaeffer*[4]*, (1)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (2)Ecological Chemistry, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (3)Department of Exposure Science, Helmholtz Centre for Environmental Research (UFZ), Germany, (4)Institute Environmental Research, RWTH Aachen University, Germany*

The fate of polymers has been in the focus of the new restriction (Commission Regulation (EU) 2023/2055) issued by the European Commission on intentionally added microplastics to products used for specific purposes. The restriction is based on the biodegradation of polymers, which is determined with the help of OECD test guidelines (TG), for example TG 301 and TG 307. It only considers synthetic polymers. Therefore, producers strive to shift to natural polymers, which are considered degradable by default, and those synthetic polymers which show proof of fast biodegradation. The biodegradation rate and formed degradation products of a synthetic polymer are mostly unknown. During product development a fast screening is needed to obtain a projection of the polymer’s biodegradation potential to decide if the polymer can be considered for the product.

In order to address the degradation of polymers a modified screening method has been developed, based on the OECD 301B guideline. As modifications the test volume was reduced, the duration of the experiment was shortened and a different measurement endpoint was chosen, which led to an adjusted experimental set-up. The chosen set-up saves time and space. Instead of the mineralisation the recovery of the total organic carbon content is measured. The modified screening method showed comparable results to the OECD 301B guideline and can be used to quickly determine if further testing for a polymer during product development is relevant.

For validation of the modified screening method ^{14}C-radiolabelled sodium alginate was used. The synthesis of the radiolabelled alginate was done by a nucleophilic substitution (S_N2) of the alginate’s hydroxyl groups with ^{14}C-radiolabelled 2-bromoethanole. Post-synthetic chemical modification of polymers may represent a facile access to different natural ^{14}C-radiolabelled polymers. Care must be taken to reduce the impact of the derivatisation on the physico-chemical properties and the biodegradation of the polymer. However, if performed successfully the resulting ^{14}C-radiolabelled polymers can significantly improve the determination of the environmental fate of polymers. Details of the synthesis procedure and characterisation will be presented as well as the results of the validation experiments.

3.07.P-Th307 Downscaling of syntheses and preparation of a variety of 14C -labelled polymers and oligomers

Dieter Hennecke[1]*, Michael Huben*[1]*, Boris Meisterjahn*[2]*, Mike Kruse*[1] *and Erik Wischerhoff*[3]*, (1)Ecological Chemistry, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (2)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (3)Department Sensors and Actuators, Fraunhofer IAP - Institute for Applied Polymer Research, Germany*

The use of ^{14}C-labelled substances in environmental studies is highly advantageous, because it enables the widely matrix independent detection of the parent substance and to follow resulting transformation products. While it is a well-established procedure for organic low molar mass compounds, it has rarely been applied for the investigation of environmental fate of polymers and oligomers, yet. This is mainly due to two principal challenges, first the necessary downscaling to the required small scale and second the selection and availability of the required ^{14}C-labelled monomers as the radioactivity might introduce undesired reactions of the often highly reactive monomers before the polymer synthesis starts.

Though there is no "off the rack" solution that suits for all polymers, it is possible to develop downscaling procedures for a variety of polymerisation processes and to circumvent problems related to the lack of availability of certain ^{14}C-labelled monomers. Examples for successfully synthesized substances will be presented, such as ^{14}C-labelled variants of cationic poly(acrylamide) copolymers, crosslinked calcium polystyrene sulphonate, propoxylated oligomers from a phenol-formaldehyde condensation and poly(ethylene). In each case the benchmarks for the ^{14}C-labelled polymers produced were the commercial non-labelled analogues to prove successful synthesis.

For the acrylamide copolymer, radical initiation induced by radioactivity had to be considered being a potential problem for the synthesis. The synthesis of crosslinked calcium polystyrene sulphonate required fine-tuning of dispersion polymerisation and sulphonation processes. Similarly, the synthesis of the propoxylated oligomers had to be adapted to appropriate pressure conditions in a lab-scale glass reactor to obtain an oligomer with a composition close to the commercial product. In case of poly(ethylene), a small fraction of the ethylene monomer needed to be substituted by an alternative monomer to introduce the ^{14}C-label while preserving the polymer properties, because ^{14}C-labelled ethylene is neither available nor suited for synthesis in a radioactive laboratory due to its physico-chemical properties.

^{14}C-radiolabelling offers a powerful option in the currently very challenging assessment of the environmental fate of polymers. The presentation intends to encourage industry and regulators to consider this technique for future testing of technically relevant polymers.

3.07.P-Th308 Assessing the biodegradation of polymers using 13C-labelling

Michael Sander[1] *and Taylor F Nelson*[2]*, (1)Department of Environmental Systems Science, ETH Zürich, Switzerland, (2)University of Konstanz, Germany*

Polymers play a critical role in many applications to ensure the efficiency, performance, and sustainability of these applications. For applications in which polymers are used directly in the open environment (e.g., agricultural applications such as mulch films and seed coatings), polymer biodegradability is a key sustainable and benign-by-design criterion: biodegradability ensures that microorganisms naturally occurring in a specific receiving environment can metabolically utilize the polymer as a substrate and completely convert the polymer carbon to carbon dioxide (CO_2) and new microbial biomass. As such, biodegradability ensures that biodegradable polymers do not persist in the environment and hence do not accumulate – in contrast to the stable conventional counterparts. Assessing the biodegradability performance of existing biodegradable polymers as well as conceptualizing and designing future biodegradable polymers requires a fundamental understanding of polymer biodegradation in specific receiving environments. In this contribution, we highlight the unique capabilities of using stable carbon isotope (^{13}C)-labelled polymers in advancing mechanistic insights into the process of polymer biodegradation. First and foremost, the use of ^{13}C-labelled polymers in incubations allows selective tracking of polymer carbon mineralization into $^{13}CO_2$ and thereby delineating it from $^{12}CO_2$ formed through co-occurring mineralization of natural substrates in the incubation vessels. Second, elemental analysis (i.e., combustion) of the incubation medium (e.g., soil) at the end of the incubation coupled to isotope ratio mass spectrometry allows quantifying non-mineralized polymer-added ^{13}C as $^{13}CO_2$ and, thereby, closing the mass balance on polymer ^{13}C over the course of the incubation. Assessing mass balances is difficult if not impossible when using unlabeled polymers. Finally, using ^{13}C polymers opens the possibility to directly demonstrate incorporation of polymer ^{13}C into microbial biomass. These unique advantages of using stable carbon isotope labelling, particularly when combined with solvent-based extractions and quantification of residual biodegradable polymer over the course of the incubation, will be demonstrated by case examples, including the biodegradation of structural polyesters in soils.

3.07.P-Th309 Assessing the Suitability of Standardised Tests to Monitor Polymer Biodegradation in Soil

Grace Davies[1]*, Stefan Krause*[2]*, Samantha Marshall*[3]*, Massimiliano Mascelloni*[3]*, Michaela Reay*[4]*, Charlotte E M Lloyd*[4] *and Iseult Lynch*[5]*, (1)University of Birmingham, United Kingdom, (2)Institute for Global Innovation, University of Birmingham, United Kingdom, (3)Syngenta, United Kingdom, (4)Organic Geochemistry Unit, School of Chemistry, University of Bristol, United Kingdom, (5)School of Geography, Earth and Environmental Sciences, University of Birmingham, United Kingdom*

Interest in, and use of, biodegradable polymers is increasing due to regulatory restrictions on the use of conventional polymers that result in micro/nano plastic production. Increasing amounts of biodegradable polymers will likely be used in soil applications (e.g., plastic mulching films, controlled release fertilisers, and plant protection product formulations). International standard specifications are required for assessing the biodegradability of plastics in soils, coupled with clear and robust standard test methods to verify complete biodegradation within a specific timeframe under controlled environmental conditions.

Current standardised tests focus on respirometric methods, where mineralisation is the endpoint measured by either quantifying evolved carbon dioxide (CO_2) or the biological oxygen (O_2) demand. The suitability of the standard ISO 17556 for determining the biodegradation of biodegradable polymers in soils is investigated using positive control reference materials cellulose and poly(r)-3-hydroxybutyrate (PHB). Biodegradation was measured in parallel experimental set-ups that compared CO_2 evolution using a standard flow through system and O_2 demand utilising an OxiTop®-IDS system. To determine the reproducibility of the test method across soil types, cellulose degradation was compared in three different soils; two natural soils and an artificial soil (constituents specified in ISO 17556).

Data from both approaches is compared, with results showing clear variability in measured biodegradation between soil types and the measurement methods for both reference materials. Mineralisation measures the ultimate biodegradation endpoint, but the variability seen across soil types and approaches highlights the knowledge gap in understanding how the carbon in the polymer is transformed to carbon in CO_2.

This significant knowledge gap in identifying and quantifying the residual polymer and any transformation products, means additional analysis is needed to better understand polymer biodegradation in soil. Pyrolysis gas chromatography mass spectrometry was trialled as an analytical method to quantify residual polymer in soil samples following density-based extraction from the soil matrix. Initial findings on the suitability of the method for non-labelled biodegradable polymers will be discussed.

3.07.P-Th310 Long-term field degradation of mulch films and their effect on soil microbial communities

Martine Graf[1], *Rafael Bargiela*[2], *Peter N Golyshin*[2], *Robert Griffiths*[3], *Estelle Choiselat*[4], *Athanasios Dimitriou*[5], *Robert M Elias*[5], *Qiuyun Liu*[5], *David R Chadwick*[3] *and Davey L Jones*[3], *(1)School of Natural & Environmental Sciences, Bangor University, United Kingdom, (2)Centre for Environmental Biotechnology, Bangor University, United Kingdom, (3)School of Environmental & Natural Sciences, Bangor University, United Kingdom, (4)Institut Polytechnique UniLaSalle, France, (5)BioComposites Centre, Bangor University, United Kingdom*

The use of agricultural plastic is increasing each year, and plastic mulch films have been adopted in an agricultural setting worldwide due to their many benefits. However, the removal and subsequent disposal of these plastic films can be challenging, and continued application to the soil surface can result in an accumulation of legacy plastic in soil. This has led to a shift in the agricultural industry towards degradable alternatives. To be classed as biodegradable, ≥ 90% of the polymer needs to degrade within 24 months, however, it has been shown that biodegradable mulch films often exceed these guidelines in natural environments. Microbial communities in soil are recognised to play an integral role in soil functioning and it has been shown that their composition is highly influenced by soil conditions and biodegradable polymer composition, and that changes in the microbial community can be related to the biodegradation process. In this field-based study, we therefore aimed to investigate the abiotic and biotic degradation rates of one conventional low-density polyethylene mulch film and seven different biodegradable mulch film blends over 1 year, whilst simultaneously assessing their microplastic production rate and effect on the soil bacterial and fungal community. To assess abiotic degradation under natural conditions, mulch films were laid out onto an agricultural field and sampled monthly. Biotic degradation of mulch films in soil was investigated by burying squares of each mulch film in mesh bags in the soil and recovering them over time. To determine if interactions with macrofauna play a role in the fragmentation and degradation of mulch films in soil, two different mesh sizes were used – allowing for only microfauna, and micro-, meso-, and macrofauna interaction. Measurements included changes to the chemical and physical surface structure of the mulch films, potential microplastic generation in the surrounding soil, and effects on microbial community composition. Our results suggest that although changes to chemical and physical surface structure of the films were detected, fragmentation of mulch films buried in soil does not occur within 12 months without additional mechanical stress. These results are highly relevant in our understanding of the difference between fragmentation and degradation, and suggest that degradation of biodegradable mulch films in a natural environment will exceed the current classification standards.

3.07.P-Th311 Developing New Methods for Assessing Freshwater Biodegradability of Plastics

Sebastian Groß, *Chong Becker, Glauco Battagliarin, Kai Oliver Siegenthaler and Andreas Künkel, Research Biopolymers, BASF SE, Germany*

Biodegradability of plastics is a material property which can be beneficial for selected applications enabling a circular use of resources and avoiding the accumulation of persistent microplastics. Examples of applications are certified compostable organic waste bags or certified soil biodegradable mulch films. The environmental biodegradation of plastics depends on several factors, such as microbial concentration and community composition. The development of new biodegradable plastics requires reliable biodegradation test methods. However, there is a lack of standardized methods for assessing the biodegradability of plastics using freshwater samples, e.g., from lakes and rivers. This study aims to fill this gap by developing new freshwater biodegradation test methods that might be in the future proposed for standardization.

In this work, we developed three new respirometric test methods adapted from ISO test methods used to investigate the biodegradation of plastics exposed to marine inoculum (ISO 23977-1 and ISO 19679): a sediment-freshwater test, a freshwater test and a freshwater test applying an increased microbial concentration factor, adapted from published methods. The polymeric test materials investigated include cellulose, which is ubiquitously available and biodegradable, non-biodegradable low-density polyethylene, and polybutylene sebacate-*co*-therephthalate (PBSeT). The sediment-freshwater test resulted in significantly different biodegradation of cellulose and PBSeT depending on the environmental sample source used. The freshwater test showed slow biodegradation of cellulose with less than 60% in 180 days and high standard deviations between replicates (> ±15%), which would not meet validity criteria of marine standards. The freshwater test with increased microbial concentration showed a more rapid biodegradation of cellulose and PBSeT with >95% in 90 days and less deviation between replicates (< ±5%).

This study confirms the high potential of methods using inocula with increased microbial concentration to reduce the variability of biodegradation test results. These methods should be considered for standardization and regulation to better reflect natural microbial diversity and minimize false negative test outcomes which could inhibit the development of new biodegradable materials. Methods using sediments require further optimization to reduce the impact of the inoculum composition and thus the variability of biodegradation test results.

3.07.P-Th312 Comparison of the characteristics of In-situ Freshwater biofilm development on bioplastics and petrochemical plastics

Tadar Yadar *and Jung-Hwan Kwon, Korea University, Korea, Republic of (South)*

The widespread pollution caused by petroleum-based plastics has spurred the growth of biodegradable bioplastics made from renewable sources. Polylactic acid (PLA) is a prevalent bioplastic and commonly seen as capable of biodegrading in specific settings. Nevertheless, PLA does not fully biodegrade, thus adding to the problem of microplastic pollution. This study investigates how PLA and Low-density polyethylene (LDPE) would behave differently when exposed to the In-situ freshwater environment at timepoints 14 days and 30 days. Scanning electron microscopy was used to analyze morphology of the biofilm developed. Biofilm was further visualized and quantified with the assistance of Confocal Laser Scanning Microscopy. Distinct Fluorochromes signifying the live and dead biofilm volume confirmed the increase of biofilm volume in both PLA and LDPE. It was observed that phototrophs were much higher on PLA than on LDPE at both time points. Taxonomic analysis by Whole Genome Sequencing indicated distinct and unique plastisphere communities on both PLA and LDPE after 14-day exposure. Microbial genera involved in xenobiotic compound degradation, organic acid cycling and having oxidase and catalase activity was also found. The present study gives us the firsthand biofilm characteristics of plastics of different origins. It could eventually be a step towards extending our understanding of the environmental implication of so-called Bioplastics.

3.07.P-Th313 Evaluating Bioplastic Degradation and Fragmentation Using Rainfall Simulation

***Cherrelle Johnson** and Sinead Mitchell, Mechanical Engineering, National University of Ireland Galway, Ireland*

Plastic accumulation in the open environment due to mismanagement has led to growing concern over its pollution and degradation of ecosystems and impacts on human health. The current linear consumption of conventional plastics is widely considered unsustainable. Biodegradable polymers (bioplastics) have been growing in production and use and are frequently marketed as sustainable alternatives to conventional plastics. However, the environmental impacts resulting from the mismanagement or improper disposal of bioplastics is an area of research that is still in its infancy. This is especially true in the context of Ireland, which generates the highest amount of plastic packaging waste in the EU. The expected growth in bioplastic consumption and the lack of bioplastic degradation knowledge coupled with Ireland’s high plastic waste generation and abundance of rain serves as the foundation to this research. This research aims to evaluate the degradation and fragmentation of degradable and nondegradable bioplastics in a controlled environment, simulating maritime conditions to gain a better understanding of their possible degradation in an open environment due to mismanagement or littering. Rainfall simulators can replicate natural rainfall events and provide meaningful, quantifiable data. Rainfall simulation and UV ageing will be used under controlled laboratory conditions to analyse bioplastic degradation over time. Rainfall runoff will be collected and analysed for microplastic persistence to glean insight into possible impacts to environmental receptors such as soil and waterways. Following the rainfall simulation, mechanical testing in the form of tensile strength tests will be performed to further analyse the degradation. Lastly, computational modelling and soil burial studies will act as supports to the laboratory testing. To our knowledge, this is the first study of its kind using rainfall simulation to evaluate bioplastic degradation and this research has the potential to offer a novel method for evaluating bioplastic degradation in a simulated oceanic climate environment.

3.07.P-Th314 Fragmentation of biodegradable polymers: Assessing and modeling the interim fragmentation in different environmental compartments

***Patrizia Pfohl**[1], Markus Rückel[1], Lars Meyer[1], Kai Oliver Siegenthaler[2], Glauco Battagliarin[2], Patrick Bolduan[1], Thorsten Huffer[3], Michael Zumstein[3], Thilo Hofmann[3], Sam Harrison[4] and Wendel Wohlleben, Dr.[1], (1)BASF SE, Germany, (2)Research Biopolymers, BASF SE, Germany, (3)University of Vienna, Austria, (4)UK Centre for Ecology & Hydrology (UKCEH), United Kingdom*

For specific applications, where plastics cannot be collected in its entirety and recycled, biodegradable polymers can serve as an alternative leaving no persistent microplastics behind, assuring that biodegradation leads to complete mineralization of the polymer carbon into CO_2 and biomass. The loss of the structural integrity is an inevitable part of the biodegradation process and leads to an *interim* formation of fragments.

Biodegradation of polymers is not a homogeneous process, and several factors are influencing the fragmentation of biodegradable polymers, like e.g., microbial colonization, the polymer (blend) composition and shape. The formation of defects, “peninsula” structures and increasing embrittlement during biodegradation leads to interim fragment release. To gain a mechanistic understanding of copolymer blend fragmentation and biodegradation, we studied several biodegradable copolymer blends under industrial composting conditions (ISO 14855), as well as a biodegradable mulch film in soil (ISO 17556). Using different validated extraction techniques for fragments of biodegradable plastics from compost (homogenization, Fenton oxidation, density separation) and soil (centrifugation), Raman as well as fluorescence microscopy analysis was applied to monitor fragment number, shape, size, and identity during biodegradation. The generated data was used for parameterization of the open-source FRAGMENT-MNP model. To understand the chemical and physical mechanisms during fragmentation, we used scanning electron microscopy (SEM) to compare the phase separation in different blends and to determine the area between formed cracks on the surface of polymer films for comparison to Raman/Fluorescence results. In addition, we determined the molar mass distribution at different biodegradation timepoints and assessed the ratio of hydrolyzed polymer to remaining polymer.

The combination of these methods allows to compare fragmentation mechanisms of different types of copolymer blends and helps to predict the timepoint where the total particle counts of different size classes peak during biodegradation. The previously formed fragments will further degrade until mineralized into CO_2 and biomass. Modelling approaches enable the prediction of half-lives of interim fragments, which will depend on the polymer type and environmental conditions.

3.07.P-Th315 The Fate of "Compostable" Plastic Bags in Municipal Composting Plants

Julia Naima Möller[1], *Thomas Steiner*[2], *Martin G.J. Löder*[3], *Lion Schöpfer*[4], *Christian Laforsch*[5], *Ansilla Bayha*[6], *Holger Pagel*[4], *Ellen Kandeler*[4], *Jürgen Geyer*[7], *Ulrike Kröner*[7], *Jens Forberger*[6], *Ruth Freitag*[3] *and Gabriela Gromer*[6], *(1)Wageningen University & Research (WUR), Netherlands, (2)Bioprozesstechnik, University of Bayreuth, Germany, (3)University of Bayreuth, Germany, (4)University of Hohenheim, (5)University of Bayreuth, Animal Ecology I, Germany, (6)Fraunhofer ICT, (7)BEM Umweltservice*

Compostable plastic bags are commonly used in Europe for the purpose of collecting organic waste, and are certified to degrade under specific conditions found in industrial composting plants. According to the standard EN 13432 a material is compostable if less than 10% of the original mass remains after 12 weeks of composting and sieving through a 2 mm mesh; at least 90% of the organic material has been converted into CO_2 after 6 months and the material has no negative effects on plant growth. It does not, however, consider realistic composting times in municipal biowaste-treatment plants (Germany 6-9 weeks), nor what happens to fragments below 2 mm in size.

In a consortium project, we distributed three different kinds of biowaste-collection bags made of compostable plastic to citizens of three different municipalities. During the project, we analysed the input and fate of these bags in three different municipal biowaste treatment plants. The aims of the project were:

- To understand the fragmentation and degradation behaviour of the compostable bags throughout the stages in the treatment plants.
- To assess the degradation process of pristine and composted fragments of the compostable bags in soils.
- To survey the attitude, expectations and experiences of the citizens regarding the use of the distributed bags.

The study showed that the majority of compostable plastic bags disintegrated into fragments smaller than 2 mm well before the end of the composting process. However, it also showed that on average, 88% of the microplastics (<2 mm) found in the finished compost were derived from polybutylene adipate terephthalate (PBAT) - the main constituent of the introduced compostable plastic bags. Additionally, degradation tests in soils showed that the mineralisation rate of the composted material was approximately 25% in 145 days under optimal soil conditions, less than that of paper, which had a mineralisation rate of 46% in 145 days.

The distribution of free compostable plastic bags to the municipalities did not result in a visible reduction in the amount of conventional plastics in the incoming biowaste, nor was an increase in biowaste collection observed. Under the aspects of a circular economy, we question the usefulness of compostable biowaste collection bags, as there is a risk of releasing higher amounts of microplastics with potentially long mineralization rates and no obvious benefits to the biowaste stream and compost quality.

3.07.P-Th316 Degradation of Biodegradable Plastics

Sevil Vafadar Afshar[1], *Alessio Boldrin*[2], *Thomas Fruergaard Astrup*[3], *Thomas Højlund Christensen*[1], *Anders Egede Daugaard Sr.*[4] *and Nanna B. Hartmann*[1], *(1)DTU Sustain, Technical University of Denmark (DTU), Denmark, (2)DTU Sustian, Technical University of Denmark (DTU), Denmark, (3)Environmental and Resource Engineering, Technical University of Denmark (DTU), Denmark, (4)Technical University of Denmark (DTU), Denmark*

Decades of extensive production and use of conventional plastics have led to their accumulation in the environment. Bioplastics (bio-based and/or biodegradable) have been promoted as a more sustainable alternative. However, the literature reveals conflicting conclusions regarding their suitability and environmental impact. A primary area of dispute concerns their biodegradability and the conditions necessary for proper degradation. In real-world settings, e.g., composting or marine environments, biodegradable plastics may not degrade as rapidly or efficiently as laboratory tests indicate. Here, we describe two activities that were conducted to address these issues: 1) a systematic literature review to explore the current level of knowledge regarding biodegradable plastics' environmental fate and consequences and 2) a degradation test of commercial biodegradable plastics under simulated industrial composting conditions. The findings of both will be presented and discussed. The review covered the degradation of biodegradable plastic in waste management environments (e.g., compost, sludge, or landfill) and the open environment (e.g., seawater, freshwater, or soil). The results highlight challenges in comparing and quantitatively analyzing data on plastic degradation due to methodological variations, including differences in testing methods, materials, and quantification strategies. Moreover, several research gaps and limitations exist. Notably, there is a need to intensify research on polyhydroxyalkanoates (PHAs), polybutylene adipate terephthalate (PBAT), and polybutylene succinate (PBS) to match the level of polylactic acid (PLA) and starch-based plastics. Research on commercial plastic products must also be intensified. To help bridge these knowledge gaps, a degradation test was carried out on commercially available biodegradable plastics under simulated industrial composting conditions according to ISO 20200. The results indicated disintegration degrees between 75-100 % for all tested biodegradable plastic products, with five of ten reaching complete disintegration within 90 days. The outcomes of both studies offer valuable insights, particularly in guiding discussions about the prospective role of biodegradable plastics within society. Based on our findings, essential knowledge and data gaps will be highlighted, and suggestions will be provided regarding the direction of future research to assess their role as alternatives to conventional plastics.

3.07.P-Th317 Plastic Degradation In Natural Seawater Conditions

*Cynthia Gómez, Ricardo Beiras and **Sara López Ibáñez**, University of Vigo, Spain*

One of the main anthropogenic impacts on the environment is the substantial generation of solid waste that ultimately finds its way into the oceans. Plastics account for 60% to 80% of these residues and their abundance, persistence and chemical composition pose certain risks to marine habitats. In response, biodegradable plastics, commonly referred to as "bioplastics," have emerged as an alternative to traditional plastics, gaining prominence in the market.

Although biodegradable plastics alone cannot fully resolve the issue of plastic littering, which necessitates a fundamental shift in consumer behavior regarding intentional disposal, their use may play a pivotal role in mitigating plastic pollution in cases of accidental or unintended release into the natural environment. Despite their potential, there is limited research on the actual impact and biodegradability of these materials in seawater.

Hence, this study aims to contribute insights into this process. Tests were conducted to assess the fragmentation of PBSeT in comparison to two reference materials, LDPE and cellulose, in two distinct aquatic environments: an equatorial mangrove near the Amazon River mouth (Brazil) and a temperate coastal area in the North Atlantic Ocean (Ría de Vigo, Spain) under benthic and pelagic conditions. At intervals of 5, 28, 60 90 and 120 days, samples from the exposed materials were removed to assess degradation and toxicity through sea urchin embryo tests (SET).

After the initial 28 days, cellulose underwent fragmentation in both habitats (pelagic and benthic) and both exposure environments (South Atlantic equatorial mangrove and North Atlantic temperate estuary ria). Complete disintegration of cellulose occurred after 60 days in both habitats and exposure environments. In contrast, polyethylene films remained intact throughout the entire experiment in both habitats and both exposure environments. Whilst, PBSeT film took a minimum of 60 days to initiate fragmentation in both habitats and both exposure environments. By day 90, PBSeT had completely disintegrated in both habitats in the South Atlantic equatorial mangrove and in the pelagic habitat in the North Atlantic temperate estuary ria. However, under benthic conditions in the North Atlantic temperate estuary ria, a few fragments of PBSeT were still observable after 120 days of exposure. Regarding toxicity, PBSeT exhibited a slight initial toxicity before exposure which dissipated during the initial days.

3.07.P-Th318 Bioplastic Bags Degradation Under Marine Conditions In A Mesocosm Facility

***Sara López Ibáñez**[1], Jakob Quade[2], María José Abad López[3] and Ricardo Beiras[1], (1)University of Vigo, Spain, (2)RWTH Aachen University, Germany, (3)University of a Coruña, Spain*

Plastic versality has promoted its wide use around the globe for all types of applications, what has led to the current unsustainable production levels of these materials. Eventually, they end up in the environment, due to a deficient waste management, and plastic bags are one of the most prevalent products found in marine litter. Apart from persistance and visual nuisance, plastics can pose a risk to marine organisms through toxicity, ingestion and entanglement.

Alternatives to conventional plastics have been created (bioplastics), although it remains to be seen whether these materials are totally successful. In order to avoid entanglement and ingestion, for instance, there is no need of a complete degradation of the product, but rather a decay of its mechanical properties, which are useful to measure as an ecologically relevant endpoint. Also, toxicity along degradation should be also assessed to improve the understanding of these processes, so in this work we propose a method at mesocosm level to test those endpoints.

In this study we test mid-term (4 months) exposures in a mesocosm facility of three plastic bags of different nature (industrial compostable, home compostable and conventional polyethylene) and under different conditions (natural light/darkness, additional inoculum/only natural water). The endpoints measured are toxicity (using the sea urchin embryo test or SET), weight loss and mechanical properties such as tensile strength, deformation at break point and strength at break point.Results

No differences between the treatment with extra inoculum and with no inoculum added were found. Polyethylene bags remained intact along exposure. Weight decreased especially under dark conditions, as well as strength at break point. Also, a slight increase in toxicity was observed in the dark treatment, the same promoting the fastest degradation. Strength at break was selected as the most suitable endpoint for mechanical properties.

This approach is a relatively fast method to assess plastic degradation in conditions representative of the marine environment. Bio and conventional plastics show clear differences in the evolution of toxicity and degradation processes. Lower variability, high ecological relevance and the standardizations available for strength at break point are the reasons why it is recommended for study mechanical decay. This kind of works are useful to help classifying new plastics products according to their marine impact and behaviour.

3.07.P-Th319 Investigations into Ageing of Monofilaments Under Various Test Conditions in the Sea

***Sigrid Hakvåg**[1], Christian W Karl[2], Jure Brčić[3], Juan Santos[4], Lisbet Sorensen[1], Rikke P Frandsen[5], Stephan Kubowicz[2] and Kjell Olafsen[2], (1)SINTEF Ocean, Norway, (2)SINTEF AS, (3)University of Split, (4)Thünen Institute of Baltic Sea, (5)DTU, Denmark*

Problems associated with marine plastic litter caused by the fisheries and aquaculture sectors can be significantly reduced if traditional plastics like Polyamide 6 (PA, Nylon) are replaced by new biodegradable materials. Materials designed to be biodegradable, such as polybutylene succinate co-adipate-co-terephthalate (PBSAT) are intended to degrade or decompose after a certain period in water and thereby lose their ghost fishing capacity more quickly than conventional gear. The materials should be user-friendly during the service life with a short (and non-linear) degradation phase afterwards. In addition to degrade more rapidly, such materials should have stable mechanical properties during the period of use. Previous small-scale tests have however shown that further research and industrial development is necessary for the commercialization and use of biodegradable plastics in these ocean-based industries.

Here, a framework for testing of biodegradability and environmental impacts have been developed. Laboratory and field testing of biodegradable fishing lines (monofilaments) are carried out in conditions representing different marine conditions. The degradation and physical and chemical integrity of assumed biodegradable and conventional lines is evaluated during an extended test period (up to 5 years), starting in 2021. In the field, marine biodegradation of lines (PBSAT and non-degradable PA as the control) are tested *in situ* in different marine habitats (Skagerrak Sea, North Sea, Baltic Sea, Adriatic Sea, and Norwegian Sea) to cover a wide temperature range. Additionally, laboratory experiments are performed where UV-exposed materials (weathering) are included in the setup, allowing for testing of 'aged' materials. The physical-, chemical-, and microbial- degradation is quantified by a suite of tests such as mechanical properties, SEM, py-GC-MS, respirometric analysis and microbial community analysis.

The long-term study of polymers designed to be biodegradable and traditional polymers will contribute to our future understanding of the degradation of polymers in the sea and will help the fishing industry develop more sustainable innovations for the global market.

3.07.P-Th320 Laccases as a Biocatalytic Tool for the Degradation of Biodegradable Plastics

Stefanie Clauß[1]*, Daniel Zahn*[2]*, Bettina Seiwert*[2] *and Dietmar Schlosser*[3]*, (1)Environmental Microbiology, University of Leipzig, Leipzig, Germany, (2)Department of Analytical Chemistry, Helmholtz Centre for Environmental Research (UFZ), Germany, (3)Environmental Microbiology, Helmholtz Centre for Environmental Research (UFZ), Germany*

Due to the constantly increasing production of plastics, which amounts to around 400 million tons per year, the pollution of the environment by plastic waste is increasing. Biodegradable materials are seen as a solution to this problem. However, it must be noted that little is known about the fate of biodegradable polymers (BPs) in the environment and therefore it is necessary to decipher these processes. Polycaprolactones (PCL) are semi-crystalline aliphatic polyesters. Besides their classical purposes for packaging materials, it is used to produce controlled-release drugs due to their slow biodegradability.

It has meanwhile been shown that PCL microplastics can also be found in the terrestrial and marine environment, indicating that PCL is also not easily degradable under natural conditions. The literature repeatedly describes examples of how fungi, bacteria, or microbial communities are involved in degrading synthetic and biodegradable polymers.

In order to gain a more detailed insight, the possible involvement of the fungal enzyme laccase (EC 1.10.3.2) in synthetic polymer decomposition was tested. Laccases belonging to the class of oxidoreductases and have already been used for the degradation processes of various environmental pollutants.

Our results indicate that the oxidoreductase laccase can oxidatively attack various polycaprolactones. More detailed insights via UPLC-ELSD and UPLC-HRMS/SFC are in support of a significant influence of PCL structures on the degradation mechanism and their rate. It was found that diethylene glycol-based polycaprolactone offers an excellent target for laccase attack seemingly due to the diethylene glycol. UPLC-HRMS analyses have shown that the diethylene glycol is oxidatively cleaved in the first step of the reaction. It could also be demonstrated that oxidative degradation must proceed differently for PCLs with different structures, some of which are not diethylene glycol-initiated.

Therefore, another starting point for oxidative PCL degradation occurs. In our investigations, various transformation products (TPs) were detected, related structures were proposed, and their stability under the applied conditions was checked. The knowledge of the degradation pathways and stable TPs is essential for the discussion on the use of these biodegradable polymers and the anthropogenic footprint, as BPs are seen by society as the optimal and simple solution to tackle the plastic pollution problem.

3.08 Chemical Fate in the Soil-Plant System and Evaluation of Related Impacts and Risks

3.08.T-01 Soil sorption and plant uptake of five antibiotics by spinach (Spinacia oleracea) and radish (Raphanus sativus)

Inna Elina Nybom, PhD[1]*, van den Broek Sarah*[2]*,* ***Thomas D. Bucheli***[3]*, Andreas Maccagnan*[4]*, Christa McArdell*[4]*, Sebastian Doetterl*[2] *and Gina Garland*[2]*, (1)Department of Environmental Systems Science, (2)Department of Environmental Systems Science, ETH Zurich, Switzerland, (3)Environmental Analytics, Agroscope, Switzerland, (4)Eawag - Swiss Federal Institute of Aquatic Science and Technology, Switzerland*

Antibiotic residues are widely detected in agricultural soils and animal manure fertilizers. Once in agricultural lands, the fate of antibiotics depends on the physiochemical properties of the compounds, soil sorption potential, crop species and environmental conditions. In this study we investigated the fate and distribution of five co-applied antibiotics in soil-pore water-plant system, and their uptake and translocation to spinach (*Spinacia oleracea*) and radish (*Raphanus sativus*). The plants were grown for 6 weeks under controlled environmental conditions in soil spiked with antibiotics (0-10 mg kg^{-1} concentration range for individual antibiotics), after which they were harvested. The selected antibiotics, clarithromycin (CLA), sulfamethoxazole (SMZ), trimethoprim (TMP), enrofloxacin (ENR) and chlortetracycline (CTC), represented a range of characteristics, for example with cationic (CLA), anionic (SMZ), and neutral (ENR, CTC, TMP) species dominating in the experimental conditions. Soil and pore water samples were collected at the end of the experiment. Additionally, timepoint samples of soil and pore water were collected at days 0, 2, 14 and 21. The soil and plant samples were extracted with QuEChERS (**Qu**ick, **E**asy, **Ch**eap, **E**ffective, **R**ugged, and **S**afe) method and analyzed with LC- Triplequad MS/MS. The soil samples collected over the course of the experiment demonstrated different dissipation behavior of the spiked antibiotics. For example, in the 1 mg kg^{-1} spike concentration of SMZ, the half-life was calculated to be 3.3 days, whereas for CLA, the concentration remained constant throughout the experiment. The uptake of antibiotics to plants was marginal compared to the total spiked antibiotic load. Nevertheless, antibiotics were observed both in the plant leaves and roots where the uptake and translocation was dependent on both the antibiotic compound and the plant species. For example, in the 1 mg kg^{-1} treatment, SMZ was found both in the plant leave and roots fraction, but the observed concentrations were notably higher in spinach compared to the radish (1 to 3 orders of magnitude in leaves and roots, respectively). The observed sorption, dissipation, uptake and distribution patterns in this study can help to understand the varying environmental behavior of antibiotics.

3.08.T-02 Evaluating the Translocation of PPCPs into Zea mays Following Wastewater Reuse – A Model validation via an Israeli Scenario

John Nightingale[1]*, Evyatar Ben Mordechay*[2]*, Vered Mordehay*[2] *and Laura Carter*[3]*, (1)University of Leeds and Fera Science Ltd, United Kingdom, (2)Hebrew University of Jerusalem, Israel, (3)School of Geography, University of Leeds, United Kingdom*

This research addresses the pathway for Pharmaceuticals and Personal Care Products (PPCPs) to enter terrestrial soils through the reuse of wastewater in agriculture, focusing on *Zea mays*. Recognizing the limitations of current monitoring, which only considers a standard list of contaminants, this research employs a novel model framework, combining dynamic and steady-state systems, to prioritize PPCP contaminants based on their chemical structure alone. The research involved fieldwork and laboratory analyses in Israel's Negav and Hamakim districts, areas known for high rates of wastewater reuse and *Zea mays* cultivation. Corn soil and irrigation water samples were subjected to Solid Phase Extraction and analysis using LC-MS/MS, targeting 72 PPCPs. The Israeli specific model was adjusted to use experimental data derived in Israel, predictive tools were however used to assess PPCPs affinity to plant proteins (KHSA). The study identified 31.94% of screened contaminants in irrigation water and 7.2% in *Zea mays* grain. Key findings include the detection of lamotrigine and benzotriazole in high concentrations in irrigation water, and significant presence of gabapentin, caffeine, carbamazepine, and alprazolam in corn. The model framework successfully predicted 90% of the measured environmental concentrations (MECs), with some discrepancies noted for gabapentin and venlafaxine. Future work includes non-targeted screening using HR-MS/MS to confirm the presence of contaminants and refine the predictive model. The study marks the first report of pharmaceutical translocation into *Zea mays* following wastewater reuse. The Israel-specific model underscores the need for case-specific models in environmental risk assessments of PPCPs. The study validates the use of chemical structure alone for risk assessment, with improvements possible through the integration of experimental data on fate and physicochemical properties.

3.08.T-03 Comprehensive approach to model pesticide residues in plants

***Klaus Hammel** and Johannes Witt, Bayer AG - Crop Science Division, Germany*

Understanding of the fate of chemicals in plants is crucial to assess and manage pesticide residues in food commodities, with the aim to reduce dietary and environmental risk and to approach a minimum residue situation. Assessment of pesticide residues for regulatory purposes is currently based on experimental studies with few, frequently only one final sampling of plant material. These few measurements require much experimental effort but hardly allow to identify the drivers of residue formation or to explain observations at other sites under different conditions. As a consequence, the dietary safety assessment must currently be based on worst case observed residue concentrations.

In this work we present a mechanistic modelling approach to describe chemical residues in plant considering soil water flow and chemical transport, crop (biomass) growth and chemical translocation processes in plants. Uptake of chemical into the plant is implemented via the roots and via the canopy. Canopy processes include interception, dissipation from foliage, loss to the ground via washoff and penetration of chemical through the cuticula into the plant. Crop growth processes consider the assimilation rate, partitioning to different plant compartments, phenological and biomass development. Coupling of growth with soil water processes allows the consideration of drought and oxygen stress. Finally translocation, partitioning, metabolisation and growth dilution of chemicals in the plant is described using established plant compartment model approaches. Both transport systems in plant, xylem and phloem, are considered.

The current implementation uses SWAP and PEARL which are state-of-the-art 1-D soil water flow and transport models. This choice allowed to use detailed WOFOST crop growth modules coupled to SWAP. Results of the soil and growth models are stored in a specific interface which serves as input for the plant translocation model. The use of such an interface allows the use of other soil and growth models or experimentally measured data directly.

Model runs with exemplary scenarios demonstrated the functionality of the model approach and the plausibility of the model results. Next step is the application to experimental studies to explore means of parameterisation and the necessity of calibration. Currently the model is limited to the description of neutral chemicals. Specific features of dissociating chemicals (e.g. ion trapping) are foreseen to be implemented in future.

3.08.T-04 Positive Impacts of Doxycycline on Mycorrhizal Structure and Function in the Agro-Environment
Emily Durant[1]*, Brett Sallach*[2]*, Laura Carter*[3]*, Jill Edmondson*[1] *and Katie Field*[1]*, (1)Plants, Photosynthesis and Soil, School of Biosciences, University of Sheffield, United Kingdom, (2)Department of Environment and Geography, University of York, United Kingdom, (3)School of Geography, University of Leeds, United Kingdom*
As the world's population and demand for food increases, soil is being degraded and crop production is slowing due to unsustainable agriculture practices. Synthetic fertilisers are used to supplement plant nutrition in conventional agriculture, and these are reliant on energy-intensive produciton processes and/or finite natural resources. These products are common air, land, and water pollutants, and their long-term use can reduce soil quality and diversity. Manure application is a good way to improve soil quality and, in turn, crop production, helping move away from synthetic fertiliser use. Treating soils with manure can improve soil health by supplementing soil organic matter, improving soil structure, and increasing microbial biomass, including arbusuclar mycorrhizal (AM) fungi. However, veterinary pharmaceutical contaminants have been found in manures and soils after manure application. Here, we focus on the antibiotic, doxycycline. The inadvertent introduction of doxycycline to soils could negatively impact soil health, specifically AM fungi, a group of symbiotic soil fungi that significantly contribute to soil nutrient cycling and plant nutrition. Using radioisotope tracers to investigate the effect of doxycycline on the structure and function of AM fungi, we tracked carbon-for-phosphorus (C-for-P) exchange between AM fungi and dwarf runner beans exposed to environmentally relevant concentrations of doxycycline. We found that doxycycline increased AM hyphal density in soils but had no impact on root colonisation by AM fungi. Nutritionally, doxycycline increased plant assimilation of AM-acquired P, while the total amount of P in shoot tissues was unchanged. Mirroring the improved P assimilation, AM fungi assimilated a greater amount of plant-fixed C when they were exposed to doxycycline. Our results suggest that veterinary doxycycline alone improves AM structure and function. However, as doxycycline is a broad-spectrum antibiotic, there is potential for it to negatively affect beneficial soil bacteria, which could result in overall negative ecosystem impacts.

3.08.T-05 Assessing the potential risks of organic lettuce cultivated in an area irrigated with reclaimed water
Rocío Inés Bonansea[1]*, Ana Jiménez de Parga Gros*[2]*, Dana Orlando Véliz*[3]*, Pol Martin Chulio*[4]*, Manuel Garcia-Vara*[4]*, María Jose Bleda Hernandez*[5] *and Miren Lopez De Alda Villaizan*[4]*, (1)Department of Environmental Chemistry, Water, Environmental and Food Chemistry Unit (ENFOCHEM), Institute of Environmental Assessment and Water Research (IDAEA-CSIC), Spain, (2)Faculty of Chemistry, University of Barcelona, Spain, (3)Enviromental Chemistry, Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain, (4)Environmental Chemistry, Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain, (5)Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain*
Water scarcity is becoming more frequent principally as the result of longer drought periods, changes in socio-economic factors and the increase in demographic growth. In this context, circular economy routes for a sustainable use of water are currently arising, especially in the agricultural sector, in which reclaimed water is used for irrigation of crops and at the same time replenishes the aquifer. Despite these efforts, reclaimed water has been found to introduce contaminants of emerging concern (CECs) into the ecosystem, because of that, is needed to assess their prevalence, potential environmental and human health effects and to establish regulations controlling their presence. This study aimed to investigate the potential risk of organic lettuce cultivated in an agricultural area whose irrigation system incorporates reclaimed water. The objectives of this work were (1) to optimize and validate a QuEChERS extraction method for the LC-MS/MS analysis in lettuce of some selected CECs found to be present and potentially toxic for the aquatic environment in the water used for irrigation in the area of study (2) to evaluate potential differences in their occurrence between washed and unwashed lettuce, and (3) to assess their associated risk for the human health. For these purpose, QuEChERS extraction procedure was optimized through a 2^{6-2} fractional factorial design of experiments and the screening was performed using a UPLC-QTOF-MS/HRMS. Forty-three targeted CECs were monitored in wash and not-wash lettuce samples. The samples were obtained from a single organic planting plot from the Baix Llobregat Agrarian Park (Catalonia), an agricultural area influenced by the addition of reclaimed water in the irrigation system. Results showed that 10 out of the 43 targeted compounds were detected and quantified in at least one of the 10 lettuce samples with average values ranging between 0.1 and 71.1 ng/g. Dibutyl phtalate, diethyl phtalate and triethyl phosphate presented concentrations exceeding the MRL considered (10ng/g), indicating a potential risk to human health. The compounds found in higher concentrations were some phthalates and phosphates, commonly used as industrial chemicals. Considering all present CECs, no differences were observed between the concentrations found in WL and NWL. The concentration of certain identified compounds showed a significant correlation, suggesting that their uses and uptake in lettuce are similar.

3.08.P Chemical Fate in the Soil-Plant System and Evaluation of Related Impacts and Risks

3.08.P-Tu178 Organic chemical contaminants in fertilizers, amended soils, and corns

Jingyun Zheng[1], Mélanie Desrosiers[2], Rim Benjannet[3] and ***Stéphane Bayen****[1], (1)McGill University, Canada, (2)Direction des expertises et des études, ministère de l'Environnement, de la Lutte contre les changements climatiques, de la Faune et des Parcs, Canada, (3)Department of Soils and Food Engineering, Laval University, Canada*

Fertilizing residual materials (FRMs) from industrial or municipal origins are used to enhance soil fertility and considered valuable sources of nutrients for field crops. The dispersion of FRMs in agricultural soils however raises concerns about the potential chemical risks associated with emerging contaminants including bisphenols and plasticizers. To better understand the fate of these chemicals, the current study aimed at developing analytical methods for the simultaneous targeted and non-targeted analysis of contaminants in various types of fertilizers (including FRMs), amended soils, and crop plant tissues. The methods were applied to samples obtained under real controlled field conditions in Canada.

More specifically, FRM samples (n=8 types), one cattle manure, three mineral fertilizers, amended soils, and corns were obtained from two experimental fields in Quebec, Canada. After freeze-drying and homogenization, samples were extracted using an ultrasound-based method and analyzed by LC-QToF-MS. Analytical methods were validated for absolute recoveries, matrix effects, method detection limits (MDLs), and precision using a certified reference material (SRM 2781) and three FRM matrices (municipal biosolids, deinking biosolids, and ash).

The extraction methods showed overall satisfactory performances and were applied to real samples. Municipal biosolids, deinking biosolids, digestate of biosolids, and lagoon biosolids exhibited relatively high levels of bisphenols/plasticizers compared to other fertilizer samples. Deinking biosolids were notably contaminated by bisphenol S (BPS) and other related compounds such as TGSA, D-8, and D-90. The non-targeted workflow effectively identified over 40 contaminants from diverse families in the municipal biosolids and deinking biosolids. To the best of our knowledge, many contaminants revealed through this novel workflow (e.g. tetradecylamine, *p*-toluenesulfonamide, *4*-dodecylbenzenesulfonic acid, Cyanox 2246, triethylene glycol monobutyl ether, and pinosylvin methyl ether) had never been reported in FRMs, demonstrating the need to include non-targeted analysis in the surveillance of FRMs.

The presence of bisphenols (BPA, BPS, BPAF, BPBP, D-8, D-90, and TGSA) and phthalate-related plasticizers (DBP, DiBP, BBzP, DEHP, DPHP, and DiNP) was confirmed in soils after fertilizers application, at concentrations below 50 ng g^{-1} dw. Additionally, the levels of targeted bisphenols and plasticizers were monitored in corn.

3.08.P-Tu179 Fate of Hormones, Pharmaceuticals and PFAS in the Soil-Plant System and Implications for Food Safety

Ane Arrizabalaga Larrañaga*[1], Esmer Jongedijk[2], Katja CW van Dongen[2], Gregg Roelofs[3], Stefan PJ van Leeuwen[2], Bjorn Berendsen[3] and Milou van de Schans[3], (1)Wageningen University & Research, Netherlands, (2)Wageningen Food Safety Research, part of Wageningen University and Research, Netherlands, (3)Wageningen University and Research (WUR), Wageningen Food Safety Research, Netherlands*

A key requirement for a circular bio-economy is that by-products, e.g. manure, urine, sewage sludge and paper sludge are returned to soil for replenishing nutrients for crops. However, a major concern is that these by-products contain chemicals that are hazardous for humans, animals and the environment, such as hormones, pharmaceuticals and PFAS (per and polyfluoralkyl substances). Recently, a case in Germany showed that application of PFAS-contaminated paper sludge led to widespread contamination of soils. In the Netherlands, PFAS were found in soils and crops in allotment gardens close to fluorochemical production facilities, leading to the advice not to eat the crops from gardens surrounding those places.

Pollution of the soil by chemical hazards may lead to uptake of pollutants by the crops growing on those soils. The here-presented work contains a tiered strategy to assess the fate of chemical hazards in soil, considering persistence, mobility and degradation products with their activity. This strategy was applied to relevant chemicals (hormones, pharmaceuticals, PFAS) in characterized soils. Moreover, we studied the uptake of these substances from soil into plants, including uptake over time, and their subsequent translocation to the edible parts. It was proven that indeed hormones, antibiotics and PFAS are taken up by crops. Assessing uniform uptake rates of chemical food safety hazards by crops is a challenging task, as the total chemical uptake by the crops and respective translocation into edible plant parts may be highly variable, and dependent on many different factors. As such, in the mentioned experimental study, a differentiation in the translocation pattern was found between chemicals, between a leafy crop and a root crop and over time. In addition, other factors have been reported influencing chemical uptake, such as soil biotic and abiotic characteristics, climate, growing conditions and the presence of other chemicals.

Quantitative knowledge on how these different factors in the soil-plant system relate to each other and what is most determining under which circumstances, is still largely lacking. It is essential, from a food and environmental safety perspective, to increase our insights in the crucial soil-plant processes, in order to assess food safety risks and facilitate the assessment of human and environmental exposure. The authors invite the audience to exchange knowledge and ideas.

3.08.P-Tu180 Pharmaceuticals in a Soil-Plant System Irrigated with Reclaimed Water in the Mediterranean Area: Environmental and Human Health Risk Assessment.

Sara Rodriguez-Mozaz*[1,2], Marc Castaño Trias[1,2], Paola Verlicchi[3] and Gianluigi Buttiglieri[4,5], (1)Catalan Institute for Water*

Research (ICRA), Spain, (2)University of Girona (UdG), Spain, (3)Department of Engineering, University of Ferrara, Italy, (4)Quality Area, University of Girona (UdG), Spain, (5)Quality Area, Catalan Institute for Water Research (ICRA), Spain
Reuse of wastewater is a strategy to cope with water scarcity and the urgent need of alternative freshwater sources in Mediterranean Areas. The (re)use of reclaimed water for agriculture purposes offers many benefits but careful attention needs to be paid to the presence of pathogens, suspended solids, and regulated and non-regulated contaminants in the irrigation water after the polishing treatments.

The objective of this study was to prioritise the pharmaceuticals (among the most studied emerging pollutants) that might pose a risk to environment and human health when reclaimed water is used for irrigation of crops, in particular for lettuce and tomato plants. A comprehensive study was conducted to first identify the pharmaceuticals frequently detected in secondary effluent in Catalonia (NE Spain) of various therapeutic classes, such as analgesics and anti-inflammatories, antibiotics, β-blockers, and psychiatric drugs. A priority list of pharmaceuticals was established, based not only on their occurrence in secondary effluents (O) (real data of 10 years of monitoring), but also on persistence in terms of removal in conventional treatments (P), bioaccumulation potential (B), toxicity for aquatic organisms (T), and risk to terrestrial environment as well as to human health through the consumption of crops.

The findings revealed that 6 pharmaceuticals (especially iopromide) could pose a risk to the organisms living in the soil irrigated with reclaimed water and up to 7 pharmaceuticals (especially carbamazepine and its transformation products) were potentially taken up by the crops. Nonetheless, none was found at concentrations that could pose a risk for human consumption. The study highlights the need to accurately select the pharmaceutical residues to be included in wastewater monitoring programmes as well as polishing treatments to eventually reduce their presence in soils and crops irrigated with reclaimed water.

3.08.P-Tu181 Presence of Pharmaceuticals and Other Emerging Contaminants in Biogenic Matrices Used in Agriculture as Fertilizer and in Soil and Lettuce

Marco Fossati[1]*, Silvia Schiarea*[2]*, Giulia Salmoiraghi*[2] *and Sara Castiglioni*[3]*, (1)Institute of Research Pharmacological Mario Negri, Milan, Italy, (2)Istituto Mario Negri, Italy, (3)Environmental Health Sciences, Istituto di Ricerche Farmacologiche Mario Negri, Italy*
Sewage sludge is a typical by-product of our society and its reuse in agriculture is potentially an ideal solution for its disposal. The application of sludge and other biogenic matrices on overexploited agricultural land can bring great benefits due to their content of organic carbon, nitrogen, phosphorus and micronutrients. However, great attention must be paid to their potential adverse effects due to the presence of several classes of emerging contaminants (ECs), such as pharmaceuticals, antibiotics, personal care products and perfluorinated compounds. This may result in the transfer of ECs to the crops with potential risks for human health. The aim of this study was to investigate the presence of about 40 ECs in different substrates (sewage sludge, compost, digestate, pig and cow manure) and to assess ECs uptake in lettuce (*Lactuca sativa*) grown in soil mixtures containing the different substrates, as well as in the soil in which the lettuce was grown. The analysis of the ECs was performed by liquid chromatography-tandem mass spectrometry (HPLC-MS/MS). The results showed different profiles of contamination in the different substrates investigated, with prevalence of fluoroquinolones, antibiotics for human use, in sewage sludge and of veterinary antibiotics in manure. Some antibiotics and plasticizers were found in soil and *Lactuca sativa* indicating the possible uptake from soils to crops. The discharge of ECs into agricultural lands through the application of biogenic matrices can create a stressful condition for the terrestrial ecosystems threatening its functioning. Moreover, the presence of antibiotics may also promote the spread of antibiotic resistance, a serious threat for human health. This study improved information on ECs presence in sludge and manure and their uptake in lettuce, with the overall goal to convert a potentially risky practice such as the application of biogenic matrices in agriculture into a safe process of circular economy.

3.08.P-Tu182 Evaluation of the dynamics and impact of nanomagnetites (Fe3O4) on lettuce (Lactuca sativa) in a context of cadmium contaminated soil

Nolenn Kermeur[1]*, Mathieu Pédrot*[1] *and Francisco Cabello-Hurtado*[2]*, (1)Géosciences Rennes - UMR 6118, Univ Rennes, CNRS, France, (2)Ecobio UMR 6553, Univ Rennes, CNRS, France*
Soil contamination by toxic metals such as cadmium (Cd) is a major issue for our society. Over the last few decades, around 22,000 tonnes of Cd have been released into the environment worldwide. For soil remediation, several approaches have been tested. Due to their physicochemical properties and their nanometric size, nanomaterials have been receiving substantial growing attention. Among these nanoparticles, nanomagnetites (Fe_3O_4, NPs-Fe) have great potential for soil remediation. Evaluating the impact and fate of these nanoparticles therefore seems essential.

This research aimed to evaluate the effect of nanomagnetites on lettuce (*Latuca sativa*) development and their role as an adjuvant to improve the phytoextraction efficiency of Cd in soil. In this context, nanomagnetites were applied (1.2 $g.kg^{-1}$ soil) to a Cd contaminated soil (20 mg.kg^{-1} soil). Four conditions were tested: control, Cd, NPs-Fe and Cd+NPs-Fe. The plants were harvested, weighed, freeze-dried and analysed by ICP-MS after 46 days of exposure to determine metal concentrations. Photosynthetic yield measurements were also taken before harvesting. The dynamics of nanomagnetites from soil to plants were also studied by measurement of magnetic susceptibility.

The results show a negative impact of Cd and NPs-Fe on lettuce development, with a reduction in biomass of around 50% for each of the treatments alone and over 70% for the Cd+NPs-Fe treatment. While the analyses do not show any difference in Fe content between the 4 treatments, a significant difference is observed for plant Cd content, which is roughly two times higher under NPs-Fe treatments compared to nanomagnetites-untreated conditions. Concerning the photosynthetic yield, a significant difference is only observed between control and Cd+NPs-Fe. Finally, a magnetic signal is detected in plants treated with NPs-Fe (NPs-Fe and Cd+NPs-Fe), indicating the presence of NPs-Fe in plant tissues.

This study showed that at the concentrations tested, nanomagnetites have a negative impact on the development of lettuce plants, but significantly increase the plant Cd concentration. It could be interesting to study the effect of different concentrations of NPs-Fe on lettuce to complete this work.

3.08.P-Tu183 Contamination of water, soil, and plants by micropollutants from treated wastewater and sewage sludge: Results from the second-year field experiment

Radka Kodesova[1]*, Helena Švecová*[2]*, Alina Sadchenko*[2]*, Ales Klement*[3]*, Miroslav Fér*[4]*, Ganna Fedorova*[2]*, Antonín Nikodem*[4] *and Oleksandra Rieznyk*[4]*, (1)Soil Science and Soil Protection, Czech University of Life Sciences Prague, Czech Republic, (2)University of South Bohemia in České Budějovice, Faculty of Fisheries and Protection of Waters, Czech Republic, (3)Soil Science and Soil Protection, Czech University of Life Sciences, Czech Republic, (4)Dept. of Soil Science and Soil Protection, Czech University of Life Sciences, Czech Republic*

An experiment aimed at monitoring the behavior of selected micropollutants in soil-water-plant system was established in the wastewater treatment plant for České Budějovice in the Czech Republic. Here, nine raised beds were installed in March 2021 near the outlet channel. Two beds contain soil taken from the surface horizon of the Arenosol Epieuric developed on sand and seven beds contain soil from the surface horizon of the Haplic Cambisol on paragneiss. Either maize or a mixture of different vegetables was grown in the beds in 2021. Four treatments were carried out for maize grown in the Cambisol beds: A. irrigation with tap water (control); B. irrigation with wastewater; C. application of composted sewage sludge before sowing; and D. application of sewage sludge before sowing. Three treatments A, B and C were suggested for vegetables grown in the Cambisol beds and two treatments A and B were proposed for vegetables grown in the Arenosol beds. Results obtained during this year have been published (https://doi.org/10.1016/j.scitotenv.2023.167965). In 2022, two different mixtures of vegetables were grown in these beds. Potatoes, soybeans, and beans were planted in originally maize beds. Kohlrabi, parsley, radishes, and brussels sprouts were planted in the originally vegetable beds. The treatments remained the same with one difference. The beds with the compost were additionally irrigated with wastewater. Composition and average concentrations of compounds in wastewater measured in 2022 were like those in 2021. Similarly, composition and concentrations of compounds in sludge and composted sludge measured in 2022 were like those in 2021. While less compounds leaked from the beds in 2022 than in 2021, a larger spectrum of compounds was quantified in soils in 2022 than in 2021. Taken up and mobile compounds in plants were mostly accumulated in plant leaves. Mostly no compounds were quantified in fruits (e.g., soybean pods). Compounds of low mobility remained in soils and belowground plant tissues. For example, low concentrations were recorded on the surface of potato tubers but not inside. The work was supported by the Ministry of Agriculture of the Czech Republic, projects No. QK21020080 and QK23020018, and the European Structural and Investment Funds projects No. CZ.02.1.01/0.0/0.0/16_019/0000845.

3.08.P-Tu184 Determination of Polycyclic Aromatic Hydrocarbon (PAHs) Associated with Vehicular Emission and it's Effect on Air, Soil, and Food Cultivars Planted Along The Major Highways in Enugu State, Nigeria.

Kingsley Chukwuka Uhama*, Applied Biochemistry, Enugu State University of Science and Technology, Nigeria*

Air, soil, and vegetables from six farmlands around three selected highways, Enugu-Abakiliki, Enugu-Onitsha, and Eke-Iwollo in Enugu state were investigated for the presence of toxic air gaseous constituents and Polycyclic aromatic hydrocarbon (PAHs). Two of the highways (Enugu-Abakiliki and Enugu-Onitsha) are associated with high vehicular emission due to the high traffic density while Eke-Iwollo highway (control) is associated with low traffic density. Two farmlands (5meters and 500 meters away from the high way) from each location were studied. Polycyclic aromatic hydrocarbon (PAHs) in the soil and vegetables were determined using Gas Chromatography-Mass Spectrophotometer. Air-vehicular emission (NO_2, SO_2, $PM_{2.5}$, $PM_{10,}$ and total carbon) were monitored morning, afternoon, and evening with Aeroqual/Crowcon Gasman monitors and Garmin GPS. The results of the investigation revealed high levels of the toxic gaseous substances (NO_2, SO_2, $PM_{2.5}$, PM_{10}) in Enugu-Abakiliki and Enugu-Onitsha farms (5 meters from the highway). It was observed that the mean concentration of the low, medium, high molecular weight PAHs in soils were highly present and above WHO (0.3mg/kg) permissible level in both Enugu-Abakiliki and Enugu-Onitsha farmlands (5 meters away from the high way) but below the detectable limit in other study sites, Vegetables (bitter leaf, pumpkin leaf, and cassava leaf) were equally proportionately contaminated with these low and high molecular weight PAHs in Enugu-Onitsha and Enugu-Abakiliki farmlands (5 meters from the high way). Given the appreciable accumulation of these toxicants in vegetables, it suggests that food remains a major endogenous source of PAHs, among the people of these areas.

3.08.P-Tu185 Fate of Per- and Polyfluoroalkyl Substances (PFAS) from Soil to Edible Crops: Relevance for the Safety of Circular Food Systems

Katja CW van Dongen, *Charlotte F Weyhenke, Kerstin Krätschmer, Esmer Jongedijk, Hj van der Fels-Klerx and Stefan PJ van Leeuwen, Wageningen Food Safety Research, part of Wageningen University and Research, Netherlands*

Closing agricultural production loops by application of side- and residual streams for food and feed production can help to improve the sustainability of food systems. However, besides the reintroduction of nutrients, this can also result in the (re)introduction or accumulation of hazardous chemicals in the food system. To understand the subsequent possible effects on food safety, quantitative knowledge is needed on the fate of relevant chemical hazards through circular food systems. To increase this understanding, the present study evaluated the transfer of spiked per- and polyfluoroalkyl substances (PFAS) from biosolids-amended soils to edible crops. The aim was to collect experimental data on the uptake and translocation from soil to crops.

Four selected PFAS (i.e., PFOA, PFNA, PFHxS, PFOS) were spiked to sewage- or paper sludge, individually and in mixture. The spiked sludge was subsequently mixed with soil, resulting in final concentrations of 5 or 100 ng/g in the soil for each compound. The spiked biosolid-amended soils were used in a closed pot system to grow radish and greens (a leafy vegetable). After harvesting the crops, roots and shoots were separated and PFAS concentrations were quantified by extraction and clean-up of the samples and analysis by liquid chromatography-tandem mass spectrometry.

The uptake of PFAS was shown for both crops. For radish, higher PFAS concentrations were found in the shoots as compared to the roots, while for the leafy vegetable, higher PFAS concentrations were found in the roots as compared to the shoots. This illustrates the difference between crop types and parts. The PFAS concentrations in the radish roots ranged between 2.2-5.9 ng/g w.w. (exposure concentration 100 ng/g), while the concentrations in the shoots of the leafy vegetable ranged between 0.5-13.4 ng/g w.w. (exposure concentration 100 ng/g). The concentrations of the PFAS in the edible parts of both crops were ordered as follows: PFOA > PFHxS > PFNA > PFOS.

Overall, the fate of PFAS differed between the studied crops and parts. Other factors may play a role in the fate of PFAS from soil to crop as well. Combining in future the here-described approach with other (experimental) test strategies to quantify the impacts of influential factors on the fate of chemical hazards through a circular food system, will be relevant to ensure food safety.

3.08.P-Tu186 Uptake of Per- and Polyfluoroalkyl Substances From Soil to Plants – A Meta-Analysis

Elvira Rudin, *Juliane Glüge and Martin Scheringer, ETH Zurich, Switzerland*

Per- and polyfluoroalkyl substances (PFAS) are a diverse class of industrial chemicals that have been used in various products and processes for over 80 years. Due to their widespread use and persistence, PFAS can be found in all environmental compartments, including groundwater, rainwater, and soil. In addition, many PFAS have been associated with adverse impacts on ecosystems and human health.

Therefore, it is crucial to establish threshold values for PFAS in soil, water, and food to protect humans and animals that are taking up PFAS from these sources. However, in some countries, such as Switzerland, regulatory values have not yet been established or have only been established for certain PFAS. To determine soil guideline values, it is important to consider that soil contamination can result in exposure to PFAS and other chemicals through direct inhalation or ingestion of polluted soil, as well as through consumption of plants grown on contaminated land or animal products. If animals graze on polluted soil or feed on contaminated plants, they can accumulate PFAS, ultimately leading to human exposure if animal products are consumed.

The objective of the present study is to investigate the transfer of PFAS from soil to plants with a particular focus on perfluorinated alkyl carboxylates and sulfonates. This forms part of the groundwork for proposing soil guideline values at a later stage in the project.

To this end, a literature review is conducted, and experimental data are collected into an SQL database. The collected data include information on PFAS concentrations in soils and plants, as well as various experimental factors such as soil and plant features, study duration, study location and experimental design. This comprehensive database enables an in-depth analysis of PFAS uptake patterns. A similar exercise was conducted in 2020, however, more data have become available in the meantime, including data from Rastatt in Germany so that the existing database can be extended to obtain a more comprehensive overview.

Finally, the results will be presented, showing which PFAS are taken up into plants and whether certain plants are more susceptible to PFAS uptake. The collected data will be used to investigate which factors determine PFAS uptake, including chemical properties (e.g., functional groups, molecular weight), plant characteristics (e.g., compartment, fat content, protein content), and soil characteristics (e.g., organic carbon content, pH).

3.08.P-Tu187 Riparian Plant Uptake of Current-Use Pesticides in Small Streams from Vine-Growing dominated River Basins: Aquatic-Terrestrial Linkages

Franziska Fiolka[1] *and Ralf Schulz*[2]*, (1)Aquatic Ecology, Rhineland-Palatinate Technical University Kaiserslautern-Landau (RPTU), Germany, (2)iES Landau, Institute for Environmental Sciences, Rhineland-Palatinate Technical University Kaiserslautern-Landau (RPTU), Germany*

Surface water pollution is a widely recognised problem, with chemicals like plant protection products (PPP) ending up e.g. in fluvial system worldwide. Fluvial riparian zones are known as diversity hotspots, and serve as a niche ecosystem to various taxa, with plants like the stinging nettle serving as an important generalist and specialist host plant. As the introduced PPP are expected to interact with the riparian zones, it is hypothesized that non-target riparian plants, such as e.g. the stinging nettle, are exposed to PPPs. One of the proposed transport pathways from surface water contamination to non-target riparian plants is an elevated water level through flooding. This study is investigating flooding as a vector of PPPs into riparian zones with its non-target plants.

Therefore, a steep- and a close-by shallow-slope riverbank in each five streams served as paired study sites to compare frequently flooded areas with non-frequently flooded areas. Sampling root-zone soil and plant individuals from these respective areas allowed to assess the PPPs levels in these matrices and linking it to the flooding intensity. In each of the two areas in these five streams, five individuals of each of five plant species have been sampled. The soil and plant material were extracted using an acetonitrile-based extraction method and PPPs levels for 98 chemicals have been assessed using an UHPLC-ESI-MS/MS complex.

As hypothesized, we found that in frequently flooded areas, plants are more contaminated, qualitatively, and quantitatively compared to the close-by higher riverbank situated plants. These findings are underlined by the concentration levels within the root-zone soil samples, allowing to track the exposure pathway from the surface water and the sediments carried into riparian soil and the subsequent bioaccumulation in the riparian plant systems.

This newly proposed exposure pathway opens another threat for diverse and sensitive riparian ecosystem, which may have carry-on effects on the riparian food web.

3.08.P-Tu188 Bio-accumulation of Heavy metals in Crops and Pollution Index Assessment

Sung Chul Kim*, Young Kyu Hong, Jin Wook Kim, Kyeong Min Lee and Dong Ju Lee, Bio-Environmental Chemistry, Chungnam National University, Korea, Republic of (South)*

Heavy metal pollution in soil has been concerned because of bioaccumulation in crops and consequently, can cause adverse effect on human health. In this study, heavy metal pollution in soil was evaluated based on Nemerow soil pollution index (NSPI) and bioaccumulation factor (BCF) in paddy soil in Korea. Total of 100 soil sample and rice (*Oryza sativa.*) was collected for heavy metal measurement. In order to evaluate bioavailable fraction of heavy metals in soil, Mehlich 3 extractant was used for heavy metal extraction in soil. Among 3 different heavy metals (As, Cd, Pb), the average concentration of Pb was the highest in both soil (3.9 mg kg^{-1}) and crop (0.6 mg kg^{-1}) followed by As in soil (1.4 mg kg^{-1}) and crop (0.3 mg kg^{-1}). Calculated NSPI was ranged 0.04-7.71 with average value of 0.35 indicating that heavy metal pollution in soil was medium to high depending on sampling area. Among 100 crop samples, 26 samples were exceed the threshold value of Pb (0.2 mg kg^{-1}) with the highest concentration of 7.58 mg kg^{-1} whereas, none of the Cd concentration was exceeded the threshold value (0.2 mg kg-1) in rice. In addition, value of BCF was ranged for Pb (2.6 – 15.4) and Cd (0.1-0.2) and indicating that much higher concentration of Pb can be accumulated in crops compared to Cd. Our result showed that Pb pollution in soil was severe and consequently, accumulation of Pb can be concerned in rice cultivation. Given the potential adverse effects associated with heavy metal consumption, remediation strategies should be adapted to reduce heavy metal concentration in both soil and crops.

3.08.P-Tu189 Evaluating Plant Uptake Through a Standard Soil-Based Biotest: Insights from Case Studies on Flame Retardants and Nanoplastics

Giovanni Beggio[1]*, Alberto Pivato*[1] *and Tiziano Bonato*[2]*, (1)University of Padua, Italy, (2)Ca' Foscari University of Venice, Italy*

The wide set of experimental conditions performed in published soil-based studies on plant uptake of contaminants make comparisons and data quality assessment challenging. The use of standardized soil-based methods, like ISO 16198, also known as RHIZOtest, could enhance repeatability and data reliability. Considering its acknowledged advantages over other experimental set ups, its scope of application should be consistently expanded to include the investigation of plant uptake behavior of organic and emerging contaminants. Consequently, this study discusses the results from two applications of an optimized RHIZOtest procedure, on plant uptake of i) organic brominated flame retardants (four polybrominated diphenyl ethers (PBDEs) and four novel brominated flame retardants (NBFRs)) and ii) nanoplastics (in-house made Pd-enriched NPs). The main optimization consisted in using stainless steel over polyamides for the 30-μm mesh used to separated soil from roots, to avoid any possible adsorption of contaminants. In particular, uptake and translocation were investigated in tomato plants exposed to environmentally relevant soil-concentrations (i.e., 5 or 50 ng g^{-1}dw for each PBDEs and NBFRs in soil, and 0.4, and 4 mg NPs g^{-1} dw for NPs in soil), achieved by spiking the tested contaminants into soil samples. Post-exposure, all roots and shoots replicates showed concentrations of the analyzed contaminants, demonstrating occurred uptake and translocation. For PBDEs and NBFRs, roots and shoots concentrations ranged from 0.23 to 18.51 ng g^{-1}dw and 0.09 to 6.85 ng g^{-1}dw, respectively. For NPs, average concentrations ranged, between treatments, 0.09 – 1.24 mg NPs g^{-1}dw for roots and 0.02 – 0.32 mg NPs g^{-1}dw for shoots. From data quality assessment, no cross-contamination and negligible losses of spiked contaminants were assumed and good repeatability (i.e., low variability) of the experimental data was ensured. These results suggest profitable RHIZOtest potential future application on diverse contaminants and scenarios to refine the estimation of uptake parameters to be used in risk analysis.

3.08.P-Tu190 Uptake of contaminants of emerging concern and AMR into edible plants: a field study from Australia

Minna Saaristo[1]*, Kara Fry*[1]*, Erinn Richmond*[1]*, Laura Carter*[2]*, Mike Williams*[3] *and Mark P Taylor*[1]*, (1)Environment Protection Authority Victoria, Australia, (2)School of Geography, University of Leeds, United Kingdom, (3)Commonwealth Scientific & Industrial Research Organisation (CSIRO), Australia*

Irrigation of agricultural crops with recycled wastewater is becoming an increasingly important means of ensuring consistent access of water in Australia. Recycled wastewater is known to contain a vast array of chemical and biological contaminants, even after various treatment barriers. There is growing concern that these contaminants may also affect crops exposed to recycled wastewater irrigation. Accordingly, the aims of the project were to: 1) Detect and quantify a broad range of potential organic, inorganic and biological contaminants in two classes (A and B) of recycled wastewater in Victoria used for crop irrigation and their contribution to accumulation in soils and plant tissues, relative to reference sites; 2) Quantify contaminant concentrations in below (roots) and above (leaves, fruits) ground plant tissues to unravel uptake and distribution within plant tissues of a broad suite of contaminants under field conditions; 3) Measure indicators of plant condition (e.g., physiological traits) to assess whether recycled wastewater has an adverse impact on crop health and productivity. Plant, soil and water samples were collected from five farms using wastewater irrigation for edible crops (Class A) or pasture (Class C) and from two reference farms (i.e. not using recycled wastewater for irrigation). Total of 143 samples were collected, of which 41 were plants (roots, shoot floret), 41 soil, and 55 water samples. Broccoli, pasture, and lettuce were harvested along with adjacent soil and irrigation water. Our study shows that of the 1000 organic chemicals targeted, 6 were detected in water, 160 in soil and 100 in plant tissues. For example, 100 pesticides, 12 PPCPs, 30 PAHs, 25 substituted benzenes, 24 industrial chemicals, 15 phthalates, and 7 PFAS were detected. Of the nine AMR genes targeted, seven were measured in water, six in soil and two in broccoli tissues. Overall, exposure of pasture and edible crops to two different classes of recycled wastewater led to the uptake of a range of chemical and biological contaminants in edible crops. For instance, along with PPCPs and EDCs, other contaminants including PFAS, industrial chemicals, pesticides and AMR genes were detected. Despite this, our study shows no clear distinction between crops exposed to recycled wastewater and reference sites. Further analysis and assessment of contaminant residues in crops is underway to ensure that the use of recycled wastewater for irrigation is safe.

3.08.P-Tu191 Understanding the Role of Soil Properties in the Fate and Behaviour of Pharmaceuticals in Soil and Pore Water

Harriet Sleight[1]*, Sylvia Toet*[2] *and Alistair Boxall*[1]*, (1)University of York, United Kingdom, (2)Environment and Geography, University of York, United Kingdom*

Pharmaceuticals may enter agricultural environments directly from livestock excreta, or indirectly following irrigation with wastewater effluent or fertilisation with biosolids or manure. Once pharmaceuticals have been introduced to agricultural environments they may be taken up into crops, remain in the soil profile, degrade into metabolites or be leached from the system. The fate and behaviour of pharmaceuticals in agricultural environments has important implications for human and environmental health.

Whilst significant evidence on the uptake of pharmaceuticals into crops exists, our understanding of the effects of different soil properties on the fate, behaviour and uptake of pharmaceuticals is limited. This study aimed to address this by: 1) quantifying sorption behaviour of pharmaceuticals across a range of six different soil types with differing physical and chemical properties and 2) investigating the degradation of pharmaceuticals in both the soil and pore water of the same soils. The selected study pharmaceuticals were carbamazepine, lamotrigine, and sulfadimethoxine. Selected soils were characterised in terms of their pH, cation exchange capacity, organic carbon content and particle size distribution.

Sorption studies were conducted according to the Organisation for Economic Co-operation and Development (OECD) guideline 106 and were tested in the range 25-400µg/L. To understand pharmaceutical persistence, soil samples were separately spiked with the study pharmaceuticals at concentrations equivalent to 10mg/kg. The spiked soil samples were placed in a controlled temperature room at 21°C and held at 60% of the maximum water holding capacity. Soil and porewater samples were taken on days 0, 7, 14 and 40. Soil samples were then extracted using methanol analysed by HPLC-MS.

Adsorption-desorption distribution coefficients (Kd) across the tested soils ranged from 1.7-11.0 L/Kg for carbamazepine, 5.6-40.1 L/Kg for sulfadimethoxine and 5.0-15.7 L/Kg for lamotrigine. Sorption isotherms were linear across the concentration range tested. The greatest Kd values were observed in the soils with the highest organic carbon (%C) contents and highest cation exchange capacities. The significance of pH and particle size were compound dependent.

This study provides valuable insight into the differing fate and behaviour of pharmaceuticals across a range of soil types, and will contextualise future studies of plant uptake of pharmaceuticals.

3.08.P-Tu192 Sorption, Persistence, and Plant Growth Inhibitory Activity of S-Abscisic Acid in Soils
Maria del Valle Muñoz-Muñoz[1]*, Rocío López-Cabeza*[2]*, Beatriz Gámiz*[2,3] *and Rafael Celis*[2]*, (1)Spanish National Research Council (CSIC), Spain, (2)Institute of Natural Resources and Agrobiology of Seville, Spanish National Research Council (IRNAS-CSIC), Spain, (3)Departamento de Química Inorgánica, Instituto de Química para la Energía y Medioambiente (IQUEMA), Universidad de Córdoba, Spain*
Natural plant growth regulators (PGRs), primarily represented by phytohormones, are gaining increasing attention in modern agriculture as eco-friendly agrochemicals to improve the yield and quality of crops under increasingly severe environmental conditions. However, the fate of these compounds once they enter the subsurface soil environment has received very little consideration. Information regarding the behavior of natural PGRs in soils is necessary to anticipate their residual activity and associated non-target effects. S-abscisic acid (S-ABA) is a plant growth inhibitory phytohormone currently authorized for several uses in agriculture at a maximum application rate of 2 kg/ha. Little is known, however, about the sorption and dissipation processes S-ABA may undergo in different soil types and even less about how its activity in soils may differ from that observed under soilless conditions or upon its direct application to plant tissues. In this work, we characterized the sorption and dissipation of S-ABA in three soils, two alkaline and one acid, and evaluated how the soils altered the plant growth inhibitory activity exhibited by S-ABA under soilless (Petri dish) conditions. S-ABA displayed low sorption coefficients in all soils (K_d < 0.12 l/kg), and dissipation times (DT_{50}) ranged between 0.7 and 8.4 days. Notably, S-ABA displayed greater sorption and persistence in acid soil compared to alkaline soils, and both sorption and dissipation decreased with the initial concentration of S-ABA, implying increased bioavailability at higher soil concentrations. In the presence of the soils, the inhibitory concentrations (IC_{50}) of S-ABA for the germination and seedling growth of *Eruca sativa* became 3 to 125 times greater than those measured under soilless (Petri dish) conditions. Biodegradation, rather than sorption, was identified as the primary process weakening the activity of S-ABA in the soils. Despite the reduction in the activity of S-ABA provoked by the presence of the soils, the phytohormone still expressed its inhibitory activity at relatively low soil concentrations (0.3-20 mg/kg), which could be important in assessing its residual activity and non-target effects derived from its use as an agrochemical. Acknowledgment: Funded by the Spanish Ministry of Science and Innovation through grants PID2020-112563-RB-I00 and PRE2021-100664.

3.08.P-Tu193 Multiscreening of pesticides in plant biomass for detection of groundwater contamination
Stanislava Vrchovecka[1]*, Nataliia Horichenko*[2]*, Taťána Halešová*[3] *and Antonín Zajíček*[4]*, (1)Technical University of Liberec, Liberec 1, Czech Republic, (2)Technical University of Liberec, (3)ALS Czech Republic, s.r.o., Czech Republic, (4)Research Institute for Soil and Water Conservation*
Background: Pesticides are the organic molecules designed to protect and enhance agricultural production. Although the application of these substances is targeted to agricultural areas, trace amounts can be found in all environmental compartments due to the persistence and mobility of parent substances and degradation products. Pesticides are also a major contributor to groundwater pollution. The aim of this study is to use vegetation to detect and monitor groundwater contamination using phytoscreening, and to use this approach also to protect water resources through protection zones.

Methods: For the first part of the study, a hydroponic experiment was conducted with 16 pesticides and black poplar seedlings. Simultaneously, an LC/HRMS method for the determination of pesticides and relevant metabolites was also developed and optimized involving sample treatment using QuEChERS with ChloroFiltr and SPE approaches. Due to the different stability, structural and physicochemical properties of the compounds, no single preparation method could be used. The obtained sample treatment methods allow a reduction of matrix effects by up to 60%. Recovery and reproducibility of the methods were within the specified limits. The hydroponic medium and plant biomass (roots, trunks and leaves) were analyzed by target and non-target analysis for determination of the parent compounds, metabolites and changes in secondary plant metabolism.

Results and conclusion: Azole fungicides were one of the monitored groups. The target analysis showed the presence of azole fungicides in all parts of the plants. In this case, transport of the substance from the roots to the leaves was observed. This trend was more favorable for tebuconazole due to its vapor tension and Henry's constant. Furthermore, the non-target analysis of hydroponic medium and plant material was performed. The analysis of hydroponic medium showed the presence of hydroxylated transformation products of tebuconazole and degradation products of propiconazole. Similar products were also found in extracts of plant parts. In addition, conjugation of these compounds with glucose occurred in the plant biomass. Their relative increase from roots to leaves was observed. In the context of azole fungicides, the fate of 1,2,4-triazole in plant tissue was investigated. It was observed that during transport from the root to the leaf part, changes in the representation of triazole lactic and triazole acetic acids occur.

3.08.P-Tu194 Small-molecule Fingerprinting for Contaminant Screening in Reclaimed Water and Non-target Analysis of the Irrigated Rice
Keng-Jui Lin[1]*, Wen-Ling Chen*[2]*, Chen-Wuing Liu*[3]*, Feng-Wen Chen*[4]*, Yu-Chien Cho*[4]*, Jin-Jing Lee*[3] *and Shan-Li Wang*[5]*, (1)Institute of Food Safety and Health, National Taiwan University, Taiwan, (2)Institute of Food Safety and Health, National Taiwan University, Taipei, Taiwan (China), (3)Department of Water Resources, Taiwan, (4)Agricultural Engineering Research Center, Taiwan, (5)Department of Agricultural Chemistry, National Taiwan University, Taiwan*

Reusing reclaimed water for rice irrigation is a potential resolution to mitigate water scarcity. However, reclaimed and conventional irrigation water differ in chemical composition, and the effects of reclaimed water irrigation on crops are not fully clarified. Aiming to elucidate the contaminants in reclaimed water and the effects on irrigated rice, this study fingerprinted small molecules in water and rice.

Reclaimed (n =10) and river (n =10) water used to irrigate rice paddy were collected from March to November 2023. Water samples were prepared by filtration and solid-phase extraction. Thirty-five whole rice plants were sampled for each irrigation group (reclaimed or river water). The homogenized white rice samples were processed through solvent extraction and cartridge cleanup. The samples were analyzed using liquid chromatography–high-resolution mass spectrometry.

The molecular features in water samples were searched in the database, which recorded around 2800 contaminants. The features in the rice with high variabilities (relative standard deviation, RSD >30%) were filtered. Multivariate analysis models were constructed to compare the distribution of rice samples between groups. The selection of candidate markers of reclaimed water irrigation was conducted based on the variable importance in projection (VIP) scores in the partial least squares discriminant analysis (PLS-DA) model.

Thrity-six and 14 contaminants with detection rates above 50% were found in the reclaimed and river water, respectively. Twenty-five contaminants were only detected in the reclaimed water, probably resulting from the compromised removal efficiency of wastewater treatments. Although only three contaminants were found solely in the river water, their control is challenging given the diverse sources. As for rice, nearly 60% of the molecular features exhibited low RSDs (<30%) in the pooled samples, indicating high analytical reproducibility. The PLS-DA model constructed using 2240 features significantly discriminated between rice irrigated with two waters (R^2 =0.751, Q^2 =0.661). Ninety-five features were selected as candidate markers (VIP >2).

This study successfully applied contaminant screening and non-target analysis to illustrating the small-molecule distribution in water and rice. Different small-molecule fingerprints in two waters and the rice of two irrigation groups were evident. Further studies will include a whole-year rice investigation and marker identification.

3.08.P-Tu195 Multitarget and suspect-screening of antimicrobials in vegetables samples: uptake experiments and identification of transformation products

*Irantzu Vergara[1], Mónica Jin[1], Juan Carlos Báez-Millán[1], **Belen Gonzalez-Gaya**[2], Irati Ijurco[3], Maite Lacuesta[3], Maitane Olivares[4] and Ailette Prieto[1], (1)Analytical Chemistry, University of the Basque Country (UPV/EHU), Spain, (2)Department of Analytical Chemistry, University of the Basque Country (UPV/EHU), Spain, (3)Plant Biology and Ecology, University of the Basque Country (UPV/EHU), Spain, (4)Analtytical Chemistry, Research Center for Experimental Marine Biology Biotechnology "Plentziako Itsas Estazioa", University of the Basque Country (PiE-UPV/EHU), Spain*

Antimicrobial (AM) contamination in vegetables and the formation of unknown transformation products (TPs) have raised concern about the emergence and dissemination of resistant-bacteria. Within this context, an accurate analytical method to perform a multitarget analysis of five sulfonamides, four tetracyclines, four macrolides, nine fluoroquinolones and quinolones, one imidazole and one nitroimidazole, one triazole, one diaminopyridine, one derivative of *Penicillium stoloniferum* (DP) and three antifungals in several vegetable samples (lettuce, onion, tomato, and carrot) using liquid-chromatography coupled to a low-resolution triple quadrupole mass spectrometer (UHPLC-MS/MS) was developed. Moreover, the method was extended in order to monitor the potential TPs by means of UHPLC coupled to a high-resolution mass spectrometer (HRMS) using an UHPLC-q-Orbitrap. Both analysis techniques were instrumentally compared in terms of limits of quantification and matrix effect at the detection. The method was applied to determine the presence of AMs in different case studies. On the one hand, the evaluation of AMs in organic and non-organic vegetable samples (lettuce, onion, tomato and carrot) acquired in supermarkets from the Basque Country (Spain) shown the presence of sulfadiazine and mycophenolic acid in carrots regardless of the agriculture type. On the other hand, the potential transference capacity of some AMs (trimethoprim, sulfamethazine, enrofloxacin and chlortetracycline) from soils to vegetables, using lettuce as a model, was evaluated through controlled uptake experiments. In this case, each of the AMs previously spiked in the soil were also found in the exposed lettuces. In both case studies, specific TPs of the target analytes were identified. For instance, (4E)-6-(4,6-dihydroxy-7-methyl-3-oxo-1,3-dihydro-2-benzofuran-5-yl)-4-methylhex-4-enoic acid, derived from the demethylation of mycophenolic acid, was tentatively identified and found in carrots from organic and non-organic agriculture, whereas 1-cyclopropyl-7-{[(1Z)-2-(ethylamino)ethenyl]amino}-6-fluoro-4-oxoquinoline-3-carboxylic acid, derived from enrofloxacin, was detected in the exposed lettuce samples.

3.08.P-Tu196 The influence of Bio-based fertilizers (BBFs) on the degradation of anionic pharmaceuticals

***Yan Dong**[1], Boris Jansen[2], John Parsons[3], Antonia Praetorius[4], Eva of Amsterdam - Institute of Biodiversity and Ecosystem de Rijke[5] and Chris Slootweg[6], (1)1091 BD, University of Amsterdam (UVA), Netherlands, (2)University of Amsterdam, Institute for Biodiversity and Ecosystem Dynamics, Netherlands, (3)Ibed, University of Amsterdam, Netherlands, (4)Institute for Biodiversity and Ecosystem Dynamics, University of Amsterdam, Netherlands, (5)University of Amsterdam (UVA), Netherlands, (6)Van 't Hoff Institute for Molecular Sciences, University of Amsterdam, Netherlands*

Pharmaceutical residues have been increasingly identified in agricultural soil due to anthropic activities. Bio-based fertilizers

(BBFs), as sustainable alternatives to chemical fertilizers, can help close nutrient loops, while affecting the degradation of pharmaceuticals in soil. To comprehensively understand this influence, degradation experiments were performed in which four pharmaceuticals (naproxen, ketoprofen, diclofenac and ibuprofen) were spiked in soils previously amended with a plant-based or an animal-based BBF. The data generated from the experiments were compared to those from a control without BBF addition and used to develop a degradation model for the first time that takes into account the distribution of pharmaceuticals in soil over the bioavailable fraction (BFS) consisting of the dissolved and rapidly desorbing fractions, and the strongly adsorbed fraction (SDS), The dynamics of pharmaceutical degradation based on the fate of the total extractable fractions (TES) encompassing the BFS plus the SDS fraction generally followed a single first-order model. After the addition of BBFs to the soil, the ratio of the bioavailable to the total extractable fractions i.e. SDS to TES increased, indicating an enhanced, strong sorption capacity for each pharmaceutical compound. This shift implies that a larger proportion of these compounds had a higher tendency to be adsorbed by the amended soil, reducing the bioavailable fraction for degradation. Simultaneously, we observed a decrease in the overall degradation rates of all fractions, including the BFS fraction for each pharmaceutical upon BBF amendment. This study presents a valuable model for elucidating the fate of pharmaceutical compounds in soil and the effects of BBFs on their persistence, taking into account their distinct chemical properties and the intricate interplay of each fraction in both soil and amended soil. Moreover, these methods hold considerable potential for assessing the consequences of wastewater irrigation on pharmaceutical degradation and how BBFs influence the uptake of pharmaceuticals by plants in soil.

3.08.P-Tu197 Occurrence of Microplastics in Soils Irrigated With Reclaimed Water

***Jose Javier Flores Morales**, Laura Cortés Corrales, Amadeo Rodriguez Fernández-Alba and Maria Jesus Martinez Bueno, Chemistry and Physics Department, University of Almería, Spain*

Suggesting the use of reclaimed water for agricultural irrigation offers a practical solution to combat water scarcity in the coastal regions of Mediterranean countries. To date, reclaimed water for crop irrigation has been poorly evaluated in terms of microplastics (MPs) load. Extended exposure to advanced treatment processes results in the gradual decomposition of plastic materials into numerous smaller plastic particles known as MPs. Those particles are accumulated in large quantities in agricultural soils irrigated with reclaimed water, posing a potential threat to terrestrial ecosystems. Despite the intensive use of plastics in agriculture, little is known about the presence of MPs in the agro-environment. Long-term plastic pollution may even lead to a further reduction of agricultural production. However, the extent to which terrestrial ecosystems, especially agri-food systems, are affected is still largely unknown. Thus, the main objective of this work was to determine the presence and/or accumulation of MPs in agricultural soils irrigated with reclaimed water in protected crops (greenhouses).

For the analysis of MPs in the reclaimed water samples, 25 µm stainless steel filters (volume 30 L) were used. The filters were subjected to an ultrasonic bath and the organic solvent filtered through a 0.45 µm nitrocellulose filter. Soil samples were sieved on stacked stainless steel sieves with mesh sizes of 1 mm, 300 µm, 100 µm and 25 µm. The fractions were then dehydrated in an oven at 60 °C for 24 hours. The MPs were separated from the soil matrix by density flotation using a saline solution. Finally, a stereomicroscope in combination with a micro-FTIR was the instrumentation used to identify the number of MPs and classify them in terms of morphology, color, and type. Preliminary results showed that reclaimed water is a source of MPs. Fibers and fragments were the most abundant MPs in the reclaimed water samples analysed. A total of 5 different types of polymers and only 1 non-plastic material (cellulose) were identified. The polymers detected by FTIR analysis were PTFE, PET, PP, PE and PVC. The work supports the reuse of water for agricultural irrigation. Nevertheless, reclaimed water constitutes a source of MPs, and its presence should be evaluated in future studies.

Acknowledgments. The authors are grateful to the MICINN for the financial support given to the project PID2020-116230RB-I00 and to the University of Almeria for the project TRFE-I-2023/007.

3.08.P-Tu198 RISK ASSESSMENT OF ORGANIC MICROCONTAMINANTS AND MICROPLASTICS IN PROTECTED CROPS IRRIGATED WITH RECLAIMED WATER

***Maria Jesus Martinez Bueno**[1], Laura Cortés Corrales[1], Maria del Mar Gómez Ramos[2], Harshit Sahai[3], María Dolores Hernando Guil[3] and Amadeo Rodriguez Fernández-Alba[1], (1)Chemistry and Physics Department, University of Almería, Spain, (2)University of Almería, Spain, (3)Spanish National Research Council (CSIC-EEZA), Spain*

Reclaimed water contributes to mitigating water stress and offers a sustainable alternative for farmers in areas which suffer from greater water scarcity. Some scientific studies have documented the presence of organic microcontaminants, such as pharmaceuticals or pesticide residues, in reclaimed water. But, new contaminants, plastic waste, are posing a new challenge to the scientific community. To date, reclaimed water for crop irrigation have been poorly evaluated yet in terms of microplastics (MPs) load. In recent years, studies have shown that the use of reclaimed water for crop irrigation can be an important pathway for the introduction of organic pollutants into agricultural production and their subsequent entry into the food chain; this could pose a risk to health and the environment. Thus, due to due to the increasing presence of these pollutants in the environment and their potential negative effects on ecosystems and human health, an assessment of the possible risks derived from the use of reclaimed water for agricultural irrigation of protected horticultural crops in greenhouses is relevant.

Almería is the main production area of horticultural products for Spain and Europe. According to data published in a recent report by the Junta de Andalucía, 48% of Almeria's farmers use reclaimed water as their sole source of supply. The goal of the work was to provide scientific-technical knowledge regarding the impact on the water-soil-plant continuum of using reclaimed water for commercial crops irrigated over a long period, as well as the human risks associated with consuming the vegetables produced.

Reclaimed water is a source of MPs and organic microcontaminants. PTFE, PET, PP or PE were the most frequently detected polymers in reclaimed water. The accumulation rate of the organic contaminants detected in the edible parts of the vegetables permanently irrigated with reclaimed water was very low (~1%), whereas it was 33% in the soils. Thus, the results revealed that consuming fruits harvested from plants irrigated for a long period with reclaimed water does not represent a risk to human health. Nonetheless, the study highlights the importance of carrying out a long-term control strategy on agricultural soil that is permanently irrigated with reclaimed water to avoid high accumulation rates among certain organic microcontaminants that could migrate over further crop seasons.

Acknowledgments. To the projects PID2020-116230RB-I00 and TED2021-131609B-C31

3.08.P-Tu199 Assessment of a multi-test protocol investigating fate and ecological impacts on soil environment due to potential contaminants in fertilizers

Giovanni Beggio[1]*, Claudio Ciavatta*[2]*, Cavani Luciano*[2] *and Tiziano Bonato*[3]*, (1)University of Padua, Italy, (2)Alma Mater Studiorum University of Bologna, (3)Ca' Foscari University of Venice, Italy*

A multi-test experimental protocol was developed to gather empirical data for risks analysis, investigating the exposure of the human food chain to crops grown in agricultural soil treated with fertilizing products that may contain contaminants.To ensure repeatability and reliability of generated data, the proposed activities within the protocol are planned to be performed accordingly to internationally validated standards. In particular, both chemical availability and bioavailability of contaminants were assessed, by leaching tests with different media simulating interactions between soil, chemicals and roots exudates, and by the performance of the so called RHIZOtest (ISO 16198), to experimentally investigate their plant uptake. This latter was proposed due to its acknowledged benefits over hydroponic- and non-standard soil-based tests.

The experimental activity addressed a single solid fertilizer product, composed of green compost, chicken manure, urea, triple superphosphate and potassium chloride, specifically manufactured by the authors in accordance with the requirements for organo-mineral solid fertilizers laid down in Regulation 2019/1009/EU.

Together with a sample of fertilizer products alone, one sample of standard soil alone, each soil-fertilizer sample previously prepared underwent leaching (extraction) test using 3 different leaching media to simulate rhizospheric processes (H_2O demi, a 0.01 M solution of $CaCl_2$ and a 0.015 M solution of oxalic acid) with a L/S ratio of 10:1 (EN ISO 18772 and EN ISO 17402) . Each leaching test was performed in triplicate and analyzed to determine its chemical composition. Simultaneously, each soil-fertilizer test sample, including the untreated soil control, were subjected to plant uptake tests following the so called RHIZOtest configuration, standardized as per ISO 16198.

Finally, the investigated fertilizer products were subjected to ecotoxicological characterization using representative organisms from both terrestrial and aquatic environments, through methods align with those recognized by the scientific community for waste hazard classification (HP 14 – Ecotoxicity) and the regulation for product classification and labeling and the analysis methods provided therein 440/2008/EC.

3.08.P-Tu200 Evaluation of the potential toxicity of swine wastewater treated with recycled oyster shell and pumice in soil environments

Yung-Chih Yang[1] *and Chi-Wei Huang*[2]*, (1)Department of Marine Environmental Engineering, National Kaohsiung University of Science and Technology,Department of Marine Environmental Engineering, Taiwan, (2)Department of Marine Environmental Engineering, National Kaohsiung University of Science and Technology, Taiwan*

Despite the abundant nutrients that could be reutilized in swine wastewater, excessive metals, such as copper and zinc, and inadequate wastewater management can engender ecological impacts to the aquatic and terrestrial ecosystems. Herein, this study aims to reuse oyster shell and pumice waste as filter medium for swine wastewater treatment, intercepting nutrients for agricultural application. To assess the potential toxicity of treated medium in soil environments, this study employed the soil nematode (*Caenorhabditis elegans*) and Chinese cabbage (*Brassica rapa chinensis*) assays, indcluding growth assays and seed germination assay. In addition, the field test of the treated medium was conducted in farmland with corns and cucumbers. Our findings showed the nutrients and metals were largely removed from the swine wastewater treated with oyster shell and pumice. For *C. elegans* assays, the growth and reproduction were not adversely affected by treated medium, whereas the non-treated air-dried sludge of wastewater completely inhibited the growth and reproduction of *C. elegans*. For Chinese cabbage assays, the treated medium (10%–40%) did not significantly inhibit germination and growth of Chinese cabbage, whereas the non-treated air-dried sludge of wastewater would be harmful to Chinese cabbage growth. Furtheremore, the treated medium (20%–40%) could further promote growth of Chinese cabbage. In farmland, the treated medium (30% and 50%) slightly increased the corn growth. In addition, the total cucumber harvest was increased by 224% in treated medium group (50%). In conclusion, recycling oyster shells and pumice for swine wastewater effectively reduces contamination, and the treated medium has no significant adverse effects to soil environment and agricultural use, supporting its reuse suitability and enhancing the value of oyster shells, pumice, and swine wastewater while minimizing environmental impact.

3.08.P-Tu201 Health Impact of Vegetable Consumption from Urban Gardens in Andalucia, Spain
*Sabina rossini Oliva[1] and **Rafael López-Núñez**[2], (1)University of Sevilla, Spain, (2)Institute of Natural Resources and Agrobiology of Seville, Spanish National Research Council (IRNAS-CSIC), Spain*
Urban food production plays a crucial role in mitigating climate change by reducing the need for food transportation, packaging and energy consumption. Plants acquire essential elements from the air and soil. However, human activities contribute to increased potentially toxic elements (PTEs) concentration in urban areas. Therefore, it is imperative to monitor the quality of food, as plants serve as a primary pathway for PTEs to enter the food chain. Urban soils display notable diversity in their physicochemical characteristics, indicating a broad spectrum of contamination levels. Various vegetable species were gathered from urban gardens in Seville, Cordoba, and Huelva (Southern Spain), as well as from two small towns in a mining region (Riotinto), along with topsoil samples near the plants. The levels of potentially toxic elements (As, B, Ba, Cd, Co, Cr, Cu, Mo, Ni, Pb, and Zn) were assessed in the edible parts of the plants and the soil. Additionally, the same species obtained from the local market in Seville and a peri-urban area (a domestic garden in a rural region) were analyzed. The relationship between plant/soil pollution was examined, and the potential risks to human health were evaluated using various parameters. The soils in urban gardens from the mining area exhibited higher contamination levels compared to the others, and generally, the soils in the city displayed higher values of potentially toxic elements than those in the peri-urban area. Leafy species generally had higher mean concentrations of almost all potentially toxic elements compared to fruiting and bulbous species. Arsenic, Cd, and Pb concentrations were below the health-based guidance values in all vegetables, except for Cd in one sample from the peri-urban area. Overall, the vegetables from urban gardens in the city did not exceed the market concentrations for most of the studied elements, except for Pb in onion, lettuce, and chard. The Hazard Quotient (HQ) values for all elements in plant species from the studied gardens were below one, as were the Hazard Index (HI) values, indicating that the consumption of these vegetables can be considered safe and poses no risk to human health. Furthermore, the cancer risk values for As were below the established limits in all vegetables from the studied urban gardens, including the mining area, suggesting that urban agriculture in this region is safe, even in soils contaminated with high levels of As and Pb.

3.08.P-Tu202 Assessing the Efficacy of Reactive Barriers in Mitigating Emerging Contaminants: Laboratory Insights into Aquifer Recharge with Treated Wastewater
*Gaelle Cabaret[1], **Linda Luquot**[2], Geoffroy Duporte[3] and Elena Gomez[3], (1)Géosciences Montpellier and Hydrosciences Montpellier, (2)Geosciences Montpellier, University of Montpellier, CNRS, France, (3)HydroSciences Montpellier, University of Montpellier, CNRS, IRD, France*
Water scarcity is a pressing global concern exacerbated by population increase and the adverse impacts of climate change. Declining water resources require immediate attention, particularly in the context of depleting aquifer levels. Managed aquifers recharge has emerged as a critical strategy to sustain water availability. However, the use of treated water from wastewater treatment plants for aquifer recharge requires additional treatments due to the presence of emerging contaminants, such as pharmaceuticals and personal care products.

This study focuses on enhancing the efficiency of aquifer recharge by employing reactive barriers, which serve as a final treatment step for water infiltrating aquifers. To evaluate the effectiveness of these barriers, laboratory experiments were conducted using column setups that mimic reactive barriers. Over a three-month period, treated wastewater from a sewage treatment plant was injected through a sand column (representing conventional aquifer conditions) and a barrier column composed of a mixture of natural materials, including compost, sand, and wood.

The results reveal that certain molecules, notably venlafaxine and metoprolol, exhibit significant retention in the barrier columns, highlighting the efficacy of the barrier. Conversely, some molecules, such as irbesartan, show partial retention in both media. This study comprehensively presents the spectrum of molecules tracked during the experiment, along with associated sorption and degradation models. The discussion focuses on the effectiveness of the barrier in dealing with the fate of emerging contaminants, highlighting the importance of such strategies in water resource management.

3.08.P-Tu203 A Higher Sensitivity of HMA Genes and Better Photosynthetic Performance Led to Improved Cd Phytoextraction by Brassica napus under Future Climate
*Austra Dikšaitytė[1], Inesa Kniuipyte[2], **Jurate Zaltauskaite**[1], Mostafa Abdel-Maksoud Dr.[3] and Hamada Abd Elgawad[4], (1)Vytautas Magnus University, Lithuania, (2)Lithuanian Energy Institute, Lithuania, (3)cDepartment of Botany and Microbiology, King Saud University, Saudi Arabia, (4)Biology, University of Antwerp, Belgium*
Changing climatic conditions undoubtedly influence heavy metal behavior and fate in the environment and thus influence the plant-heavy metal interaction. This study aimed to investigate the underlying physiological, biochemical, and molecular mechanisms responsible for *Brassica napu's* potential to remediate Cd-contaminated soil under current climate (CC, 400 ppm of CO_2 and 21/14 °C) and future climate (FC, 800 ppm of CO_2 and 25/18 °C) conditions. *B. napus* exhibited good tolerance to low Cd treatments (Cd-1, Cd-10, i.e., 1, 10 mg kg^{-1}) under both climates without visible phytotoxicity symptoms. The tolerance index (TI) of shoots sharply decreased by 47% and 68% ($p < 0.05$), respectively, in Cd-50 and Cd-100 treated shoots under CC, but to a lesser extent (−26% and −53%, $p < 0.05$) under FC. This agreed with increased photosynthetic apparatus performance under FC, primarily due to the higher amount of active reaction centers (RCs) of photosystem II (PSII). It was indicated by a higher density of active RCs on PSII antenna chlorophyll *a* basis (RC/ABS) and per excited cross section (RC/CSm), lower increases in the rate of RCs closure (dV/dt)o, and less dissipated excitation energy (DIo/RC, φDo), especially under Cd-100. Calvin Benson cycle (CBC)-related enzyme activity also improved under FC with 2.2-fold and 2.4-

fold ($p < 0.05$) increases in Rubisco and triosephosphate isomerase (TPI) under Cd-50 and Cd-100, respectively. As a result, a 2.2-fold and 2.3-fold ($p < 0.05$) increase in photosynthetic rate (P_r) resulted in a 2.3-fold and 2.4-fold ($p < 0.05$) increase in the shoot dry weight of Cd-50 and Cd-100 treated rapeseed, respectively. This also led to a decrease (26%, $p < 0.05$) in shoot Cd concentration under both high Cd treatments with a slight reduction in bioconcentration factor (BCF). Translocation factor (TF) decreased (on average 42%, $p < 0.05$) by high Cd treatments under both climates. However, under Cd-100, FC increased TF by 1.7-fold ($p < 0.05$) compared to CC, which was explained by significant increases in HMA genes, especially *BnaHMA4a* and *BnaHMA4c*, expression. Finally, the total uptake (TU) index of Cd increased under FC by 65% and 76% ($p < 0.05$) under Cd-50 and Cd-100. This led to a shorter hypothetical remediation time for reaching the Cd pollution limit by 35 ($p > 0.05$) and 61 ($p < 0.05$) years, respectively, compared to CC.

3.09.A Complex Mixtures of Chemicals in the Environment and the Human and Eco-Exposome – Next Generation Monitoring (NGM), Toxicity Driver and Source Tracking to Meet Regulatory Needs

3.09.A.T-01 Feature Tracking in NTS: Staying In Touch With The Unknown

Geert Corné Franken *and Eelco Nicolaas Pieke, Het Waterlaboratorium, Netherlands*

The application of non-target screening (NTS) for water monitoring is essential for a comprehensive understanding and management of environmental contaminants. Traditional NTS methods excel in detecting unknown substances, but often lack a systematic approach for naming and tracking these substances, which is essential for detailed analysis and comparison. Therefore we introduce a new methodology for feature tracking in high-resolution LC-MS NTS, focused on the principle of "Leave No Feature Unnamed." Key to this method is the understanding of the important role of metadata in prioritizing, annotating, and selecting features accurately and based on evidence. This methodology also contributes to clearer reporting of results, allowing for adjustments in retention time (rt) and mass-to-charge ratio (mz) prior to final reporting. An imporant part in this methodology is the Feature Tracking Database (FTDB), where systematically both analytical data and extensive metadata of features is stored, facilitating their detailed tracking.

To assess this methodology, three years of routine NTS data from two critical monitoring stations along a Dutch river, a significant source of drinking water, and a related drinking water production facility was processed. The application of the workflow allowed for the systematic organization and storage of features found at these locations in the FTDB. This enabled the prioritization of key features appearing in both the river and drinking water samples, showcasing the potential of the methodology for environmental monitoring.

As an evolving concept, this methodology is open for collaboration and the exchange of expertise for further development. This feature tracking methodology aligns with significant initiatives such as the European Commission's Green Deal and the Partnership for the Risk Assessment of Chemicals (PARC), marking a step towards integrating NTS into regulatory frameworks and advancing towards a sustainable, pollution-free environment.

3.09.A.T-02 Cross-laboratory Non-Target Screening in an International River Catchment – the Case for Monitoring the Rhine River and its Tributaries in Real-Time

Martin Loos*, enviBee, Switzerland*

The rise of non-target screening (NTS) has enabled a concise monitoring of long-term micropollutant trends at various sampling points in a broad range of surface waters. While the analytical methodology is steadily improving and its results are becoming gradually accepted among regulatory bodies, a framework to harmonize and compare NTS data in large transnational catchments at short timescales has been lacking to date. This shortcoming has impeded the fast detection and tracking of pollutant trends and their sources of emissions across boundaries and has not allowed to bundle all available information and forces from existing laboratories to prioritize and communicate nontarget masses for identification efforts.

We therefore present a harmonized and vendor-independent approach to compare LC-HRMS data across monitoring sites, combined with a real-time data mining and synchronization routine on a common server. While data from each sampling point in a river network is measured and profiled in a user-friendly workflow by one of several participating laboratories, the synchronization routine automatically screens for any updated data in the background. The new data is then aligned, its cross-laboratory comparability estimated and the annotated LC-HRMS masses grouped and stored in a joint database for various query purposes. The database can then be searched with a convenient user interface on the same server. Therein, laboratories can also dynamically merge their sets of known compounds, as well as exchange information on non-targets and trends of interest on a joint platform. The framework has been thoroughly tested and streamlined by five participating laboratories in the catchment of the river Rhine, paving its way for daily international routine usage.

The presented implementation makes a strong case for pushing NTS past retrospective and locally restricted screening, and towards a real-time and distributed next generation monitoring of pollutant dynamics. We underline its feasibility with several use cases which have led to the successful prioritization and identification of non-target compounds of catchment-wide concern for the protection of an international water body.

3.09.A.T-03 Development and Application of Non-Target and Suspect Screening for Environmental Chemical Regulatory Purposes in the United Kingdom

Emmelianna Kumar[1], *Lindsey Sturdy*[2] *and Jonathan Ray Newman*[3], *(1)Environment Agency United Kingdom, United Kingdom, (2)Chief Scientist's Group, Environment Agency (England), United Kingdom, (3)Environment Agency (England), United Kingdom*

The diversity of chemicals entering the environment present a challenge for effective regulation of chemicals, as few data are available for a large proportion of these chemicals. A fundamental obstacle to assessing the environmental risk of chemicals is that traditional targeted monitoring covers a small proportion of the chemicals that are produced or used. Selecting chemicals to focus monitoring, research, and regulatory efforts on requires prioritisation of those that are expected to pose the greatest environmental risk. Monitoring approaches using high-resolution mass spectrometry (HRMS) followed by non-target/suspect screening workflows can contribute towards this process by providing preliminary information about exposure to a much broader range of chemicals, permitting a more holistic assessment of environmental quality. These approaches can also contribute towards identification of chemical mixtures responsible for environmental incidents and can provide information about chemical effects on organisms when implemented in combination with biological information, such as from effect-based methods, through effects-directed analysis. The Environment Agency in England is working with other UK and international organisations to develop and apply non-target and suspect screening approaches to enhance chemical management strategies in the UK. These techniques are being applied in various workstreams, and some of these will be showcased in this presentation. These include the development of in-house methods for analysing water, sediment, soil and biota samples. Suspect screening is also being applied to monitor chemicals of emerging concern in Eurasian otters (Lutra lutra) as part of the H4 Otter Project, in passive samplers, and in wastewater influent and outputs as part of the Chemicals Investigation Programme (CIP). A UK cross-government Working Group for Non-Target and Suspect Screening has also been initiated to provide a forum for exchanging knowledge using a co-ordinated approach and to set priorities that are relevant to the UK environment. We will explain how the use of non-target and suspect screening approaches offers multiple benefits and how limitations and challenges can be managed, leading to simplification of monitoring protocols and enabling complex data evaluation, storage and sharing.

3.09.A.T-04 The innovative pull-down approach as an efficient tool for the identification of endocrine-disrupting compounds in environmental mixtures

Petra Mikusova[1], *Zuzana Toušová*[2], *Ludek Sehnal*[1,3], *Jan Kuta*[4], *Roman Grabic*[5], *Kateřina Grabicová*[6], *Ganna Fedorova*[6], *Klara Hilscherova*[1] *and Martin Marek*[7,8], *(1)RECETOX, Masaryk University, Czech Republic, (2)RECETOX, Faculty of Science, Masaryk University, Czech Republic, (3)Interfaculty Institute of Microbiology and Infection Medicine, University of Tübingen, Germany, (4)Recetox, RECETOX, Masaryk University, Czech Republic, (5)University of South Bohemia in Ceske Budejovice, Faculty of Fisheries and Protection of Waters, Czech Republic, (6)University of South Bohemia in České Budějovice, Faculty of Fisheries and Protection of Waters, Czech Republic, (7)Experimental Biology and RECETOX, Loschmidt Laboratories, Department of Experimental Biology and RECETOX, Masaryk University; International Clinical Research Center, St. Anne's University Hospital, Czech Republic, (8)International Clinical Research Center, St. Anne's University Hospital, Czech Republic*

Endocrine-disrupting compounds commonly occur in environmental mixtures as it has been widely documented by various bioassays. Nevertheless, even though several methods, like effect-directed analysis, are used for effect driver identification, the drivers of endocrine-disrupting effects often remain unknown. Recent studies document that complex environmental mixtures associated with discharges from wastewater treatment plants can contain compounds disrupting thyroid hormone transport facilitated by transthyretin (TTR protein), which is crucial for proper neuro/development and metabolism in vertebrates. We have developed and optimized a novel method called a pull-down assay to identify them in a water matrix. This method is based on separating TTR ligands from a sample by interaction with designed, expressed, and purified TTR protein. Immobilized TTR protein (through its Histidine tag binding to magnetic particles) with its ligands is separated from the rest of the sample. Protein is degraded, and ligands are identified using non-target HPLC-HRMS analysis and confirmed using TTR bioassay.

Extracts from water samples were used in pull-down assay to trial the real-world use of the TTR pull-down workflow. Non-target HPLC-HRMS analysis identified twenty-two compounds, of which thirteen were verified by their standards using TTR bioassay, including diclofenac and its metabolites, linear alkyl benzene sulfonates (LAS), lupulone, citalopram, and telmisartan. Among these compounds, we identified several pharmaceuticals and their metabolites that showed even higher affinity to TTR than the parent compound. An interesting identified group was LAS, which accounted for a major part (5.5% - 39%) of the TTR-binding inhibition effect of the field samples, which we could explain with known and newly identified ligands. These findings emphasize the need to investigate the possible endocrine-disrupting effects of commonly used chemicals and their metabolites released into the environment. We document that pull-down assay can be a valuable versatile method for identifying ligands from different samples through almost any expressable protein for various purposes.

3.09.A.T-05 Chemicals with Evidence for Presence in Humans and in Food Packaging

***Birgit Geueke**[1], Lindsey V. Parkinson[1], Ksenia J Groh, PhD[2], Chris Kassotis[3], Maricel Maffini[4], Olwenn Viviane Martin[5], Lisa Zimmermann[1], Martin Scheringer[6] and Jane Muncke[1], (1)Food Packaging Forum Foundation, Switzerland, (2)Eawag - Swiss Federal Institute of Aquatic Science and Technology, Switzerland, (3)Wayne State University, (4)Independent Consultant, United States, (5)Brunel University London, United Kingdom, (6)ETH Zurich, Switzerland*

Over 12,000 food contact chemicals (FCCs) may be intentionally used during the manufacture of food packaging and other food contact articles, and more than 1800 FCCs have been shown to migrate from food contact materials (FCMs) into the packaged foods or food simulants. Collectively we refer to these chemicals as “universe of known FCCs”. However, it has not been systematically assessed which of these FCCs have been detected in humans, although such an assessment is crucial to understand how FCMs contribute to human exposure to FCCs, encompassing potentially harmful chemicals and mixtures. Therefore, in a stepwise approach, we compared the known FCCs to metabolome/exposome databases and human biomonitoring programs. Then, we prioritized a set of FCCs without any evidence for presence in humans and performed a targeted systematic evidence mapping.

Twenty-five percent of the FCCs have varying types of evidence for presence in humans. In step 1, the majority of FCCs have been identified in metabolome/exposome databases. A subset of 194 FCCs has been monitored and detected in biomonitoring programs, while 70 FCCs have been monitored but never detected. Phthalates and alternative plasticizers and metals have been detected most frequently in humans and in FCMs, followed by volatile organic compounds, phenolic compounds, and per- and polyfluoroalkyl substances. Dioxin-like compounds, pesticides, and flame retardants have also been detected in humans, but they have been less frequently found in FCMs. Reasons could be contaminations or the illicit use of these chemicals during manufacture, as many of these FCCs are not listed for intentional use. Step 2 showed that antioxidants have a high level of evidence for presence in FCMs, but there is only limited information on their presence in humans. Whether this is due to data gaps or degradation of the FCCs will be a question for follow-up work. On the other hand, bisphenol A-based derivatives (like BADGE), commonly found in can coatings and known to migrate into foods, have a high level of evidence for presence in humans.

This study provides a systematic overview of FCCs with links to human exposure. With over 3500 FCCs, the FCChumon database will be made accessible as a user-friendly, interactive and free dashboard. These data can also inform further research by indicating knowledge gaps and inform evidence-based decision-making, for example, by highlighting hazardous FCCs commonly detected in humans.

3.09.B Complex Mixtures of Chemicals in the Environment and the Human and Eco-Exposome – Next Generation Monitoring (NGM), Toxicity Driver and Source Tracking to Meet Regulatory Needs

3.09.B.T-01 Advanced High- Throughput Effect-Directed Analysis (HT-EDA) Workflow for the Identification of Androgenic Compounds

***Iker Alvarez-Mora**[1,2], Katarzyna Arturi[3], Aset Muratuly[4], Florian Jünger[5], Sarah Johann[5], Carolin Huber[2], Martin Krauss[2], Werner Brack[2] and Melis Muz Massei[2], (1)IBeA Research Group, Centre for Experimental Marine Biology and Biotechnology (PiE-UPV/EHU), Spain, (2)Department of Effect-Directed Analysis, Helmholtz Centre for Environmental Research (UFZ), Germany, (3)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (4)Helmholtz Centre for Environmental Research (UFZ), Germany, (5)Evolutionary ecology and environmental toxicology, Goethe University Frankfurt, Germany*

Effect-directed analysis (EDA) is a promising tool for understanding environmental sample mixtures and unravelling toxicity drivers, yet its routine use is hindered by time and labour intensity. However, advances in high-throughput (HT) fractionation systems and toxicity assessment have improved EDA's efficiency. Still, current HT-EDA approaches face some challenges mainly due to constrained chemical analysis conditions and the non-target screening bottleneck. In this study we have addressed these issues by exploring APCI alongside ESI for an expanded chemical space coverage, while mitigating increased feature detection with computational prioritization tools to focus on relevant compounds linked to specific toxicity endpoints. A hospital effluent sample with high androgenic activity was analyzed, employing the Fractiomate™ system for microfractionation followed by androgenic activity biotesting by AR-CALUX. The chemical analysis, using an Orbitrap Exploris 480 with ESI and APCI ionization, was focused on both the original sample and detected toxic fractions. The non-targeted analysis strategy involved MZmine data processing, prioritization of potential androgens using the MLinvitroTox tool, and subsequent structure elucidation using SIRIUS and compound annotation using Massbank and endpoint specific suspect-lists. The AR-CALUX bioassay revealed up to 8 toxic fractions in the sample, guiding the focused chemical analysis on this retention time window. A two-level comparison of ESI and APCI ionization modes indicated a higher feature detection with ESI, but after prioritization with MLinvitroTox, the gap narrowed, and 13 potential androgenic features unique to APCI were detected, aligning with the decision to use ionization source to extend the detectable chemical space. The non-target results showed 60 prioritized features, with notable overlap between these features and toxic fractions. The in-house database match suggests the presence of compounds like 4-Androstene-3,17-dione, Testosterone, or 11-Ketotestosterone, emphasizing the utility of MLinvitroTox in focusing efforts on relevant compounds for further identification. The proposed effectively aligns with the requirements of HT-EDA, specifically addressing the need to expand the detectable chemical space and incorporating a non-target screening approach focused on endpoint-specific relevant candidates.

3.09.B.T-02 Effect-Directed Analysis in Human Serum Samples - the Challenges of Dealing with Endogenous Molecules

Maria Margalef[1], *Jeroen Meijer*[2], *Peter Cenijn*[1], *Timo Hamers*[3], *Maria Valente*[4], *Christina Rørbye*[5], *Anne Marie Vinggaard*[4] *and Marja Lamoree*[3], *(1)Amsterdam Institute for Life and Environment (A-LIFE), Vrije University Amsterdam, Netherlands, (2)Amsterdam Institute for Life and Environment (A-LIFE), Section Environment & Health, Vrije University Amsterdam, Netherlands, (3)Vrije University Amsterdam, Netherlands, (4)Technical University of Denmark (DTU), Denmark, (5)Hvidovre hospital, Denmark*

Effect-directed analysis (EDA) is an innovative and advanced approach designed to pinpoint and evaluate potential risks associated with complex mixtures of chemicals. EDA integrates state-of-the-art analytical techniques with *in vitro* bioassay testing, which allow the identification of specific components responsible for observed toxic effects. Generally, EDA involves assessing the biological activity of the original extract, followed by its fractionation and subsequent biological and chemical analysis. The question is: are we missing important active chemicals in the analysis just because they coelute with endogenous molecules that appear at higher intensities in the mass spectra? The data processing workflow used for chemical identification is essential to elucidate which chemicals may trigger an effect on the bioassay. In this study, a high-throughput EDA approach was utilized to evaluate the capacity of chemical mixtures found in human serum samples to compete for the binding to thyroid hormone (TH) serum protein—an essential molecular initiating event linked to TH system disruption. Different data acquisition, annotation, mass spectra (MS) alignment and evaluation strategies are used to assess the chemical composition of the active fractions.

Extracts obtained from pooled human umbilical cord serum and various adult serum samples were subjected to high throughput EDA. Briefly, serum extracts and their matching procedural blanks were fractionated by high performance liquid chromatography (HPLC) coupled to a fraction collector (FractioMate™). The activity of the fractions was assessed using the a TTR-binding assay. Non-targeted chemical profiling of the extracts was performed using the same chromatographic conditions coupled to a qTOF mass spectrometer. Data Dependent Acquisition (DDA) and iterative-DDA were used for the acquisition. Suspect screening and data evaluation was performed using different spectral libraries before and after aligning the anotated results to a suspect list of chemicals of emerging concern.

This study shows different data processing strategies that can be used for EDA in complex biological samples. Aligment of the results with suspect lists prior the data (MSMS) evaluation can be useful to determine whether some active fractions contain coeluting exogenous and endogenous chemicals. In addition, an alternative data adquisition approach to increase the sensitivity of the chemical analysis is also proposed.

3.09.B.T-03 Identification of AhR and ER agonists in eggs of black-tailed gulls in the West Sea Coast of Korea using effect-directed analysis

Jihyun Cha[1], *Jiyun Gwak*[1], *Mungi Kim*[1], *Junghyun Lee*[2], *Gi Myung Han*[3], *Sang Hee Hong*[3], *Jong Seong Khim*[4] *and Seongjin Hong*[1], *(1)Department of Marine Environmental Science, Chungnam National University, Korea, Republic of (South), (2)Department of Environmental Education, Kongju National University, Korea, Republic of (South), (3)Ecological Risk Research Department, Korea Institute of Ocean Science and Technology, Korea, Republic of (South), (4)School of Earth and Environmental Sciences & Research Institute of Oceanography, Seoul National University, Korea, Republic of (South)*

In this study, major aryl hydrocarbon receptor (AhR) and estrogen receptor (ER) agonists were identified in eggs of black-tailed gulls collected from Nando Island (n=3) and Gyeongnyeolbi-yeoldo Island (n=2) in the West Sea Coast of Korea, utilizing effect-directed analysis. Results of the bioassay, conducted using H4IIE-*luc* and T47D-kb*luc* cell lines, revealed that AhR-mediated potencies were relatively high in the mid-polar fraction, while ER-mediated potencies showed a significant response in the polar fraction of the egg extracts. Full-scan screening was performed on the mid-polar and polar fractions using GC-QTOFMS and LC-QTOFMS, respectively. A five-step selection process was applied to identify AhR agonist candidates in the mid-polar fraction. In addition, ER agonist candidates in the polar fraction were selected through a six-step criteria application. A total of 25 AhR and 22 ER agonist candidates were identified in the mid-polar and polar fractions, respectively. Among these, three AhR agonists (ethyl benzoate, 3-phenylpropanal, and 1,4-dicyclohexylbenzene) and one ER agonist (hydroxyvalerenic acid) were newly identified. Ethyl benzoate, 3-phenylpropanal, and hydroxyvalerenic acid were natural products, while 1,4-dicyclohexylbenzene was derived from combustion sources. Targeted 27 AhR agonists accounted for approximately 67% of the total AhR-mediated potencies in the mid-polar fractions. Of these, 20-methylcholanthrene (mean=36%), benz[*b*]anthracene (mean=16%), and 10-methylbenz[*a*]pyrene (mean=7.5%) contributed significantly to the AhR-mediated potencies in the mid-polar fractions. Meanwhile, targeted 7 ER agonists contributed 12–95% (mean=53%) of the total ER-mediated potencies in the polar fractions, with estradiol being the major ER agonist (mean=48%), followed by estriol (mean=4.2%) and hydroxyvalerenic acid (mean=0.58%). Further studies are needed to investigate the maternal transfer mechanism according to the partition coefficient of AhR and ER agonists in egg samples. In addition, it is crucial to identify other key factors that determine the maternal transfer characteristics of these substances.

3.09.B.T-04 A Data-Derived Reference Mixture Representative of European Wastewater Treatment Plant Effluents to Complement Mixture Assessment

Liza-Marie Beckers[1]*, Rolf Altenburger*[2]*, Werner Brack*[3]*, Beate Escher*[4]*, Jörg Hackermüller*[5]*, Enken Hassold*[6]*, Martin Krauss*[3]*, Gianina Illing*[7]*, Janet Krüger*[7]*, Paul Michaelis*[7]*, Andreas Schuettler*[8]*, Sarah Stevens*[9]* and Wibke Busch*[7]*, (1)German Federal Institute of Hydrology (BfG), Germany, (2)Department of Bioanalytical Ecotoxicology, Helmholtz Centre for Environmental Research (UFZ), Germany, (3)Department of Effect-Directed Analysis, Helmholtz Centre for Environmental Research (UFZ), Germany, (4)Department of Cell Toxicology, Helmholtz Centre for Environmental Research (UFZ), Germany, (5)Department of Computational Biology, Helmholtz Centre for Environmental Research (UFZ), Germany, (6)Chemicals, German Environment Agency (UBA), Germany, (7)Helmholtz Centre for Environmental Research (UFZ), Germany, (8)Federal Institute of Hydrology (BfG), Germany, (9)Norwegian University of Science and Technology (NTNU), Trondheim, Norway*
Aquatic environments are polluted with a multitude of organic micropollutants, which challenges risk assessment due the complexity and diversity of pollutant mixtures. The recognition that certain source-specific background pollution occurs ubiquitously in the aquatic environment might be one way forward to approach mixture risk assessment. To investigate this hypothesis, we prepared one typical and representative WWTP effluent mixture of organic micropollutants (EWERBmix) comprised of 81 compounds selected according to their high frequency of occurrence and toxic potential. Toxicological relevant effects of this reference mixture were measured in eight organism- and cell-based bioassays and compared with predicted mixture effects, which were calculated based on effect data of single chemicals retrieved from literature or different databases, and via quantitative structure-activity relationships. The results show that the EWERBmix supports the identification of substances which should be considered in future monitoring efforts. It provides measures to estimate wastewater background concentrations in rivers under consideration of respective dilution factors, and to assess the extent of mixture risks to be expected from European WWTP effluents. The EWERBmix presents a reasonable proxy for regulatory authorities to develop and implement assessment approaches and regulatory measures to address mixture risks. The highlighted data gaps should be considered for prioritization of effect testing of most prevalent and relevant individual organic micropollutants of WWTP effluent background pollution. The here provided approach and EWERBmix are available for authorities and scientists for further investigations. The approach presented can furthermore serve as a roadmap guiding the development of archetypic background mixtures for other sources, geographical settings and chemical compounds, e.g. inorganic pollutants. The study is published in Environment International (https://doi.org/10.1016/j.envint.2023.108155).

3.09.B.T-05 Predicting, diagnosing and reducing biodiversity impacts of chemical pollution in surface waters
Leo Posthuma[1,2]*, Francesco Bregoli*[3,4]*, Nikola Rakonjac*[5]*, Caterina Zillien*[6]*, Erwin Roex*[7]* and Ad M. J. Ragas*[3]*, (1)Centre DMG, National Institute for Public Health and the Environment (RIVM), Netherlands, (2)Department of Environmental Science, Radboud University Nijmegen, Netherlands, (3)Environmental Science, Radboud University Nijmegen, Netherlands, (4)Water Resources and Ecosystems, IHE Delft Institute for Water Education, Netherlands, (5)Wageningen University & Research (WUR), Netherlands, (6)Radboud University Nijmegen, Netherlands, (7)National Institute for Public Health and the Environment (RIVM), Netherlands*
Environmental quality is not sufficiently protected due to a lack of predictive approaches to anticipate exposures to unintended mixtures. Such an approach would fill the gap between prospective, generic per-chemical safety assessments (as under REACH) and retrospective environmental quality assessment (as under the Water Framework Directive). This presentation was triggered by extensive diagnostic investigations in European and Dutch surface water systems, showing that unintended mixtures are a major driver of water quality deterioration. Apparently, the dual approach of prospective and retrospective approaches currently in place is insufficient to reach the aspired ‘toxic-free’ environment goal. Further consideration showed region-specific prospective approaches that consider regional unintended mixtures exposures and risk to be lacking. Hence, based on observed exposures and impacts of mixtures in contemporary surface waters, this presentation employs a ‘model train’-approach, with step 1 considering land use, step 2 emissions of chemicals, step 3 regionalized predicted environmental concentrations and step 4 integrated mixture risks. The results appear useful in two major ways. First, prospectively, current and future land uses can be evaluated regarding potential harm to water quality, resulting in opportunities for pro-active, preventive management. Second, the land-use-related chemical footprint of a study area can be ‘traced back’ to dominant sources. The dual utility offers an important extra tool to protect and restore water quality. The presentation will show how the model train is built, and how it yields spatio-temporally explicit exposure and mixture risk patterns for chemicals of emerging concern (CECs).

3.09.P Complex Mixtures of Chemicals in the Environment and the Human and Eco-Exposome – Next Generation Monitoring (NGM), Toxicity Driver and Source Tracking to Meet Regulatory Needs

3.09.P-We162 Ad-hoc assessment of non-target screening data for regulatory water monitoring of the future
Alexander Badry[1]*, Anna Lena Kronsbein*[1]*, Kevin S. Jewell*[2]*, Tobias Schulze*[1]*, Nicole Bandow*[1]*, Eric Rosenheinrich*[1]* and Jan Koschorreck*[1]*, (1)German Environment Agency (UBA), Germany, (2)German Federal Institute of Hydrology (BfG), Germany*
The Green Deal's Zero Pollution Ambition aims for a non-toxic environment and, together with the new Chemicals Strategy for Sustainability, will ensure a sustainable chemicals market that protects human health and the environment from hazardous substances. However, regulatory monitoring programmes in support of environmental, emissions and chemicals legislation rely on conventional target analyses that cover only a fraction of the marketed chemicals. To achieve the goals of the European Green Deal, regulatory agencies need to implement a more comprehensive assessment of chemical mixtures in the environment. Non-Target Screening (NTS) using high-resolution mass spectrometry (HRMS) is increasingly being used for regulatory monitoring of organic pollutants as it facilitates the systematic characterisation of chemical mixtures and identification of previously unknown compounds. At the German federal level, national and state laboratories collaborate via a

database called NTS-Portal (developed by the Federal Institute of Hydrology (BfG)), bringing together HRMS data from different laboratories. The NTS Portal currently contains data from several federal states, the daily water measurement station of the BfG and suspended particulate matter samples of the German Environmental Specimen Bank (2005-2021). The data is structured in two layers, one for the discovery and analysis of unknown HRMS features and one for securely annotated features using a reference library to bridge the gap to conventional target analysis (Database Assisted Screening). An upcoming challenge is the regulatory assessment of HRMS datasets as guidance for the use of semi-quantitative data is missing. Furthermore, there is no central database that provides information on all marketed chemicals including their regulatory status, physicochemical (PC) properties and hazard data. As a regulatory agency, UBA has access to the hazard endpoints provided in the registration dossiers and to emission data of relevant industries. We aim to integrate these data in the NTS Portal, and provide prioritisation and assessment options as well as statistical approaches to identify relevant sources. We have identified 26,470 chemicals listed in the EU chemicals legislation and will enrich the data with PC properties and hazard data from a UBA database and other sources. Furthermore, we provide prioritisation options and give examples for the assessment of typical and atypical chemicals and mixtures.

3.09.P-We163 Advancing Environmental Monitoring: Promising Insights into Non-Target and Suspect Screening

Jacqueline Meng-Reiterer[1], *Anna-Lena Grabher*[1], *Stefan Weiß*[1], *Christina Hartmann*[1], *Katharina Lenz*[1], *Vanessa Parravicini*[2], *Liad Weisz*[2], *Norbert Kreuzinger*[2] *and Romana Hornek-Gausterer*[1], *(1)Environment Agency Austria (EAA), Austria, (2)Vienna University of Technology*

Non-target analysis (NTA), a qualitative analysis method, aims to identify both known and unknown substances by comparing molecular and fragment masses with internal and external databases. Suspect screening allows to search for substances of interest in an environmental sample. Monitoring projects using NTA and suspect screening methods are presented to give an overview of promising applications.

- NTA to assess the potential impact of the pandemic measures by analysing organic substances before and during the first Austrian Covid19 lockdown in 2020 in wastewater: A total of 440 different substances were detected, with differences found before and during the lockdown, especially in pharmaceuticals and drugs and their metabolites.
- NTA as a tool to investigate the elimination of organic substances in wastewater treatment plants (WWTP): The use of NTA to analyse influent and effluent samples from WWTP demonstrated that ~ 1/3 of organic substances were eliminated. However, ~1/3 of the substances remained, highlighting the need for further treatment improvements. Approximately 47% of pharmaceuticals and their metabolites were still detected in the effluent.
- NTA to perform chemical source tracking of industrial wastewater: Examining modern approaches to address the challenge of complex industrial wastewater discharge.
- Advancements of NTA and suspect screening methods for better identification of emerging contaminants: Internal identification databases are extended continuously for identification (high confidence level) of emerging contaminants, for example the antioxidants para-substituted phenylenediamines (PPDs), namely IPPD, 6PPD, 7PPD, 77PD, 8PPD, and their highly fish toxic quinones.
- Usage of NTA identified substances as dataset for identifying possible river-basin specific pollutants in surface waters: NTA identified substances in industrial wastewater are used as basic data to establish a prioritized scheme for river basin specific pollutants.

Future developments in these modern monitoring techniques include securing financial support for future and retrospective analysis, establishment of in-house digital monitoring, trend recognition, development of an early warning system, focusing on volatile substances as well as on polar substances and supporting risk management strategies and regulatory measures to better protect the environment by evidence-based information.

3.09.P-We164 Harmonized LC-HRMS Non-Target Screening in the International Regulatory Framework of the River Rhine Catchment Area

Pavel Ondruch, *International Commission for the Protection of the Rhine (ICPR), Germany*

The Convention on the Protection of the Rhine is a framework for collaboration among the governments of Germany, France, Luxembourg, the Netherlands, Switzerland, and the European Community to protect the Rhine ecosystem. This legal foundation of the International Commission for the Protection of the Rhine (ICPR), outlines measures to ensure sustainable development, water quality preservation, flood prevention, and ecosystem restoration. The collaborative efforts have led to significant improvements of water quality. Nevertheless, the large number of mostly low concentrated emerging pollutants (EPs) from point and diffuse sources remains challenging. This challenge is regularly addressed, amongst others by the EU Water Framework Directive (WFD) and the Extended Rhine Convention signed in 1999. Especially the program "Rhine 2040" focuses on addressing global environmental challenges, particularly concerning climate change's impact on water management and quality. It aims to ensure sustainable and climate-resilient management of the Rhine River. Additionally, the program emphasizes continued monitoring, collaborative projects. In this framework, the Rhine Project NTS (2021-2024) initiated with the aim to assure NTS data comparability allowing faster information exchange across environmental authorities about increasing number of EPs. In this project a centralized system for fast processing, evaluation and storage of NTS data was developed and applied in daily routine of international monitoring stations of the River Rhine.

The system, called "the NTS Tool", provides:
a) Centralized processing with shared databases allowing for more comprehensive screening of EPs (currently >1450)
b) Near-realtime aggregation of data over the river's course supporting the classification and identification of sources of Eps
c) Assistance in the identification of unknowns by supporting knowledge exchange

This NTS Tool will contribute to the fulfilment of the objectives declared in the "Rhine 2040" programme such us the MICROMIN system aiming the reduction of the influx of micropollutants from municipal wastewater systems, industry, and agriculture by at least 30% compared to the 2016-2018 period across the catchment. In the NTS Follow up Project (2024-2029), the NTS Tool will be adapted for early warning of known and unknown substances and enhance the water supply protection. The NTS Tool will help to achieve goals specified in mentioned programs, agreements and the WFD.

3.09.P-We165 Improving the monitoring of water bodies through the use of LC-HRMS from the perspective of state environmental monitoring

Klaus Furtmann *and Susanne Brueggen, LANUV NRW*

The main task of the North Rhine-Westphalia Agency for Nature, Environment and Consumer Protection (LANUV NRW) within the framework of statutory water monitoring are, the monitoring of wastewater, groundwater and surface waters in accordance with various regulations (Water Directive, Wastewater Ordinance, ...) by
(target-) analysing up to 600 individual substances at about 3.000 monitoring sites. This target-based monitoring currently requires the application and maintenance of several different methods, each with complex quantification and quality assurance.

As this traditional approach does not provide any information on other potentially relevant substances beyond the specified list of substances, suspect and non-target analyses based on LC-HRMS have been added to the portfolio since 2014.

In future, LC-HRMS will be used for quantitative (targets) and qualitative analyses. In addition, a digital sample archive for retrospective analyses is created for each measuring point.

The change from conventional target analysis with many individual methods that are complex to maintain to the use of a single LC-HRMS measurement, which is subsequently evaluated in different ways (target, suspected target, non-target), holds considerable potential for making water monitoring more effective. However, there are still a few hurdles to overcome before the system can be completely changed:

- Unfortunately, the current version of the Water Framework Directive does not describe how to handle qualitative data.
- The new technology generates very large amounts of data that need to be processed and archived properly.
- The use of the techniques by several users, e.g. along watercourses, requires careful methodological coordination to ensure that comparable data is generated.
- The number of analysis results per sample will increase significantly. New evaluation concepts must be developed that allow the environmental administration to handle the results correctly and implement them in measures.

This concept could change water monitoring and assessment and make it much more efficient without losing information. There is a chance to measure less but learn more about the water bodies.

3.09.P-We166 High-Resolution Mass Spectrometry and Nontarget Screening combined to High-Throughput Toxicity Assessments to Address Community Concerns Related to Organic Contaminants in Surface Water

Chloe Fender[1], Miranda Elizabeth Jackson[2], Makenzie Williamson[1], Jason Schindler[1], Katrina Brown[1], Diana Rohlman[1], Lisa Truong[1], Cassie Cohen[3], Robyn Leigh Tanguay[1] and ***Manuel Garcia-Jaramillo****[1], (1)Oregon State University, (2)Environmetnal and Molecular Toxicology, Oregon State University, (3)Portland Harbor Community Coalition*

Decades of industrial activity led to the designation of the lower 10 miles of the Willamette River as a Superfund Site by the US EPA in 2000. Surface water monitoring and remediation efforts at this site have traditionally focused on legacy pollutants. Community organizations have expressed concerns about overlooked and emerging contaminants in this site. We employed a community engaged approach and selected six locations in the Willamette River for monthly surface water sampling over a 6-month period. Locations above and below the designated Superfund Site were also sampled. We utilized ultra-high performance liquid chromatography coupled to high-resolution mass spectrometry for water analysis. Samples were analyzed using both reverse phase and hydrophilic interaction chromatography to cover a broad range of organic contaminants. Chemical data was processed using suspect and nontarget screening methods, allowing for the detection of compounds not routinely monitored. Multivariate statistical approaches were used to describe trends and prioritize chemical features for further identification and testing. Organic chemical profiles significantly differ among sites, with Site 6 being the most divergent among them. These differences in the chemical profile may be due to the proximity of Site 6 to the confluence with the Columbia River and a wastewater treatment plant. Clustering analysis revealed that collection month was more relevant than location in describing the differences between samples. The overlap among the annotated compounds each month was lower than hypothesized. Using our *in-house* library and the NORMAN suspect list exchange we annotated 1,025 organic compounds, including pesticides, pharmaceuticals, natural toxins, and food additives. We utilized the high-throughput embryonic zebrafish platform to assess the bioactivity and potential toxicity of collected water samples. Using the Hazard

Comparison Dashboard, we assessed toxicity previously reported for the annotated compounds. The combination of suspect and nontarget chemical analysis with high throughput *in vivo* and *in silico* toxicity testing is a novel approach for the prioritization of water contaminants and further assessment and monitoring. Our results can help inform community groups and regulatory agencies about the hazards associated with emerging water contaminants and the potential risks of exposure from surface waters in the Portland Harbor and other Superfund Sites.

3.09.P-We167 Non-Target Screening of Surface Water Samples to Identify Exposome-Related Pollutants: A Case Study from Luxembourg

Dagny Aurich[1]*, Philippe Diderich*[2]*, Rick Helmus*[3] *and Emma Schymanski*[4]*, (1)Luxembourg Centre for Systems Biomedicine, University of Luxembourg, Luxembourg, (2)Luxembourgish Ministry, Luxembourg, (3)Institute for Biodiversity and Ecosystem Dynamics (IBED), University of Amsterdam, Netherlands, (4)Luxembourg Centre for Systems Biomedicine (LCSB), University of Luxembourg, Luxembourg*

Non-target screening of surface water samples collected over an extended period enables the identification of temporal patterns in exposome-related pollutants. This approach, combined with geographical data on pollution sources, chemical classification, and flow paths, provides valuable insights into the origins and potential risks associated with tentatively identified chemical compounds. In this study, 271 surface water samples from Luxembourg were analysed using high resolution mass spectrometry, complementing routine target monitoring efforts in 2019-2022. Data analysis was performed using the open-source R-package 'patRoon' with a customized non-target workflow. Various scoring terms and identification levels were used to prioritize tentative identifications based on factors such as spectral similarity. Additional database information (*PubChemLite*) and classification software (*classyFire*) were utilized to assess the overall threat posed by the tentatively identified chemicals and prioritize them for future confirmation through targeted methods. The study tentatively identified 378 compounds associated with the exposome, including benzenoids or organoheterocyclic compounds (11 *classyFire* superclasses, 50 sub-classes). The analysis of these compounds revealed temporal variations, with a notable increase in numbers of agrochemicals in May to July. The prevalence of pharmaceuticals such as tramadol in surface waters was also observed. Furthermore, the study investigated potential sources of pollutants by considering common uses and geographical information. The commercial uses of the identified chemicals were largely known (almost 100%), indicating potential contributions from sources like the metallurgic industry and household products. The findings of this study complement existing knowledge on the pollution status of surface water in Luxembourg by tentatively identifying chemicals of concern for potential future inclusion in targeted monitoring methods following additional confirmation and quantification efforts.

3.09.P-We168 Exploring the environmental risk of pesticides and transformation products in agricultural area using extensive LC-HRMS screening

Daeho Kang *and Junho Jeon, Department of Environmental Engineering, Changwon National University, Korea, Republic of (South)*

The intensive use of pesticides and the formation of active transformation products (TPs) are of increasing concern as they are extensively detected in agricultural areas. A comprehensive screening approach is needed to profile pesticides and TPs in watershed near agricultural fields. In this study, an extensive screening method using LC-HRMS was developed not only for 328 targets but also for suspects and unexpected substances. To enrich samples, the solid-phase extraction method using a multi-layer cartridge was utilized. High-frequency composite sampling was performed to explore time-dependent contaminant profiles during 12 stormwater and 7 dry events. Consequently, 21 pesticides and 2 TPs were recognized as major pollutants in the study field. The priority pesticides included bromobutide with the highest mean concentration of 1,800 ng/L, followed by bentazone (910 ng/L), and imidacloprid (560 ng/L). Gaussian curve fitting demonstrated a significant relationship between the pesticide application date and the concentrations of the major pesticides (slope: 0.8365, R^2: 0.8634). The occurrence trend of pesticides during stormwater event was distinguishable from their TPs, resulting in the identification of clothianidin as TP of thiamethoxam. Additionally, suspect and non-target screening revealed 8 pesticides and 49 TPs. Several TPs (e.g., metolachlor-ESA, thiacloprid-amide, 2-amino-4,6-dimethoxypyrimidine) exhibited more frequent and intense detections compared to their parent compounds. Following European Directive 2013/39/EC criteria (100 ng/L), typically, pesticides showed higher concentrations at stormwater events (51.8%) than dry season (33.6%). Among them, thiacloprid and penoxsulam exceeded criteria only during storm events. This result suggests that the occurrence profile of pesticides and TPs in agricultural fields is highly affected by the application period. To assess environmental risk for pesticides and their TPs, toxicity values were retrieved from environmental quality standards, regulatory acceptable concentrations, and ECOTOX experimental data. For 2 pesticides (i.e., clothianidin and chlorantraniliprole), acute toxicity criteria exceedances above 50% were detected. Especially, the high RQ estimate for clothianidin indicates the potential hazard to aquatic organisms in adjacent streams.

3.09.P-We169 Identification of source-specific pollutant patterns and possible indicator parameters of particulate matter emissions from rail transport

Sabrina Michael[1]*, Gina Elisa Bode*[1]*, Ulrich Vogt*[2]*, Daniel -Ricardo Obando-Nunez*[2]*, Ingo Düring*[3] *and Markus Zingelmann*[4]*, (1)Environment and Sustainable Mobility, German Centre for Rail Traffic Research at the Federal Railway Authority, Germany, (2)Institute of Combustion and Power Plant Technology, University of Stuttgart, Germany, (3)Lohmeyer Ltd, Germany, (4)Beak Consultants GmbH, Germany*

Since 2021, the German Centre for Rail Traffic Research (DZSF) has been operating an environmental monitoring network along railroads in Germany by investigating the source-related pollution via various entry paths into different environmental compartments. The investigations focus on seepage water, surface water, groundwater and soil. In addition to engine-related and operational emissions, the need for robust information and studies on abrasion-related emissions has also increased due to possible legal regulations. The primary sources are brake abrasion, rail abrasion, and to a lesser extent, wheel and contact wire abrasion. The aim of the current study is to identify abrasion-related pollutant patterns and the associated elementary indicator parameters of rail traffic in different environmental compartments. For this purpose, extensive test bench and field studies on particulate air pollutants and abrasion emissions were carried out and compared with the results of the environmental monitoring network. The particulate matter emissions were collected on quartz fibre filters (PM10) at a brake test bench and at two field locations (open track and marshalling yard). The measurement setup of the field sites consists of four sampling points (cross-sectional profile and luv-lee-concept) with a measurement duration of several months each. The elemental composition is characterized using inductively coupled plasma - mass spectrometry. In addition, soil samples at different depths and at different distances from the track-axis, precipitation-dependent seepage water samples as well as surface and groundwater samples were taken and analysed at the DZSF environmental monitoring sites. All analyses and sampling were carried out using standardized methods. The results show that both, the particulate matter filter samples from the air monitoring and the environmental samples, have a comparable element composition, particularly in the upper soil layers. In addition, a clear zoning of the heavy metal contamination from the center of the track to the peripheral areas can be demonstrated. The combination of test bench and field tests with different dispersion modelling approaches enables a deeper understanding of the dispersion of pollutants along track systems. The investigations form the first step towards an adapted environmental risk assessment of railroad tracks and the identification of possible indicator substances from abrasion processes in rail traffic.

3.09.P-We170 Identifying Source-Specific Contaminant Fingerprints in Waste and Surface Water from High Resolution Mass Spectrometry Data

Alain Hoyek[1,2]*, Carolin Huber*[1]*, Melis Muz Massei*[1]*, Jörg Hackermüller*[3]*, Martin Krauss*[1] *and Werner Brack*[1,4]*, (1)Department of Effect-Directed Analysis, Helmholtz Centre for Environmental Research (UFZ), Germany, (2)Faculty of Biological Science, Goethe University Frankfurt, Germany, (3)Department of Computational Biology, Helmholtz Centre for Environmental Research (UFZ), Germany, (4)Evolutionary Ecology & Environmental Toxicology, Goethe University Frankfurt, Germany*

The increasing presence of chemicals in our environment poses a significant risk to both humans and the ecosystems in water and soil. The extensive abundance of substances available can lead to complex chemical combinations affecting both people and organisms, potentially causing harm to human health and ecosystems. Therefore, this study aimed to investigate these complex mixtures, establish connections between their chemical compositions and their origins of pollution and pinpoint unique contaminant patterns specific to different sources. Employing a comprehensive approach using statistical analysis and machine learning, the study analyzed the chemical composition of many wastewater samples from different sources to identify source-specific contaminant fingerprints associated with each source, enabling the prediction of where contaminants originate from.

Wastewater samples were collected from eight distinct sources: food industry, healthcare, landfills, laundries, metal industry, snow, stormwater and vehicle industry. These samples were subjected to analysis using LC-HRMS technology and a variety of analytical screening techniques to decode their chemical compositions. Following this, statistical methods were utilized to examine the variations in chemicals among the different sources, identify the compounds most associated with each source and isolate compounds suitable for predictive analysis. Subsequently, machine learning models were developed to classify and predict the source of each sample. The validity of the models was confirmed using the leave-one-out cross-validation method and the performances of the models were assessed based on their accuracy, precision, recall and specificity.

The top-performing model accurately predicted the sources of 88% of the samples. Some samples showed higher accuracy in predicting their sources, like stormwater (100%), metal industry (92%) and food industry (89%), while others like landfills had a lower accuracy at 71%. This suggests that sources with higher prediction accuracy display a more unique chemical pattern specific to their source, making their identification comparatively easier than those with lower prediction accuracy.

These findings show that certain sources release distinct chemical traces into the environment, highlighting the need to identify these patterns for better monitoring. This is critical, especially in detecting harmful compounds affecting human health and ecosystems.

3.09.P-We171 What Does Brake Abrasion in Rail Traffic Consist of? – Physical and Chemical Characterization of Different Brake Abrasion Samples From Rail Traffic

Gina Elisa Bode[1]*, Simon Wieland*[2]*, Holger Kress*[2]*, Andreas Schäffer*[3] *and Sabrina Michael*[1]*, (1)Environment and Sustainable Mobility, German Centre for Rail Traffic Research at the Federal Railway Authority, Germany, (2)Experimental Physics VI, Biological Physics Group, University of Bayreuth, Germany, (3)Institute for Environmental Research, RWTH Aachen University, Germany*

Non-exhaust emissions become increasingly important in the transport sector, particularly as a result of new drive systems. Although rail transport is generally regarded as an environmentally friendly mode of transport, significant abrasion-related emissions are produced during operation. A major source of these emissions are mechanical brakes. Mechanical brakes include disc brakes (sintered, organic brake pads), which are mainly used in passenger transport and block brakes (cast iron, organic brake blocks (LL-, K-blocks)), which are used in freight transport. Organic brakes show improved noise characteristics compared to cast iron brakes, but the exact composition of the used composite materials is currently unregulated and largely

unknown.
In order to be able to identify brake emissions in environmental samples and assess the potential risk to humans and the environment, information on the morphology and chemical composition of the abrasion particles is necessary. Due to the large number of different brake types and their diverse material composition, little information is currently available on the characteristics of these emissions.

Therefore, in this study we analyzed the morphology and chemical composition of brake abrasions of different brake types. To obtain pure abrasion samples, air pollutant measurements were carried out on a brake test bench using disc brakes and block brakes consisting of cast iron, sintered and organic materials. Selected filter samples were analyzed regarding their elemental composition and morphology, using scanning electron microscopy with energy dispersive x-ray spectroscopy (SEM-EDX). First results show that C, O, Na, Mg, Al, S, Ca, Ti, Mn, Fe and Zn could be identified in different samples from block brakes. The material composition of the abrasion emissions of the different brake blocks differ from each other, whereby Fe, C and O could be detected in all samples. In a next step, further chemical analyses (e.g. pyrolysis gas chromatography/mass spectrometry) are planned to characterize the material composition of abrasion emissions from organic brakes. The data collected will be incorporated into an initial risk assessment, the identification of indicator parameters and contribute to a cross-modal assessment of non-exhaust emissions.

3.09.P-We172 Assessment of endocrine disruptive potencies of air and dust samples from different indoor environments by a battery of in vitro bioassays

Jiri Novak[1]*, Felipe Vidal*[1]*, Lisa Melymuk*[1]*, Jonathan W. Martin*[2]*, Adria Sunyer*[2] *and Klara Hilscherova*[1]*, (1)RECETOX, Masaryk University, Czech Republic, (2)Stockholm University, Sweden*

Humans are exposed to complex mixtures of chemicals throughout their lives. Besides food, the indoor environment is probably the main source of exposure. Major part of human population spends most of their life in the indoor environment, which, due to limited ventilation and the presence of significant sources of chemicals, makes it very relevant for human exposure and potential adverse health impacts. Moreover, numerous chemicals detected indoors exhibit endocrine-disrupting properties.

To assess the endocrine disruptive potential of indoor chemical mixtures, a series of in vitro bioassays were conducted on both indoor and outdoor air samples, as well as indoor settled dust samples collected from various indoor environments. Human-based reporter gene assays were employed to evaluate the effects associated with endocrine system disruption, including estrogenicity, anti-androgenicity, and AhR-mediated toxicity. The results revealed multiple endocrine-disrupting potentials in the majority of the samples.

To place these findings in context with chemical analysis, the identified potentials were compared with potencies predicted by the iceberg modeling based on the analytical data. However, due to either insufficient toxicity data for the identified chemicals or incomplete coverage of the effect drivers in the chemical analyses, the explanatory power was relatively low for most of the observed effects.

The gaps in pinpointing indoor pollutants responsible for the evaluated effects, coupled with the widespread presence of endocrine-disrupting potentials within indoor environments, raise concerns about potential health risks for the human population in these settings.

This project received funding from the European Commission Horizon Europe, HADEA, research and innovation programme under grant agreement Project No 101057499 - INQUIRE.

3.09.P-We173 Effects of textile wastewater from wet processing using effect-based methods

Stella Jennes[1]*, Mira Goßen*[2]*, Dhivakar Govindarajan*[3]*, Anju Anna John*[4]*, Indumathi M Nambi*[5]*, Sabrina Schiwy*[6] *and Henner Hollert*[6]*, (1)Evolutionary Ecology & Environmental Toxicology, Goethe University Frankfurt, Germany, (2)Goethe University Frankfurt, Germany, (3)Indian Institute of Technology Madras (IITM), Chennai, India, (4)Indian Institute of Technology Madras (IIT Madras), India, (5)Indian Institute of Technology Madras, India, (6)Evolutionary ecology and environmental toxicology, Goethe University Frankfurt, Germany*

Only 3 % of the water on earth is freshwater, making it a limited resource. Textile wastewater is one of the main factors for surface water pollution, especially in central textile-producing countries such as India. Contributing factors include India's high population density and increasing industrialisation. Currently, water quality assessment of textile wastewater in India is limited to analysing physico-chemical parameters such as pH, biochemical oxygen demand (BOD) and chemical oxygen demand (COD), leading to an underestimation of the environmental risk. If untreated or insufficiently treated wastewater enters the environment, it can have adverse effects on aquatic organisms such as acute toxicity, neurotoxicity and endocrine activity. Therefore, further test systems are needed to assess the complex mixture of components contained in textile effluents and develop better wastewater treatment technologies. In this context, effect-based methods (EBMs) are useful to detect the mode of action of chemicals. Samples of the raw textile wastewater were obtained from the textile industry MS/Rohini, Erode in Tamil Nadu in India. The samples were divided into two fractions via SPE using HLB cartridges. One hydrophilic and organic fraction and one lipophilic and inorganic fraction. The hydrophilic fraction of wastewater often contains pharmaceuticals, hormones and detergents whereas the lipophilic phase can contain heavy metals. Cytotoxicty of the raw textile wastewater and fractions was tested on cell-based level using the Neutral Red assay. First results show the highest cytotoxicity for raw wastewater and the lowest cytotoxicity for the hydrophilic and organic fraction. Further, endocrine effects will be investigated in the CALUX® Assay as well as dioxin-like effects with the micro-EROD assay. In addition neurotoxic effects will be tested in behavioural assays using *Danio rerio*.

3.09.P-We174 Aromatic Amine Fingerprints of Different Human Activities From Indoor Environments – Textiles as Passive Samplers

Anna Goellner[1,2]*, Tomisin Ifeoluwa Babalola*[1]*, Özge Edebali*[3]*, Lisa Melymuk*[4]*, Martin Krauss*[1]*, Werner Brack*[1,2] *and Melis Muz Massei*[1]*, (1)Department of Effect-Directed Analysis, Helmholtz Centre for Environmental Research (UFZ), Germany, (2)Department of Evolutionary Ecology and Environmental Toxicology, Goethe University Frankfurt, Germany, (3)Faculty of Science, RECETOX, Masaryk University, Czech Republic, (4)RECETOX, Masaryk University, Czech Republic*

Indoor human activities lead to the generation of many contaminants that could end up in grey water and reach surface waters when they are not efficiently removed by wastewater treatment plants. When reaching the receiving waters, they contribute to observed adverse effects including mutagenicity. This poses problems for the drinking water production as well as the aquatic habitat itself. Aromatic amines (AAs), many of which are suspected/known mutagens, have been shown to play a role in surface water mutagenicity, although their emission sources have not yet been fully investigated. It is known that several human activities such as smoking tobacco, meat frying, and hair dying generate AAs in indoor environments. Their transport from indoors to surface waters can be one of the sources with a significant contribution to their presence in water bodies. A pathway of indoor-related AAs to surface waters is through adhering to textiles which act as passive samplers and release to grey water by laundry washing of these textiles.

In this study, we aim to obtain chemical fingerprints of AAs linked with well-known AA related indoor activities. For that purpose, we organized a sampling campaign in smoking pubs (n=3) hair salons (n=3) and restaurant kitchens with high meat throughput (n=3), where we hung different types of fabrics (cotton, wool and polyester) representing typical textile surfaces indoors to understand their affinity to AA adsorption. In order to evaluate background AA contamination, households of non-smokers that did not prepare and consume meat were also included (n=3).

Several challenges complicate the extraction of AAs from different fabrics. Specifically, high matrix effects due to additives used on textiles such as waxes and fats, and strong bonds forming between functional groups of fabrics and amines. Considering these aspects, we developed a total extraction method that resulted in characterizing indoor activity-specific fingerprints of AAs from 24-hour exposed textiles in aforementioned sampling locations. Using a target and suspect screening method for AAs known to be linked with these activities, the results allow us not only to characterize the AAs humans are exposed to from indoor environments but also to understand the extent of indoor environments as a source of AAs in surface waters for better mitigation efforts to reduce surface water mutagenicity.

3.09.P-We175 Passive Air Sampling Networks Combined with Multivariate Statistics Reveal Widespread Non-Aroclor Polychlorinated Biphenyl Sources to the Atmosphere

Jenny Oh[1]*, Chubashini Shunthirasingham*[2]*, Faqiang Zhan*[3]*, Yuening Li*[3]*, Ying Duan Lei*[4]*, Amina Ben Chaaben*[5]*, Zhe Lu*[6]*, Frank Gobas*[7]*, Kelsey Lee*[7]*, Hayley Hung*[8] *and Frank Wania*[3]*, (1)Department of Chemistry, University of Toronto, Canada, (2)Environment and Climate Change Canada, Canada, (3)Department of Physical and Environmental Sciences, University of Toronto, Canada, (4)University of Toronto, Canada, (5)Institut des Sciences de la Mer de Rimouski (ISMER), University of Quebec at Rimouski (UQAR), Canada, (6)University of Quebec at Rimouski (UQAR), Canada, (7)Simon Fraser University, Canada, (8)Air Quality Processes Research Section, Environment and Climate Change Canada, Canada*

Polychlorinated Biphenyls (PCBs) are the archetype of a complex chemical mixtures in the environment. Atmospheric PCBs were initially thought to originate from the volatilization of commercial Aroclor mixtures, but there is growing evidence of non-negligible atmospheric emissions of non-Aroclor, i.e., unintentionally produced, PCBs. However, the abundance of congeners with both Aroclor and non-Aroclor origins proves distinguishing and quantifying Arolor and non-Aroclor sources to be a difficult task, and thus studies have been limited. In particular, a comprehensive source appointment of atmospheric PCBs has yet to be done in Canada. To overcome these challenges, we obtained the PCB fingerprints from PAS networks installed across the coastal regions of Quebec (QC) and British Columbia (BC), Canada. The measured fingerprints were then investigated with hierarchical cluster analysis (HCA), to identify distinct regional PCB sources with characteristic congeneric patterns of Aroclors and non-Aroclors. Urban areas, such as Vancouver, BC; Montreal, QC; and Quebec City, QC, showed high levels of a wide range of congeners suggesting origins of Aroclor use. This is consistent with the region's high population density and industrial history. Non-Aroclor exclusive congeners, e.g., PCB-11, were also found, suggesting the widespread release of non-Aroclor congeners to the Canadian atmosphere. PCB-47, 51, and 68, known byproducts of the decomposition of the cross-linking agent 2,4-dichlorobenzoyl peroxide (2,4-DCBP) used in silicone rubber production, were also found together in multiple regions across Canada. These congeners were also strongly associated with PCB-7 and 25, suggesting that the two congeners are minor but non-negligible byproducts of 2,4-DCBP decomposition. Positive matrix factorization (PMF) was then employed to quantify non-Aroclor PCBs contributions to the Canadian atmosphere and had estimated that at least 25% may have non-Aroclor origins. Of the known non-Aroclor sources, decomposition of 2,4-DCBP has only been previously observed as a source of PCBs to indoor air or as a point source, whereas evidence here suggests that the use of 2,4-DCBP is an ongoing widespread non-Aroclor source in Canada. It is likely that 2,4-DCBP is still prevalent in the manufacturing of commercial products not just in North America but also elsewhere in the world, despite alternative non-chlorinated cross-linkers being available, such as bis(4-methylbenzoyl)peroxide.

3.09.P-We176 Mapping the Gaseous Outdoor Inhalation Exposome: Archetypes of Spatial Concentration Variability of Organic Trace Contaminants in the Atmosphere

*Faqiang Zhan[1], Yuening Li[1], Chubashini Shunthirasingham[2], Jenny Oh[3], Ying Duan Lei[4], Amina Ben Chaaben[5], Zhe Lu[5], Kelsey Lee[6], Frank Gobas[7], Hayley Hung[8] and **Frank Wania**[1], (1)Department of Physical and Environmental Sciences, University of Toronto, Canada, (2)Environment and Climate Change Canada, Canada, (3)Department of Chemistry, University of Toronto, Canada, (4)University of Toronto, Canada, (5)Institut des Sciences de la Mer de Rimouski (ISMER), University of Quebec at Rimouski (UQAR), Canada, (6)Simon Fraser University, Canada, (7)Resource & Environmental Management, Simon Fraser University; School of Resource & Environmental Management, Canada, (8)Air Quality Processes Research Section, Environment and Climate Change Canada, Canada*

Whereas inhalation exposure to organic contaminants has been proven to negatively impact human health, knowledge of spatial patterns of such contaminants remains limited. Extracts from a total of 170 passive air samplers, deployed at 119 unique sites across two Southern Canadian regions between 2019 and 2022, were analyzed for 353 organic trace substances. Hierarchical clustering, applied to deployment-length normalized concentrations in units of pg per day of sampling using R, revealed four common types of spatial concentration variability in the outdoor atmosphere. "Point Source" signatures are characterized by elevated concentration in the vicinity of major release locations. A “Population” signature applies to compounds whose air concentrations are highly correlated with population density and is often seen for compounds that originate from the use of consumer products. The “Water Source” signature applies to substances with elevated levels in the vicinity of water bodies, from which they evaporate. Another group of compounds displays a “Uniform” signature, indicative of a lack of major sources within the study area. These spatial patterns can be applied to support the identification of sources, quantify emissions, examine associations with health effects, support environmental justice investigations and facilitate prioritization of chemical feature during non-target analysis. In particular, "Point Source" spatial patterns can serve in the identification of individual facilities or industrial sectors likely to contribute atmospheric emissions. By assuming that the emission intensity of chemicals with "Population" signatures scales spatially with population density, it is possible to apply inverse modeling approaches to the measured atmospheric concentrations to derive population-normalized emission factors. Knowledge of spatial pattern of toxic organic air pollutants can further support environmental justice investigations or epidemiological studies seeking associations with health effects. Finally, spatial pattern in the peak intensity of chemical features detected in the non-target analysis of samples from a PAS network could serve in the prioritisation of those features that are worthy of closer investigation and structure elucidation.

3.09.P-We177 A fast and novel workflow for screening smoke from forest fires affecting food quality by SPMESH-DART-MS/MS

***Noud van der Borg**[1], Carsten Baessmann[2], Terry Bates[3], Jordan Krechmer[3] and Francois Espourteille[3], (1)Bruker Nederland B.V., Netherlands, (2)Bruker Daltonics GmbH, Germany, (3)Bruker*

Smokes from bushfires can seriously influence the quality of food and beverages in adjacent regions. E.g., in case of bushfire events near vineyards, potentially generated volatile phenols (VP) are monitored via chromatography-based analyses for quality control. Throughput limitations inherent to chromatography-based approaches can lead to analytical bottlenecks when a large sample number needs to be run in a short time period like during harvest. We report a rapid screening method for routinely monitored VP using solid phase mesh enhanced sorption from headspace to a chromatography-free direct analysis mass spectrometer (SPMEsh-DART-MS) in a highly automated mode. This workflow provides enhanced data quality, faster results, and improved cost efficiency compared to traditional chromatographic screening approaches.

The screening workflow includes the VP 4-ethylphenol (**1**), 4-ethylguiacol (**2**), guaiacol (**3**), 4-methylguaiacol (**4**), and o-cresol (**5**). Sample preparation (~1.5 hours) was performed for 24 samples in parallel as described in [1]. Following sample preparation and extraction, the SPMEsh sheet was transferred to the automated positioning stage of an EVOQ DART-TQ+ triple quad mass spectrometer. MS/MS parameters were optimized (collision energies, collision cell pressure, and scan speed). Matrix matched calibration QC were analyzed, using d3-guaiacol as IS for all compounds. Regression curves were analyzed at 6 calibration levels in quadruplicate including matrix blanks. Accuracy was assessed using 2 QCs analyzed in quadruplicate.

The automated DART-MS/MS analysis of 24 samples was performed in just 12 minutes. Data processing was performed using as tandard MS quantitation software with linear regressions of $R^2 \geq 0.99$ and recoveries of 90 – 110% at 5 µg/L and 25 µg/L concentration levels. The total workflow time for 24 samples was < 1.5 h. Full workflow simplicity, sample throughput, and data quality meet or exceed the accepted metrics of conventional approaches.

References: [1] Terry L. Bates, Gavin L. Sacks. Rapid headspace solid-phase microextraction sheets with direct analysis in real time mass spectrometry (SPMESH-DART-MS) of derivatized volatile phenols in grape juices and wines, Analytica Chimica Acta, Volume 1275, 2023.

3.09.P-We178 Leveraging Machine Learning and Multi-modal Analytical Techniques for Enhanced Source Tracking of Microplastics

Huy Manh Nguyen *and Roxana Suehring, Chemistry and Biology, Toronto Metropolitan University, Canada*
Regulatory interventions in mitigating microplastic pollution face significant obstacles due to the inherent challenges in accurately identifying sources, due to the variety of microplastics and microplastic sources in the environment. To enhance source tracking capabilities, our study introduces a sophisticated computational fingerprinting workflow. This workflow integrates non-targeted data gathered from two analytical techniques—thermal desorption gas chromatograph–mass spectrometer (TD-GC-MS) and high-performance liquid chromatography with quantitative time-of-flight mass spectrometry (HPLC-qToF-MS)—to discern unique chemical fingerprints based on additive compositions. To interpret this rich dataset, an ensemble of supervised machine learning algorithms was applied, including Random Forest, Gradient Boosting, Support Vector Machine, and Penalized-Multinomial Logistic Regression (P-MLR). These algorithms were employed to classify and identify the sources of both store-bought and environmental microplastics in environmental samples from five major plastic product categories: children's toys, construction materials, food contact materials, cigarette tips, and face masks. Using multiple Wilcoxon tests and p-value correction methods, a set of at least 26 tracer compounds was identified, capable of distinguishing between the selected product categories. Among the tested machine learning methods, Random Forest and P-MLR showed the highest prediction accuracy, especially when trained with the composite dataset from TD-GC-MS and HPLC-qToF-MS. Our results underscore the potential of machine learning algorithms in advancing the science of microplastic source identification. The study further elucidates a robust methodology for classifier and feature selection, offering valuable insights for optimizing source tracking efforts based on additive compositional fingerprints. In summary, this research stands as a pioneering effort that fuses artificial intelligence with advanced analytical chemistry methods to provide an innovative approach for tackling the critical environmental challenge of microplastic pollution.

3.09.P-We179 “In Vivo” ECOD Assay: A Proxy To Unveil Biotransformation In Sediment-Dwelling Invertebrates.
Elettra D'Amico[1]*, Martina Santobuono*[2]*, Kevin Noort*[3]*, Wing Sze Chan*[2] *and Henriette Selck*[2]*, (1)INM, Roskilde University (RUC), Denmark, (2)Roskilde University (RUC), Denmark, (3)UK Centre for Ecology & Hydrology (UKCEH), United Kingdom*
The purpose of this study was to optimize the "in vivo" ECOD assay (7-ethoxycoumarin-O-dealkylation) for sediment-dwelling organisms to assess their biotransformation abilities when exposed to sediment-associated hydrophobic contaminants. The ECOD assay is a powerful tool used to measure Cytochrome P450 (CYP450) activity in aquatic invertebrates. The "in vivo" assay is considered more accurate than the “in vitro” method for quantifying CYP450 activity and provides a time-dependent quantification using live test species. However, "in vivo" ECOD assay has only been performed on a few aquatic invertebrate species, and to our knowledge, it has not been optimized for sediment-dwelling organisms. The principle of the ECOD assay involves exposing the organisms to the substrate 7-ethoxycoumarine, which is metabolized to metabolites that produces fluorescence under specific conditions. The intensity of fluorescence is correlated with the metabolite concentration, allowing for quantification of CYP450 activity. This assay was optimized for *Capitella teleta*, a sediment-dwelling organism known for efficient biotransformation of persistent organic pollutants. Individual worms were exposed to sediment spiked with PCBs or Sertraline, and fluorescence detection was performed at regular intervals. Statistical analysis showed that time and treatment interactions were significant, indicating that the treatments had a significant impact on the results. The optimized "in vivo" ECOD assay successfully quantified CYP450 activity in sediment-dwelling organisms exposed to hydrophobic compounds. The method proved to be effective in measuring CYP450 activity in deposit-feeding organisms and can be used as a powerful tool for assessing the effects of sediment-associated contaminants. Further investigations with different species and contaminants are needed to evaluate the efficiency of this optimization.

3.09.P-We180 "Identification of AhR active compounds in sediments of highly industrialized area: Application of effect-directed analysis combined with full-scan screening"
Jiyun Gwak[1]*, Junghyun Lee*[2]*, Jihyun Cha*[1]*, Hyo-Bang Moon*[3]*, Jong Seong Khim*[4] *and Seongjin Hong*[1]*, (1)Department of Marine Environmental Science, Chungnam National University, Korea, Republic of (South), (2)Department of Environmental Education, Kongju National University, Korea, Republic of (South), (3)Department of Marine Science and Convergence Engineering, Hanyang University, Korea, Republic of (South), (4)School of Earth and Environmental Sciences & Research Institute of Oceanography, Seoul National University, Korea, Republic of (South)*
Gamcheon Harbor, the largest port city (Busan) in South Korea is surrounded by various industrial complexes, such as a ship repair pier, container yard, building material yard, aquatic product plant, and Busan international fish market. The concentrations of traditional polycyclic aromatic hydrocarbons (t-PAHs, n=15), emerging PAHs (e-PAHs, n=16), and styrene oligomers (SOs, n=10) in the sediments of Gamcheon Harbor were detected at all sites (n=12, S1–S12). Several t-PAHs, e-PHAs, and SOs are known to be aryl hydrocarbon receptor (AhR) agonists. The concentration ranges of AhR-active t-PAHs, e-PAHs, and SOs in sediments of S1–S12 were 44–790, 72–290, and 12–420 ng g^{-1} dm, respectively. These results indicated that AhR-active substances might be introduced from surrounding industrial complexes. Effect-directed analysis (EDA) combined with full-scan screening analysis (FSA) was conducted to identify novel AhR agonists in sediments from Gamcheon Harbor. The AhR-mediated potencies were assessed in organic extracts, silica gel fractions, and RP-HPLC fractions of the sediments using the H4IIE-*luc* bioassay. Relatively high AhR-mediated potencies were observed in F2.7–F2.8 (mid-polar, log K_{OW} 6–8) and F3.6–F3.7 (polar, log K_{OW} 5–7) of S1 and S4. Target AhR agonists accounted for only a portion of induced AhR-mediated potencies (up to 43%). FSA was performed for the F2.7–F2.8 and F3.6–F3.7 of S4 using GC-QTOFMS and LC-QTOFMS, respectively. Through four-step selection criteria, such as 1) all detected peaks, 2) matched with library 3) matching score ≥70, and 4) presence of aromatic ring, triphenlybenzene in F2.7 and trenbolone, daphnoretin, and isorhamnetin in F3.6 were selected as tentative AhR agonists. Among these, daphnoretin and isorhamnetin showed significant AhR-mediated potency.

The relative potency values of daphnoretin and isorhamnetin compared to benzo[*a*]pyrene were 0.4×10^{-3} and 6.5×10^{-5}, respectively. The results of this study are significant that provide useful information for the selection and management of the priority substances in the coastal environments.

3.09.P-We181 Effect-directed analysis of proteins with high antibacterial activity. A proof-of-concept.
*Maddi Salvoch Vilches[1], Olatz Sainz[1], **Naroa Lopez**[2], Zuriñe Baña[1], Mireia Irazola-Duñabeitia[3] and Nestor Etxebarria[2], (1)University of the Basque Country (UPV/EHU), Spain, (2)Department of Analytical Chemistry, University of the Basque Country (UPV/EHU), Spain, (3)Analytical Chemistry, University of the Basque Country (UPV/EHU), Spain*
The increasing prevalence of antimicrobial-resistant pathogens has become a global public health concern. Therefore, in the search and development of new antimicrobial agents, the oceans become an attractive source. With the aim of identifying new proteins with antimicrobial properties of marine bacteria origin, a new application based on effect-directed analysis (EDA) is proposed in the present work. Based on the conventional EDA scheme, a new methodology readapted for the identification of proteins in exudates of marine bacteria is proposed. The aim of this work has been to develop both the fractionation and the subsequent proteomic analysis for the identification of new antimicrobial agents, replacing the bioassays by evaluation of antimicrobial activity. In previous studies, the well diffusion test was optimised as a method for the detection of antimicrobial activity in marine bacteria. Once the activity had been detected, in order to simplify the exudate’s complexity, fractionation was carried out with a high-resolution size exclusion column and the antimicrobial activity was re-evaluated in each fraction. Finally, once the active fraction was identified, the fraction was analysed by ultrahigh-performance liquid chromatography coupled to high-resolution tandem mass spectrometry in order to identify the protein or peptide responsible for the antimicrobial activity. A first study was conducted to confirm that the new antifungal property detected in the exudate of the marine bacterium *Marinomonas mediterranea* originates from the same protein as the antibacterial property. As seen that the developed method is applicable to another type of marine bacterial exudates, its application has been extended to the identification of antimicrobial agents from the Marine Microbial Collection of the UPV/EHU, which have already demonstrated both antibiotic and antifungal activities of clinical interest. This work shows an extended approach to effect-directed analysis focused to the identification of proteins with a high bioactive role such as the antibiotic and antifungal activity. Size exclusion chromatography with rapid antibiograms and LC-HRMS were successfully combined to demonstrate the affordability of this approach.

3.09.P-We182 Assessment of sediment-associated marine microalgal toxicants in industrialized area, South Korea: Application of effected-direct analysis using microalgal bioassay with multiple endpoints
***Junghyun Lee**[1], Jiyun Gwak[2], Hyo-Bang Moon[3], Seongjin Hong[2] and Jong Seong Khim[4], (1)Department of Environmental Education, Kongju National University, Korea, Republic of (South), (2)Department of Marine Environmental Science, Chungnam National University, Korea, Republic of (South), (3)Department of Marine Science and Convergence Engineering, Hanyang University, Korea, Republic of (South), (4)School of Earth and Environmental Sciences & Research Institute of Oceanography, Seoul National University, Korea, Republic of (South)*
Microalgal toxicants in marine sediment from industrialized areas in South Korea were identified using effected-directed analysis (EDA). In the first study, EDA was performed to use microalgal bioassay. It was conducted with three marine microalgal (*Dunaliella tertiolecta*, *Isochrysis galbana*, and *Phaeodactylum tricornutum*) and utilized multiple endpoints using flow cytometry. In sub-fractions of S1 sediment raw extracts (RE), the most potent fractions at three species were only F2.6 (non-polar, Log KOW 5–6) based on growth inhibition. However, the cell viability endpoints were affected in more fractions, including F2.6–7 (non-polar, Log KOW 5–7) and F3.5–6 (polar, Log KOW 4–6). Among the cell viability endpoints, esterase activity seemed to be more sensitive, cell membranes and Chl. a were similar, and cell size and intracellular complexity indicated more insensitive than growth inhibition. In the second study, we combined full-scan screening analysis (FSA) to identify unknown microalgal toxicants. In Ulsan Bay, the concentration of targeted compounds could not be sufficiently explained by toxic responses, indicating the presence of unknown toxicants. From the FSA, thirty-one compounds were selected as candidates toxicants. Seven commercially available compounds were confirmed for distribution in Ulsan Bay. Among them, 2-Nitrophenol, 3-Nitrophenol, and 4-Nitrophenol were suggested as unmonitored algal toxicants. In the third study, we performed EDA with improved microalgal bioassay and FSA. The result of exposed sediment extracts and silica gel fractions from Gamcheon Harbor showed differences between microalgal species. The *D. tertiolecta* was more sensitive at F2 and *P. tricornutum* is F3. It seems to be different type of cell membrane (*D. tertiolecta*: glycocalyx-like cell membrane, *P. tricornutum*: thick and hard cell wall). Result of FSA, the 8 microalgal toxicants were confirmed. And, the EC50 of newly microalgal toxicants in sediment from Gamcheon Harbor was suggested. Identified unknown microalgal toxicants were performed successfully using EDA. Microalgal bioassay combined cell viability with flow cytometry provided more sensitive and detailed physiological responses, which do not allow traditional endpoints. Unknown microalgal toxicants were successfully identified by use of EDA with FSA. In further study, the distribution, source, fate, and ecotoxicity of newly identified microalgal toxicants need to investigate.

3.09.P-We183 Developing an Effect-Directed Analysis Approach for Prioritizing CECs in Urban Groundwater
***Lyen Castro**, Anna Jurado and Victoria Osorio, Institute for Environmental Assessment and Water Research, Spanish*

Research Council (IDAEA-CSIC), Spain
Climate change exerts growing pressure on freshwater resources, particularly in southern Europe, where droughts are projected to be more frequent, intense and long. In the metropolitan area of Barcelona (Spain), the underlying urban groundwater (UGW) may serve as an alternative freshwater resource during these dry periods. However, its use may be hampered by the presence of a wide range of contaminants of emerging concern (CECs) which may pose risks to human health. A proper assessment of the groundwater quality in Barcelona is therefore necessary to ensure the safety of this potential drinking water resource. The primary objective of this work is to identify CECs that can be the main drivers of toxicity in UGW. To do this, an effect-directed analysis (EDA) approach using a zebrafish embryo bioassay will be developed as a strategic prioritization tool to identify CECs with relevant human health effects. In this approach, transcriptional alterations will be used as the basis for evaluating the toxicity of UGW samples and their fractions. Suspect and nontarget screening will be performed for the identification of CECs associated with the bioactive fractions, and when the key toxicants have been identified, target analysis will be conducted to quantify their concentrations in the aquifer. The EDA workflow developed in this project has the potential to be applied in the effect-based monitoring of other aquatic systems, and the results obtained in this study will be useful in contributing to a watchlist of priority substances in groundwater.

3.09.P-We184 Effect Assessment Of Urban Waters In Malawi And Identification Of Effect Drivers Using Pull-down Assay Coupled To Non-target Mass Spectrometry Analysis

Zuzana Toušová[1]*, Petra Mikusova*[2]*, Ludek Sehnal*[2,3,4]*, Roman Grabic*[5]*, Kateřina Grabicová*[6]*, Andrew Singer*[7]*, Nicolas Feasey*[8] *and Derek Cocker*[8,9]*, (1)RECETOX, Faculty of Science, Masaryk University, Czech Republic, (2)RECETOX, Masaryk University, Czech Republic, (3)Interfaculty Institute of Microbiology and Infection Medicine, University of Tübingen, Germany, (4)Cluster of Excellence EXC 2124 Controlling Microbes to Fight Infections, University of Tübingen, Germany, (5)University of South Bohemia in Ceske Budejovice, Faculty of Fisheries and Protection of Waters, Czech Republic, (6)University of South Bohemia in České Budějovice, Faculty of Fisheries and Protection of Waters, Czech Republic, (7)NERC Centre for Ecology & Hydrology, United Kingdom, (8)Department of Clinical Sciences, Liverpool School of Tropical Medicine, United Kingdom, (9)David Price Evans Infectious Diseases and Global Health Group, University of Liverpool, United Kingdom*

Water contamination with a broad spectrum of micropollutants originating from wastewaters, industry and agriculture is a global environmental issue, however, most research addressing this theme was performed in developed countries. Data on water pollution from developing countries are scarce despite of pressing need to introduce measures to ensure satisfactory water quality in poor regions with quickly growing populations suffering from multiple natural and socio-economic pressures.

Urban river water samples were collected with passive samplers at two streams draining a large high-density urban settlement (Ndirande) in Blantyre, Malawi, to compare chemical and effect profiles to the situation in Europe, and between dry and wet seasons typical for Sub-Saharan Africa. A battery of *in vitro* bioassays targeting endocrine endpoints was used to characterize the overall effects of compounds contained in the highly complex water extracts. We detected several effects i.e. estrogenicity, androgenicity, dioxin-like activity, agonism on thyroid hormone receptor and inhibition of binding to transthyretin protein (TTR). There were only minor differences between locations and seasons and we selected the TTR binding inhibition endpoint for detailed investigation to identify the causative compounds.

To this end, novel pull down assay approach based on highly specific protein-ligand interaction was used for separation of active ligands from the complex environmental extracts. Eluted ligands were subjected to non-target screening using a two-stage workflow. HRMS (High resolution mass spectrometry) full scan in ESI- and ESI+ (electron spray ionization) was acquired. Full scan data were processed by CompoundDiscoverer 3.3 workflow consisting of differential analysis to identify suspect signals for consequent LC – full scan MS1 combined with PRM (parallel reaction monitoring) MS2 acquisition. There were 40 compounds bound selectively to pull down protein at all investigated localities. On the other hand, there were about the same number of compounds specific only for one combination of site and season. Natural and synthetic chemicals were identified among pulldown-selected compounds at various Schymanski levels. Despite different pollution profiles and development levels, some highly active TTR compounds were identical to those in European waste and surface waters. The project has received funding from the Czech Science Foundation (GACR) under grant agreement GX20-04676X.

3.09.P-We185 Effected-directed Analysis of Belgian Municipal Wastewater Treatment Plant Effluent Using Cyanobacteria Microcystis Aeruginosa

Warich Leekitratanapisan[1]*, Frederic Lynen*[2] *and Karel De Schamphelaere*[1]*, (1)Ghent University - GhEnToxLab, Belgium, (2)Organic and Macromolecular Chemistry, Ghent University - Seperation Science Group, Belgium*

Municipal wastewater treatment plant (WWTP) effluents are a primary source of organic micropollutants (OMPs) in the aquatic environment. Pesticides, industrial chemicals, human drugs, and antibiotics are examples of OMPs that have low removal efficiency with conventional wastewater treatment technologies.This could lead to a harmful impact on aquatic wildlife. Therefore, identifying the main toxicity drivers is imperative for developing advanced wastewater treatment technology to eliminate such risks. However, this identification process is challenging due to the myriad of OMPs and their transformation products in the environmental samples and the limited analytical capacity to detect trace concentrations of these compounds.Effect-directed analysis (EDA) is a useful approach that involves effect-based monitoring and fractionation to reduce the compound mixture complexity before identifying compounds of environmental relevance. In this study, 50 L of a secondary WWTP effluent from a major city in Flanders, Belgium, was sampled and extracted using large-volume solid phase extraction with Chromabond HR-X. *Microcystis aeruginosa* was selected to assess toxicity according to OCED201 guidelines for 96 hours of exposure due to its sensitivity to antibiotics and herbicides. This effluent extract revealed a growth inhibition to cyanobacteria with the EC10 equal to a relative enrichment factor (REF) of 6.8. The sample was fractionated with reversed-phase high-performance liquid chromatography (RP-HPLC), collecting twenty-eight fractions at two-minute intervals. Subsequently, the fractions were recombined to assess toxicity recovery after the fractionation procedure. Three fractions exhibited significantly different growth rates than the control group, as determined by Mann Whitney test U test ($P < 0.01$). The toxicity was well recovered after the fractionation, with 87% of toxicity recovery. Mass spectrometry analysis is under investigation to identify potentially toxic compounds in these fractions that pose an effect on the cyanobacteria.

3.09.P-We186 Event driven taxonomy (EDT): Deep learning links EDA and NTA

Fei Cheng, Huizhen Li and ***Jing You****, Jinan University, China*

Ecosystems are often exposed to complex mixtures of chemicals. Identifying causative toxicants is essential to mixture risk assessments but there are data gaps among chemicals and bioactivities. In the big data era, scientific decision based on data mining and machine learning has been proposed as a powerful strategy. The collection retrospective risk-related big data can greatly promote scientific decisions on endpoint selection rather than traditional arbitrary decision-making that merely depends on expert judgment. We proposed an event-driven taxonomy (EDT) concept to integrate adverse outcome pathway-based metadata in risk assessments. Using EDT, molecular initiating events and the substances causing the events were fused in a data matrix, which was named an event driver (ED). Results showed narcosis, estrogen receptor- and aryl hydrogen receptor-mediators were the major EDs in aquatic systems across China. Individual regions had distinct ED fingerprints. Subsequently, an EDT-based artificial intelligence-assisted integrated testing strategy (ITS) was constructed for assessing aquatic risk by integrating high-throughput screening bioassays and chemical predictions. This EDT-based ITS was evaluated using complex sediment mixtures eliciting aryl hydrocarbon receptor activation and oxidative stress response. While mixture prediction using expert knowledge-oriented target analysis only explained <10% of observed sediment bioactivity, a big data-driven suspect analysis expanded the fraction explained to >80%. Additionally, deep learning models were developed to extract structure fingerprints of bioactive suspect candidates and then convert these fingerprints to HRMS-recognizable fragment ions for non-target analysis. The EDT-based ITS tool provides a promising strategy for mixture risk assessments in the big data era.

3.09.P-We187 Analysis of polychlorinated n-alkanes (PCAs) in food from the Swedish market

Idoia Beloqui[1]*, Bo Yuan*[2]*, Anders Borgen*[3]*, Pernilla Bohlin-Nizzetto*[3] *and Thanh Wang*[1]*, (1)Department of Physics, Chemistry and Biology (IFM), Linköping University (LiU), Sweden, (2)Department of Chemistry, Norwegian University of Science & Technology (NTNU), Norway, (3)Department of Environmental Chemistry and Health Effects, Norwegian Institute for Air Research (NILU), Norway*

Polychlorinated n-alkanes (PCA) are the main constituent of chlorinated paraffin (CP) mixtures. PCAs are persistent, bioaccumulative, and toxic. Thus, the use and production of short chain chlorinated paraffins (SCCPs, i.e. PCAs-C_{10-13}) were banned in 2017 at the Stockholm convention. Even so, CPs are still produced in large volumes and used in a wide range of applications. Consequently, humans are exposed to these ubiquitous contaminants, and dietary intake is usually the main exposure route. Recently, concerns have been raised about this complex group of compounds, however, there is still a lack of knowledge on their presence, distribution, and temporal trends of dietary intake in order to assess human risks. The current study aims to fill the knowledge gap on PCA levels in food items. In 2015 Swedish National Food Agency (SLV) conducted a market basket (MB) study, in which representative food samples from the Swedish market were analyzed for PCAs. In this follow-up study, we analyzed the MB collected by SLV during 2022, together with three samples from the previous MB of 2015. The food groups with an average consumption of 0.5 kg per person per year or more were included, covering approximately 90% of the total annual consumption, in kg/person. The MB represents more than 130 food items, which were pooled together for each category. A total of 17 different categories were studied, such as dairy, meat and cereals. Samples were extracted following the same method applied in 2015, with minor changes, and analyzed using liquid and gas chromatography coupled with quadrupole time of flight. The instrumental setups allowed to measure $\sum$PCA-C_{9-30} with 3-14 chlorine atoms. Preliminary results show different homolog patterns dependent on the food groups. This holds considerable significance as the bioavailability of PCAs hinges on the carbon length and chlorination degree. For instance, the $\sum$PCAs-C_{18-30} in dairy liquid and solids samples was relatively higher compared to the other food categories. PCAs-C_{10-13} were present for most of the samples. Moreover, preliminary findings include an increase of $\sum$PCAs-C_{10-13} for the sweets sample from 2015. Overall, this new study will provide more information regarding estimated per capita exposure to PCAs, as well as their homolog pattern and possible temporal trends. This information is crucial for assessing the risk associated with PCA intake through food.

3.09.P-We188 Assessing the Accuracy of Findings in Oil Pollution Cases Using Likelihood Ratios

Ana Catarina Carvalho da Rocha[1]*, Carla Palma*[1] *and Ricardo Bettencourt da Silva*[2]*, (1)Division of Chemistry and Pollution of the Marine Environment, Hydrographic Institute, Portugal, (2)Centre for Structural Chemistry - Institute of Molecular Sciences, University of Lisbon, Portugal*

The liability of an oil spill has been established in court using chemical analyses as evidence. These analyses, performed on spill and suspected sources samples, rely on identifying the chemical composition of the samples, called oil fingerprints, and comparing them using statistical approaches. The oil fingerprints are expressed as a set of ratios between abundances of oil-discriminating compounds, named diagnostic ratios (DR). The Nordtest method and EN 15522-2 standard are two methods that have been used to compare DR of oil samples under different DR comparison conditions and using distinct statistical approaches. The Nordtest method suggests using the *t*-Student test (S-t), assuming the normality of the DR probability distributions, whereas EN 15522-2 requires applying a maximum relative difference of 14%, a single criterion (SC) based on the most expectable dispersion for comparison of all DR of the DR set. Assessing DR agreement using parametric statistics that rely on assumptions or approximations, such as S-t and SC, may increase the probability of inaccurate findings. Thus, to ensure the quality of the identifications, new statistically sound approaches to result interpretation must be developed. Furthermore, it is important to present the chemical analysis's weight in court, which is often provided as likelihood ratio (LR). The LR is interpreted as a conditional probabilities ratio that, in the case of oil pollution, evaluates the compositional equivalence claim between samples in relation to the prosecution's and defense's hypotheses, which claim that the polluter is the defendant and the polluter is someone other than the defendant, respectively. Determining LR can be tough and demands the use of statistical models or databases.

This study was applied to spill and suspected source samples from different oils to present a novel approach that produces statistically sound criteria for the DR comparison. The new approach was developed as a computation tool and is based on DR simulation using the Monte Carlo Method (MCM). Using the DR comparison conditions recommended by Nordtest and EN 15522-2 methods, the tool simulates DR for two samples that is used to assess DR equivalence and estimate the probabilities of true and false compositional equivalence claims for MCM, S-t and SC. These probabilities allow us to calculate LR and assess the accuracy of the findings for each oil spill case investigated.

3.09.P-We189 Assessing VOC Performance, Perception and Indoor Air Impacts of Commercial Plug-in Fragrance Diffusers

*Neil Owen[1] and **Arturo Mendoza**[2], (1)Givaudan UK Ltd, United Kingdom, (2)Givaudan Suisse SA, Switzerland*

Volatile organic compounds (VOCs) are contained in many materials found in the home, including household and personal care products, paints and adhesives and are released from cooking, plants and combustion. Quantifying the air quality effects of a product is complex; it adds incrementally to a pre-existing background of chemicals and is influenced by physical factors including air exchange rate (AER) and deposition. Emissions from product use depend on formulation and on human behaviour. The potential impacts on indoor air quality from the use of plug-in diffusers have been assessed using GC-MS based measurements from 60 homes using controlled experiments with variable room size and AER; human sensory panels to determine perception and potential patterns of use. This is the first such combination of advanced sampling, broad VOC analysis and quantification, combined with non-biased ‘normal’ residences and the statistical analysis of all product use in the home; followed by increased device use in both home and controlled conditions. A statistically significant increase in alpha-pinene, a major diffuser ingredient, was only detectable in homes with low ventilation rates. Use of test rooms under controlled AER allowed for incremental product addition and a predictive numerical model of concentrations effects indoors to be tested. The effect of additional device use was evaluated by trained panellists showing that beyond 2 devices little benefit was seen indicating that even in abnormal use, VOC levels are likely to be self-limiting as no sensory benefits arise. This work bridges the understanding of real-home exposure to VOCs of all types, demonstrating the added value of study design to better understand and inform the public on exposure levels

3.10 Direct and Indirect Impacts of (Nano- And Micro-)Plastics in Terrestrial Ecosystems: Current Status and Future Trends

3.10.T-01 Towards an improved fate assessment of microplastics: Inclusion of specific analyses and abiotic degradation in regulatory tests

***Eva-Maria Teggers**[1,2,3], Markus Simon[4], Svetlana Heck[5], Jonas Hardebusch[3], Werner Hoheisel[1], Holger Egger[6], Philipp Dalkmann[7], Boris Meisterjahn[3], Dieter Hennecke[5], Annika Jahnke[8] and Andreas Schäffer[9], (1)INVITE GmbH, Germany, (2)RWTH Aachen University, Institute for Environmental Research, Germany, (3)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (4)Ecotoxicology, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (5)Ecological Chemistry, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (6)Bayer AG, Research & Development, Germany, (7)Environmental Safety, Bayer AG, Research & Development, Germany, (8)Department of Exposure Science, Helmholtz Centre for Environmental Research (UFZ), Germany, (9)Institute for Environmental Research, RWTH Aachen University, Germany*

Intentionally added microplastics are now restricted by the European Union. Exempt from this restriction are (i.a.) biodegradable polymers. Most of the available test methods to classify microplastics as biodegradable target mineralization (e.g., CO_2 evolution) as pass criterion. However, it is questionable, whether the overall degradation of a polymer is well described by its mineralization. For example, other processes such as abiotic degradation and the release of fragments and transformation products are not adressed. Nevertheless, these changes can have an impact on assessing the environmental fate and toxicity of microplastics. Therefore, in this study we aimed to combine a test for abiotic degradation (photolysis) with one of the available methods for testing biodegradability. Finally, we included analytical tools to improve our understanding on how microplastics degrade.

In this study capsules used in agricultural applications were investigated as ^{14}C-labelled product. An aqueous suspension was exposed to simulated sunlight. Thereafter, a sequential filtration was performed to identify major alterations in size. Further, the aim was to identify dissolved and more bioavailable molecules released from the capsules (<0.2 µm). Therefore, Liquid Chromatography - High Resolution Mass Spectrometry coupled with radio detection (radio-LC-HRMS) was employed. Lastly, the biodegradability of the irradiated and non-irradiated suspension was tested by performing an OECD 301B – CO_2-evolution test in an aqueous medium.

Our findings demonstrate that the size distribution of the suspension was highly effected by the light exposure. The polyurea capsules were “degraded” from approx. 15 µm down to nanoscale. Radio-LC-HRMS analysis enabled to identify the release of one major polymer component (aminocaproic acid). Most likely the release of this molecule was the key driver that lead to a biodegradation test result of 28 % in 28 days.

In summary, when released to the environemnt, MP are prone to biotic and abiotic degradation. Therefore, it is reasonable to additonally include abiotic degradation as part of regulatory tests, resulting in a more realistic and environmentally relevant assessment. Further, study results revealed that light exposure can largely affect polyurea microcapsules degradation - transformation products and fragments of different polymer sizes were shown to be released whose fate in the environment are still unknown.

3.10.T-02 Photolysis on soil surface makes persistent microplastic biodegradable

*Svenja Winterhoff[1], Svetlana Heck[1], **Eva-Maria Teggers**[2,3,4], Markus Simon[5], Werner Hoheisel[2], Holger Egger[6], Philipp Dalkmann[7], Boris Meisterjahn[4], Dieter Hennecke[1], Annika Jahnke[8] and Andreas Schäffer[9], (1)Ecological Chemistry, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (2)INVITE GmbH, Germany, (3)RWTH Aachen University, Institute for Environmental Research, Germany, (4)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (5)Ecotoxicology, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (6)Bayer AG, Research & Development, Germany, (7)Environmental Safety, Bayer AG, Research & Development, Germany, (8)Department of Exposure Science, Helmholtz Centre for Environmental Research (UFZ), Germany, (9)Institute for Environmental Research, RWTH Aachen University, Germany*

Increasing human population and climate change lead to an urgent need for a more efficient agricultural production to guarantee food security. For instance, advanced plant protection products have been realised by the encapsulation of the active ingredient in a polymeric shell, which can reduce pesticide application loads. Nevertheless, the release of microplastic (MP) into the environment could as well have negative impacts. Therefore, intentionally added MP to products are now restricted, with exemptions for (i.a.) biodegradable polymers. The degradability of MP needs to be tested, however, abiotic degradation is not included in regulatory assessment. Thus, the aim of this study was to combine a phototransformation test on soil surfaces with a biodegradation test in soil. Furthermore, the implementation of a new extraction method from soil is scheduled to get insights on capsule alterations regarding the size in a forthcoming analysis.

Polyurea MP capsules, applied in agriculture, were investigated as ^{14}C-radiolabeled product. In a first step, the capsules were applied to dry soil and exposed to simulated sunlight. Further, a dark control was prepared at 80°C. This approach aimed to reliably distinguish between degradation induced by thermal effects from photolytic degradation. In a second step, soil aliquots of the first test were mixed into pre-incubated soil for the downstream biodegradadation test (OECD TG 307). In both, the light and the biotically induced degradation test, mineralization ($^{14}CO_2$-evolution) was tracked. The remnants of the polyurea capsules are intended to be extracted from the soil with a newly established oil extraction method using octanol to analyse possible MP fragmentation or the release of transformation products.

During the exposure to simulated sunlight 11 ± 5 % of the total applied radioactivity (AR) was found to be mineralized. The downstream tested biotically induced mineralization reached 11 ± 4 % AR during the first 11 days (to date). Contrarily, a negligible amount of non-irradiated polyurea capsules were mineralized.

The results of this study demonstrate that the (bio)degradability of polyurea capsules is highly effected by photodegradation. To achieve a more realistic fate assessment, abiotic effects such as the photolysis tested here need to be considered to get a more accurate picture of possible pathways that MP can undergo.

3.10.T-03 A Two-Year Incubation Study: Investigating the Vertical Transport of Microplastics in Soil and its Impact on Soil Pore Development

***Roman Schefer**[1], Johannes Koestel[2] and Denise M Mitrano[1], (1)Environmental Systems Science, ETH Zurich, Switzerland, (2)Agroscope ñ Standort Reckenholz, Switzerland*

With escalating concerns regarding sustainable resource management, the influence of microplastics (MPs) on soil ecosystems has become a subject of growing interest. The unintentional introduction of MPs into agroecosystems through various agricultural practices has sparked concerns regarding their long-term implications for soil structure and fertility. This study presents a comprehensive exploration of the influence of MPs on soil pore structure and MPs transport dynamics in agricultural environments. Leveraging the results of an two-year investigation, we assessed how MP morphology (fragments, fibers) plays a role on these aspects in an agricultural field. We installed packed soil columns (9 cm height) with two variations: one without the addition of MPs (control) and another spiked with polyethylene terephthalate MPs (1% w/w Indium doped for tracking) in the top 2 cm. These columns were exposed to natural weather conditions and underwent crop cultivation cycles. Each treatment and timepoint had a minimum of 5 replicates. We monitored the evolving soil pore structure using X-ray computed tomography at the beginning of the experiment as well at the 1- and 2-year timepoints. MPs transport vertically through the column was monitored at the same time intervals, where columns were sacrificed at the specified time point, segmented into four, 2 cm sections. MPs were analyzed after homogenization and subsampling of the soil layers and subsequently quantified by Inductively Coupled Plasma Mass Spectrometry, taking advantage of the Indium doping as a proxy for the plastics. The total recovery of the MPs was 94.7% ± 2.5%, suggesting both minimal MPs migration out of the columns and an appropriate sampling strategy. Initial results for the 1-year timepoint suggest that MPs are transported through depth, with 24.8%, 0.9%, 0.5% at 2-4 cm, 4-6 cm, and 6-9 cm depths, respectively. This transport is likely a combination of advective particle transport and bioturbation, both from soil dwelling organisms and plants. Our research delves into the intricate impacts of MPs on soil pore structure, aiding informed decisions for sustainable agriculture and environmental stewardship. By employing a realistic experimental design mirroring natural soil networks and incorporating soil biota, our study sheds light on the enduring consequences of MPs contamination, providing practical insights for sustainable resource management in agricultural ecosystems.

3.10.T-04 Microbial activity in field-plot experiment samples (Spain, Germany, and Finland) contaminated by conventional and biodegradable microplastics

Klára Šmídová[1]*, Salla Kristiina Selonen*[2]*, Paula E. Redondo*[3]*, Melanie Braun*[4] *and Jakub Hofman*[1]*, (1)RECETOX, Masaryk University, Czech Republic, (2)Suomen ympäristökeskus, Finland, (3)IMDEA Water Institute, Spain, (4)Bonn University, Germany*

A significant amount of agricultural plastics introduced into the European market each year ultimately finds its way into the soil, degrading into microplastics (MPs). Besides single species and microcosm tests, field plot experiment studies give us more environmentally relevant results covering different biogeographic regions and climatic zones.

In the field plot experiment study, which ran as a part of the Papillon project (Horizon 2020), the soil was contaminated by two agricultural microplastics: (i) conventional LLDPE (M-rPE-black-A0, P3) and (ii) biodegradable starch-PBAT blend (M-rBIO-black-A0, P4) at environmentally relevant concentrations (0.005 and 0.05% weight of MPs / weight of soil). Five replicates of each concentration and agricultural plastic plus controls (no added contamination) gave 25 field plots, which were settled in spring 2022. Three different biogeographic regions of Europe (Spain, Germany, and Finland) were included to elucidate behavior in soil. The soil samples were taken in two consecutive seasons (autumn 2022 and autumn 2023).

Microorganisms form basal functions in the soil and are crucial for critical processes in the soil ecosystems. Four methods describing N- and C- mineralization were measured for each treatment of the field plot experiment study and in both seasons: basal respiration, substrate-induced respiration, potential ammonification, and potential ammonium oxidation. All methods were measured in a sufficient number of subsamples, and some subsamples were remeasured repeatedly in time to get a time-dependent response. This approach minimized the variability of the measurement.

In Spain, microbial activity was unaffected by the treatment in 2022, but changes were observed in 2023. For all methods measured, significant decreases ($p < 0.05$) of microbial activity were shown for the high concentrations of both conventional and biodegradable microplastics. In other regions, the soil behaved differently. In Germany, the trend was visible only for basal respiration in 2023, where all treatments showed significantly lower values of microbial activity than control ($p < 0.05$). In Finland, significant differences ($p < 0.05$) were found between the substrate-induced respiration of control soil samples and samples contaminated with high concentration of P4, again only in 2023. Different behaviors in different regions strengthen the climate regime's importance and should be considered in agriculture plastic management.

3.10.T-05 Transfer of nanoplastics into subsequent plant generations

Dokyung Kim *and Youn-Joo An, Konkuk University, Korea, Republic of (South)*

Microplastics including nanoplastics, small piece of plastics less than 1 mm, threaten to soil ecosystems. Plant are producers and food sources, and they can transport microplastics into predators and humans through food chain. Though numerous studies for the effects of microplastics on plants have conducted, the transfer of microplastics into subsequent plant generation are not explored yet. Thus, this study aimed to investigate the parental transfer of microplastics in plants. We exposed 200-nm nanoplastics to pea Pisum sativum for about 60 d. The pea fruits (F1) were harvested and were replanted in clean soil for 14 d. After incubation, the collected pea fruits and pea plants were observed by confocal laser scanning microscope. The significant nanoplastic fluorescence was distributed in pea fruits and plant, both. Within F1 pea fruits, fluorescence was located a circular pattern in the embryo area, in contrast, it exhibited scattered in the cotyledon area. Frequency of nanoplastic fluorescence in F1 plants were similarly identified in roots and stems. Nanoplastics were distributed in vascular bundles rather than epidermis, indicating that they were transported from parent plant through circulation, not through external exposure. Our findings presented evidence of parental transfer of nanoplastics absorbed by plants from soil. They provide the possibility for the transport and cycling of nanoplastics within soil ecosystem.

3.10.P Direct and Indirect Impacts of (Nano- And Micro-)Plastics in Terrestrial Ecosystems: Current Status and Future Trends

3.10.P-Tu204 Lateral Microplastic Transport Following Heavy Rainfall Events

***Sebastian Pietz**[1], Tobias Schmitt, Dipl. Bio.[1] and Mirco Bundschuh[2], (1)University of Kaiserslautern-Landau (RPTU), Germany, (2)Institute for Environmental Sciences, RPTU Kaiserslautern-Landau, ., Germany*

Microplastics (MPs) can accumulate in (agricultural) soils. These soils can either act as a sink or a secondary source to other parts of the environment. Lateral water-driven transport and soil erosion are potentially important processes for MP to enter aquatic ecosystems. However, these transport processes from (agricultural) topsoils are not well understood. To address this knowledge gap, we investigate the transport of MP during heavy rainfall events as a function of slope (1°, 3°, and 9°) and tillage, using eight independent soil-filled containers (80 x 80 x 20 cm). The soil originates from the Riparian Stream Mesocosm facility of the RPTU Kaiserslautern-Landau and is incubated for about eight weeks prior to each experiment and spiked with field-relevant contents (10 g/m², about 70 mg/kg dw) of polystyrene (PS), polyvinyl terephthalate (PET) and tire wear (TW). The studies are based on a rainfall simulation (about 60 mm/h) with spatial homogeneous rainfall coverage of the area (i.e., 80 x 80 cm) using a small-scale irrigation plant. The runoff is collected from each container to assess the transport of each MP. The MPs are either spread onto the soil to simulate worst-case conditions (Runoff Experiment 1) or incorporated into the soil to increase field relevance (Runoff Experiment 2). Our dataset is expected to give valuable insights on the fate of MPs and their transport from soils to aquatic ecosystems, thus indicating exposure risk for different organism groups.

3.10.P-Tu205 MICROPLASTICS DISTRIBUTION AND CHARACTERIZATION IN SOIL, WATER, SEDIMENTS AND PLANTS IN DIFFERENT URBAN AREAS OF SAUDI ARABIA

*Yolanda Pico[1], Vanesa Sanz[2], Ahmed Alfarhan[3], Mohamed El-Sheikh[3], Alotaibi M Bashayer[4] and **Damia Barcelo**[4,5], (1)Centro de Investigaciones sobre Desertificación, Universidad de Valencia, Spain, (2)Sama-UV, University of Valencia, Spain, (3)2Department of Botany and Microbiology, King Saud University, Saudi Arabia, (4)King Saud University, Saudi Arabia, (5)Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain*

More and more researchers are directing their attention to the pollution of water and sediment by microplastics (MPs). However, there is limited understanding of how these MPs are distributed in soil and plants. Hence, the objective of this study is to examine the distribution, morphological features, and physicochemical indices of MPs in different environments within Riyadh, Al-Jubail, and Dammam cities in Saudi Arabia. Riyadh is the capital and largest city of Saudi Arabia whereas Al-Jubail and Dammam are major industrial centres and homes of the largest petrochemical complexes in the world. The MPs were identified by both visual inspection and microFTIR to characterize them chemically. The results exhibited that, water and sediment, soil and plants growing on it have been polluted by MPs. They were present in the form of pellets, fragments, film, fibers, and foam. MPs with 0.05 to 0.5 mm possessed the largest proportion in the water, followed by MPs with < 0.05 mm. However, soils and sediments mainly contained larger-sized MPs, including a high proportion of those ranging between 2 and 5 mm even through the fraction of MPs between 0.05 and 0.5 mm is also very relevant. In water, sediment and soil polyethylene and polypropylene were the most important plastics. The MPs in plants were all small, <0.05 mm, and were mainly composed of viscose fibers and polyethylene. Several endogenous compounds such as cuticle proteins, cellulose, and other plant-characteristic proteins were found in the plants. The MPs found in various compartments highlight that irrigation water can be a source of MPs, but clearly not the only one. Other sources, such as the degradation of plastics and MPs in soils, the application of substances to prevent compaction, or wind and airborne deposition, are responsible for the presence of larger-sized MPs in soils and sediments. Finally, it is evident that plants can absorb MPs. However, in this case, the MPs are always of smaller size (which is logical since they have to traverse several biological barriers). This is coherent with the literature. This study sheds light on the distribution of MPs in the environment, including cities with different characteristics under a desert climate and affected by climate change.

3.10.P-Tu206 Assessing the presence of plastics within the European hedgehogs diet - supplementary food and wild prey

***Emily Thrift**[1] and Fiona Mathews Dr[2], (1)University of Sussex, United Kingdom, (2)Life sciences, University of Sussex, United Kingdom*

To understand the movement of plastics through a terrestrial food web, both the European hedgehog's supplementary feed and wild prey species were analysed for potential microplastics. This was achieved by carrying out a survey of 30 rescue centres and testing the top 8 brands of dog, cat and hedgehog foods, which resulted in 48 samples being tested and analysed using micro FTIR. For the wild prey species > 600 samples of 6 different insect groups were collected from 5 different habitat types across Sussex, UK. The samples were analysed for microplastics using micro FTIR. This allowed for an understanding of the plastic content in both types of food and their potential impacts on the European hedgehog.

3.10.P-Tu207 The Combined Effect of Microplastic Exposure (PBAT or PET) and Seawater Inundation on the Coastal Plant Plantago coronopus

*Sze Wan Harmony Cheung[1], **Winnie Courtene-Jones**[2] and Mick E Hanley[2], (1)1 School of Biological and Marine Sciences, University of Plymouth, United Kingdom, (2)School of Biological and Marine Sciences, University of Plymouth, United Kingdom*

Coastal ecosystems face a multitude of pressures including plastic pollution and climate change-driven sea level rise which are predicted to intensify over the coming decades. As such, it is necessary to assess how coastal species may fare under these

changing environments, and how stressors may interact. The effect from exposure to polyethylene terephthalate (PET): a conventional non-biodegradable plastic, and the biodegradable polymer polybutylene adipate terephthalate (PBAT), in combination with seawater inundation on endpoints associated with growth and stress was examined in the coastal dune species *Plantago coronopus. P. coronopus* were grown for three-months from seeds (15°C; 18:6h photoperiod, watered 3 times per week), before being transplanted to compost containing PBAT (n = 20) or PET (n = 20) at 0.02 g/kg (<300µm diameter) and a no plastic control group (n = 20). After 35 days, replicates (n = 10) from each plastic group were flooded to pot height with artificial seawater for 72 hours and grown for a further 29 days. Throughout the experiment plant mortality, necrosis and photosynthetic efficiency (Fv/Fm) were recorded. Surviving plants were harvested and roots and shoots were separated and dried for biomass determination. There were clear synergistic effects of plastic and seawater on the photosynthetic efficiency of plants. Plants exposed to biodegradable PBAT + seawater, and conventional PET + seawater, had significantly reduced Fv/Fm values compared to all other treatments, with effects most potent in the PBAT + seawater treatment. Plants were able to mediate adverse effects, with no differences in photosynthetic efficiency detected 18 days post-inundation. Seawater inundation was the main stressor explaining the quantity of necrotic tissue, however interactions between microplastics and seawater influenced resource allocation (root:shoot ratio) of plants. Coastal plants have vital roles in preventing erosion and providing food and habitat for a diversity of species. This study demonstrates the complex interactions of exposure to biodegradable and conventional microplastics in combination with seawater flooding events on selected plant endpoints, with potential ramifications on coastal ecosystems.

3.10.P-Tu208 Characterization and spatial distribution of mesoplastic particles in an arable soil

Kristof Dorau[1]*, Daniel Rückamp*[1]*, Christian Weber*[2]*, Georg Scheeder*[2]*, Korinna Altmann*[3]*, Ronja Reßing*[2]*, Stephan Peth*[4]*, Phillip Otto*[5]*, Elke Fries*[1] *and Martin Hoppe*[2]*, (1)Groundwater and soil, Federal Institute for Geosciences and Natural Resources (BGR), Germany, (2)Federal Institute for Geosciences and Natural Resources (BGR), Germany, (3)Federal Institute for Materials Research and Testing (BAM), Germany, (4)Institute of Soil Science, Leibniz University Hannover, Germany, (5)School of Mathematics and Statistics, University of Glasgow, United Kingdom*

Extraction of plastic particles from soil is challenging and time-consuming and this is one reason why currently exceptionally little spatial information on plastic distribution at the field scale has been gathered. For risk assessment, adequate sampling should complement coherent morphological, physical, and chemical plastic profiling. In this study, we investigated the spatial distribution of mesoplastic (MeP; size > 5 mm) particles in an arable soil (Haplic Cambisol) managed intensively by 12-years of compost application. Geo-referenced samples (n = 128) were collected at a three hectare study site in Northern Germany. In addition to the detailed characterization of MeP, the dataset was complemented by the simultaneous recording of soil properties in order to compare dispersion measures of MeP with non-technogenic soil properties such as pH, soil organic matter, cation exchange capacity, and bulk density. In total, we found 259 MeP particles with a predominance of transparent packaging foils and colored fibers, likely due to insufficient separation during recycling of biowaste. Caution is advised when measuring the particle mass. As an example, fibre bundles harbored the largest polymer-associated soil (PAS) mass with, on average, 0.544 mg soil per mg^{-1} particle. We recommend using a 0.1 mol L^{-1} tetrasodium pyrophosphate (TSPP) solution to purify MeP particles by removing attached soil before weighting and using these mass data for risk assessments. Otherwise, we found a radical overestimation of particle weights retrieved without the cleaning procedure between 160% (films) up to 296% (fragments), and this will bias the results. The MeP count and mass featured the highest coefficient of variation in comparison to soil properties, e.g., pH or bulk density. After removal of the top three extreme values, a pure nugget variogram indicated that no spatial dependency for particle counts existed. In this case, simple random sampling approaches are applicable. Bootstrapping revealed that eight samples are sufficient to estimate mean soil pH with an average error of ±10% and 95% confidence level, but over five times larger number of replicate samples are expected to determine the MeP polymer mass.

3.10.P-Tu210 Microplastic Omnipresence: Automated Detection of Atmospheric Microplastic Deposition in Alpine Environments using µFTIR Mapping and Open Specy

Aleksandra Karapetrova[1]*, Win Cowger, PhD*[2]*, Alex Michell*[3]*, Audrey Jeanne Braun*[4]*, Edward H. Bair*[3]*, Andrew Gray*[4] *and Jay Gan*[5]*, (1)Environmental Toxicology, University of California Riverside (UC Riverside), Riverside, United States, (2)Moore Institute for Plastic Pollution Research, (3)Earth Research Institute, University of California Santa Barbara, (4)University of California Riverside (UC Riverside), (5)Department of Environmental Sciences, University of California Riverside (UC Riverside)*

While the presence of microplastics (MPs) in the atmosphere is known, there are few studies that are focused on MP air transport patterns, origins, and deposition rates into terrestrial environments. This study aims to calculate the flux of MP atmospheric particles into terrestrial environments with a novel automated µ-Fourier Transform Spectroscopy (µFTIR) technique. This method will transform MP detection workflow by shifting from picking individual MPs to an automated detection of MPs, which can become a standardized method. Additionally, it will allow detection of MPs down to 50 µm and high throughput analysis of spectra. To demonstrate the effectiveness of this method, environmental samples from 15 alpine sites were collected using hydrology snow density measurement approaches. Once the samples were collected, the meltwater was filtered onto gold-sputtered polycarbonate filters. Filters were mapped in reflectance mode using a Nicolet iN10 (µFTIR) with a two-dimensional focal plane array. Once spectra were collected, up to 300,000 spectra were analyzed using the open-source program Open Specy. A novel automated MP identification program and database was developed to identify the shape, polymer type, and count of MPs on each filter. We estimate flux from the atmosphere to terrestrial ecosystems, create a back trajectory model, and conduct statistical analysis to identify the potential sources of MPs. In this study, a distribution of MPs is shown for the first time in the Cascade and Sierra Mountain ranges, a major water supply source for communities in these two states. Sites of various proximity to anthropogenic activity have relative MP counts ranging from approximately 20-300 MP per liter of snow meltwater. Consistent concentrations within a site, field blanks, and positive and negative controls further show that this method is replicable and robust. The future of this workflow lies in its application to measure MP presence and flux in any environmental matrix at a high throughput scale. We envision researchers will be able to expand their sampling within sites and increase the number of study sites with this automated MP detection method, and ultimately having stronger evidence of MP transport rates.

3.10.P-Tu211 Multifaceted Effects of Microfibers on Soil-Plant Systems: Exploring the Response Under Different Crop Cultivations

***Zhangling Chen**[1], Steven A. Banwart[1], Paul Kay[2], Devlina Das Pramanik[3] and David Ashley[2], (1)School of Earth and Environment, University of Leeds, United Kingdom, (2)School of Geography, University of Leeds, United Kingdom, (3)School of Food Science and Nutrition, University of Leeds, United Kingdom*

Microplastics (MPs) are emerging pollutants that have been receiving global attention due to uncertainties around their occurrence, fate, environmental and human health risks. While research on the impact of MPs on aquatic systems is growing, studies investigating their influence on terrestrial systems are limited. Agricultural soil serves as a dominant sink for MPs, with microfibers being a predominant form due to the application of organic amendments. Despite their ubiquity, the transport mechanisms of these particles and their effects on soil-plant systems remain largely unknown. This study focused on the impact of polyester (PES) fibers on soil quality and plant performance, selecting lettuce, Chinese cabbage, and radish as biological models. Plants were cultivated in glass jars with soil containing 100mg/kg microfibers. Soil endpoints revealed that microfibers had significant effects on soil physical properties, including a reduction in bulk density, inhibition of macro-aggregate formation, and promotion of micro-aggregate formation. These trends were consistent across all plant treatments. Additionally, microfiber addition, in conjunction with different crop cultivations, led to alterations in soil chemical properties. For instance, lettuce-growing soil pH decreased, while cabbage-growing and radish-growing soil pH increased in response to microfibers. Microfibers also slightly increased soil organic carbon content in radish-growing soil. Regarding plant endpoints, impacts varied among plant species. Lettuce germination accelerated in the presence of microfibers, while radish root length was adversely affected. Lettuce and cabbage experienced diminished chlorophyll content, while radish leaves exhibited an increase when exposed to microfibers. This study highlights the negative, positive, and neutral effects of microfibers on soil properties and plant growth. It also reveals that microfibers may affect organic carbon stocks in soil-plant systems. The observed outcomes are attributed to the distinctive characteristics of fibers, including their unique shape, surface area, and flexibility, which may interact with soil particles and crops. Given the widespread distribution and accumulation of microfibers in agricultural soil, this study provides crucial insights for ecotoxicological assessments related to soil and terrestrial higher plants. It also holds implications for stakeholders in environmental pollution, food safety, and human health.

3.10.P-Tu212 Quantitative tracking of nanoplastics along the food chain from lettuce (Lactuca sativa) to snails (Cantareus aspersus)

***Laura Zantis**[1], Maria Kazour[2], Caterina Borchi[2], Rebecca Agati[2], Romain Colpaert[3], Frédéric Gimbert[3], Martina G. Vijver[4], Willie Peijnenburg[5] and Thijs Bosker[2], (1)Leiden University, Netherlands, (2)Institute of Environmental Sciences, Leiden University, Environmental Biology, Netherlands, (3)Chrono Environnement, University of Bourgogne Franche-Comté, France, (4)Institute of Environmental Sciences (CML), Leiden University, Netherlands, (5)National Institute for Public Health and the Environment (RIVM), Netherlands*

Terrestrial systems are a significant sink for plastic contamination, including nano- and microplastics (NMPs). Several studies showed that both invertebrates and plants are able to uptake NMPs directly from their environment. Another exposure pathway for invertebrates and higher-level organisms is the transfer of NMPs up the food web via trophic transfer. To date, only limited information is available about this exposure pathway, however, concerns about trophic transfer of NMPs in the terrestrial food chain have been raised. Our study aims to examine and quantify the trophic transfer of europium doped polystyrene nanoplastics (Eu-PS; NPs) within a terrestrial food chain. The uptake of 100 nm spherical Eu-PS particles from water through the roots of the plants to the leaves and finally to garden snails (*Cantareus aspersus*) was assessed. Lettuce (*Lactuca sativa*) was cultivated in Hoagland solution spiked with different concentrations of Eu-PS (15, 150 and 1500 µg/L) for three weeks. Then, lettuce shoots were used as food for snails for 19 days at a rate of 1 g of shoots per day. The Eu-PS primarily accumulated in the roots for all treatments, with a limited transfer to the shoots (only quantifiable in the highest treatment; translocation factor: TF<1). No detectable levels of Eu-PS were found in the snails' digestive gland; however, the Eu-PS particles were detected in their feces (trophic transfer factor: TFF>1). In addition, only limited effects were observed on lettuce biomass by the NPs treatments. No effects of the Eu-PS particles on snails were observed, with the exception of a consistent decrease in the snails' shell diameter. Overall, our research illustrates that NPs can be absorbed by plants through their roots, subsequently transported to the shoots. However, we did not find detectable trophic transfer into snail tissues, but direct elimination through their feces. Thus, our findings show limited transfer of NPs from plants to snails at a higher trophic level. This provides important insight into the potential within the human food basket. Nonetheless, NPs did cause effects on lettuce and snails, indicating a potential health risk to consumers posed by NPs which can accumulate in crops.

3.10.P-Tu213 Species-dependent responses of crop plants to polystyrene microplastics

***Laura Zantis**[1], Annebelle Rombach[2], Sylwia Adamczyk[3], Sannakajsa Velmala[3], Bartosz Adamczyk[3], Martina G. Vijver[4], Willie Peijnenburg[5] and Thijs Bosker[2], (1)Leiden University, Netherlands, (2)Institute of Environmental Sciences, Leiden University, Environmental Biology, Netherlands, (3)Natural Resources Institute Finland (Luke), Finland, (4)Institute of Environmental*

Sciences (CML), Leiden University, Netherlands, (5)National Institute for Public Health and the Environment (RIVM), Netherlands
Only recently there has been a strong focus on the impacts of microplastics (MPs) on terrestrial crop plants. Nonetheless, the large difference in experimental design between studies makes comparison of effect size and even the direction of the impacts among species difficult. This study examines and compares the effects of MPs on two monocotyledonous (barley, *Hordeum vulgare* and wheat, *Triticum aestivum*), and two dicotyledonous (carrot, *Daucus carota* and lettuce, *Lactuca sativa*) plant species through two complimentary experiments. First, we investigated the effects of low, medium, and high (10^3, 10^5, 10^7 particles/mL) concentrations of 500 nm polystyrene microplastics (PS-MPs) on seed germination and early development. We found species-dependent effects on the early development, with MPs only significantly affecting lettuce and carrot. When acutely exposed during germination, PS-MPs significantly delayed the germination of lettuce by 24%, as well as promoted the shoot growth of carrot by 71% and decreased its biomass by 26%. No effect was recorded on monocot species. Secondly, we performed a chronic (21 d) hydroponic experiment on lettuce and wheat. We observed that PS-MPs significantly reduced the shoot growth of lettuce by up to 35% and increased its biomass by up to 64%, while no record was reported on wheat. In addition, stress level indicators and defence mechanisms were significantly up-regulated in both lettuce and wheat seedlings. Overall, this study shows that PS- MPs affect plant development: impacts were recorded on both germination and growth for dicots, and responses identified by biochemical markers of stress were increased in both lettuce and wheat. This highlights species-dependent effects as all crops were grown under identical conditions. Some responses, be it during short- or long-term exposure, were observed for all tested species. Although a variety of responses were observed for the apical endpoints, the biochemical markers showed a similar trend for all plants species. Biochemical markers indicate that both monocots and dicots were stressed due to the exposure to MPs, which may have further consequences on growth, functioning and yield. To conclude, research on the differences of crop specific impacts of MPs continues to be of great importance. In addition, testing under more environmentally realistic conditions, including several stressors, is necessary to use these results to make realistic interpretations for field scenarios.

3.10.P-Tu214 Disentangling Microplastics Effects on Oxygen Diffusion, Microbial Activity and Greenhouse Gas Emissions in Soil

Denise M Mitrano[1]*, Jonathan Nunez*[1]*, Joaquin Jimenez-Martinez*[2] *and Andrea Carminati*[3]*, (1)Environmental Systems Science, ETH Zurich, Switzerland, (2)Department of Civil, Environmental and Geomatic Engineering, ETH Zurich, Switzerland, (3)Usys, ETH Zurich, Physics of soils and terrestrial ecosystems, Switzerland*
Understanding the responses of soil ecosystems to the presence of microplastics (MPs) becomes important as multiple stressors can act together to impact this environmental compartment. MPs impact soil structure, nutrient cycling, and greenhouse gas (GHG) emissions. However, the mechanisms underpinning the direction and magnitude of MPs effects on these soil properties are uncertain, mainly due to the lack of knowledge of how the presence of MPs drives changes in soil structure and the subsequent linkages between soil structure and microbial activity. Here, we hypothesized that the presence of MPs affects soil structure, affecting pore connectivity, leading to higher or lower O_2 availability and consequently higher or lower soil respiration.Furthermore, we anticipated that the magnitude or direction of the effects would be dependent on soil texture and the shape of MPs. We spiked PET MPs fibers (500 µm length) and fragments (125 – 250 µm) into custom built rhizotrons (5 x 5 x 1 cm) filled with either clay or sandy loam soils (contrasting textures) with a MPs treatment of 1 w/w%. First, we determined the differences in pore connectivity in air dried soil using the rate of O_2 diffusion as a proxy. Next, we determined the O_2 concentration in the soil in optimal conditions for respiration (50% water holding capacity and addition of 20 mg g soil^{-1} of glucose). O_2 diffusivity and O_2concentration were determined by mapping O_2 concentrations using optode imaging, over the course of 48 hours. Fluxes of CO_2 were measured under the same conditions by placing replicate set-ups in a Tedlar bag and collecting gas samples for estimates of CO_2 concentration using gas chromatography. O_2 diffusion was faster in the sandy loam compared to the clay soil. The addition of MPs reduced O_2 diffusion rate in the sandy soil but increased it in the clay soil. In optimal conditions for soil respiration, the treatments showed the same trend for O_2 concentrations, suggesting that O_2 concentration in the soil matrix is likely to be regulated by pore connectivity opposed to respiration. Collectively, we show the impacts of MPs addition to soil and their impacts on the linkages between soil structure, microbial activity and GHG emissions. This study can serve as a baseline for understanding the important impacts of MPs have on soil functioning, which is relevant as plastics are increasingly used directly in agriculture and consequently have direct releases to terrestrial ecosystems.

3.10.P-Tu215 Comparing Approaches to Terrestrial Ecotoxicity Studies for Micro- and Nanoplastic Particles and Engineered Nanomaterials: A SWOT Analysis Approach

Kate Schofield[1]*, Megan Griffiths, MSc*[2]*, Emma Pemberton*[2]*, Karsten Schlich*[3]*, Markus Simon*[3] *and Christopher Hughes*[2]*, (1)Ricardo-AEA Ltd, United Kingdom, (2)Ricardo, United Kingdom, (3)Ecotoxicology, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany*
A rising interest in understanding the impact of micro- and nanoplastic particles (MNP) on ecosystems has led to an increased number of research and review articles. Initially focused on marine ecosystems, recently, interest in MNP ecotoxicological effects on terrestrial ecosystems has gained momentum. However, concerns raised around the reliability and relevance of studies on the ecotoxicological effects of MNPs highlight issues with the reporting of MNP properties and a lack of environmental representativeness [1,2]. To advance understanding of the terrestrial ecotoxicity of MNPs, it is imperative that these issues are identified and addressed.

The study of engineered nanomaterials (ENMs) ecotoxicity has parity with MNPs. Both are ubiquitous in the environment and, from a risk assessment perspective, represent non-traditional materials for which observed biological effects may be influenced by a variety of parameters (e.g. size, shape and composition). However, the study of ENM ecotoxicity is more established and, thus, by examining the differences between ENM and MNP terrestrial effects studies, we aim to identify opportunities to enhance the conduct of MNP studies.

As part of the Holistic Environmental Risk Assessment for Microplastics in the Terrestrial Environment (HERA-MP) project, a review of recent (published between January 2020 and June 2023) terrestrial effects studies for both ENMs and MNPs was performed, from which a comparative strengths, weaknesses, opportunities and threats (SWOT) analysis was conducted to facilitate a comprehensive comparison.

Both MNP and ENM studies exhibited robust experimental design and thorough reporting of basic experimental parameters. Weaknesses included poor harmonisation, limited environmental relevance, and exposure assessment. Based on ENM studies, opportunities to improve MNP studies included additional particle characterisation parameters (e.g. surface properties) and endpoints (e.g. reactive oxygen species), as well as promoting harmonisation and data sharing opportunities. Threats were associated with limited knowledge of effects mechanisms, MNP detection in soil, data transparency and resource constraints. These findings will inform future research and risk assessment of MNPs by contributing to the development of a robust risk assessment framework for MNPs in terrestrial ecosystems.

3.10.P-Tu216 Effects of microplastics pollution to soil fungi and fungi feeding springtails

Jin Il Kwak*, Lia Kim and Youn-Joo An, Konkuk University, Korea, Republic of (South)*

Despite research on impacts of nano- or microplastics in terrestrial ecosystems has been increased, we know relatively little about response of springtails. The aim of this study is to investigate effects of microplastics pollution to soil fungal community and fungi feeding springtails. Test soils were amended with high-density polyethylene microplastics. Soil fungal community was analyzed and multigenerational effects on springtail *Folsomia candida* were evaluated to F2 generation. After one month of exposure period, soil fungal groups excreting toxins or entomopathogenic fungi were increased. Springtails at F2 generation were significantly affected in the contaminated soil by microplastics after three months of exposure period. As a result, we observed a correlation between MPs pollution, soil fungi, and fungi feeding springtail. These results indicated that soil health can be negatively influenced by microplastic pollution. *Acknowledgement-This work was supported by the National Research Foundation of Korea (NRF) grant funded by the Korea government (MSIT) (2021R1C1C2012628).*

3.10.P-Tu217 Polystyrene Nanoplastic (NPs) and Sulfamethoxazole: a Multidisciplinary Approach to Assess the Impact of a Contaminant Mixture on Lactuca Sativa and Rhizosphere Microorganisms

*Michela Pirredda[1], **Ludovica Rolando**[2], Francesca Spataro[3], Luisa Patrolecco[3], Carmela Spiniello[2], Paola Grenni, PhD[4], Carmen Martin[5] and Anna Barra Caracciolo[2], (1)Universidad Politécnica de Madrid, Spain, (2)Italian National Research Council (IRSA-CNR), Italy, (3)National Research Council- Institute of Polar Science (ISP-CNR), Italy, (4)Water Research Institute (IRSA), National Research Council (CNR), Italy, (5)Biotechnology-Plant Biology, Universidad Politécnica de Madrid, Spain*

Plastics have significantly improved humans quality of life. However, owing to their continuous use in various daily activities, the persistence and inadequate collection and disposal of larger plastic debris, are found in environment in huge quantities. Micro (MPs between 1 to 5,000 µm) and Nano plastics (NPs, <1 µm) cause particularly concern because they can be accumulated in food chains and can represent potential adsorption carriers of organic pollutants (e.g. antibiotics, antibiotic resistance genes), increasing their environmental spread. NPs, due to their high surface area and penetration properties, can be more harmful for biota; moreover, their possible interactions with microcontaminants and in particular antibiotics in soil ecosystem are still unclear. Among others, polystyrene NPs are considered a widespread emerging contaminant arising from agricultural soil management.In this context, the aim of the work was to investigate the effects of polystyrene NPs and sulphamethoxazole (SMX), a sulfonamide antibiotic which may be adsorbed by the NPs, on *Lactuca sativa* L. plants and its associated rhizosphere microbial community. For this purpose, lettuce plants were grown on soil spiked with 20 mg/L of NPs, 20 mg/L of SMX and a mix of them (MIX, 20 mg/L NPs + 20 mg/L SMX). Soil microbial community was evaluated in terms of microbial abundance and activity and *L. sativa* plant in terms of chlorophylls and malondialdehyde content. Moreover, antibiotic concentrations (HPLC-MS/MS), resistance genes for sulfonamides (*sul1*, *sul2*) and the *intI1* mobile genetic elements were determined in soil and leaf phyllosphere at different experimental times (0, 3 and 28 days). Physical and physiological plant parameters were affected by the treatments. Microbial abundance was negatively influenced by the NPs and SMX co-presence.

3.10.P-Tu218 Two-generation Full life Cycle Tests with Mealworms Tenebrio molitor: Effects of Agricultural Microplastics

*Ana Nagode, Andraz Dolar, Damjana Drobne and **Anita Jemec Kokalj**, University of Ljubljana, Biotechnical Faculty, Slovenia*

Agriculture is considered one of the most important inputs of microplastics (MPs) in soil. Most of the studies so far tested the effects of MPs during one generation after relatively short exposure times (up to 3-4 weeks), but few are available for longer exposure durations and multiple generations. With this purpose, we have investigated the effects of agricultural MPs on two generations of mealworms *Tenebrio molitor* investigating the whole life-cycle. We tested MPs obtained from two mulching films commonly used in agriculture: conventional non-degradable fossil-based (low-density polyethylene LLDPE; 36 ± 12 µm; numeric distribution) and biodegradable fossil-based (poly(butylene adipate co- terephthalate; starch PBAT; 81 ± 38 µm; numeric distribution). Mealworms were fed with wheat bran at 0.005, 0.05, 0.1, 0.5, 1, and 5% MPs (w/w dry weight). The first generation was exposed for 12 weeks at 20 °C. During the experiments, adults were collected and transferred to new pots with corresponding concentrations of MPs. The larvae that emerged from these adults were then synchronized for size (60-90 mg) and exposed again until the completion of the second life-cycle which was faster (9 weeks). We followed the metamorphosis of organisms (larvae->pupae->adults), larval growth, adult and pupae final emergence success, moult and mortality.

Overall tested MPs did not induce effects on the survival of mealworms. The final emergence of pupae and adults was decreased only in the case of 5% PBAT (1. generation). However, changes in moult and growth of larvae were observed in the case of both types of MP (LLDPE and PBAT) as well as in both generations. The types of responses were not the same for all types of exposures. Namely, while a trend of decreased growth was observed in the case of 5% LLDPE (1. generation), it was increased in the second generation (1% and 5%). In the case of PBAT, no effect on growth was observed in the first generation, while a trend of growth was observed at all test concentrations in the second generation with the most significant changes at 5%. Changes in moult were not as clear. Moult was decreased at 5% LLDPE (1.generation), increased at 5% PBAT (1.generation) and decreased at 5% PBAT (2. generation).

In conclusion, our results show that both types of MPs; conventional non-degradable fossil-based and biodegradable fossil-based, induce alterations in mealworm development but these are the most evident at the highest test concentration (5%)

3.10.P-Tu219 Lessons learned from research with model polystyrene nanoplastics in different environmental approaches

Martin Hoppe[1]*, Jan Köser*[2]*, Federico M. Ivanic*[3]*, Kristof Dorau*[2]*, Axel Lamparter*[1]*, Georg Scheeder*[1] *and Karsten Schlich*[4]*, (1)Federal Institute for Geosciences and Natural Resources (BGR), Germany, (2)Groundwater and soil, Federal Institute for Geosciences and Natural Resources (BGR), Germany, (3)Instituto de Investigación e Ingeniería Ambiental, Argentina, (4)Ecotoxicology, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany*

There is a lack of knowledge about the fate and impact of microplastics and nanoplastics (MNPs), as well as their potential uptake and impact on plants and microorganisms. It is difficult to detect polymers in soils, which explains the knowledge gaps, and the need of model particles. The presented research can be categorized into three cornerstones: First (I), commercial polystyrene particles (PS-P_c, 1000 nm) were applied to quartz sand columns. Second (II), polystyrene particles (PS-P, 343 nm) and palladium (Pd) nanoparticle-doped polystyrene particles (PS-Pd-PS-P, 442 nm) were synthesized, characterized, and applied to agricultural soils for a toxicity test (Cambisol, Podzol). Third (III), polystyrene particles with a core of silver (Ag) nanoparticles (Ag-PS-P, 262 nm) were synthesized, characterized, and applied to a model wastewater treatment plant (MWTP).

(I) UV-Vis spectroscopy was used to determine the column breakthrough of the PS-P_c. Adsorption of dissolved organic matter facilitated the transport of PS-P_c by reducing their surface hydrophobicity. Hence, mobility of MNPs in soils seems very likely.

(II) Different techniques, such as inductively coupled plasma-mass spectrometry (ICP-MS), pyrolysis-gas chromatography-mass spectrometry (Pyr-GC-MS), and scanning electron microscopy (SEM), were used to characterize the PS-Pd-PS-P and the PS-P in dispersions, soils and plants. The spiked soils were applied to a plant toxicity test with oat. The applied particle contents could be recovered from both soils by ICP-MS (Pd, 89% - 99%) and Pyr-GC-MS (PS, 73% - 120%). Moreover, non-aggregated particles in soils and on oat roots were visualized through SEM. The ratio obtained for the Pd contents in oat roots to that in the soils (2.2 - 2.7) implied that particles accumulated on the root surface or in the roots. No Pd was detected in the oat shoots, which indicated that no translocation occurred from the roots to the shoots. Despite the particle accumulation at or in the roots, no clear effects on plant growth were observed.

(III) High amounts of the applied Ag-PS-P were retained in the sewage sludge during wastewater treatment in the MWTP. Therefore, sewage sludge applications to soils should also be considered as a source of MNPs for the terrestrial environment.

In summary, the model PS-P, PS-Pd-PS-P, and Ag-PS-P greatly benefit the development and validation of methods to investigate MNPs in complex environmental matrices.

3.10.P-Tu220 Do We Have the Ingredients for Soil Microplastic Policies based on Environmental Risk Assessment?

Elmer Swart[1]*, Melvin Faber*[1]*, Willie Peijnenburg*[1]*, Albert Koelmans*[2]*, Arjen Wintersen*[1] *and Joris T.K. Quik*[1]*, (1)National Institute for Public Health and the Environment (RIVM), Netherlands, (2)Aquatic Ecology and Water Quality Management, Wageningen University & Research (WUR), Netherlands*

Recently, it has been demonstrated that microplastics are ubiquitous in the environment, including in soils, and that they pose a hazard to organisms. However, risks of microplastics remain uncertain, especially for soil ecosystems. Without scientific consensus on the actual risk and its specific drivers (e.g. the polymers and/or applications that have the greatest contribution to the risk), policy makers are limited in the options for policy actions they can take. Hence, they may have to rely on generic precautionary regulation and policy to reduce the uncertain impact of plastic pollution. In part, this uncertainty relates to the limitations with respect to the relevance and reliability of available scientific data. Furthermore, the uncertainty relates to the extent in which risk assessment approaches can deal with the complexity of microplastics pollution, i.e., the diversity of particles, physical, chemical and microbiological effects. Thus far, several scientists have proposed approaches to environmental risk assessment of microplastics and used these to estimate the risks to the environment, including terrestrial ecosystems. Pragmatic choices have been made to deal with uncertainties and the complexity of microplastics pollution. Overall, state-of-the-art risk assessments have suggested that risks to the environment cannot be excluded. The question remains whether the right ingredients for a scientifically sound risk assessment of microplastics are available that can feed policy making. And if not, which ingredients are missing or which need further development or testing? In this presentation, currently available approaches to risk assessment of microplastics in soils are presented and compared. These include novel approaches specifically designed for microplastics, as well as existing approaches for conventional substances or materials. Information needs of Dutch policy makers collected in several workshops held in the Netherlands will be presented. With this presentation and together with the audience, we strive to collect input on the current state-of-the-art of environment risk assessment of microplastics. Specifically, we want to explore future directions of research and the current scientific acceptance of available approaches and their role in the development of microplastics policy for soils. This should help ensure that science better meets policy needs, allowing policymakers to make evidence-based decisions.

3.10.P-Tu221 Assessment of Microplastic Emissions from Artificial Turf Pitches
***Maria Kittner**[1], Korinna Altmann[1], Sven Hamann[2], Rüdiger Weyer[2] and Ute Kalbe[1], (1)Federal Institute for Materials Research and Testing (BAM), Germany, (2)Polytex Sportbeläge Produktions-GmbH, Germany*
Following the recommendation of the European Chemicals Agency, on 25 September 2023 the European Commission passed a comprehensive new regulation to reduce emissions of microplastics (MP) into the environment, which includes the sale and use of intentionally added MP. This also applies to the application of synthetic rubber granulate infill in artificial turf systems and will ultimately have an impact on recreational sports. In Germany, rubber granulate made of ethylene-propylene-diene-monomer rubber (EPDM) is currently predominantly used. So far, there is no sufficient database for estimating MP emissions from artificial turf pitches into the environment and thus their relevance as a source of MP pollution. This topic is controversially discussed due to the complexity of sampling and analytics. To close this research gap, this project has the goal to determine mass balances for the emissions of MP from artificial turf pitches to allow an estimation of the amount of MP released per turf pitch and year.

Within this study, MP emissions of three artificial turf scenarios at different ageing states (unaged, artificially and real-time aged) are compared: the past (old turf: fossil based, synthetic infill), present (1. most commonly installed in Germany: fossil based, EPDM infill; 2. turf with bio-based gras fibres and EPDM-Infill with hemp), and the future (turf with recycled gras fibres, no synthetic infill). To simulate the outdoor weathering during the lifespan of approx. 15 years, new artificial turf and EPDM granulate were accelerated aged by UV weathering and mechanical stress. Potential MP emissions into surface and groundwater are simulated by lysimeter and shake experiments. MP mass contents are subsequently determined by Thermal Extraction Desorption Gas Chromatography/Mass Spectrometry. Using special microfilter crucibles allows the estimation of the particle sizes of the emitted MP, which is a fundamental requirement for an assessment of potential health hazards for humans.

First results of shake experiments of unaged turf components to determine maximum MP contents potentially emittable into surface waters (5 - 50 µm) showed that the highest MP mass contents of 1,761.5 - 5,784.2 µg/g were determined for EPDM granulate. For the recycled artificial turf, total MP contents of 7.1 - 18.3 µg/g were determined: 1.3 - 4.1 µg/g from PE grass fibres, 0.4 - 0.5 µg/g from PP backing, 0.0 - 5.9 µg/g from PET winding yarn and 5.4 - 7.8 µg/g from PU adhesive.

3.10.P-Tu222 Impacts of Conventional and Biodegradable Microplastics on Plant-Soil Systems
***Giovana P. F. Macan**[1], Manuel Anguita-Maeso[2] and Blanca B. Landa[1], (1)Institute of Sustainable Agriculture (IAS-CSIC), Spanish National Research Council, Spain, (2)Department of Biology, University of North Carolina at Chapel Hill*
Over the last few years, there has been an increasing awareness of microplastic (MP) pollution worldwide. Previous studies have confirmed their ubiquitous presence in all environments, including agricultural soils, where plastic mulch represents a major source of MPs due to incomplete recovery after each cropping season. However, understanding the potential impacts of these anthropogenic materials on soil and plant health remains limited. In this context, to assess the long-term impact of different types of MPs (conventional and biodegradable) on the growth of cotton plants and on the functioning and biodiversity of soil and the associated-plant microbiome, a cycling plant growth experiment using cotton has been conducted. The process of seed sowing, plant growth, and harvest has been repeated for a total of four cycles. Several parameters associated with plant development including indicators of plant growth and foliar stress, and community composition and metabolic activity of soil microbiota were assessed over time. The results of the plant bioassay indicate a temporary impact of biodegradable MPs on plant development. Specifically, during the first cultivation cycle, the addition of biodegradable microplastics to the soil led to reduced plant growth compared to other treatments, as evidenced by decreased values in plant height, stem diameter, aerial

fresh weight, and the number of flowers. However, in subsequent cultivation cycles, none of the evaluated parameters related to plant development showed a significant difference. Furthermore, additional data regarding potential changes in the microbial community, both in terms of their structure and physiological profile, have been collected and still need to be statistically evaluated. These findings may contribute to a better understanding of the impacts of these pollutants on the soil microbiota and, consequently, the observed effects on plant development. Moreover, assessments over time, as outlined in this project, will also provide valuable information on the temporal dynamics of the soil and plant-associated microbiome in response to MP pollution, which have not yet been fully described. Understanding the impacts of MPs on the environment may contribute to further policy formulation and recommendations aimed at addressing plastic pollution on a global scale, as well as the development of new alternatives to plastic mulch using technologies involving non-toxic materials.

3.10.P-Tu223 Effects of environmentally relevant mixtures of microplastics on terrestrial organisms

Sara Martínez-Pérez[1]*, Theresa Schell*[1]*, Daniel Franco*[1]*, Rudo A. Verweij*[2]*, Sam van Loon*[2]*, Paula E. Redondo*[1]*, Virtudes Martinez-Hernandez*[1]*, Cornelis A.M. van Gestel*[3] *and Andreu Rico*[1,4]*, (1)IMDEA Water Institute, Spain, (2)Amsterdam Institute for Life and Environment (A-LIFE), Vrije University Amsterdam, Netherlands, (3)Amsterdam Institute for Life and Environment (A-LIFE), Vrije Universiteit Amsterdam, Netherlands, (4)Cavanilles Insititute of Biodiversity and Evolutionary Biology, University of Valencia, Spain*

Although attention has mainly been given to plastic pollution in aquatic ecosystems, soils may also act as a sink of microplastics. Little is known, however, about their fate and effects in soil. The main objective of this study was to evaluate the effects of a realistic mixture of microplastics (MPs) present in terrestrial ecosystems on two soil ecotoxicological model organisms, the earthworm *Eisenia andrei* and the springtail *Folsomia candida.* For this, high density polythylene (HDPE) and polypropylene (PP) fragments were generated by cryomilling recycled plastic pellets, and polyester (PES) fibers were generated cutting and grinding a blanket, with a final particle size range between 36 and 3887 µm. Chronic tests following toxicity test guidelines 222 and 232 from the Organisation for Economic Co-operation and Development (OECD) were performed for earthworms and springtails, respectively, using LUFA 2.2 natural standard soil. The organisms were exposed to the mixture of 55% HDPE, 42% PES, 3% PP in mass at test concentrations of 0, 0.64, 1.6, 4 and 10 g/kg dry soil in the test with *E. andrei*, and 0, 0.64, 1.6, 4, 10, 25, 50 g/kg dry soil in the test with *F. candida*. Survival (number of alive adults) and reproduction (number of juveniles produced) were assessed for both species and growth for *E. andrei* to determine No-Observed Effect Concentrations (NOECs). MP ingestion was determined in both species at concentrations of 0.64 and 4 g/kg, and at 50 g/kg in *F.candida.* In addition to assessing the number of ingested particles, size of ingested particles was compared to the initial size distribution. Egestion was also analized at the same concentrations in *E.andrei* after 24 hours of depuration. First results showed that *E. andrei* was not affected by the exposure concentrations, while *F.candida* showed a significant and dose-related reduction in the number of juveniles with a NOEC of 4 g/kg dry soil. However, MP ingestion by *F. candida* was very low (0.75 particles per individual at the hightest concentration), and only observed for HDPE fragments. This suggests that MP shape can influence ingestion; however, effects may also be caused by other mechanisms, such as changes in soil properties, direct dermal effects of the MPs, or the presence of residual additives.

3.10.P-Tu224 Quantification of Nanoplastic Uptake and Distribution in the Root, Stem and Leaves of the Edible Herb Lepidum sativum

Harshit Sahai[1,2]*, Maria Jesus Martinez Bueno*[3]*, Amadeo Rodriguez Fernández-Alba*[3]*, María del Mar Gómez-Ramos*[3] *and María Dolores Hernando Guil*[1]*, (1)Spanish National Research Council (CSIC-EEZA), Spain, (2)Jozef Stefan International Postgraduate School, Slovenia, (3)Chemistry and Physics Department, University of Almería, Spain*

Reports of micro and nanoplastics in agricultural settings around the world and their potentially harmful effects on plant and agricultural health, demand an immediate investigation of this issue. Research regarding the uptake and bioaccumulation of micro and nanoplastics in crops is still at its infancy and the trends and patterns underlying this phenomenon need to be explored. Although few earlier studies have been useful in examining the qualitative aspect of nanoplastic (NP) accumulation in plants, quantifying it is still a difficult task. Finding a solution to this problem could aid in our understanding of this phenomenon and allow us to investigate the distribution of NPs in plant tissues. In this work, we confirm the uptake and bioaccumulation of 100 nm polystyrene nanoplastics by the roots of the edible herb *Lepidum sativum* at exposure concentrations of 10 µg/L, 100 µg/L, 1 mg/L, 50 mg/L and 100 mg/L, and their effective translocation to the stem and leaves of the plant. Nanoplastic presence was confirmed in the root tips, root surface, stele, lateral roots, root hairs, stem vascular bundles, leaf veins and mesophyll and leaf epidermis including stomatal sites. Here, we also propose a novel approach for the quantification of accumulated NPs which utilizes confocal laser scanning fluorescence microscopy coupled with image analysis. Quantification results show that majority of the particles were retained in the root [ranging from 0.023/mm^3 at 10 µg/L to 3.936/mm^3 at 100 mg/L exposure concentration]; while accumulation in the stem [0.020/mm^3 at 10 µg/L to 0.683/mm^3 at 100 mg/L] and leaves [0.003/mm^3 at 10 µg/L to 0.683/mm^3 at 100 mg/L] was only about 18.04% and 13.04% of the median value in roots respectively. Furthermore, accumulation in plant tissues was characterised by aggregation in the intercellular spaces and heterogeneous distribution. Apoplastic pathway seemed to be the mode of NP translocation. The proposed methodology was successfully able to quantify NPs accumulated in different plant parts with a resolution of unit mm^3 and a future scope for inter-sample and intra-sample comparisons. Additionally, there was a reduction of about 38.89 % in the germination rate, 55 % in plant fresh weight, as well as in root weight (> 80 %), root length (> 60 %), shoot weight (51 to 78 %) and number of lateral roots (> 28 %) at exposure concentrations of 50 mg/L and 100 mg/L. However, lower exposure concentrations did not affect plant health significantly.

3.10.P-Tu225 Parking Lots as a Source of Microplastics in Urban Environments: Site Characterization and Interaction With Soil Microarthropods

Marco Scaramelli[1,2,3]*, Maria Agnese Sabatini*[1]*, Roberto Simonini*[1]*, Daniela Prevedelli*[1] *and Elisa Bergami*[1,3]*, (1)Department of Life Sciences, University of Modena and Reggio Emilia, Italy, (2)Department of Chemical and Geological Sciences, University of Modena and Reggio Emilia, Italy, (3)Nbfc, National Biodiversity Future Center, Italy*

Microplastics (MP, size < 5 mm) are ubiquitous in terrestrial ecosystems, being found both in soils exposed to different anthropogenic activities and in remote areas, as a result of long-range atmospheric transport and deposition. The widespread occurrence of MP in soils is as source of concern as they may impair soil health and functions as well as significantly affect soil organisms throughout their life cycle. Notwithstanding, records of local sources of MP in urban environments are still limited and urge further research on MP monitoring in order to adopt measures to preserve soil biodiversity in our cities.

This study aimed to assess: (i) the level of MP contamination in topsoil from urban parking lots in the Emilia-Romagna region (Italy); (ii) the interaction between soil microarthropods and MP within the contaminated sites; (iii) the effects of parking-related MP on the model organism *Folsomia candida* (Collembola).

Topsoil samples and microarthropods were collected in urban parking lots characterised by parking plastic grids or concrete grid pavers, in comparison. MP were extracted from soils and biota using an environmentally friendly protocol based on canola oil floatation (for soil samples) and oxidative treatment (for both types of samples). MP were then isolated on glass-fibre filters and analysed using an optical digital microscope, which allows for a semi-automatic count and size measure of the MPs. Sub-samples were further analysed by Raman microscopy to determine MP prevalent polymers, used for the ecotoxicity testing with *F. candida*.

First results showed high MP levels in the urban parking lots characterised by weathered green plastic grids. For filter portions of 10 mm^2, about 1000 micro-sized green fragments made of high-density polyethylene (HDPE) were found, with a wide size distribution ranging from 20 to 830 µm (average MP size of 160 ±130 µm). These MP were further searched within specimens of soil microarthropods collected from the field to determine the presence of MP traces in their digestive tracts. Furthermore, the preliminary effects of parking-related MP (100-1000 mg/kg) on springtails (*F. candida*) mortality and behaviour were evaluated.

This study allows to understand the risk of MP to urban soil biodiversity. Our findings underline how choices in urban design can determine important sources of MP contamination. Sustainable-oriented urban planning may prevent further human-caused disturbances to urban soil biodiversity.

3.10.P-Tu226 Effects of conventional and biodegradable mulching film microplastics on the earthworm Eisenia andrei

Venla Julia Forsell[1]*, Vili Saartama*[2]*, Raisa Turja*[3]*, Jari Haimi*[2] *and* ***Salla Kristiina Selonen***[3]*, (1)Faculty of Biological and Environmental Sciences, University of Helsinki, Finland, (2)University of Jyväskylä, Finland, (3)Finnish Environment Institute (SYKE), Finland*

Microplastic contamination of soils has become a critical environmental concern, carrying potential repercussions for terrestrial ecosystems. Earthworms, being bioindicators of soil health, offer insights into broader ecological impacts through their responses. Understanding these effects is crucial for predicting and managing the consequences of microplastic contamination in terrestrial environments.

The objectives of this study were to assess the ecotoxicological effects of conventional and biodegradable microplastics on the earthworm *Eisenia andrei*, focusing on reproduction, growth, and oxidative stress. By comparing the effects of conventional polyethylene (PE) and biodegradable polybutylene adipate terephthalate (PBAT) based microplastics, the experiment addresses potential differences in their impact on earthworms.

The experimental setup included a standard eight-week earthworm reproduction test, wherein adult earthworms were exposed to seven different microplastic concentrations (0%, 0.005%, 0.05%, 0.1%, 0.5%, 1%, 5%), ranging from environmentally relevant to high concentrations. After the first four weeks, adults were removed, counted, weighed, and transferred into biomarker assays. The experiment continued with juveniles for an additional four weeks, with the number of juveniles calculated. Additionally, oxidative stress, a critical indicator of an organism's physiological well-being, was evaluated by analyzing five different enzymatic antioxidants and lipid peroxidation levels in tissues of adult earthworm. These parameters contribute to forming a Biomarker Index, providing a comprehensive overview of the antioxidant system's functionality across various microplastic treatments. Furthermore, the soil water-holding capacity and pH were measured.

We anticipate identifying differences in response patterns between conventional PE and biodegradable PBAT microplastics, reflecting the distinct ecological implications associated with these materials.

Filling the knowledge gap in this field is crucial, and this experiment will provide new information on the interactions between earthworms and microplastics in terrestrial environments. The study is part of the PAPILLONS, funded under Horizon2020.

3.10.P-Tu227 Tracking Polyethylene Degradation in Soil Using a 13C-labelling Approach

Hannah Forsyth[1], *Filippo Vaccari*[2], *Andre Velescu*[3], *Edoardo Puglisi*[2], *Wolfgang Wilcke*[3] *and Moritz Bigalke*[1], *(1)Technical University Darmstadt, Germany, (2)Department for Sustainable Food Process, Università Cattolica del Sacro Cuore, Italy, (3)Karlsruhe Institute of Technology (KIT), Germany*

Plastic waste is pervasive in agricultural soil, with polyethylene (PE) being the largest contributor, known for its recalcitrance. Despite this, polyethylene degrades into micro- and nano-plastics in soil. These can affect soil properties and plant health, posing risks to ecosystem services. However, quantitative bacterial mineralization rates of polyethylene, as well as the fate of polymer-derived C in different soil compartments (incorporation into microorganisms, soil structure, etc) are not known. Traditional techniques, such as spectroscopic and imaging techniques, weight loss studies, and microbial respiration lack precision in quantifying PE degradation rates and confirming microbial involvement. Employing ^{13}C-labelled PE is a promising approach, offering precise quantification of mineralization rates and the ability to track polymer-derived carbon assimilation by microorganisms. This can be done by sequencing of the ^{13}C-containing DNA (identifying plastic degraders) and through analysis by nanoscale secondary ion mass spectrometry (NanoSIMS, tracking the polymer-derived C in soil).

This study incubates ^{13}C-labelled PE in a soil microcosm for 2 years. CO_2 formed through microbial mineralisation is trapped in NaOH and quantified via total inorganic carbon concentrations and $\partial^{13}C$ values are determined via elemental analysis isotope ratio mass spectrometry (EA-IRMS) every 4 weeks. Soil samples are collected at 1, 6, 12, and 24 months to identify plastic-degrading microbes, and ploughing/harvest is simulated through addition of organic matter to the soil every 6 months. Initial results show 0.073 mol% of C in PE degraded after 4 months, with a decreasing monthly degradation rate (0.027, 0.020, 0.016, and 0.009 mol% for month 1, 2, 3, and 4). By May 2024, results for the first 9 months of the experiment as well as isolation of microbes responsible for degradation will be available.

The ^{13}C-labelling approach allows for quantification of PE mineralization at very low rates and short timescales and can provide unequivocal proof of biodegradation by microorganisms. Further, will be able to map incorporation of polymer – derived C into soil and microorganisms via NanoSIMS and DNA sequencing. Our study offers an important contribution to understanding the environmental fate of polyethylene, allowing risk assessment to be carried out and addressing pressing concerns related to soil health, crop productivity, and food security.

3.10.P-Tu228 Toxicity assessment of metal mixtures on E. crypticus: effect of Polyethylene microplastic

İrem Öztürk Ufuk[1], *Zeynep Göktepe*[2], *Beyzanur Emanet*[3] *and Emel Topuz*[1], *(1)Environment Engineering, Gebze Technical University, Turkey, (2)Environmental Engineering, Gebze Technical University, Turkey, (3)Gebze Technical University, Turkey*

The ubiquitous presence of plastics, notably Polypropylene (PP), polyethylene (PE), and polystyrene (PS), coupled with the accumulation of heavy metals including Cadmium (Cd), Copper (Cu), Lead (Pb), Nickel (Ni), Zinc (Zn), and Chromium (Cr) in natural ecosystems, raises critical concerns regarding environmental health. Both microplastics and heavy metals pose significant threats as they infiltrate soil, water systems, and ecosystems, impacting diverse organisms and ecological balance. This research aims to elucidate the complex interactions between microplastics and heavy metals in soil environments, focusing on their combined impact on *E. Crypticus* nematode a crucial component of soil ecosystems. While individual toxic effects of these pollutants are well-documented, their combined impact remains a critical knowledge gap, especially concerning multiple metal mixtures. This study pioneers an investigation into the synergistic, antagonistic, or additive effects of PE microplastics in the presence of six heavy metals, examining their influence on the reproductive toxicity of *E. crypticus*. The experimental design includes testing binary and six-metal mixtures against regulatory standards and metal NOEC values. By employing concentration addition and independent action models, the study evaluates the suitability of current regulatory guidelines in estimating mixture toxicity and elucidates discrepancies between regulatory limits and scientific realities. Results indicate substantial alterations in metal toxicity within the presence of PE microplastics, highlighting the importance of considering individual NOEC values for accurate toxicity assessments in mixtures. The study unveils synergistic effects among metals and the role of microplastics in altering metal toxicity profiles, emphasizing the need for a more realistic assessment framework for environmental regulations. This pioneering investigation contributes significantly to understanding the combined effects of microplastics and heavy metals on soil organisms, providing essential insights for regulatory evaluations and emphasizing the necessity of incorporating NOEC values for more effective environmental regulations. The findings underscore the urgency of further research into the fate of metals and microplastics in soil matrices, essential for developing predictive models and refining environmental risk assessments.

3.10.P-Tu229 Earthworm (Eisenia andrei)-Mediated Degradation of Commercial Compostable Bags and Potential Toxic Effects

Luís André Mendes[1], *Ricardo Beiras*[1] *and Jorge Domínguez*[2], *(1)University of Vigo, Spain, (2)Universidade de Vigo, Spain*

The availability of compostable bags has greatly increased over the past few years. Consumers generally perceive that the bags will be degraded after disposal. However, there are still some knowledge gaps regarding the potential effects on the ecosystem due to improper disposal of this type of bags. With the development of degradable polymers such as poly (butylene adipate co-terephthalate) (PBAT) or polylactic acid (PLA) and their application, one such gap is the role that the composition of compostable bags have in their degradation and potential toxic effects.

In the present study, we assessed the degradation rate of polymer films from 4 different types of commercial compostable bags (PLA/PBAT/corn starch, Bioplast (PLA)/PHA, Mater-Bi/corn starch and PBAT/potato starch) in continuous vermicomposting systems, with the earthworm species *Eisenia andrei*, using two different substrates: sewage sludge (SS) from wastewater treatment plant (WWTP) and spent coffee grounds (SCG). This was complemented with the assessment of the biological response of *E. andrei* (survival and reproduction) to microplastics obtained from fragments of the plastics (< 2000 µm) and the seeding emergence in common garden cress (*Lepidium sativum L.*) exposed to micronized plastic (<250 µm) and the respective leachate, following OECD and ISO guidelines respectively.

The degradation rate of the plastic samples differed significantly depending to the type of plastic used in the vermicomposting system, with Bioplast (PLA)/PHA being less degraded, while the addition of starch, e.g., from potato, potentiated the degradation of polymers. These findings suggest the degradation process is more dependent on the microbial community that can colonize the different types of plastic than the earthworm activity. Regarding the biological response of the soil systems, the *L. sativum* seedling emergence was not significantly affected, however it was observed that the microplastics (MPs) of the plastic bags can affect earthworm reproduction, with the less degraded Bioplast (PLA)/PHA being the most toxic. This suggests that although compostable, some of these formulations may potentially be toxic for soil fauna.

3.10.P-Tu231 From Particles to Plants: Exploring Nanopolystyrene's Impact on Lettuce Growth
Hannah Elizabeth Case[1]*, Carol Wagstaff*[2]*, Richard Murphy*[3] *and Maya Al-Sid-Cheikh*[1]*, (1)Department of Chemistry, University of Surrey, United Kingdom, (2)Department of Food and Nutritional Sciences, University of Reading, United Kingdom, (3)Centre for Environment and Sustainability, University of Surrey, United Kingdom*
In horticulture, plastics are crucial in enhancing crop yield and quality. Nonetheless, plastic contamination, notably micro- and nanoplastics, is a growing concern for the potential adverse effects on soil properties and terrestrial organisms. Plastic impact assessments commonly use particles which can contain synthesis impurities and stabilisers, necessitating their impact assessment alongside the plastics. The objectives of this research were to assess the biological response of lettuce (*Lactuca sativa)* exposed to increasing concentrations of nanopolystyrene (*n*PS) using model particles in a laboratory germination and hydroponic system, and to discern whether observed results could be attributed primarily to the *n*PS over synthesis impurities. Here, the synthesis, characterisation, and purification of 30nm *n*PS is described. Increasing concentrations of 0, 0.01, 0.5, 500, and 1000mg/L *n*PS, or surfactant impurities, were used in the exposure to lettuce. Thermogravimetric analysis quantified the *n*PS residual surfactant to inform surfactant controls relative to the *n*PS mixture. To assess the impacts on lettuce, germination rate, biomass, photosynthetic pigment, water uptake, and elemental analysis were measured. Purification of the crude *n*PS achieved 70% surfactant removal. After 3 days, 95% of unexposed seeds had germinated, with a statistically significantly higher germination rate than all *n*PS exposures; however, after 8 days, no significant difference was observed. The surfactant had no impact on germination. After 28 days of *n*PS exposure, all measured parameters demonstrated decreased plant growth with increasing *n*PS concentration, except for leaf moisture and photosynthetic pigment content. Surfactant only exhibited a statistically significant decrease in total leaf area and leaf fresh/dry weight at high exposures, although considerably less than with *n*PS. These findings display the importance of adequate plastic impurity controls for high concentration exposure experiments. Significant negative results on lettuce head growth and root system integrity were discernible even at low level nPS exposure. This poses a concern for horticultural systems, as the continued influx of plastic could progressively compromise lettuce yield and quality, harvest delays, and revenue. Insights into nanoplastic-crop impacts can inform long-term cultivation practices; current research will determine *n*PS uptake and translocation by lettuce as a potential food system input.

3.10.P-Tu232 Nanoplastics in Terrestrial Ecosystems: Linking Exposure to Effects Through Dose-Response Relationships
Christopher Whitshaw[1]*,* ***Michael Peter Meissle***[2]*, Thomas D. Bucheli*[3] *and Denise M Mitrano*[4]*, (1)ETH Zurich, Switzerland, (2)Research Division Agroecology and Environment, Agroscope, Switzerland, (3)Environmental Analytics, Agroscope, Switzerland, (4)Environmental Systems Science, ETH Zurich, Switzerland*
To date, many studies have focussed on the toxicity of nanoplastics (NPs) on aquatic species, yet there is little information available about their impacts on terrestrial organisms. Moreover, studies which have exposed terrestrial organisms to NPs often could not fully assess particle ingestion due to the methodological difficulties of NPs identification and quantification. Here, we achieve NPs quantification within soil organisms with Pd-doped NPs, which can be detected via ICP-MS and can be quantified at magnitudes of orders lower concentrations than previously observed in NPs research. We exposed two important soil organisms, *Folsomia candida* and *Enchytraeus crypticus*, to such NPs in a range of 0 – 5000 mg/kg through spiked feed. Both species were fed *ad libitum* for a period of 21 days. Biological endpoints monitored in assessment of organism health included growth, reproduction, and mortality. Following the exposure period, a subset of organisms were fed a NPs-free diet to quantify particle depuration over a period of 72 hours. Our goals were to 1) quantify NPs ingestion and retention within soil organisms, and 2) investigate the dose-response relationship between NPs ingestion and organism health. While data analysis is still ongoing, we have already quantified nanoplastic ingestion within organisms above background levels at expected limits of detection, with a difference in uptake observed between *F. candida* and *E. crypticus*. We hypothesise that NPs ingestion impacts terrestrial organism health, with resultant effects on growth and reproduction. Through this work, we demonstrate the utility of Pd-doped NPs in quantifying the bioaccumulation of NPs at trace concentrations within organisms, and in enabling dose-response ecotoxicology studies in the field of nanoplastics. Furthermore, we elucidate the risks of NPs to terrestrial organisms beyond growth and reproduction. Collectively, these results on exposure and impact will contribute to the assessment of risks of NPs to terrestrial ecosystems.

3.10.P-Tu233 Seasonal and Population-Driven Microplastic Pollution Highlighted by Wastewater: Soil-Aquifer Treatment as a Potential Solution for Mitigation

Albert Contreras Llin[1]*, Lurdes Martínez-Landa*[2]*, Cristina Valhondo*[3]*, Jesus Carrera*[4] *and Silvia Diaz-Cruz*[4]*, (1)Agencia Estatal Consejo Superior de Investigaciones Científicas, Spain, (2)Tecnical University of Catalonia UPC, Spain, (3)University of Montpellier- CNRS, France, (4)Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain*

While the study of temporal trends is common for other contaminants of emerging concern (CECs), microplastics (MPs) have not been as extensively investigated in this context. This research aims to address this gap of knowledge by examining the seasonal variations in MPs pollution in wastewater treatment plants (WWTPs) in the coastal and tourist-heavy regions of Cambrils and Palamós, Spain. In addition a soil aquifer treatment (SAT) system, which consists of different reactive barriers irrigated with the effluent of Palamós' WWTP, has been studied as a sustainable, efficient, and innovative mitigation approach to reduce massive release of these pollutants into the environment.

Wastewater samples were collected from both WWTPs, at the three different stages of the treatment process. Autosamplers were used to collect 24-hour composite samples. Regarding the SAT system, sampling was performed by grab sampling method, following the dismantling of the reactive barriers. Subsequently, MPs where isolated from the samples performing an oxidative treatment followed by density separation. The solution is filtered through a silicon filter. Once particles are retained onto the filter, visual characterisation is performed under the microscope to evaluate the morphology, color, and size of the MPs. Afterwards filters are analysed by FTIR *imaging*, using a Nicolet™ iN™ 10 MX infrared imaging microscope.

Preliminary results revealed higher MP concentrations in effluent, with subsequent treatment stages significantly enhancing removal. The presentation will delve into polymer distribution across treatment stages, providing insights into the seasonal variation's impact on MP removal in WWTPs. SAT system barrier materials exhibited MP concentrations ranging from 60 to 236 nkg^{-1}, showcasing high accumulation and retention efficiency. Dominant morphologies were fragments (60%) and fibers (17%), primarily white (51%) and transparent (20%). Polypropylene (PP) constituted 47%, followed by polyethylene (PE, 34%).

These results stress the need for continuous monitoring and chemical analysis of MPs in WWTPs to comprehend their source, pathways, and environmental impact, guiding effective mitigation strategies. They also underscore the link between tourism, population growth, and MPs pollution in wastewater. Effective mitigation approaches, like SAT systems, are crucial for improving wastewater treatment and safeguarding ecosystems from microplastics pollution.

3.10.P-Tu234 Vertical Transport of Microplastic Fragments from Mulching Films and Associated Chemical Additives in Soil Ecosystems

Rachel Hurley[1]*, Chiara Consolaro*[1]*, Sam van Loon*[2]*, Aristeidis S Tsagkaris*[3]*, Darina Dvorakova*[4]*, Lotte de Jeu*[5]*, Laura Zantis*[6]*, Cornelis A.M. van Gestel*[7] *and Luca Nizzetto*[1]*, (1)Norwegian Institute for Water Research (NIVA), Norway, (2)Amsterdam Institute for Life and Environment (A-LIFE), Vrije University Amsterdam, Netherlands, (3)University of Chemistry and Technology Prague (UTC), Czech Republic, (4)Department of Food Analysis and Nutrition, University of Chemistry and Technology Prague (UTC), Czech Republic, (5)Vrije Universiteit Amsterdam, Amsterdam Institute for Life and Environment (A-LIFE), Netherlands, (6)Leiden University, Netherlands, (7)Amsterdam Institute for Life and Environment (A-LIFE), Vrije Universiteit Amsterdam, Netherlands*

Soils are an important environmental recipient of microplastic pollution. A dominant source of microplastic to soils is the degradation and fragmentation of plastic mulching films during and after use. Yet, very little is known about the environmental fate of these particles. This is important, as the fate will determine the magnitude and spatial extent of exposure – including whether soil environments represent a release pathway of contamination to other environments or if particles are instead effectively retained and could reach high concentrations following successive inputs over time. These particles may also represent a source of chemical additive to soils, the environmental fate of which is also poorly understood. This study tracked the vertical transport of microplastic fragments derived from relevant plastic mulching films and associated chemical additives within soils. This included an investigation of the influence of potentially relevant factors that may affect fate: bioturbation and soil water inputs.

The experiment was conducted in the CLIMECS (CLImatic Manipulation of ECosystem Samples) facility at Vrije Universiteit Amsterdam, which comprises 40 soil columns that simulate ecosystems – with soil, vegetation, and fauna – and are individually controlled for different environmental conditions. Two types of microplastics: fragments of conventional (LLDPE) and biodegradable (starch-PBAT blend) plastic mulching films where added to the upper layer (10 cm) of soil columns (total length: 40 cm) to represent a contaminated plough layer. Different treatments included high and environmentally relevant microplastic concentrations (0.5% LLDPE + 0.5% starch-PBAT and 0.05% LLDPE + 0.05% starch-PBAT, respectively), high and low watering regimes, and the presence and absence of earthworms. The columns were maintained for a period of three months. At the end of the experiment, each column was divided into six depth layers and the microplastic and chemical additive content was measured at each depth to assess the vertical transport of particles. The results from this study reveal important insights on the mobility of mulching film fragments within soil systems and some of the important controls on particle movement. This provides crucial context related to the exposure of soil environments to soil microplasticand chemical additive pollution derived from mulching film use.

3.10.P-Tu235 Adding it up: Effects of microplastics with additives and increased monomer contents to springtails (Folsomia candida)

Éverton Souza da Silva[1], *Max Valentin Richard Döring*[2], *Magdalena M. Mair*[3] *and Heike Feldhaar*[1], *(1)University of Bayreuth, Germany, (2)Animal Ecology I - Population Ecology, University of Bayreuth, Germany, (3)Statistical Ecotoxicology, University of Bayreuth, Germany*

Antioxidant additives are used in plastic materials to delay their oxidation and prevent aging. When such materials enter the environment, for instance through inappropriate disposal, these additives may leach from the polymers, particularly when they come into contact with non-polar substances or when they are taken up by organisms and translocate into fat tissues. Despite the growing evidence for negative effects of micro- and nanoplastic particles (MNPs) on various organisms, the effects of plastic-associated additives are still largely unknown. In particular, it is often unclear if observed effects of MNP are causally linked to the polymer particles themselves or if they are instead caused by the additives. Generalizations are even more difficult considering that additives and their concentrations are usually not disclosed by the manufacturers and are thus unknown. In addition to these intentionally added chemicals, the monomer contents in MNP can vary and influence the particles' toxicity.

In the presented study, we assess the impacts of polystyrene (PS) fragments with two different additives (Irganox 1010 and Irgafos 168) at two defined concentrations and PS particles with different monomer contents on the springtail *Folsomia candida*. We compare the springtails' responses for two different exposure routes, i.e. via the soil substrate and via feeding. The endpoints assessed include mortality, reproduction, and avoidance behavior. We discuss the results in the context of increased plastic accumulation particularly in soils and develop hypotheses on mechanisms that may be causally linked to the observed effects.

Keywords: soil organisms, microplastics, additives and monomers

3.10.P-Tu236 Plastic Mulch And Pesticides Residues Effecting The Lettuce Growth: Insights of the soil Microbiome and nutrients availability

Nicolas Beriot[1], *Raul Zornoza*[2], *Esperanza Huerta Lwanga*[3], ***Julia Naima Möller***[3] *and Violette Geissen*[4], *(1)SLM, Wageningen University & Research (WUR), Netherlands, (2)UPCT, Spain, (3)Wageningen University & Research (WUR), Netherlands, (4)Soil Physics & Land Management Group, Wageningen University & Research (WUR), Netherlands*

In arid and semi-arid regions, the use of plastic mulch and pesticides in conventional agriculture is nearly ubiquitous. The most common plastic used for mulching is Low Density Polyethylene (LDPE). LDPE mulch needs to be removed after harvest and LDPE debris accumulates in the environment. Some plastic producers have tried to avoid plastic mulch removal and plastic debris accumulation by adding pro-oxidant additives to LDPE, so called Pro-oxidant Additive Containing (PAC) plastics or by using biodegradable polymers (BIO). However PAC plastics leave residues when ploughed into the soil and some BIO plastic don't degrade as fast as expected in the field conditions. Similarly pesticides are known also to accumulate in the soil.

Studies investigating the effect of these contaminants on the soil fertility most often consider pristine plastic or single pesticides. We investigated the effect of one year incubation of plastic debris and pesticides in soil on the growth of lettuces in south east Spain. More precisely, we tested three plastic mulch residues and 3 commercial pesticides, including a treatment with the cocktail of the 3 pesticides compared to controls for a total of 20 treatments. The plastic mulches were first exposed 3 months to the summer weather in the field, cleaned, cut, grounded into macro- and micro-plastics debris and added in 1kg soil mesocosm at a 0.1% content w/w. Pesticides were applied 3 times, every 6 months, following the prescribed application doses. The 1kg soil mesocosms were incubated 1 year and were irrigated to recreate farming conditions. After one year lettuces seedlings, Lactuca sativa, were planted in the incubated soil. The plant growth was assessed during the growing period (number of leaves, chlorophyll content, stomatal conduction) and at the harvest (fresh and dry biomass, leaf area, stem diameter). The soil chemical properties were analysed again. The soil bacterial and fungal communities were analysed through 16S and ITS sequencing and qPCR. In the previous SETAC conference we showed that lettuces growing in soil incubated with the BIO plastic produced a significantly lower biomass compared to the control or the soil incubated with LDPE plastic. We left the audience with two hypothesis to explain the lower biomass i) Is it due to a lesser availability of nutrients? ii) Is it due to a change in the soil microbiome? The microbiome and nutrient data is being analysed to answer this two questions.

3.10.P-Tu237 Linking the occurrence of microplastics and adsorbed organic pollutants in beaches from the Cantabrian Coast (Northern Spain)

Uxue Uribe Martínez[1], *Thomas Maupas*[2], ***Juan Francisco Ayala Cabrera***[3], *Leire Mijangos*[4], *Mireia Irazola-Duñabeitia*[3], *Olivia Gomez-Laserna*[3], *Leire Kortazar*[1] *and Alberto De Diego*[3], *(1)University of the Basque Country (UPV/EHU), Spain, (2)Analytical chemistry, University of the Basque Country (UPV/EHU), Spain, (3)Analytical Chemistry, University of the Basque Country (UPV/EHU), Spain, (4)Analytical Chemestry, University of the Basque Country (UPV/EHU), Spain*

Microplastics (MPs) are not only considered dangerous for the environment due to their petrochemical origin, but also because they have the ability to release their manufacturing additives and concentrate pollutants from the surrounding environment. In addition, their small size makes them easily dispersed in all environmental compartments (water, soil and air), increasing the risk of ingestion by living beings in affected ecosystems, being accumulated and redistributed through food chains. Thus, they are a clear route capable of increasing the distribution, bioavailability, bioaccumulation and ecotoxicity related to them. Nevertheless, the MPs potential as environmental indicators have not been yet exploited, as most of the studies are often focused on their monitoring to identify and quantify which type of plastics are present instead of what they carry on. Thus, this work aims to both identify and quantify the MPs that are arriving to the Spanish northern coast beaches, and assess the levels of organic pollutants that are adsorbed into them. For this purpose, a bi-annual sampling campaign was performed in three significant points of the Cantabrian Coast (Bay of Biscay) to cover pristine, touristic and urban scenarios. As the MPs role as reservoirs depends on their surroundings but also on the nature of the plastic matrix, firstly, a non-destructive characterization based on hyperspectral imaging (HSI) was used to classify and quantify the MPs collected. After that, the occurrence of organic pollutants was assessed using both a target analysis and a suspect screening by gas chromatography coupled with mass spectrometry (GC-MS) using an orthogonal approach with separation in non-polar and polar stationary phases.

According to the results, 3 types of polymers were found as main components of the MPs matrices: polyethylene (PE), polypropylene (PP) and polystyrene (PS). Besides, the presence of 50 organic contaminants (PAHs, PCBs, pesticides, UV filters and fragrances) were quantified showing the highest levels for fluoranthene, cashmeran, PCB 29, tonalide, lindane and PCB 154. In addition to the targeted analysis, several additional compounds were tentatively identified by suspect screening. Thus, this research evidenced the role of MPs as vectors for transport and release of organic contaminants in aquatic environments, and the potential of their use as indicators of the environmental risk of the compartment studied.

3.10.P-Tu238 Fate of Antimony (Sb) from polyethylene terephthalate (PET) micro and nanoplastics: combined toxicity study in soil-plants

***Nithyapriya Manivannan** and Geert Cornelis, Swedish University of Agricultural Sciences (SLU), Sweden*

Polyethylene terephthalate (PET), is a thermoplastic and non-biodegradable polymer with significant commercial use and they make up a significant fraction of plastic waste and are ubiquitous in wastewater treatment sludge in the form of microplastics (MP) and nanoplastics (NP). When this sludge is applied as cheap fertilizers, soils organisms and plants are exposed to PET, but also to additives. Antimony (Sb), is an additive used in the production of PET and can be found in various amounts in the matrix of the finished product.

The release of Sb from PET into water or food under high temperature, has raised concerns in the food and beverage industry, and the migratory properties are being researched. However, such migration in the terrestrial environment has not yet been investigated Plastics (MP& NP) and metals, including Sb, are soil pollutants of concern that are reported to affect the soil biota. Moreover, their coexistence and the impact of nanoplastics in plants mechanisms is not studied or fully understood. We therefore studied Sb migration from PET (MP & NP), Sb speciation in soils, uptake of Sb or PET by wheat or peas and the resulting effect on toxicity to these plants.

Pot experiments using an agricultural soil were set up in a controlled chamber environment where wheat and peas plants, were used as model crops. The plants were grown until full maturation and the life cycle of Sb and PET (MP & NP) in the soil-plant system was analysed. The plants were subjected to different treatments including weathered PET micro and nanoplastics, along with two inorganic species of Sb (Sb (III) & Sb (V)). The soil and plant samples were characterized for elemental concentration using ICP-MS, and direct speciation of Sb is investigated by X-ray absorption spectroscopy (XAS) at Sb K-edge. Additionally, varied concentrations is analysed in pre-experiments to understand the toxicity of these treatments in young plants. The results showed toxicity behaviour in plants respect to their height and biomass for grounded PET of 0. 25% treatment compared to control and other treatments.

The results of the work will help to know the migration effects of Sb from PET in soil, co-existence of PET and Sb ,Sb speciation in soil, and in particular those up taken by plants and whether the speciation influences the effects in the concerned mechanisms. It will help to understand and control the harmful migration effects of Sb, micro and nanoplastics in soil and plant systems.

3.10.P-Tu239 Combining FTIR and Py-GC-MS to monitor microplastics in an agricultural watershed during dry periods

***Lucas Friceau**[1], Guilherme Calabro-Souza[2], Mathilde Lê[3], Nadia Bouzid[4], Max Beaurepaire[5], Bruno Tassin[2], Johnny Gasperi[6], Hocine Hénine[7], Arnaud Blanchouin[7] and Rachid Dris[2], (1)ParisTech School of Bridges, France, (2)Leesu, Ecole des Ponts ParisTech, Université Paris Est Créteil, France, (3)LEESU, Ecole des Ponts, Univ Paris Est Creteil, France, (4)Laboratoire Eau Environnement Systèmes Urbains (LEESU), France, (5)Water Environment and Urban Systems Laboratory (LEESU), France, (6)Gustave Eiffel University, France, (7)UR HYCAR, INRAE, University of Paris Saclay, France*

The last decades have shown an intensified focus on the analysis of microplastics present in the environment, with a recent interest in the continental environment. Only limited knowledge is available regarding the sources and transfer of this pollution in rivers under agricultural impact. This study aims at enhancing the understanding of microplastic transfer along an agricultural watershed.

This study evaluates the microplastic contamination level of a river in an agricultural watershed (Orgeval, 50 km²) 70 km east of Paris. Sampling took place during dry period over a month and enabled us to collect eleven samples. Samples are collected using a plastic-free pumping system combined with in-situ filtration (UFO, particle sizes 10-300 µm) with a median value of 206 L of water filtered.

Samples underwent pre-treatment protocol to remove organic matter and the mineral matrix and were then recovered on Anodisc filters. Three procedural blanks were conducted during sample pre-treatment and showed significantly lower microplastic levels than in samples. Two analytical methods were employed: pyrolysis-gas-chromatography-mass-spectrometry (Py-GC-MS) and Fourier transform infrared microspectroscopy (µFTIR).

Concentrations varied from 111 to 2088 items/m³ (median: 655 items/m³), with samples primarily comprising polyethylene (80%) diverging from a study conducted on the same site on total atmospheric fallout showed predominantly polypropylene (70%) microplastics indicates differing pollution origins.

Among the five targeted polymers with Py-GC-MS, only PP was present in levels above the detection limit. By combining the analysis results with the flow rate, mass fluxes could be calculated for PP. The mass flux values obtained by µFTIR range from 0.01 – 1.11 mg/day with a median value of 0.12 mg/day, whereas values range from 0.07 – 1.20 mg/day but with a median of 0.38 mg/day in Py-GC-MS. Both methods provide results on the same order of magnitude for the PP fluxes.

Although these results are preliminary, they provide crucial information for understanding the dynamics of microplastics within the watershed. The differences in typology between microplastics from atmospheric fallout and those from rivers suggest that the sources of atmospheric microplastics differ from those in the hydrosystem. Moreover, the combining of Py-GC-MS and µFTIR indicates the potential to use these methods for estimating PP fluxes in natural aquatic ecosystems

3.10.P-Tu240 Ecological Impacts of Microplastics and Other Contaminants in Urban Waste Products Used as Fertilizers in Agroecosystems.

Annemette Palmqvist[1]*, Jesper Liengaard Johansen*[2]*, Mette Vestergård Madsen*[3]*, Monica Hamann Sandgaard*[4] *and Jakob Magid*[2]*, (1)Dept. of Science and Environment, Roskilde University (RUC), Denmark, (2)Department of Plant and Environmental Sciences, University of Copenhagen, Denmark, (3)Department of Agroecology, Aarhus University, Denmark, (4)Department of Science and Environment, Roskilde University (RUC), Denmark*

Recirculation of urban organic waste as fertilizers in agriculture offers multiple benefits, i.e., reducing reliance on NPK fertilizers, enhancing soil carbon content, thus positively affecting climate and plant yield. However, waste products also contain xenobiotic residues, including microplastics, raising concerns about their impact on terrestrial ecosystems.

Based on a review of published data, the study aimed to evaluate the prevalence and effects of microplastic pollution in agricultural soils, particularly from recycled waste products like household waste and sewage sludge. A case study related to a long-term Danish field trial, CRUCIAL, where individual plots were fertilized with urban waste products or agricultural reference treatments since 2003, was included in the analysis.

The analysis, not surprisingly, revealed that urban waste products used as fertilizers contribute to microplastic pollution in soils, with significant variability in concentrations. Most effect studies were conducted at concentrations above what is environmentally realistic and focused on effects at the sub-organism or organism level. Furthermore, many studies failed to observe effects within the tested concentration range. The CRUCIAL-related experiments with soil organisms showed no negative effects on soil health due to urban waste products.

The study highlighted the necessity for improved quantification methods for microplastic pollution in soils and emphasized the need for ecologically relevant impact studies. It was concluded that current levels of plastic pollution pose a limited risk to agroecosystems based on existing data. However, this conclusion is constrained by knowledge gaps regarding higher biological impacts and ecological effects under realistic exposure conditions. Standardized analytical methods and long-term field studies could provide a more comprehensive understanding of microplastic fate and impacts in agroecosystems, aiding in a more robust risk assessment.

3.10.P-Tu241 Assessing the Impact of Microplastics on Soil Resilience

Rachel Hurley*, Hafeez Ur Rehman and Luca Nizzetto, Norwegian Institute for Water Research (NIVA), Norway*

Soil ecosystems are highly dynamic self-organizing complex systems. They are spatially extensive and cover 71% of the global land surface; yet, soil resilience is largely underpinned by processes physically occurring at the micrometre scale. Even small changes occurring at this scale can introduce knock-on effects across much wider scales and there is an intricate interplay between the physical, chemical, and biological components of soil. The potential for microplastics to disrupt several of these physical, chemical, and biological components has already been documented in the scientific literature. Hence, microplastics have the potential to impact soil resilience. Addressing microplastic effects by considering the responses of individual organisms or properties in isolation is insufficient to understand the role of microplastics as both widespread habitat modifiers and direct toxicants. Instead, microplastic pollution should be interrogated within the content of soil resilience as part of a more holistic assessment of impact.

Several approaches to quantify soil resilience in response to various disturbances have been proposed in the literature. These measure different aspects, such as the characteristic return time, renewal rate, or ability to resist stress. However, many of these are compiled to specifically address extrinsic and transient factors and are not necessarily directly transferable in the case of a persistent, particulate, and heterogeneous contaminant such as microplastics. An adapted approach is required to measure the impact of microplastics on soil resilience. Here, we present the outcome of a laboratory experiment to track the evolution of microplastic effects on soils over time and use these data to propose a frame for assessing the impact of microplastic on soil resilience. The laboratory experiment measured changes in several soil physicochemical and biological properties over a period of 6 months in response to exposure to microplastic fragments derived from agricultural mulching films. This reveals how soils respond and adapt to the addition of microplastic particles, including a conventional polymer type (which persists for the duration of the experiment) and a biodegradable polymer type (which transforms over time). The new statistical frame for assessing soil microplastic pollution in the context of soil resilience represents a new holistic tool for evaluating microplastic impact in soil ecosystems.

3.10.P-Tu243 Evaluation Method of Ecotoxicity for Biodegradable Plastics II

Norihisa Tatarazako[1] *and Yukiyo Okazaki*[2]*, (1)Ehime University, Ehime, Japan, (2)Ehime University, Japan*

Marine pollution caused by plastics has become a global environmental problem. The prevailing use of biodegradable plastics is one of the solution, and their development is underway around the world.

The new materials are expected to have no ecotoxicity with their high molecular weight at the point of manufacturing and shipping, although, the impact of their degradated products are concerned because they are supposed to be decomposed in the environment and there is not established method for evaluating the environmental safety of biodegradable plastics.

Currently, there is a test method for the ecotoxicity of biodegradable plastics, ISO 5430, which is proposed for assuming the oceanic degradation. Although the method is designed only for the toxicity of soluble components of the sample. So that those method is not suitable for evaluation of the biodegradable plastics with their decomposed intermediate products which should be taken into account.

Also, a wide variety of structures and properties of the biodegradable plastics makes difficulties for uniform application of any method to those samples.

Therefore, the purpose of this study is to investigate the environmental impact under more realistic conditions.

First, the biodegradable plastics are classed by hydrolysis rate, and sorted into biodegradable or not based on those hydrolyze or not. In those flow scheme, when samples are assumed biodegradable, the ecotoxicity tests will be conducted.

We tested five representative biodegradable plastics on fish, crustaceans, and luminescent bacteria using above scheme and those results will be presented.

3.10.P-Tu244 Assessment of Microplastic Presence Along an Atlantic Coastal Region

Vanessa Morgado[1]*, Ricardo Bettencourt da Silva*[2]*,* ***Ana Catarina Carvalho da Rocha***[3] *and Carla Palma*[3]*, (1)University of Lisbon, Portugal, (2)Centre for Structural Chemistry - Institute of Molecular Sciences, University of Lisbon, Portugal, (3)Division of Chemistry and Pollution of the Marine Environment, Hydrographic Institute, Portugal*

Microplastics are currently affecting numerous aquatic systems worldwide. The significant prevalence of microplastics in the environment has attracted the scientific community's interest in monitoring these contaminants across various aquatic environments and matrices, including ocean floor sediments. Implementing policies and legislation to control and manage (micro)plastic pollution is crucial for safeguarding the environment, particularly coastal areas. The development of regulations should be informed by the recognised significance and trends of this form of pollution. The true importance and potential sources of this contamination can only be comprehended through the objective characterisation of contamination levels and trends.

The present work describes the first bottom-up evaluation of the uncertainty of the quantification of microplastics in environmental sediment samples, taking into account the sampling uncertainty.

This evaluation involved the identification and quantification of systematic and random effects affecting the analysis, using different probability density functions. Poisson-Lognormal distribution was used to model the random and systematic components that affect the counting of microplastics, and continuous rectangular and *t*-Student distributions were associated with uncertainty components of the sediment sample weighting. The sampling uncertainty over the 700 km^2 studied oceanic area was characterised considering the contamination heterogeneity and representativeness of sampling. The distribution of the microplastics number concentration was modelled by combining the above distributions and sampling uncertainty components by the Monte Carlo method. The confidence limits that enclose the true value of the contamination were defined for a 99% probability.

The methodology developed was successfully applied to the quantification of the following types of particles in sediments: i) microplastics, regardless of their physical-chemical properties; ii) polyethylene terephthalate (PET); iii) polypropylene (PP); and iv) polyethylene (PE). This investigation unequivocally demonstrates that the contamination level in the studied area did not significantly change between 2018 and 2019, with PET microplastics being the predominant polymer type. The collected data pertaining to the environmental area play a crucial role in establishing an objective and binding assessment of microplastic contamination significance.

3.10.P-Tu245 The Deterioration of Bio-based PLA Plastic Teabags Under Natural Soil Conditions and Their Effect on Earthworms

Winnie Courtene-Jones[1]*, Fannie Burgevin*[2]*, Lily Munns*[1]*, Maia Shillam*[1]*, Francesca De Falco*[1]*, Richard D. Handy*[1]*, Antoine Buchard*[2]*, Richard C. Thompson*[1] *and Mick E Hanley*[1]*, (1)School of Biological and Marine Sciences, University of Plymouth, United Kingdom, (2)Institute for Sustainability and Department of Chemistry, University of Bath, United Kingdom*

In response to the widespread concern about plastic pollution, countries have set targets to eliminate or make plastic packaging reusable, recyclable or compostable. This includes teabags, where manufacturers have substituted the conventional plastic content with bio-based, biodegradable polymers, such as PLA. The rate at which PLA degrades varies widely within and between industrial facilities and home compositing, which can result in plastic residues being transferred to the natural environment through the application of compost. Despite widespread use, the degradation rate of PLA/PLA-blended materials in natural soil and their effects on soil biota are not well quantified. The deterioration of teabags with differing PLA:cellulose compositions, exposed to natural soil (-10cm depth) for 7-months were examined using a suite of analytical techniques. The effect of 28-days exposure to teabag discs at environmentally relevant concentrations (0.02 %, 0.04 % and 0.07 % w/w) on the survival, growth and reproduction of the soil detritivore *Eisenia fetida* was assessed (OECD 222). After 7-months, 1:3.5 PLA:cellulose blend teabags and 1:2.4 blend teabags had lost on average 82 % and 66 % of their mass respectively, while 1:0 PLA bags remained unchanged. Changes were attributed to degradation of the cellulose component of the teabag, confirmed by microscopy and FTIR spectroscopy. Earthworms exhibited different resource allocation strategies in response to the teabag compositions between treatments. The reproductive output of earthworms was significantly suppressed following exposure to ≥0.04 % w/w of the 1:0 PLA teabags, however survival and growth were not impeded. In contrast, earthworm mortality increased and egg production significantly increased following 28-day exposure to 0.07 % w/w of the 1:2.4 PLA:cellulose blend teabag. Consequently, we show that the PLA:cellulose content of teabags affects degradation and can have complex effects on the reproductive output, and thus population dynamics, of the ecologically important earthworm *E. fetida*. The results highlight the necessity to better understand the environmental fate and ecotoxicity of PLA/PLA-blended materials, often proposed as plastic alternatives.

3.11.A Fate and Toxicity of Metals: Recent Scientific Advancements, Challenges for (Data-Poor) Metals, and Application to Environmental Regulations

3.11.A.T-01 Effects of Biochar amendment on earthworm heavy metal bioaccummulation from e-waste contaminated soil

Patricia Bi Asanga Fai *and Tenonfo Ngouefack Sophie Rella*[2]*, (1)University of Dschang, Cameroon*

Waste Electrical and Electronic Equipment (WEEE), commonly referred to as e-waste, has emerged as a rapidly expanding waste stream and a significant environmental issue globally. The growth and reproduction of earthworms exposed to e-waste contaminated soils has been shown to be severely inhibited and this was linked to heavy metal uptake and bioaccummulation by the earthworms. Biochar is recognized for its ability to remediate various contaminants from soil, including excessive heavy metals, by reducing their bioavailability and disrupting their exposure pathway. However, effects of biochar applications on macrofauna such as earthworms have received very limited attention. The effects of 1% biochar amendment to e-waste contaminated soil on heavy metal bioaccummulation by the tropical anecic earthworm, *Alma nilotica*, was studied. We found that the concentrations of all five heavy metals studied (Cd, Cu, Ni, Pb and Zn) decreased continuously from the amended as well as unamended e-waste soil over the study duration, while increasing in the exposed earthworms. More interestingly, the earthworms bioaccummulated the metals more in the unamended e-waste soil when compared to the biochar-amended soils, despite the fact that the amended soils contained a higher metal concentration. Consequently, the bioaccummulation factors (BAFs) of all five heavy metals were 3.7 to 5.8 times higher in the unamended e-waste soil compared to the amended soil. Pb had the highest BAF, followed by Cu and Zn, which had very similar BAFs. These results confirm the potential of biochar for soil heavy metal remediation. However, it is necessary to determine if this observed lowering of heavy metal uptake and bioaccummulation will correspond to increased earthworm growth and reproduction.

3.11.A.T-02 Antimony Release Upon Soil Flooding- Influence of Contamination Source and Soil Properties

Ursina Morgenthaler[1]*, Karen Viacava*[1]*, Steven Doherty*[2]*, Susan C Wilson*[3]*, Julie Tolu*[4] *and Adrien Mestrot*[1]*, (1)University of Bern, Switzerland, (2)Southern Cross University, Australia, (3)University of New England, Australia, (4)Water Resources and Drinking Water, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland*

Antimony (Sb) is a toxic and potentially carcinogenic metalloid, which is listed as a pollutant of primary concern. Despite its increasing production over the last years, environmental concerns about Sb have emerged only recently and many aspects of its biogeochemistry remain unclear. When mobilized from contaminated soils to water, Sb poses a potential threat to surrounding environments and might become bioavailable. Soil Sb can be very mobile under flooded conditions, which are expected to occur more frequently in the future due to climate change.

Here, we incubated six Sb-contaminated soils under flooded conditions in mesocosms, which allowed for soil, porewater, surface water, and head-space sampling over an incubation time of three months. This talk focuses on the soil porewater, which was analyzed for Sb speciation, Sb size fractionation, and a series of explanatory parameters.

The study soils differ in their contamination source and properties including organic matter, pH, iron, manganese, and sulfur concentrations, which led to contrasting Sb release patterns in the soil porewater. In shooting range soils, highest porewater Sb concentrations were observed immediately after flooding through the release of easily soluble, dissolved anionic Sb(V). The Sb release pattern of mining-polluted soils differed greatly with contrasting soil properties: in inorganic Fe-rich soils, Sb release was mainly driven by co-release with reductive dissolution of iron-hydroxides, while the drivers behind Sb release in the organic soil are more complex.

Size fractionation of porewater Sb showed that the majority of Sb was present as very small, dissolved ions, meaning that colloidal transport only played a minor role in Sb mobility. Size exclusion chromatography analysis nonetheless revealed an association of Sb with Fe-oxides and organic matter, which increased with time after flooding. Interestingly, Sb-bearing particles >0.45µm were only measured in one organic mine-impacted wetland soil.

These results demonstrate the complex biogeochemistry of Sb, which underlines the difficulty of risk assessment of Sb-contaminated sites. By implementing new analytical methods and including soil, water, and air, this study enables a more comprehensive picture of Sb geochemistry in flooded soils and contributes to improved prediction of Sb behavior in the environment to better manage contamination events under changing climate regimens.

3.11.A.T-03 Understanding the multiple fates of rare earth elements (REEs) in abiotic and biotic compartments of the St. Lawrence River, Canada.
Marie-Christine Lafrenière, *Jean-François Lapierre and Marc Amyot, Groupe de recherche interuniversitaire en limnologie (GRIL), University of Montréal, Canada*
The demand for rare earth elements (REEs) is increasing due to their numerous applications, including low-carbon energy and digital technologies. Canada owns one of the largest REE deposits worldwide and has started exploiting its first mine in 2021. Combined with the intensification of urban development and agriculture, and climate change effect on browning and precipitations patterns, we can anticipate an increased mobilization of REEs to freshwater ecosystems that supports important ecological services and biodiversity. Therefore, there is a need to gain an integrated understanding of the fate of these metals in the abiotic (water, sediments) and biotic (invertebrates, fish) compartments of the fluvial landscape. Our recent work showed that REEs in the surface waters of the St. Lawrence River were increasingly associated with colloids and particles along the upstream-downstream gradient, which was linked to the terrestrial organic-rich inputs from its main tributary draining REEs-rich geology, the Ottawa River, and which was further reflected in the relative distribution of light and heavy REEs. Here, our main objectives are to assess their accumulation and relative distribution in the biotic and abiotic compartments from the same river, and to identify the related environmental or biological predictors to understand their global fate at the ecosystem scale. Sediments were the most important sink for REEs and their accumulation was related to smaller grain-size and was relatively enriched in middle REEs, probably due to their association with Fe and Mn oxides. Uptake by both invertebrates and fish depended on species, feeding behavior and trophic position. In addition, organisms with more diversified diet, such as a combination of sedimental organic matter, plankton, and invertebrates, tended to accumulate more REEs than more pelagic or piscivorous organisms. In addition, our results showed that amphipods accumulated seemingly anthropogenic Gd around Montreal area and that, although walleye and sauger did not accumulate important concentration of REEs, their accumulation was directly correlated with the free ion form of REEs in surface water. These findings highlight major differences in REE concentration and composition among biotic and abiotic compartments of a large river, suggesting that sediments are the most susceptible to respond to future contamination and this this response is likely to decrease going up in the trophic chain.

3.11.A.T-04 Ecotoxicology of Rare Earths in aquatic systems:Integrated overview of fate and behavior of Rare Earth in river, their trophic transfer and environmental impacts in a Life Cycle Assessment perspective
Laure Giamberini[1] *and Arno C. Gutleb*[2]*, (1)Université de Lorraine, CNRS, LIEC, France, (2)Erin, Luxembourg Institute of Science and Technology (LIST), Luxembourg*
Rare Earths are a group of 17 metals including the lanthanide series, Sc and Y. They are used in high-tech devices. Anthropogenic use is disrupting the biogeochemical cycle and enrichments of La, Ce, Nd, Sm and Gd are already detectable in waters. The current literature on REE-associated health effects is mostly confined to 3 REE, thus the information for several REE remains relatively scarce, notwithstanding their growing industrial utilization and, hence, environmental spread and human exposures. However, evidence gathers that REEs must be acknowledged as new, emerging contaminants with manifold ways of entry into the environment. The objectives of the project were : linking the speciation of REEs to their biological effects, combining field observations with laboratory experiments, to follow a tiered and interdisciplinary approach from field observations through screening to focused experimental manipulation under increasing environmental realistic conditions and developing an AOP framework and integrate this into a life cycle perspective.

ECOTREE represents a holistic and interdisciplinary proposal outside a mining context covering large parts of the REE life cycle, from the geochemistry of anthropogenic REEs, their dynamics in (waste)water systems, their speciation and related bioavailability, their trophic transfer and environmental impact assessment at different biological levels and include a Life Cycle Assessment perspective. The approach proposed in this project combines field observations and realism-checked laboratory experimentations to ensure that speciation, bioavailability, bioaccumulation and toxicity pathways for REEs were studied in realistic conditions on 5 living organisms representative of freshwater systems, allowing to better extrapolate of the laboratory results to field conditions.

The results obtained suggest erosion of soils as the main source of particulate REE in the two rivers, although a Nd anomaly of industrial origin occurred in the particulate and coarse colloidal fractions of the industrialized river basin. Toxicity of the series of REEs could not be correctly evaluated using the exposure nominal concentrations for algae and *Daphnia magna*, but on the concentrations of free ions that for some REEs changed during exposure time. The calculated EC_{50} values ranged from tens of nanomoles for La, Ce, Pr, Sm, Eu, Gd, Tb and Dy to (sub)micromolar for the remaining elements with common biological modes of action.

3.11.A.T-05 Periphyton Is a Unique Ecological Niche Playing Critical yet Underrated Roles in Aquatic Mercury Cycling and Bioaccumulation

Yong Cai[1]*, Guangliang Liu*[2]*, Yuping Xiang*[3] *and Afia Anjuman*[2]*, (1)Department of Chemistry and Biochemistry and Institute of Environment, Florida International University, (2)Department of Chemistry and Biochemistry, Florida International University, (3)Research Center for Eco-environmental Sciences, Chinese Academy of Sciences, China*

As a global pollutant, mercury (Hg) cycles between air, water, soil, and sediment involving transport and transformation of various Hg species, forming a complicated biogeochemical Hg cycle. Mercury poses adverse health effects to millions of people worldwide, primarily due to production of methylmercury (MeHg) in aquatic environments and bioaccumulation of MeHg along the food chain. Despite global effort to reduce Hg emission for alleviating its health risk, Hg time trends in fish often do not agree with concurrent decreasing trends in atmospheric Hg deposition to aquatic environments. This divergence suggests the current incomplete understanding of the biogeochemical processes controlling MeHg production and bioaccumulation in aquatic ecosystems. Although sediment is long known as the primarily site for Hg methylation, recent studies suggest the enhanced Hg methylation in periphyton, a unique algae-bacteria synergistic community and ubiquitous food web base in various aquatic environments and thus playing a critical role in MeHg bioaccumulation. Our effort here is to provide a summary of our previous work on the effects of periphyton on MeHg distribution and bioaccumulation and the literature on Hg methylation in periphyton, from the perspective of understanding the potential mechanisms underlying the enhanced Hg methylation and the implications of periphyton as a major source for MeHg bioaccumulation. Our work and others, albeit the number of studies being limited, have indicated that periphyton is conducive to Hg methylation with dissolved organic matter playing a critical role and periphyton-produced MeHg can have a major impact on aquatic MeHg cycling and bioaccumulation. Future microscale studies to elucidate the mechanisms of the coupled algal and bacterial Hg and C metabolism regulating Hg methylation in periphyton and macroscale investigations to comprehensively evaluate the role of periphyton in environmental distribution and bioaccumulation of MeHg are both urgently needed.

3.11.B Fate and Toxicity of Metals: Recent Scientific Advancements, Challenges for (Data-Poor) Metals, and Application to Environmental Regulations

3.11.B.T-01 Internalization of Organically Complexed Copper by a Coastal Dinoflagellate in Synthetic and Natural Seawater Samples

Paula Sánchez-Marín[1]*, Esther Barber-Lluch*[2]*, Maria Sol Hernandez Conesa*[3]*, X. Antón Álvarez-Salgado*[2]*, Mar Nieto-Cid*[1]*, Patricia Bernárdez*[1] *and Juan Santos-Echeandía*[1]*, (1)Vigo Oceanographic Center of the Spanish Oceanographic Institute, Spanish National Research Center (IEO-CSIC), Spain, (2)IIM-CSIC, Spain, (3)Spanish Institute of Oceanography - Spanish National Research Council (IEO-CSIC), Madrid, Spain*

Copper (Cu) is by far the most studied metal concerning the effects of organic complexation on metal bioavailability, and it is widely accepted that the presence of organic matter has a protective effect on Cu uptake and toxicity, by decreasing the concentration of free metal ions. However, this idea is based in laboratory experiments either performed at higher Cu concentrations than those that are environmentally relevant, or in experiments that used synthetic chelates (such as EDTA) to control for Cu speciation. The present experimental work was designed to test if Cu bioavailability actually depends on the free ion concentration at an environmentally relevant concentration of Cu (20 nM), using both synthetic and natural samples in the absence of synthetic chelates. As synthetic samples, artificial seawater was amended with fulvic acids or Marine-DOM extracted by ultrafiltration. Natural samples were collected from a mining-impacted coastal lagoon (Mar Menor, SW Spain), presenting dissolved Cu concentrations ranging from 3.5 to 14 nM. The samples were enriched in ^{65}Cu (15 nM) in order to study the short term internalization of Cu by the coastal dinoflagellate *Prorocentrum micans*. Results show that net Cu internalization by *P. micans* is higher than that expected on the basis of Cu speciation (either analysed by anodic or cathodic stripping voltammetry). The results are consistent and occur in all samples, both the synthetic and the natural ones, suggesting that organically complexed Cu can be accessed by marine phytoplankton. This work challenges the applicability of current bioavailability models for Cu in coastal waters.

3.11.B.T-02 Concentration Addition or Independent Action: Which Model Better Predicts Aquatic Toxicity of Environmentally Realistic Metal Mixtures?

Maria Laura De Donno[1]*, Franz Marius Schmitt*[1]*, Charlotte Nys*[2]*, Karel Viaene*[2]*, Hugo Waeterschoot*[3] *and Karel De Schamphelaere*[1]*, (1)GhEnToxLab, Ghent University (UGent), Belgium, (2)ARCHE Consulting, Belgium, (3)Chemicals Management*

Risk assessment of chemical mixtures is conveniently regulated following the concentration addition (CA) model. A more accurate alternative for chronic metal mixture toxicity is provided by the independent action (IA) model. A quantifier to assess the deviations of observed toxicity from toxicity predicted with CA at low effect levels is called the MIF (Mixture Interaction Factor), which indicates a trend toward synergistic (MIF<1) or antagonistic (MIF>1) interactions, relative to CA, if present.

This study aims to test the hypothesis that IA generally predicts better metal mixture toxicity than CA. In addition, it will, based on theoretical and mathematical considerations, test the hypothesis that the MIF increases with the number of metals in the mixture. This work is part of the comprehensive Eurometaux MEED (Metals Environmental Exposure Data) program, as project 5.

Ag, As, Ba, Cd, Cr, Cu, Mn, Ni, Pb, and Zn were selected for testing as they were estimated to be the major contributors to mixture toxicity for *Raphidocelis subcapitata* in European freshwaters. For this species, it was estimated that in a mixture experiment, five metals are usually sufficient to explain 90% of the toxicity of the risk of the whole mixture. Therefore, 3 environmentally relevant groups of the above-mentioned 10 metals were selected for testing (i. As-Cu-Pb-Ni-Cd, ii. Mn-Zn-Ba-Cr-Cd, iii. As-Zn-Pb-Ag-Cu). Each experimental design consisted of testing simultaneously the 5 individual metals separately and in mixtures. The set of mixtures consisted of a binary (2 metals), a ternary (3), a quaternary (4) and 2 quinary (5) combinations. The experiments were conducted following an equitoxic ray design based on EC10 values, with one additional quinary mixture at environmentally relevant concentration ratios.

Overall, the two models showed rather similar results, with no clear trend toward synergistic or antagonistic interactions relative to the models. However, at environmental and regulatory more relevant concentrations (i.e., at 10% effect level), CA generally overestimated the mixture toxicity, as confirmed by the MIF values being all above 1, with an average MIF of 1.59 ± 0.59 (±: SD). Finally, the MIF did not increase with the number of metals in the mixture. Possibly, the toxicity of the metal mixture (and the magnitude of the deviation from CA) is more influenced by the relative concentration of the metals in the mixture.

3.11.B.T-03 Investigating Population versus Individual Sensitivity of Lymnaea stagnalis to Nickel (Ni)

***Kristi Weighman*[1]**, *Karel Viaene[2] and Karel De Schamphelaere[1], (1)Ghent University - GhEnToxLab, Belgium, (2)ARCHE Consulting, Belgium*

Lymnaea stagnalis, known as a particularly sensitive species to various metals, exhibits inconsistent responses across different studies regarding its sensitivity to nickel (Ni). Understanding the variability in the snail's sensitivity to Ni remains pivotal for effective risk assessment but poses a challenge due to the lack of a clear explanation for its toxicity mechanism. This study aims to create an experimental dataset which allows for the calibration of a DEB model to describe the toxicity of Ni to *L. stagnalis* and the validation of extrapolations to the population level using a DEB-IBM.

To examine the effect of Ni on different life stages of *L. stagnalis*, we conducted a series of 28 day toxicity tests. These experiments assessed the impact of Ni on endpoints such as growth, ingestion, and reproduction of the snails. Ultimately, these experiments revealed a stark contrast in sensitivity between juvenile and adult snails. While juveniles displayed sensitivity at relatively low Ni concentrations (11 µg/L), adult snails remained unaffected up to 166 µg/L. This divergence in individual level sensitivities prompted further population level experimentation.

During an extended 133-day exposure, populations of *L. stagnalis* showed significant decline in biomass and reproduction at 79 µg/L of Ni. These results call into question the protective efficacy of traditional reproduction tests for higher levels of biological organization. The discrepancy between individual and population responses highlights the need for a better understanding of the mode of action of Ni toxicity in *L. stagnalis*. The results of this population level test can be used as a potential validation for the existing *L. stagnalis* DEB-IBM, which incorporates population dynamics (e.g. competition for food) that do not impact standard individual level tests. Further refining population simulations may also allow for insights into the mode of action of Ni toxicity to the snails, which could not be determined based on individual testing.

Toxicity tests have demonstrated differing sensitivity between adult and juvenile *L. stagnalis*. Extended population exposure showed significant effects on population biomass and reproduction at lower concentrations than observed in adult reproduction studies. Further work is needed to more fully understand the mechanism of Ni toxicity to *L. stagnalis* and to investigate what factors are most impactful the relationship between individual and population sensitivity.

3.11.B.T-04 Estimating and Using Ambient Background Concentrations in Surface Waters for Nickel in Europe

***Elizabeth Middleton*[1]**, *Adam Peters[2], Iain Wilson[2], Graham Merrington[2], Emily Rogevich Garman[1] and Christian Schlekat[1], (1)NiPERA Inc., (2)wca environment Ltd., United Kingdom*

Naturally occurring substances such as nickel will always be present at some level in the environment, although the concentrations at which they are present may be increased by anthropogenic activity. Recent activities on substance prioritisation and Environmental Quality Standard (EQS) derivation under the European Water Framework Directive (WFD, Commission Directive 2000/60/EC) have demonstrated that the use of assessment factors on HC5s in deriving metals EQS can result in values that are within the range of ambient background concentrations (ABCs) and lead to potential non-compliance even in some relatively pristine areas. EQS derived in this way may provide little or no ecological benefit, but may drain limited regulatory resources. Taking account of local background concentrations due to the naturally occurring nature of nickel may therefore be appropriate in some situations and inline with current guidance.

We have developed an approach for identifying situations where local background concentrations should be considered, and for deriving them if required, that is straightforward, transparent, scientifically defensible, and readily implementable by non-experts.

A checklist was developed to identify whether there is a potential need to derive a local background concentration at a site and an assessment was performed from a collated regulatory freshwater monitoring dataset of 545,577 samples, covering 21,092 sites in 26 countries. Surface water data are the most appropriate source to use for the derivation of background concentrations due to their direct relevance and likely availability to the assessors needing to derive local background concentrations. Data from sites that are relatively close to those for which background concentrations are required and are not significantly impacted by anthropogenic disturbances is recommended to use as the source of background concentrations.

Following the completion of the tiered risk assessment, three countries (Cyprus, France and Spain) were identified to support case-studies and the methodology for Tier 3 failures was applied. For both Cyprus and France a number of Tier 3 failures could be resolved by applying this methodology, and therefore country-wide compliance rose. This presentation will include example sites from these case studies showing the application of the derived methodology.

3.11.P Fate and Toxicity of Metals: Recent Scientific Advancements, Challenges for (Data-Poor) Metals, and Application to Environmental Regulations

3.11.P-Mo133 Tracing Potential Emissions from Corrosion Protection Systems for Offshore Wind Farms in the Marine Environment

Anna Ebeling[1,2]*, Dominik Wippermann*[1,2]*, Alexa McCormick Zonderman*[1,2]*, Ole Klein*[3]*, Tristan Zimmermann*[1]*, Torben Kirchgeorg*[4]*, Simone Hasenbein*[4]*, Ingo Weinberg*[4] *and Daniel Pröfrock*[1]*, (1)Inorganic Environmental Chemistry, Helmholtz-Zentrum Hereon, Germany, (2)Universität Hamburg, Germany, (3)Inorganic Environmental Chemistry, Helmholtz Center Hereon, Germany, (4)German Federal Maritime and Hydrographic Agency (BSH), Germany*

In order to combat climate change, the share of renewable energy production must increase drastically. Offshore solutions are gaining more and more importance and the number of offshore wind farms is growing steadily. As of 2021, 28 GW of offshore wind energy was installed in Europe and 55.9 GW worldwide. The UN has set an even higher / more ambitious goal, to increase the global offshore wind capacity to 380 GW by 2030.

The impact of these offshore constructions on the marine environment remains unclear in many aspects. In fact, little is known about potential chemical emissions from corrosion protection systems such as galvanic anodes composed of AlZnIn alloys, used to protect offshore structures. Those anodes are designed to corrode in place of the structural steel, resulting in the continuous emission of metals (e.g. >2000 kg Al-anode material per pile for the lifetime of 25 years) into the marine environment. In a previous study the elements Al, Zn, Cd, Pb, Ga and In were identified as potential tracers for offshore-wind-induced emissions.

Seawater, sediment, and blue mussels were sampled from offshore wind farms in the German Bight and analyzed via inductively coupled plasma mass spectrometry to obtain multielement and isotope data. In the seawater samples an accumulation of metals along the residual current was observed in some years, and for sediment samples some local hotspots were identified. However, Sr isotope data suggests a large influence of sediments from the tributaries. Blue mussels did not show elevated levels of Cu, Zn and Pb compared to the North Sea and to international health standards, however, no accumulation of In and Ga were observed. In conclusion, multielement datasets can be used to trace emissions from offshore wind farms. In particular, the TCEs Ga and In are promising tracers, and first hints for emissions from corrosion protection systems were found in seawater and sediment samples. However a clear source assignment is currently difficult, because source differentiation remains challenging and demands a continuous monitoring of old and new tracers

3.11.P-Mo134 Influence of the initial speciation of platinum and palladium on their bioavailability to a green alga

Julien Michaud-Valcourt[1]*, Séverine Le Faucheur*[2]*, Sylvie Blanc*[3]*, Louis Courtois*[3]*, Jelle Mertens*[4] *and Claude Fortin*[5]*, (1)INRS - Centre Eau Terre Environnement, Canada, (2)Universite de Pau et des Pays de l'Adour, E2S-UPPA, CNRS, IPREM, France, (3)Université de Pau et des Pays de l'Adour, France, (4)EPMF, Belgium, (5)INRS, Canada*

The unique properties of platinum-group elements (PGE) have led to many applications for these metals. Consequently, multiple emission pathways have been investigated and a relation was firmly established between global demand for these metals and their subsequent release in the environment. It is therefore necessary to better understand the potential risks associated with PGE. In classical metal toxicity studies, it is often assumed that thermodynamic equilibrium in the exposure medium is reached rapidly. This however, may not be true for platinum (Pt) and palladium (Pd) due to their inherently slow kinetics. Indeed, the water exchange rate - a key indicator of reaction kinetics - for most transition metals is in the order of 10^{-7} to 10^{-10} s^{-1}, while for Pt and Pd, the rate constants are orders of magnitude higher (~ 10^{3} s^{-1}). If the equilibrium period is long relative to the total exposure time, aquatic organisms may be mostly exposed to the complexes present at the start of the test rather than those expected to be present at equilibrium (or to a mixture of the two).

In this project, we examined the accumulation of five Pt and Pd complexes ($Pt(IV)Cl_6^{2-}$, $Pt(II)Cl_4^{2-}$, $Pt(II)(NH_3)_4^{2+}$, $Pd(II)Cl_4^{2-}$ and $Pd(II)(NH_3)_4^{2+}$) by the unicellular green alga *Pseudokirchneriella subcapitata* and their subsequent toxicity after 96 h of exposure in USEPA medium. An investigation of the stability of the tested complexes was carried out by spectrophotometry and reaction kinetics calculations. Our results point at the rapid dissociation of Pd complexes leading to the formation of $Pd(OH)_2$ in the case of $Pd(II)Cl_4^{2-}$ and the formation of a mixture of $Pd(NH_3)^{2+}$, $Pd(OH)_2$ and $Pd(NH_3)_2^{2+}$ in the case of $Pd(II)(NH_3)_4^{2+}$. Similar Pd accumulation was measured for both studied complexes but $Pd(NH_3)_4^{2+}$ was slightly more toxic, maybe due to the presence of $Pd(NH_3)^{2+}$and $Pd(NH_3)_2^{2+}$. On the other hand, all three Pt complexes tested resulted in similar accumulation by the algae but only $Pt(IV)Cl_6^{2-}$ led to a significant growth inhibition. Interestingly, $Pt(II)(NH_3)_4^{2+}$ was shown to be stable in test medium for at least 96 h whereas $Pt(II)Cl_4^{2-}$ was much less stable with indications of dissociation occurring within less than 24 h. This suggests that, initial speciation of Pt(II) complexes does not affect toxicity over the concentration range tested (0 - 150 µg/L). Furthermore, the surprising $Pt(IV)Cl_6^{2-}$ toxicity was potentially linked to free radical species formed during the reduction to Pt(II).

3.11.P-Mo135 Knowledge gaps in thermodynamic data needed to predict the aqueous speciation of platinum-group elements

Claude Fortin[1]*, Peter G. C. Campbell*[2] *and Séverine Le Faucheur*[3]*, (1)Institut national de la recherche scientifique (INRS), Canada, (2)Centre Eau Terre Environnement, University of Quebec, INRS, Canada, (3)Universite de Pau et des Pays de l'Adour, E2S-UPPA, CNRS, IPREM, France*

The current tenet of metal bioavailability stipulates that the uptake and toxicity of a metal are not related to its total concentration in solution but rather to its free-ion activity (the other main toxicity modifying factors being hardness and pH). Ideally, the free-metal ion activity (or concentration) would be measured analytically. However, currently available analytical techniques do not allow for routine measurements as most are metal-specific, labour-intensive, subject to matrix interferences or lack sensitivity. On the other hand, aqueous metal speciation can be effectively predicted using the appropriate thermodynamic data (formation constants). Typically, metals will form inorganic complexes with ligands such as hydroxide, carbonate, chloride and fluoride ions. For many transition elements (e.g. Cu, Pb, Zn), thermodynamic data for these complexes are readily available and speciation can be calculated with a high degree of confidence. Even in the presence of polyfunctional heterogeneous natural organic matter (humic and fulvic acids), complexation can normally be estimated with reasonable confidence.

The growing demand for less traditional elements (e.g. technology critical elements) is driving environmental regulators to develop new criteria for environmental protection. However, these cannot be derived without the appropriate ecotoxicological data, and the production of such data requires basic knowledge of metal aqueous chemistry. We reviewed the available formation constants for platinum group elements (Ru, Rh, Pd, Os, Ir and Pt) and identified key missing data. Among these metals, palladium is the one for which the most comprehensive data set is available. At the other end of the spectrum, there are currently no thermodynamic data available for iridium. We also explored the use of Linear Free-Energy Relationships (LFER) to fill data gaps. These involve the establishment of empirical relationships between complexes. For example, the binding constants of the first hydroxo-complex of metals (MOH) are usually available and can be correlated with the formation constant with a more highly substituted complex (e.g. $M(OH)_2$) or with another ligand (e.g. MCO_3). LFER can thus be used to estimate missing data or to select a value when large discrepancies are observed among available values. Examples will be provided with a focus on Pt(II). Future research priorities will be discussed.

3.11.P-Mo136 Comprehensive Analysis of (Ultra)trace Elements in Seawater: Method Development, Dilution Studies, and Matrix Effects Investigation

Andreia Sofia Filipe Farinha[1]*, Fernanda Tavares*[2]*, Mariana Elizabeth Rodrigues*[2]*, Micaela Sofia dos Santos Justo*[3]*, Susana Carvalho*[1]*, Daniel Asfaha*[1] *and Geert-Jan Witkamp*[2]*, (1)King Abdullah University of Science and Technology, Saudi Arabia, (2)Water Desalination and Reuse Center, King Abdullah University of Science and Technology, Saudi Arabia, (3)Red Sea Reasearch Science, King Abdullah University of Science and Technology, Saudi Arabia*

There is a growing need for the development of rapid and accurate methods to quantify trace and ultra-trace elements in complex matrices like seawater. The determination of such elements is often hindered by the lack of sensitivity, contamination, artifacts, spectral overlap, or memory effects. These challenges can be partially addressed by employing high resolution inductively coupled sector field mass spectrometry (HR-ICP-MS) in a clean room. In this study, using HR-ICP-MS, we assess various analytical approaches for directly measuring trace and ultra-trace elements in seawater. In particular, dilution factors of 10 to 3000 were tested to verify the consistency of the results throughout the concentration range. Additionally, we analyze the concordance of these results against pre-concentrating (ultra)trace elements and removing the sodium matrix with the seaFAST cation exchange method followed by HR-ICP-MS analyses. Matrix effects are investigated by using seaBlank samples and standard addition methods. The validation of the method was carried out using certified seawater material. The method developed within this work allows researchers to fast and accurately quantify (ultra)trace elements, including technological critical elements in complex matrix samples, such as seawater, marine sediments, and corals. This approach provides a valuable tool for expanding our knowledge of the fate of these elements in marine ecosystems and their potential effects on organisms.

3.11.P-Mo137 Metals and Particulate Matter in the Discharges Resulting from In-water Hull Cleaning Conducted via Remotely Operated Vehicle (ROV): Levels and Rates of Release into the Marine Ecosystem

***Moonkoo Kim**[1], Zhi Yang Soon[1,2], Taekhyun Kim[1,2], Jee hyun Jung[1,2] and Dongju Shin[1,2], (1)Korea Institute of Ocean Science and Technology (KIOST), Korea, Republic of (South), (2)University of Science and Technology (UST), Korea, Republic of (South)*
The increased utilization of remotely operated vehicles (ROVs) for in-water hull cleaning (IWC) has raised concerns regarding the environmental impact of IWC effluent discharge. This study aims to explore the characteristics of wastewater produced during IWC, specifically focusing on concentrations of suspended solids (SS) and metals, as well as their release rates and total environmental load. Notably, IWC effluents contain significant amounts of SS and metals, with copper (Cu) and zinc (Zn) being the predominant metals. These metals are mainly associated with fine antifouling paint particles, posing a potential risk of secondary pollution upon entering the marine environment. Although treatment systems have shown effectiveness in reducing SS and particulate metals, achieving complete removal of dissolved and particulate metals below ambient levels has proven challenging. To address this, the study suggests the implementation of multistage filtration systems based on particle size analysis, with an optimal filtration pore size for efficient effluent treatment. In summary, this research underscores the potential environmental risks associated with IWC activities. Given the strong affinity of metals towards particles in wastewater, the effective removal of particles emerges as a crucial factor in mitigating environmental stress at IWC sites. The release rate is an essential factor to predict the environmental concentration of contaminants and to assess the environmental risk posed by IWC. This manuscript will provide scientific foundation for the regulation and management of IWC to protect the marine environment.

3.11.P-Mo138 Speciation of Lithium, Manganese, Cobalt and Nickel in Fresh Water by Field-Ion Exchange Technique
***Mathieu Milhe-Poutingon**[1], Clementine Gelber[2], Patrick Baldoni-Andrey[3], Nick Gurieff[4] and Séverine Le Faucheur[1], (1)Universite de Pau et des Pays de l'Adour, E2S-UPPA, CNRS, IPREM, France, (2)TotalEnergies, Pole d'Etudes de Recherche, France, (3)TotalEnergies, Pole d'Etudes de Recherche de Lacq, France, (4)Rio Tinto, Closure R&D, Australia*
Metal speciation is a key parameter to take into account when evaluating metal bioavailability in natural waters. The free ion activity (concentration) is especially of interest as being identified as the best proxy to predict metal accumulation and toxicity towards aquatic organisms. One way to achieve the determination of the free ion concentration is the use of thermodynamic calculation but it might become inaccurate in a complex and fluctuating environment, such as in a river. Another approach is the direct determination of the free ion concentration using analytical techniques, such as Ion Exchange Technique (IET). This approach consists of equilibrating a cation exchange-resin with the solution to be analyzed. The free metal ion concentration in solution is then proportional to the metal bound to the resin. If generally performed into the laboratory, the IET use can be extended into the field with the resin placed into a dialysis cassette. In the present study, we evaluated the use of the field-IET to determine the free ion concentrations of Co, Ni, Mn and Li present in freshwaters.

To that end, field-IET cassettes were prepared by placing ~30 mg of DOWEX 50W-X8 resin into dialysis cassettes made of low-binding regenerated-cellulose membrane of 20 kDa cutoff. This resin was firstly preconditioned using Ca and Mg concentrations of the Gave de Pau, which was the river of interest. The field-IET cassettes were then deployed in mesocosms (TotalEnergies facility, France) filled with the Gave de Pau river to be exposed to increasing Li (2, 10 and 20 mg/L), Mn, Co, and Ni (6, 30 and 60 mg/L) for 7 days.

Three days of deployment were required to achieve an equilibrium between the resin and the ambient water. Extended period of deployment led to a decrease in the metal bound to the resin, most probably due to the fouling of the dialysis membrane. The concentrations of Ca and Mg in ambient water were also found to influence the distribution coefficients of all studied metals, requiring the measurements of Ca and Mg in all analysed samples. Further analyses will be performed to compare the free ion concentrations using the fied-IET and thermodynamic determination.

3.11.P-Mo139 Long-term feasibility assessment of in-situ heavy metal immobilization using calcium polysulfide in groundwater
***Hee Sun Moon**[1], Sanghun An[1], Dong-Hun Kim[1], So-Jeong Kim[1], Sungpil Hyun[1], Jin Chul Joo[2] and Kyoungphile Nam[3], (1)Korea Institute of Geoscience and Mineral Resources, Korea, Republic of (South), (2)Hanbat National University, (3)Seoul National University, Korea, Republic of (South)*
The in-situ immobilization of high-concentration heavy metals (Cd^{2+}, Zn^{2+}) in groundwater using polysulfide (CaS_x, CPS) was demonstrated for the field application. When CPS introduced into the aquifer, CPS solution descended rapidly and reacted with heavy metals in groundwater since the density (d = 1.27 g/cm^3) of CPS solution was greater than that of water. Both Cd^{2+} and Zn^{2+} in filed groundwater were rapidly reacted with injected CPS solution and effectively and instantly immobilized. The majority of heavy metals in complexly-contaminated roundwater generated metal sulfide precipitation in the field. The XRF, FE-EPMA and SEM/EDS results showed metal sulfide precipitates were clearly observed through the reaction between the CPS solution and heavy metals. In addition, microbial communities in groundwater were monitored using next-generation sequencing during the demonstration period. After CPS injection, the microbial diversity of groundwater was reduced, and sulfur-related bacteria were dominant in the groundwater monitoring wells which most of heavy metal were immobilized. This showed that microbial communities in groundwater also play important roles in of heavy-metal immobilization by CPS usage. Finally, an injection protocol optimized for various factors such as injection concentration, injection amount, and injection method of CPS solution for site-specific subsurface systems should be established to prevent clogging, re-mobilization and relocation of heavy metals.

3.11.P-Mo140 Occurence, fate, transfer of lithium and its isotopes in freshwater ecosystems: implication for its environmental risk assessment

Nicolas Lachaux[1]*, Laetitia Minguez*[2]*, Carole Cossu-Leguille*[1]*, Yves Marrocchi*[3] *and Laure Giamberini*[1]*, (1)Université de Lorraine, CNRS, LIEC, France, (2)French National Centre for Scientific Research (CNRS), Paris, France, (3)Centre de recherches pétrographiques et géochimiques (CRPG), CNRS, France*

The development of renewable energies and digital technologies requires critical raw materials including lithium (Li). The increasing demand (+3535 % by 2050 in EU) and uses of Li will lead to its release into the environment including freshwater ecosystems, which could potentially affect them. However, Li bioaccumulation and its potential biological effects towards aquatic species are currently unknown. Lithium can thus be considered as data-poor metal.

The present postdoctoral project aims to 1) determine Li exposure in freshwater ecosystems by analysing its environmental concentrations in abiotic and biotic compartments; 2) study the natural variations and fractionation of Li isotopes in a freshwater food web and assess the potential Li trophic transfer; 3) investigate the distribution of Li and its isotopes at tissue and subcellular levels and their potential hazard/ toxicity by analysing Li toxicokinetic in a freshwater bivalve through experimental and modeling approaches.

To tackle these issues, we have selected three study sites in France (Lorraine and Auvergne regions) having different geogenic (sandstone, marlstone, granite) and anthropogenic sources of Li (mining activity, battery recycling). The concentrations of Li that we have measured in the sediment and water were higher than French median concentration (3 µg L^{-1}) by around 1,000-fold in the stream located in the former coal mining area, which represents the highest hotspot of Li currently known in France. The results also pointed out relatively high concentrations of Li in aquatic organisms. The aquatic plant *Myriophyllum spicatum* accumulates more Li (6.9-16.0 µg g^{-1}) than the crustacean *Gammarus sp.* (1.5-7.4 µg g^{-1}) and the bivalve *Corbicula fluminea* (2.4-3.0 µg g^{-1}).

Isotope analyses are ongoing and will allow deciphering different sources of Li in aquatic systems. ^{6}Li isotope is supposed to be more biologically reactive than ^{7}Li because of its different mass. Thus, the investigation of ^{6}Li/^{7}Li ratios will help to better understand Li bioaccumulation and subsequent biological effects. Produced data will be considered for Li environmental risk assessment.

3.11.P-Mo141 Adsorptive removal of Heavy metal in aqueous phase by biochar combined with biosulfur material

Sung Chul Kim*, Young Kyu Hong and Jin Wook Kim, Bio-Environmental Chemistry, Chungnam National University, Korea, Republic of (South)*

Biochar has been used to remove heavy metals in aqueous phase as an adsorbent. This study was conducted to evaluate heavy metal removal efficiency in aqueous phase utilizing biochar (BC) combined with biosulfur (BS), the sulfur rich materials produced from landfill leachate treatment process. In order to manufacture combined biochar and biosulfur (BCBS), BC, BS, and distilled water (1:4:5, v/v/v) were mixed at the 25℃ for 1 hour. Different mixing ratio (0.05, 0.1, 0.5%) of BCBS was mixed with solution containing 1,000 mg/L of Cd and Pb. The adsorption efficiency of Cd and Pb was ranged from 78% to 98% and the highest adsorption was observed when 0.1% of BCBS was applied in the heavy metal solution. The reaction rate and isothermal adsorption showed that the pseudo second order and Langmuir model were the best fit for describing adsorption of the both Cd and Pb. X-ray infrared techniques such as SEM-EDS, FT-IR, and XPS were also examined to verify the removal mechanism of soluble heavy metals. According to result of various X-ray infrared techniques, ionic format of Cd (Cd^{2+}) and Pb (Pb^{2+}) makes complexation with sulfide or sulfate at the surface of BCBS. Thus, ionic complexation or co-precipitation of ionic form of heavy metals and sulfur compounds were the main removal mechanism of heavy metals when BCBS was applied in the aqueous phase.

3.11.P-Mo142 A mesocosm study to assess selenium dynamics in a Mediterranean floodplain wetland

María Mercedes Andres[1]*, Manuel Ortiz Santaliestra*[2] *and Rafael Mateo*[3]*, (1)Toxicology, Institute for Game and Wildlife Research, IREC (UCLM-CSIC), Spain, (2)Instituto de Investigación en Recursos Cinegéticos (IREC) CSIC-UCLM-JCCM, Spain, (3)Wildlife Toxicology, Instituto de Investigación en Recursos Cinegéticos (IREC) CSIC-UCLM-JCCM, Spain*

The Tablas de Daimiel National Park (TDNP) is a floodplain wetland formed by Cigüela and Guadiana rivers in central Spain whose water levels have drastically dropped over recent decades because of overexploitation of freshwater resources, worsened by climate change, and that receives pollutant inputs form WWTP discharges and the runoff from surrounding agricultural lands. High selenium levels have been found in sediments and biota, which could be linked to the Se-rich soils in the area but also to anthropogenic pollution. Se speciation in the environment depends, among others, on pH and redox potential, and determines bioavailability of the element. The change of the hydrological regime that affects TDNP, with longer droughts and shorter flooding periods, could be influencing the Se speciation and its bioavailability. To study the processes of transformation and bioaccumulation of Se in the food chain, we have designed mesocosm trials simulating three hydrological regimes: (i) constant flooding with a water renewal mimicking the optimum TDNP hydrological regime (10 hm^3/month for a flooded surface area of 1600 ha); (ii) drought-flood cycles, with complete refilling every three months, simulating the action of an existing dam at the wetland mouth, and (iii) prolonged drought, with complete water evaporation and full system reflooding. Mesocosms were set in 1000 L-containers with a 20-cm deep layer of sediment from the Park area with higher Se levels (4 µg/g), 800 L water and three plant species *(Scirpus maritimus, Chara* sp. and *Typha domingensis).* Samples of each matrix have been be taken every two months to analyze total Se through ICP-MS and Se species using HPLC coupled to ICP-MS. We hypothesized that drought-flood cycles favor the mobilization of Se from sediments, so we expect bioavailability, and therefore bioaccumulation in plants, to be highest in the last scenario immediately after reflooding events. Study funded by the Spanish Organism of National Parks (ref. SPIP2021-02790).

3.11.P-Mo143 Heavy Metals Extraction From Industrial Sludges

***Sam Li**, NUS, Singapore*

Globally, large volumes of industrial sludge are produced throughout the municipal wastewater treatment process. Proper disposal of industrial sludge is required to avoid secondary pollution. A range of metals are usually present in the sludge, some of which are harmful to human health and others may have a high recycling value. As a result, eliminating the metals from sludge ash will lessen its toxicity and produce some useful products. This study concentrated on a raw material known as CuPbZn (CPZ) sludge. By using the well-known BCR sequential extraction procedure, 87% Cu and 37% were determined as the mobility fractions of these metals. Subsequently, three extraction techniques based on the use of HCl and EDTA as extraction reagents followed by electrodialysis was evaluated, and the deposit on the electrode was collected and examined. According to experimental results, the highest extraction rates of Cu and Ni were obtained by using 1M HCl as extraction medium (75.69% and 86.00%, respectively). Cu and Ni were only partially extracted using either 6% EDTA or 2M HCl + 6% EDTA as extraction solvents. Within eight hours of electrodialysis, Cu could be nearly completely extracted (>99%) from the sludge for all three types of extraction solutions. By extending the electrolysis period and forming agglomerates through coagulation, free nickel in 1M HCl extraction solution could be extracted (84.70% recovery rate). The results obtained demonstrated that appropriate combinations of sequential extraction with electrodialysis could provide more accurate analytical data for evaluating fate and toxicity of metals.

3.11.P-Mo144 Accessing the Past: How a Sediment Core can Help to Reveal Anthropogenic Impacts of Technology-Critical Elements.

***Dominik Wippermann**[1], Ole Klein[2], Anna Ebeling[1], Tristan Zimmermann[1], Hendrik Wolschke[3] and Daniel Pröfrock[1], (1)Inorganic Environmental Chemistry, Helmholtz-Zentrum Hereon, Germany, (2)Inorganic Environmental Chemistry, Helmholtz Center Hereon, Germany, (3)Laboratory for Environmental Radiochemistry, Helmholtz-Zentrum Hereon, Germany*

Technology-critical elements (TCEs) have undergone a dramatic increase in industrial applications in recent years. Still, many studies and legal directives only consider legacy pollutants like Cd, Pb and Zn as elements of interest. With the expansion of high-tech applications, the environment is becoming exposed to TCEs. Even though these potential emerging contaminants are getting more attention recently, the applications causing the release of TCEs into the environment already exist, making it difficult to assess current anthropogenic inputs or to access background values. A promising approach are sediment cores, which can be resolved, if deep enough, into recent and anthropologically un-impacted background levels.

A sediment core was taken in August 2022 in the Baltic Sea. The core was cut into 79 slices (1 cm thick), each of which was freeze-dried and milled. Every second slice was subsequently introduced to microwave-assisted acid digestion and analyzed for the mass fractions of 47 elements using inductively coupled plasma tandem mass spectrometry (ICP-MS/MS). The other core slices were used for age determination by ^{137}Cs and ^{210}Pb dating.

Age determination showed that slices from 30 cm and deeper are about 60-70 years and older, which allows the calculation of background values for the Baltic Sea from around 1950-1960. For legacy pollutants like As, Cd and Pb average mass fractions of 9400 μg kg^{-1} ± 900 μg kg^{-1}, 970 μg kg^{-1} ± 80 μg kg^{-1} and 23000 μg kg^{-1} ± 6000 μg kg^{-1} were found within 30 cm to 79 cm of the sediment core, respectively. Ga, as an example of a new emerging contaminant, due to its use in corrosion protection systems (galvanic anodes) of offshore wind farms was found with average mass fractions of 12600 μg kg^{-1} ± 400 μg kg^{-1} within the same lower part of the sediment core.

This study aims to provide background mass fractions for the Baltic Sea environment for new emerging contaminants, which are currently missing for a sound assessment of the role of potential emission sources into the marine environment such as offshore renewable energy production.

3.11.P-Mo145 Impact of the Heavy Metal Chemical Speciation Method selection and its Implications on the Results of the Health Risk Assessment

***Agata Wódkowska**[1] and Agnieszka Gruszecka-Kosowska[2], (1)Faculty of Geology, Geophysics and Environmental Protection, University of Science and Technology (AGH), Poland, (2)Faculty of Geology, Geophysics and Environmental Protection, AGH University of Krakow, Poland*

Heavy metals due to their persistence and long-term adverse effects on the environment and human health became a major global issue. Risk assessment evolved into an important tool in evaluating the probability of the adverse effects occurrence for the environmental and human health due to the anthropogenic pollution and in numerous countries is nowadays a mandatory step in environmental decision-making.

As the heavy metal (HM) content is the major constituent of the risk assessment calculations, the choice of method that determines their chemical speciation and related concentrations in defined environmental samples together with HM fate and metabolism, becomes a paramount issue. Relying solely on the total HM contents can overestimate the real risk values, while the bioavailable fraction of HM is considered to be more reliable in assessing risk of the adverse health effects occurrence.

In this study the differences in the HM contents obtained using various extraction methods were investigated to provide the input values of HM contents in following health risk assessment calculations. Following chemical speciation methods, commonly used in the risk assessment research, were used in our study to obtain HM contents: total content (TC), 3-stage Sequential Extraction (BCR), Simple Bioavailability Test (SBET), Standardized Bioavailability Test (BARGE), ISO Bioavailability Test (17924:2018), USEPA Bioavailability Test (Method 1340), and Physiologically Based Extraction Test (PBET). Concentrations of As, Cd, Co, Cr, Cu, Fe, Hg, Mn, Ni, Pb, Sb, Sn, Tl, and Zn were measured using Inductively Coupled Plasma - Mass Spectrometry (ICP-MS) and Inductively Coupled Plasma - Optical Emission Spectrometry (ICP-OES) in a diverse range of environmental samples, including soil, vegetables, fruits, cereals, and teas, both natural and Certified Reference Materials (CRMs).

Based on the results of HM contents from various chemical speciation methods the risk values for investigated groups of environmental samples will be calculated using Monte Carlo simulations. The analysis will encompass an examination of how choice of speciation method may affect the obtained HM contents and further how these values influence the risk values and following regulatory environmental decisions.

The results of the study will provide the new insight into the unification of risk assessment methodologies to support performing environmental regulations relevant to exposure to metals.

3.11.P-Mo146 Assessing the effects of iron smelters on soil quality utilizing earthworms

*Jaco Van Eeden[1], Rasheed Adeleke[2], James P. Odendaal[3], Kazeem Alayande[2] and **Mark Maboeta**[1], (1)Zoology, North-West University, South Africa, (2)Microbiology, North-West University, South Africa, (3)Environmental and Occupational Studies, Cape Peninsula University of Technology, South Africa*

Pollution of the natural environment is not a new concept, but it is still a pressing matter worldwide. This study aimed to assess which metals are introduced into the surrounding soil environment (at different distances from the source point of pollution) by iron-smelting plants and the effect thereof on earthworms as bioindicator species.

The metal analysis performed on the collected soil samples indicated elevated levels of metals close to the smelting facilities and the concentrations decreasing as the distance to the iron smelting facility increased. The concentrations of Fe and Al were the highest of all metals tested in all three sampling locations.

The earthworm bioassays and avoidance behaviour test results paint a similar picture. The growth data confirms that at one of the sites, earthworms showed a positive growth rate over the experimental period compared to the other two sites investigated.

Results regarding reproduction indicated that the concentration of metals did not affect the adult earthworms and their ability to reproduce, but it did influence the survival rate of juveniles after hatching. Avoidance-behaviour results also correlate with the previous results, with the earthworms showing some avoidance, but not enough to be considered actively avoiding the soil and statistically significant.

It was concluded that some of the metal concentrations seen are elevated, but in most cases, they are not in high enough concentrations to be considered polluted, or if they are characterised as pollutants, the bioavailability of the metals might be a limiting factor.

3.11.P-Mo147 Metals Concentrations and Bioaccessibility in Soils at Parks and Playgrounds in Fort McMurray, a Major Oil and Gas Hub in Canada

*Abdul Abbas and **Matt Dodd, PhD**, School of Environment and Sustainability, Royal Roads University, Canada*

Characterization and mapping of metals in soils is an important first step in the evaluation of ecological and human health risks towards the overall achievement of the United Nation's Sustainable Development Goal 3: Good Health and Well-being. Results from investigations conducted in parks and playgrounds in Western Canadian cities including Vancouver, Victoria, Edmonton, and Calgary indicate some metals (e.g., As, Cu, Pb, Zn) in soils exceed the Canadian Council of Ministers of the Environment (CCME) soil quality guidelines at few locations. Metal concentrations reflect the regional natural-occurring differences in concentrations and physicochemical properties or anthropogenic sources such as proximity to industrial activities, pesticide treated wooden structures, and heavy traffic corridors. Fort McMurray, an urban service area in the Regional Municipality of Wood Buffalo is perched above the Athabasca bitumen sands formation. This region is one of Canada's major hubs of oil and gas production. Sixty soil samples collected from 20 parks and playgrounds in Fort McMurray were analyzed for total metals by x-ray fluorescence. The mean metal concentrations (in mg/kg dry weight) were As: 1.0, Cd: 2.8, Cr: 31.8, Cu: 9.7, Pb: 8.0, Ni: 10.2 and Zn: 55.6 mg/kg which were all below the Canadian Council of Ministers of the Environment (CCME) soil quality guidelines for park land use. Ongoing work include determining soil physicochemical properties such as pH and total organic carbon content and in vitro bioaccessibility. The results will be evaluated to ascertain how industrial activities including oil and gas production in the community impact metal distribution in the parks studied. The

Fort McMurray data will be compared to results from the other Canadian cities listed above. The relationship between soil physicochemical properties and metal bioaccessibility and how they impact the risk associated with incidental soil ingestion during playtime at the parks will be explored. The estimated daily intake will be determined for each element using CCME human health risk assessment protocols incorporating the bioaccessibility data and the overall hazard index will be calculated. Finally, recommendations on limiting exposure to potentially contaminated soils during playtime at the parks will be developed with the aim of achieving the United Nation's Sustainable Development Goals.

3.11.P-Mo148 Leaching of Rare Earth Elements in Soil Samples from Electronic Waste: La, Nd and Dy as case study

***Vernon Somerset**, Martin Makombe and Charlton Van der Horst, Cape Peninsula University of Technology, South Africa*

The dumping of waste electrical and electronic equipment (WEEE) and its recycling commonly known as "urban mining" has caused undesirable impacts on the environment. Many of these products are rich with rare earth and hazardous elements that end up in rubbish dumps and recycling centres. Harmful metals are exposed and leached into the environment. The fate of rare earth elements (REEs) through the disposal of electronic waste and urban mining into the environment has caused pollution and pose a threat to human health and the aquatic ecosystem. In this work, we report the results of several microcosm studies using conditioned soil to investigate the leaching of REEs in lab-scale experiments. The effective leaching of specific rare earth elements (La, Nd and Dy) were conducted under different experimental conditions. The effects of major variables on REE leaching were evaluated, which included lixiviant type and concentration, time, stirring speed, pH and solid to liquid ratio. The temperature was kept constant during all experiments at 23 ± 2 °C. The leaching efficiency of La, Nd and Dy was found to be significantly dependent on acid concentration and leaching time. The best leaching efficiency was obtained with 1 M HCl with a leaching time of 30 minutes, 300 rpm stirring, 50 g/L solid to liquid ratio. It was found that the leaching efficiency of 69%, 75% and 77% was achieved for La, Dy and Nd, respectively. In speciation studies, the results showed that 90% of REEs were obtained from acid-soluble fraction and residual fraction. The study is currently investigating the availability of the fractions, chemical behaviour in soil under environmental conditions, and the uptake of the REEs by biota.

3.11.P-Mo149 Assessment of Metal Content in Urban Synthetic Soils Made of Crumb Rubber Including Playgrounds and Synthetic Football Fields

***Andres Duque-Villaverde**[1], Sergio Soñora[1], Thierry Dagnac[2], Enrique Roca[3] and Maria Llompart[4], (1)Department of Analytical Chemistry, Nutrition and Food Science, University of Santiago de Compostela, Spain, (2)Unit of Organic Contaminants, Apartado 10, Agronomic and Agrarian Research Centre (AGACAL-CIAM), Spain, (3)Department of Chemical Engineering, School of Engineering, Spain, (4)Department of Analytical Chemistry, Nutrition and Food Science, CRETUS, Spain*

The disposal of end-of-life tires (ELTs) is an important problem in solid waste management. In the last decades, the main recycling route is the transformation in crumb rubber, which is largely used in playground and sports fields as infill. This microplastic material presents high metal concentration including toxic and heavy metals. Crumb rubber infill of artificial turf fields represents the largest individual source of intentional microplastics in the environment. The new EU regulation 2023/2055 bans granular infill for use on synthetic sports surfaces but these kinds of facilities will still survive for at least a transitional period (8 years).

In this study, element and metal distribution in a high number of real samples taken from different urban places, including playgrounds and sports fields from Santiago de Compostela (NW, Spain) and surroundings, is presented. Most of the samples were collected outdoors but some indoor samples were included (e.g. airport playground). Some synthetic and natural surface alternatives (cork, sand, soil, and thermoplastic pellets) were also collected and analysed. 28 elements including metals (Ag, Al, Ba, Be, Bi, Ca, Cd, Co, Cr, Cu, Fe, In, K, Li, Mg, Mn, Mo, Na, Nb, Ni, Pb, Se, Sr, Ti, Tl, U, V, and Zn) and 4 metalloids (As, B, Sb, Si) were considered. The samples were subjected to microwave digestion followed by ICP-MS analysis. The results shown high concentrations. Zn levels were extremely high, with values between 1-2 % in all the crumb rubber samples. Heavy and toxic metals such as Pb and Cr were found in most samples reaching values above 20 ppm. Some high values were found in root retainers made from crumb rubber, which could facilitate the plant intake of the toxic metals. The data were subjected to ANOVA analysis showing in some cases statistical differences between metal content in playgrounds and football fields. Other materials showed to be a safer alternative from a chemical point of view regarding toxic metal content.

This study is also based upon work from the Sample Preparation Study Group and Network, supported by the Division of Analytical Chemistry of the European Chemical Society. All these programs are co-funded by FEDER (UE). Authors would like to thank the use of RIAIDT-USC analytical facilities.

3.11.P-Mo150 Characterization of Nanoparticulate Metals Generated from Transportation, Tire Wear, and Urban Wildfires

***Carmen Maria Villarruel**[1] and James Ranville[2], (1)Colorado School of Mines, (2)Chemistry, Colorado School of Mines*

Vehicular transportation generates nanoscale tire wear particles (TWP) and brake dust, collectively referred to as road dust sediments (RDS). RDS can contain high concentrations of Nanoparticle (NPs)-associated metals (Cd, Cu, Co, Cr, Ni, Pb, Ni, and Zn), as well as microplastics. NPs are highly reactive due to their high surface area to mass ratio, which can facilitate the environmental and biological uptake of trace metals, making their quantification in environmental systems essential. TWPs are

sources of Zn and Cr to the environment, although it is difficult to distinguish TWP-associated metals from other anthropogenic or geogenic sources. Characterizing RDS for metals associated with TWP .in environmental samples presents many analytical challenges, due to the ubiquity of microplastics in the environment, associated with particle sizing instrumentation, and analytical interferences due to the complexity of environmental samples.

We capitalize on the high sensitivity and elemental specificity of single particle Inductively Coupled Plasma-Mass Spectrometry (spICP-MS) to identify and quantify metal containing NPs in RDS runoff from precipitation events. Using crumb rubber particles and established Zn and Cr content of tires, we determined particle size distributions of TWPs. We applied this methodology to precipitation runoff samples and crumb rubber that had burned during a wildfire, with the latter showing an alteration in the Cr particle size distribution. Results suggest a difference in the form of Cr in TWP post-combustion. We measured the RDS samples for 28 total metals, including metals associated with catalytic converters and vehicle brake pads such as Pt and Rh. We also analyzed samples for 8 NP associated metals. Particle size distributions were used to distinguish between dissolved and particulate metals, which can have different modes of toxicity. We found that RDS samples contained high concentrations of NP-associated Cu, Pb, Cd, and Zn. This study represents a novel application of spICP-MS for RDS characterization in complex environmental samples. The result will lead to more accurate quantification of metal containing NPs in RDS and other matrices, which is essential for understanding environmental toxicity potential from contaminants including microplastics and toxic metals.

3.11.P-Mo151 Analysis of Drinking Water to Soil With a Single Method on ICP-MS and an Auto-Dilution System

*Rentaro Yamashita Dr.[1] and **Nikolay Kovachev**[2], (1)Atomic Spectroscopy Division, Hachioji, Japan, (2)Agilent Technologies, Inc.*

ICP-MS, which can measure multiple elements simultaneously with high sensitivity, is used in many environmental laboratories to quantify hazardous elements in environmental samples. As environmental laboratories often need to analyze many samples on a daily basis, it is very important to increase the efficiency of work and reduce the demands on lab staff through automation. To improve workflow efficiency, a new application for environmental analysis of drinking waters through to soils is described. Utilizing new capabilities of inline auto-dilution for ICP-MS and ICP-OES, consisting of three main functions.

The first is the ability to make calibration curves from a single stock solution, which significantly reduces the preparation time for standard solutions. The second is the ability to automatically dilute samples directly prior to measurement, reducing the preparation time for samples with high matrix concentrations such as sediments and soils. The third is the ability to automatically dilute and re-measure samples immediately when the concentration of target elements exceed the calibration range or the internal standard elements exhibits suppression or enhancement.

This makes it possible to prevent post-analysis rework by avoiding manual dilution of affected samples. Inline auto-dilution not only reduces manual labor, but also avoids the risk of human error and contamination, further improving laboratory productivity. This poster will also report on the evaluation of dilution accuracy, precision and long-term stability using certified reference materials.

3.11.P-Mo152 Comparison of Voltammetric Techniques to Determine the Chemical Speciation of Dissolved Copper in Mar Menor Lagoon

***Maria Sol Hernández-Conesa**[1], X. Antón Álvarez-Salgado[2], Mar Nieto-Cid[3], Juan Santos-Echeandía[3] and Paula Sánchez-Marín[3], (1)Institute of Oceanography, Spanish National Research Council (IEO-CSIC), Spain, (2)IIM-CSIC, Spain, (3)Vigo Oceanographic Center of the Spanish Oceanographic Institute, Spanish National Research Center (IEO-CSIC), Spain*

Las concentraciones totales de metales no son predictores adecuados de su biodisponibilidad, por lo que se debe considerar la especiación química de los metales. La especiación de Cu disuelto en agua de mar está dominada principalmente por ligandos orgánicos, como la materia orgánica disuelta (DOM). El presente estudio tiene como objetivo estudiar la especiación química del Cu en una laguna costera, afectada por la minería y la eutrofización, y que presenta altos niveles de Cu y DOC. La especiación química del cobre (Cu) disuelto se estudió mediante dos métodos voltamétricos diferentes conocidos como voltamperometría de stripping catódico (CLE-ACSV), utilizando salicilaldoxima (SA) como ligando competidor, y voltamperometría de stripping anódico (ASV). Se tomaron muestras en diferentes localizaciones de la laguna del Mar Menor en diferentes eventos de 2021 y 2022. Los parámetros de especiación de Cu (capacidad de complejación y constante de estabilidad condicional) se calcularon mediante el software ProMCC, y los valores obtenidos para las diferentes muestras se relacionaron con variables fisicoquímicas. (pH, salinidad) y con diferentes variables relacionadas con la DOM como DOC, fluorescencia y absorbancia de la DOM, mediante análisis de correlación y regresión múltiple. Los resultados de la capacidad de complejación de Cu (L_{Cu}) variaron de 15,89 a 90,82 nM para el método CLE-ACSV y de 58.28 a 193.5 para el método ASV. Además, los valores de la constante de estabilidad condicional (Log $K_{Cu^{2+}}$) variaron entre 11.36 y 12.92 para el método CLE-ACSV y 8.195 y 9.609 para el método ASV. Los parámetros derivados de ambos métodos no se correlacionan entre ellos, lo que sugiere que estas técnicas podrían detectar diferentes clases de ligandos que tienen diferentes fuentes y comportamientos. Se observaron relaciones claras entre los parámetros de complejación obtenidos por CSV y DOC y los picos de fluorescencia relacionados con la materia húmica. Se considera que el uso de enfoques de ventanas múltiples que combinan los resultados de ambas técnicas describen completamente la complejación de Cu en muestras naturales.

3.11.P-Mo153 Understanding the influence of environmental factors on Co-magnetite interactions mechanisms in at the nanoscale

Laura Fablet[1], *Mathieu Pédrot*[2], *Fadi Choueikani*[3] *and Rémi Marsac*[4], *(1)Géosciences Rennes UMR 6118, University of Rennes, France, (2)Géosciences Rennes - UMR 6118, Univ Rennes, CNRS, France, (3)Synchrotron Soleil, France, (4)IPGP, France*

Magnetite nanoparticles (MNs, Fe_3O_4) are abundant in the environment and are used for various applications due to their unique magnetic, adsorbing or redox properties. The stoichiometry of magnetite (Fe(II)/Fe(III)) is dependent on environmental factors (pH, presence of organic ligands), which largely affects MNs physico-chemical properties, such as adsorption of contaminants. However, the joint effects of environmental factors and MNs stoichiometry MNs-metal cations interaction are elusive. This study focusses on Co as an important contaminant in the environments, and because Co-doped MNs are of high interest for nanotechnology applications.

Magnetite nanoparticles (~10nm) with different stoichiometries were synthesized by co-precipitation, and partially oxidized using H_2O_2 to obtain the desired stoichiometry. Batch studies were carried out with different [Co] (“adsorption isotherms”), using three different stoichiometries (0.1, 0.3 and 0.5), at different pH values and in the presence or the absence of natural organic matter (NOM). The electronic and magnetic properties of Co bound to MNs was probed by X-ray absorption spectroscopy (XAS) and magnetic circular dichroism (XMCD) at the Co $L_{2,3}$-edges.

Experimental and modeling results revealed three Co species according to Co concentration, which could be attributed to (i) surface complexed or incorporated Co^{2+} with a ferrimagnetic behavior at low loadings, (ii) magnetically-silent small Co polymers at intermediate loadings and (iii) precipitation of antiferromagnetic $Co(OH)_{2(s)}$-like phase onto the MNs surface (i.e. core–shell $Fe_3O_4@Co(OH)_2$ nanoparticles) for highest Co concentrations. Their proportions depended on the physico-chemical conditions: Co-polymers and precipitates were favored on high-stoichiometry MNs, at high pH and in the absence of NOM.

This study provides detailed knowledge of the effects of environmental factors on the Co-MNs interaction mechanisms, and on the chemical and magnetic properties of these particles. This will help to predict the behavior and fate of Co in the environment and to understand the impact of environmental factors for an appropriate use of MNs for environmental applications.

3.11.P-Mo154 A Comparison Between a Simplified and an Extended Method for the Determination of Metals and Metalloids in Urban Park Soils

Ainhoa Lekuona-Orkaizagirre[1], *Ainara Gredilla-Altonaga*[2] *and Maite Meaurio-Arrate*[1], *(1)Applied Chemistry, University of the Basque Country (UPV/EHU), Spain, (2)Analytical Chemistry, University of the Basque Country (UPV/EHU), Spain*

The soil, together with the metals and metalloids present on it, can be incorporated into the human body by direct inhalation, ingestion and absorption by dermal contact. According to the recommendations of United States Environmental Protection Agency (USEPA), the daily ingestion values for soils are 200 $mg \cdot day^{-1}$ for children from 1 to 12 years of age and 100 $mg \cdot day^{-1}$ for people over 12 years of age. The bioaccessible fraction is defined as the fraction of the contaminant that is mobilised from soil into the digestive juice chyme and that fraction can be absorbed, transported through the intestinal wall and transferred to the bloodstream. As an alternative to in vivo experiments, it is possible to calculate the bioaccessible fraction through in vitro tests, such as SBET (Simplified Bioaccessibility Extraction Test) which simulates human gastric conditions and RIVM (Dutch National Institute for Public Health and Environment) which simulates mouth, gastric and intestinal conditions.

In this study, a total of 26 urban soil samples were collected in some parks of San Sebastian (Spain) and the bioaccessibility of some metals and metalloids was determined by SBET and RIVM methods. The main objectives of this study were to determine the bioaccessibility of the maximum number of metals and metalloids using two in vitro techniques and to compare the results obtained from both methods. Concentrations extracted with SBET method were generally above the concentrations extracted by RIVM. Cd was the most bioaccessible element in both methods, and the order from the most bioaccessible metal/metalloid to the least bioaccessible was quite similar in SBET and RIVM, except for Pb and Zn. Pb was identified as the second highest bioaccessible element by SBET (80.7%) and nearly the least bioaccessible by RIVM (0.9%), and the percentage of Zn was 34.7% by SBET and almost 0% by RIVM. The RSD of SBET triplicates was below 5% in almost all elements and LOD values were far from the metal concentration in SBET samples. In RIVM, RSD values were generally below 10% but for some metals (Zn, Ti, Cr) the LOD was quite high. Therefore, SBET resulted more economical but it can overestimate the risk on human health. On the other hand, RIVM is longer and more expensive, but it can provide a more realistic approach. However, in some elements, the high detection limit caused by the complexity of the matrix prevents the calculation of bioaccessibility by RIVM.

3.11.P-Mo155 Development of a predictive model for metal accumulation (Cu, Ni, and Zn) in periphytic biofilm

Amandine Greil[1], *Claude Fortin*[2], *Soizic Morin*[3] *and Isabelle Lavoie*[4], *(1)University of Bordeaux, France, (2)Centre Eau Terre Environnement, Institut National de la Recherche Scientifique – Eau Terre Environnement, Canada, (3)INRAE UR EABX, France, (4)Centre Eau Terre Environnement, Institut national de la recherche scientifique (INRS), Canada*

In Canada, the mining sector is a major part of the economy but leads to an increase in metal mobility. The increase in metal concentrations in the environment can impact aquatic ecosystems and adequate monitoring is needed. Biofilm can be used as a bioindicator for metal contamination and reflects actual metal bioavailability as opposed to simple measurements of metal concentrations in water. Bioavailability depends on many parameters such as pH, hardness, competition with other metals, and metal speciation. This study aims to develop a predictive model based on the premises of the Biotic Ligand Model (BLM) for copper, nickel and zinc accumulation in biofilm. Different environmental conditions were tested in the laboratory to calibrate the predictive model. We collected rocks with their biofilm in the Cap Rouge River (Quebec, Canada). This biofilm was placed in reconstituted water spiked with metals. A single parameter was modified at a time for each experiment to determine its influence on metal accumulation. A first experiment was completed in which a range of nine nickel concentrations were tested (from 0 µM to 20 µM) at neutral pH and constant zinc and copper concentrations (0.1 µM). Similar experiments were carried out, varying the copper and zinc, while maintaining the concentrations of the other two metals constant (0.1 µM). As expected, metal accumulation increased in biofilm in proportion to the concentration present in the water. Additional experiments were conducted to test the protective effects of cations on biofilm accumulation. Copper, nickel and zinc concentrations were constant (10 µM) while pH, calcium and magnesium concentrations were individually varied in each experiment. Hardness cations are expected to compete with metals for accumulation in the biofilm; analyses are underway and results will be presented. This project will provide a predictive tool to estimate the impact of water quality on nickel, zinc and copper bioavailability.

3.11.P-Mo156 Metal(loid)s and Rare Earth Elements in Posidonia oceanica Banquettes along Mediterranean Coasts
***Alice Rotini**[1], Stefania Chiesa[1], Loredana Manfra[1], Massimiliano Scalici[2], Marco Trifuoggi[3] and Giovanni Libralato[4], (1)Italian National Institute for Environmental Protection and Research (ISPRA), Italy, (2)Roma Tre University, Italy, (3)University of Naples Federico II, Italy, (4)Department of Biology, University of Naples Federico II, Italy*
The accumulation of *Posidonia oceanica* dead leaves occurs naturally along Mediterranean coasts constituting the so-called *banquettes*. They can provide important ecosystem services for beach nourishment and protection. Despite their important key role for energy transfer through marine-coastal habitats, *banquettes* are poorly investigated, especially concerning their double role as a contaminant accumulator and vector as well. Indeed, few studies exist in literature on the metal(loid)s occurrence and no data are available on emerging contaminants such as the Rare Earth Elements (REEs) in *Posidonia banquettes*. The present work investigated for the first time the concentrations of 28 metal(loid)s (Al, Sb, A, Ag, Ba, Be, Bi, B, Cd, Co, Cr, Fe, Li, Mn, Mo, Hg, Ni, Pb, Cu, Rb, Se, Sn, Sr, Tl, Te, U, V, and Zn) and 15 REEs (Ce, Dy, Er, Eu, Gd, Yb, Y, La, Lu, Nd, Ho, Pr, Sm, Tb, and Tm) in three well-structured *banquette* along the Mediterranean coasts: Lazio Region (Italy), Favignana Island (Sicily, Italy) and Cyprus. Sampling was carried out in 2021 (Lazio) and 2023 (Sicily, Cyprus).

Preliminary results showed (i) how metal(loid)s and REEs occurred in *Posidonia* deposits along eastern and western Mediterranean coasts, although values suggested no clear contamination patterns; (ii) that *Posidonia banquettes* may also represent an interesting biological model for monitoring metal(loid)s and REEs occurrence in coastal ecosystems.

3.11.P-Mo157 Characterizing monomethylmercury and selenium bioaccessibility from Alaskan fish and marine mammals
***Angela R Gastaldi**[1], Todd O'Hara[2], Robert J. Taylor[2], Benjamin D Barst[3] and Jill Hiney[2], (1)University of Alaska Fairbanks, (2)Texas A&M University, (3)Institute of Northern Engineering, University of Alaska Fairbanks*
Mercury (Hg) is a global contaminant with known health risks to wildlife and humans. In Alaska (USA), humans are mostly exposed to Hg in the form of monomethylmercury through the consumption of fish and marine mammals, which compose large proportions of some traditional subsistence diets. Risk assessments of traditional Alaskan diets must weigh the cost of monomethylmercury exposure with the health benefits (e.g., nutrition, culture) associated with traditional foods. Risk assessors may assume that 100% of the monomethylmercury present in ingested food is released into the gastrointestinal fluid during digestion (i.e., is bioaccessible), despite growing evidence that this assumption is not accurate. In this study, we applied a dual-phase *in vitro* human gastrointestinal digestion model to characterize bioaccessibility of monomethylmercury found in muscle tissue of six fish species: burbot (*Lota lota)*, Northern pike (*Esox lucius)*, Pacific herring (*Clupea pallasii)*, sockeye salmon (*Oncorhynchus nerka*), pink salmon (*Oncorhynchus gorbuscha*), and broad whitefish (*Coregonus nasus*) and two marine mammal species: walrus (*Odobenus rosmarus*) and Northern fur seal (*Callorhinus ursinus*). These species are commonly consumed in certain Alaskan communities, represent a range of trophic levels and muscle types, and include both freshwater and marine fish species. The monomethylmercury and total selenium concentrations in undigested muscle varied by species and ranged from 0.004 ug/g to 0.71 ug/g and 0.07 ug/g to 5.9 ug/g wet weight, respectively. The percent bioaccessibility of monomethylmercury varied significantly by species, with the highest seen in burbot (95.0 ± 10.8%), followed by Pacific herring (80.0 ± 10.0%), sockeye salmon (69.5 ± 10.1%), pike (67.2 ± 14.5%), Northern fur seal (45.2 ± 4.5%), pink salmon (40.8 ± 9.9%), walrus (38.5 ± 6.4%) and the lowest seen in broad whitefish (34.3 ± 8.6%). The bioaccessibility of total selenium will be characterized for these same fish and marine mammal samples, as selenium may protect against Hg toxicity. Our results indicate that less than 100% of the monomethylmercury present in the various muscle tissues is released during digestion, suggesting that current human exposures are being varyingly overestimated for these species and tissues.

3.11.P-Mo158 Kinetics of cobalt accumulation in soft tissues and shells of the gastropod Radix balthica
***Maëva Marimoutou**[1], Gilles Bareille[1], Helene Tabouret[1], Patrick Baldoni-Andrey[2], Clementine Gelber[2], Nick Gurieff[3] and Séverine Le Faucheur[1], (1)Université de Pau et des Pays de l'Adour, E2S-UPPA, CNRS, IPREM, Chaire Ecotox, (2)TotalEnergies, Pole d'Études et de Recherche de Lacq, France, (3)Rio Tinto, Closure R&D, Australia*
Molluscs, including gastropods, are regularly used to assess the quality of natural waters through the use of their shells. Indeed,

shells have the ability to accumulate the chemical elements such as metals present in the mollusc environment throughout its life, while remaining inert. Shells should therefore serve as a bioarchive of metal contamination. Nevertheless, the link between the presence of metals in the environment and in shells is not always straightforward. The way in which individuals manage the accumulation of metals in soft bodies must play a role in this relationship. Here, we propose to study the link between metal concentration in water, soft tissue and shell in *Radix balthica*, a ubiquitous gastropod from European waters. The metal of interest was Co as pertinent substance to monitor in rivers.

To that end, *R. balthica* was exposed to four cobalt concentrations (natural background concentrations, 6, 30 and 60 $\mu g.L^{-1}$ Co) during 28 days using outdoor mesocosms (TotalEnergies facility, France) filled with the Gave de Pau river water in June and October 2021. Water and organisms were collected after 7, 14, 21, 28 days of exposure for analysis. Water was analysed for their physico-chemical parameters including pH and cation concentrations. Total Co accumulation was measured soft tissues after acidic digestion whereas its subcellular distribution was examined using chemical treatment and differential centrifugation. Its concentration was also quantified in the whole shell after acidic digestion whereas its accumulation in the last shell growth stria was measured using Laser Ablation Inductively Coupled Plasma Mass Spectrometry (LA-ICP-MS).

Total Co accumulation in the soft tissues was already at equilibrium with the ambient water after 7 d of exposure for all Co concentrations tested. That accumulation was function of dissolved Co concentrations only for the highest exposure concentration. For example, Co accumulation in soft bodies increased 5.4-fold with the increase of Co exposure concentration from 6 to 60 $\mu g.L^{-1}$ at 28 d. This equilibrium at 7 d was also observed with the whole shell and with the last growth shell stria. At 28 d, shell Co accumulation in the last growth deposit was measured to be 0.97 ± 0.47 $\mu g.g^{-1}$ and 1.64 ± 0.08 $\mu g.g^{-1}$ at 6 to 60 $\mu g.L^{-1}$, respectively. Future results on the subcellular Co distribution are expected to allow us to reconstruct Co pathway from water to the shell.

3.11.P-Mo159 Bioaccumulation of Selenium Oxyanions and Organoselenides in Stream Biota

Adrian de Bruyn[1]*, Samuel Luoma*[2]*, Kevin V Brix*[3]*, Cybele Heddle*[4] *and Mariah Arnold*[4]*, (1)ADEPT Environmental Sciences Ltd., Canada, (2)University of California San Francisco (UC San Francisco), (3)EcoTox LLC, (4)Teck Resources Ltd., Canada*

Selenium occurs in natural surface waters as a variety of inorganic and organic chemical species. The oxyanions selenate and selenite typically predominate. Organoselenide species, although hypothesized to be more bioavailable than the oxyanions, have rarely been identified or quantified in natural waters and little is known about their fate or bioaccumulative potential. We analyzed spatial patterns of bioaccumulation in relation to aqueous selenium speciation at more than 100 sites in southeast British Columbia, Canada. We used a sequential approach to fitting bioaccumulation model parameters, first using sites with no detectable organoselenium (<0.01 µg/L) to describe the bioaccumulation of selenate and selenite, then applying those relationships to the remaining sites to infer the bioavailability of three detectable organoselenides. Our analysis indicated that the methylated organoselenide methylseleninic acid was the most bioaccumulative species, followed by dimethylselenoxide and methaneselenonic acid. Organoselenides were associated primarily with mine sediment ponds, and are presumed to be degradation products of selenium metabolism by algae and bacteria. Organoselenides exported from the ponds appear to be responsible for enhanced bioaccumulation in biota in downstream reaches. Our findings indicate that managing biological productivity in mine sediment ponds could help manage selenium risk in the receiving environment.

3.11.P-Mo160 Mining impacts on Chilean wildlife: heavy metals circulating in Andean fox blood

Jessica Jiménez Peñuela[1]*, Aitor Cevidanes*[2]*, Claudia Ulloa Contreras*[3]*, Javier Millán*[4] *and Rafael Mateo*[5]*, (1)Institute for Game and Wildlife Research (IREC), Spain, (2)Department of Animal Health, NEIKER-Basque Institute for Agricultural Research and Development, Basque Research and Technology Alliance (BRTA), Parque Científico y Tecnológico de Bizkaia, Spain, (3)Departamento de Ecosistemas y Medio Ambiente, Pontificia Universidad Católica de Chile, (4)Instituto Agroalimentario de Aragón-IA2 (Universidad de Zaragoza-CITA), Spain, (5)Wildlife Toxicology, Instituto de Investigación en Recursos Cinegéticos (IREC) CSIC-UCLM-JCCM, Spain*

Mining is one of the main activities of the Chilean economy, being the world's main producer of copper. *Las Tórtolas* is a tailings deposit with a 6,75 km² surface from *Los Bronces* copper mine located 40 km north of Santiago, where the Andean fox thrive in human-dominated landscapes. Wild carnivores are good sentinels that are able to reflect the environment they inhabit. The objective of this work was to analyse the levels of heavy metals in blood of foxes inhabiting mining habitats and assess the extent of exposure of these elements linked with adverse health effects. Blood analysis may provide useful information about the current exposure for antemortem assessment of heavy metals. A total of 42 Andean foxes (*Lycalopex culpaeus*) were sampled between May 2017 and May 2018 and a blood sample was obtained from each individual. Metal concentrations of 23 elements: vanadium (V), chrome (Cr), manganese (Mn), iron (Fe), cobalt (Co), nickel (Ni), copper (Cu), zinc (Zn), gallium (Ga), arsenic (As), selenium (Se), rubidium (Rb), strontium (Sr), molybdenum (Mo), silver (Ag), cadmium (Cd), antimony (Sb), cesium (Cs), barium (Ba), mercury (Hg), thallium (Tl), pead (Pb) and uranium (U)) were determined in lyophilized whole blood using Inductively Coupled Plasma Mass Spectrometry (ICP-MS). Some metals (Mn, Co, Ni, Cu, As, Rb, Cs) have been found in different concentration between areas, others (Cr, Fe, Zn, Ga, Mo), do not have no significant differences between zones but there are individuals with slightly outlier values. We did a Principal component analyses and found that the individuals grouped the same distribution the sampling zones have in the map. It seems that the area of sampling of the fox clearly determine their heavy metals concentrations in blood. The Cu concentrations were significantly higher in the core sites of the mining area but did not reach toxic levels for wildlife (less than 4 µg/g). The levels of all the metals will be investigated and compared to already published works of other mining areas affecting wildlife. These results will proporcionate data of the current status of heavy metals in wildlife from an important mining area of Chile and its health implication.

3.11.P-Mo161 Evaluation of Metals and Metalloids in Shellfish and Fish Obtained from Nigerian Markets

Chinelo Anulika Nzekwe[1]*, Irene O'Callaghan*[2] *and Timothy Sullivan*[1]*, (1)University College Cork, Ireland, (2)University College Cork School of Engineering, University College Cork, Ireland*

Environmental pollution is currently a global challenge with metals and metalloids being predominant. They arise from both natural and anthropogenic sources and may accumulate in aquatic animals and various foodstuffs. Shellfish and fish are a veritable source of proteins, fats, vitamins, minerals, and other nutritional values. The contamination of aquatic foods by metals and metalloids could pose serious health dangers to humans, as, some of these metals and metalloids have been shown to be toxic. This study thus investigated the concentrations of the following metals Cadmium, Lead, Chromium, Mercury Nickel, Iron, Vanadium, Manganese and Magnesium in shellfish and fish obtained from African shops in the United Kingdom, The Republic of Ireland and from different markets across the Southern part of Nigeria using Atomic Absorption Spectrophotometer (AAS) and Inductively Coupled Plasma Mass Spectrometry (ICPMS). In the Catfish samples A, B and C, the concentrations levels of metals were as follows Cd< Pb< Cr < Ni < Mn < Zn< Fe. Pb, Ni were above the WHO/FAO permissible limits while the concentrations of Cr, Cd, Fe and Zn were below the WHO/FAO permissible limit. In 8 samples of fish and shell fish, which were obtained from different markets in 5 Southern states of Nigeria; periwinkles, Samples, periwinkles (*Tympanotonus fuscatus*), brackish water catfish (*Arius africanus*), Bonga fish (*Ethmalosa fimbriata*), prawns (*Macrobrachium vollenhovenii*), Crayfish (*Palaemon hastatus*), and African catfish (*Clarias gariepinus)* the range of values of the metals and metalloids found were Cr: 0.10-2.04 $mgkg^{-1}$, Pb: 0.100-0.68 $mgkg^{-1}$, Mg: 1060-18600 $mgkg^{-1}$, Hg: 0.030-0.298 $mgkg^{-1}$ Ni: 0.25-1.1 $mgkg^{-1}$ V: 0.20-3.7 $mgkg^{-1}$ and Cd: 0.005-2.08 $mgkg^{-1}$. The Periwinkle samples had the highest values of five different metals and metalloids Mg, V, Cr, Ni, Pb, while the *Arius africanus* sample a marine catfish, recorded the highest concentration of Cd which is above the WHO/FAO permissible limit. The concentrations of Pb and Hg were above the WHO/FAO permissible limit in periwinkle and marine catfish samples respectively. The result from this study indicates the contamination of the aquatic foods from Nigeria by the metals investigated, the implications of human consumption of these shellfish and fish, may lead to adverse health conditions.

3.11.P-Mo162 Incorporation of Fe Oxides as an Additional Phase for Predicting Cadmium Toxicity in Oxidized Sediments

Buyun Jeong[1]*,* ***Kyoungphile Nam***[1] *and Jinsung An*[2]*, (1)Seoul National University, Korea, Republic of (South), (2)Hanyang University, ERICA*

Traditionally, metal toxicity in sediment has been assessed by measuring sulfide concentrations, assuming the predominant formation of insoluble metal sulfides (MeS) rendering them unavailable for uptake by benthic organisms. Building on this concept, the sediment biotic ligand model was developed involving both sulfide and organic carbon in sediment (*Environmental Toxicology & Chemistry, 2005, 24, 2410*), with an assumption that an excess of metals over sulfides will partition to organic carbon. This model holds validity in anoxic environments where sulfides and organic carbon play pivotal roles in metal binding. However, heavy metals sensitive to redox changes tend to be released from both MeS and organic carbon, for instance, in oxidized sediments. Literatures show increased concentrations of dissolved Cadmium under oxidizing conditions compared to reduced sediments. Such released metals will then be re-adsorbed onto Fe oxides, another major phase for metal binding. For improved cadmium toxicity prediction, we propose an advanced model that considers both Fe oxides and organic carbon contributions as well as sulfide in oxidized sediment. Partition coefficients (K_d) for both phases were obtained using the Windermere Humic Aqueous Model, version 7 (UK Centre for Ecology and Hydrology, 2012), and the relationship with pH was derived by curve fitting to find the best fit for the data. Data obtained from previous studies show good agreement with the predicted K_d values. A comprehensive model equation incorporating these K_d values, Fe oxides, and organic carbon contents was derived. When compared to the experimental data from the sediment samples collected from 21 different regions in South Korea, the model demonstrates accurate predictions within one order of magnitude. This model serves as a valuable tool for predicting cadmium toxicity in an oxidized sediment.

3.11.P-Mo163 Effects of a chronic exposure to cobalt on primary producers and invertebrates in two microcosm studies

Michael C Cavallaro[1]*, Allison Cardwell*[1]*, Emily Stefansson*[1]*, Udo Hommen*[2]*,* ***David Boyle***[3] *and William A. Stubblefield*[1]*, (1)Oregon State University, (2)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (3)Cobalt Institute, United Kingdom*

Higher tier ecotoxicity tests that measure effects at the population and community levels are a means to assess the laboratory-to-field extrapolation of regulatory thresholds derived from single species laboratory tests. The primary objective of the current research was to validate a bioavailability normalised predicted no effect concentration (PNEC) for freshwater organisms which was derived from an SSD of chronic single species tests. Therefore, effects of constant exposure to cobalt on a freshwater community was monitored in two indoor microcosm studies. A further aim of the studies was to provide information on the fate of cobalt in freshwater ecosystems and especially on the accumulation in biota. The first study was a 56d fully replicated study, while the second was an 84d regression-based study that was conducted in larger tanks and which considered additional community level endpoints. Both studies included taxa that were identified as sensitive to chronic cobalt exposure in single-species laboratory tests, i.e., primary producers and invertebrates. The accumulation of cobalt was assessed in a sub-set of organisms - periphyton, macrophytes, snails – with the intention of providing accumulation data at different trophic levels, and food-chain transfer of cobalt from primary producers to a grazer consumer. Overall, the two microcosm studies provide population effect levels for several groups of organisms - phytoplankton, periphyton, macrophytes, zooplankton, macroinvertebrates – as well as effect levels for ecosystem functions, such as leaflitter degradation. Results are therefore valid to inform on the protectiveness of a cobalt PNEC derived from the SSD.

3.11.P-Mo164 Speciation and Ecotoxicity of the Soluble Fraction of Tellurium and Tellurium Dioxide
Dagobert Heijerick[1] *and Kerstin Heitmann*[2]*, (1)ARCHE Consulting, Belgium, (2)COM FOR CHEM, Germany*
Following an ECHA decision for the provision of additional long-term ecotoxicological information for the sparingly soluble substances Tellurium metal (EC 236-813-4) and Tellurium dioxide (EC 231-193-1), a scientific research program was initiated by the REACH Selenium and Tellurium Consortium[3] to meet the new data requirements. Since the Water-Accommodated Fraction approach cannot be applied on sparingly soluble inorganic substances, the identified data gaps could only be filled by read-across from data generated with a soluble Te-salt.

In a first step, 24h-screening T/Dp tests were conducted with both substances at different pH-levels for the identification of the Te-speciation of the soluble fraction. Similar to other metals, Te can exist in various oxidation states, and toxicity among these oxidation states may vary. Information on the speciation profile of the soluble Te- and TeO_2-fraction is therefore essential for selecting the appropriate soluble Te-salt(s) to be used in the testing program. Analysis of the T/Dp solution, performed at the Flemish Institute for Technological Research (VITO), showed that more than 99% of dissolved Te from either Te-metal or TeO_2 was present as Te(IV), and thus Na_2TeO_3 was selected as the read-across soluble test substance .

Long-term toxicity OECD Guideline studies were conducted with algae, cladocerans and fish (ELS-test), and revealed that *Daphnia magna* was the most sensitive species (21d-EC_{10} of 72 µg Te/L). The high sensitivity of *D. magna* towards Te was previously observed in short-term testing with these three species.

The concentration of 72 µg Te/L represents the chronic ecotoxicity reference value that can be used for both classification purposes and revision of the current PNEC. Chronic classifications are determined by comparing the ERV with 28d T/Dp data that were previously determined.

The revised Te-PNEC is 7.2 µg Te/L (AF of 10 on the lowest chronic value), a value that is slightly higher than the original PNEC of 5.79 µg Te/L which was determined by applying an AF of 1000 on the lowest acute value (5.79 mg Te/L for *D. magna*). Taking the molecular weight of TeO_2 into account, a PNEC of 9.0 µg TeO_2/L is also calculated. Both PNEC-values are considered relevant as they are lower than the maximum solubility of these two substances.

3.11.P-Mo165 The DOM-inating problem– Assessing the impact of organic matter chelation on mercury toxicity
Christoph Gade*, Lenka Mbadugha and Graeme Paton, School of Biological Sciences, University of Aberdeen, United Kingdom*
Current ecotoxicological testing demands full standardisation for established protocols to ensure inter-laboratory comparability as the choice and exact composition of exposure media can have a significant influence on toxicant chemistry and animal welfare. Subsequent data production and interpretation is thus subject to a deep understanding of the underlying environmental chemistry and consideration of organismal health.

Mercury is a potent neurotoxin and listed on the top ten of chemicals of major public health concern by the WHO. Its unique chemical properties enable mercury to speciate and thus change its environmental behaviour based on its surrounding. One of the key elements influencing the environmental fate of mercury is organic matter, due to its abundance of nonspecific functional groups and chelating properties. The impact of organic matter on the chemical behaviour of mercury has been demonstrated for terrestrial and freshwater systems, while a similar quantification for marine environments remains fragmentary. However, evaluating the impact of organic matter-mercury interactions at low trophic levels is important as they serve as springboards to complex environmental food webs.

We used the euryhaline crustacean *Artemia salina* to assess the bioaccumulation and toxicity of two mercury compounds in saline media with contrasting concentrations and sources of dissolved organic matter. The toxicity to cysts and hatched individuals was assessed in 24h assays, and their bioaccumulation rates determined using empirical uptake analysis and single-compartment toxicokinetic modelling. Additionally, mercury nanoparticles were employed for the first time in an acute toxicity study.

Our results suggest that media composition plays a pivotal role in marine aquatic toxicology, thus emphasising the importance of standardising the underlying procedures. Dissolved organic matter significantly impacts bioaccumulation rates as well as acute toxicity and excystment. The study emphasises the need for a standardised seawater recipe with full control of all variables to elevate marine ecotoxicological testing.

3.11.P-Mo166 A Holistic Modelling Approach to Predict Silver (Ag) Toxicity on Rainbow Trout Populations
Karel Vlaeminck[1]*, Charlotte Nys*[1]*, Katrien Arijs*[1]*, Jelle Mertens*[2] *and Karel De Schamphelaere*[3]*, (1)ARCHE Consulting, Belgium, (2)EPMF, Belgium, (3)Ghent University - GhEnToxLab, Belgium*

Metal bioavailability plays a pivotal role in determining the toxicity of silver (Ag) to aquatic fish species, such as the rainbow trout (*Oncorhynchus mykiss*). Ag exposure disrupts sodium (Na) uptake at the gills, leading to perturbations in the internal Na-balance, which results in elevated blood viscosity, cardiovascular failure, and mortality. This study builds upon the existing sodium balance model (SBM) to mechanistically describe the impact of Ag on Na-concentration within rainbow trout, thereby predicting lethal outcomes under specific exposure conditions. However, understanding the broader ecological implications of Ag toxicity and its differential effects across various life stages remain underexplored. This research aims to bridge this knowledge gap by integrating biotic ligand models (BLMs), SBM, and individual-based modelling (IBM) to assess the realistic effects of Ag on rainbow trout populations.

To achieve our objectives, we combined the BLM and SBM with an IBM, incorporating individual threshold (IT) and stochastic death (SD) approaches to simulate lethal Ag effects. We based our environmental bioavailability conditions on the FOREGS dataset to ensure realism in our predictions. The results of our integrated modelling framework highlight the significant impact of Ag exposure on rainbow trout populations, particularly when the juvenile life stages are affected. At environmentally relevant Ag concentrations, the SBM did not predict any effects under realistic bioavailability (physico-chemical) conditions. Integrating SBM with an IBM approach allowed us to extrapolate these effects to the population level, ultimately deriving population-level thresholds. Our findings reveal that the juvenile life stage appears to be the most sensitive and crucial in determining population effects, with significant implications for regulatory testing strategies.

Our modelling framework incorporates various modelling approaches (including General Unified Threshold model for Survival [GUTS], BLM, SBM, and IBM) while combining exposure and effect data, to provide predictions on Ag toxicity to rainbow trout populations. Such holistic approaches are instrumental for making informed decisions regarding further testing strategies for Ag toxicity. This research serves also as a valuable step toward developing risk assessment strategies to protect fish populations in European freshwater environments.

3.11.P-Mo167 Environmentally Relevant Toxicity Assessment of Metal Mixtures for the Egg and Sac-fry Stages of Japanese Medaka and the Reproduction of Ceriodaphnia dubia

***Hiroyuki Mano**, Kouji Ueda, Naohide Shinohara, Yuichi Iwasaki, Masashi Kamo and Wataru Naito, National Institute of Advanced Industrial Science and Technology (AIST), Japan*

To conduct risk assessments of metal mixtures that are environmentally relevant by regulatory agencies, it is essential to predict the ecotoxicological effects of these mixtures on organisms under realistic exposure profiles. In this study, we examined whether the short-term chronic toxicity of metal mixtures, reflecting the combinations and concentration ratios of metals found in Japanese rivers, could be predicted for Japanese Medaka and *Ceriodaphnia dubia*. This prediction was based on the results of toxicity tests of individual metals using the two species. We conducted short-term and chronic toxicity tests of five metals (Al, Cd, Cu, Ni and Zn) on egg and sac-fry stages of Japanese Medaka. We also collected data on toxicity tests of *C. dubia* reproduction for these metals from published articles. Subsequently, we conducted toxicity tests on metal mixtures using the two species, reflecting exposure profiles that are environmentally relevant in Japanese rivers. Metal speciation in test solutions was determined using a chemical speciation model and/or measured by the DGT filter method to estimate bioavailability-based toxicity of individual metals and metal mixtures. The bioavailability-based effects of metal mixtures on the egg and sac-fry stages of Japanese Medaka and the reproduction of *C. dubia* were then compared with estimates from results of toxicity tests of single metals based on concentration additive and independent action models. The methods for predicting the toxicity of metal mixtures from data on toxicity tests of single metals in Japanese rivers will be discussed based on results.

3.11.P-Mo168 Effects Of Essential And Non-Essential Metals In The Photosynthetic Parameters Of A Freshwater Chlorophyceae

***Giseli Swerts Rocha**[1], Nora Exposito Lorenzo[1], Jordi Sierra[2] and Marta Schuhmacher[1], (1)Chemical Engineering, Universitat Rovira i Virgili, Spain, (2)Faculty of Pharmacy and Food Sciences, Universitat de Barcelona, Spain*

Algae are at the base of the trophic chain and can impact higher trophic levels. Some metals are required for the optimal metabolism of the algae, while others are not required for metabolic processes. Independent of the essentiality, higher concentrations of metals are toxic to different trophic levels. Cobalt (Co) is an essential metal, being part of enzymes and B12 vitamin. Chromium (Cr), on the other hand, has no known functions for algae. Cr is common and persistent in the environment, being present in the forms Cr^{2+},Cr^{3+}, and Cr^{6+}, with different toxicities. Cr^{3+}, used in the present study, has low membrane permeability and low capacity of bioaccumulation in the trophic chain. In the present study, cells of the freshwater microalga *Ankistrodesmus densus* (Chlorophyceae) in exponential growth phase were exposed to three concentrations of Co and Cr: 0.2, 0.4 and 0.8 mg L^{-1}. The photosynthetic activity of microalgae (maximum and effective quantum yields, photochemical and non-photochemical quenching, and rapid light curves) was assessed using pulse amplitude modulated fluorometer (Phyto-PAM) and parameters of dark- and light-adapted samples were measured after 72 h. Under metal exposure, the relative maximum electron transport rate was the most sensitive parameter (decrease 66-70%). However, for the other evaluated parameters our data indicate that all parameters were affected in the presence of metals, with a higher sensitivity in the photosynthetic parameters of algae exposed to Co. In addition, algae was efficient in activating photoprotective mechanisms, avoiding damages in the photosynthetic machinery. Although, it is not possible to infer with certainty if the higher toxicity of Co can be related to its essentiality, which could result in higher uptake by the cells; or due to the different charges of both metals, i.e., Co^{2+} could compete with Mg^{2+} or Mn^{2+}, affecting chlorophyll and oxygen evolving complex, respectively.

3.11.P-Mo169 Effects of copper on the fatty acids' profile of standard freshwater species

*Mariana Rodrigues[1], Ana M. M. Gonçalves[2], Ana Ré[3], Isabel Campos[4], Irene Bermúdez-Gutiérrez[5], Fernando J. M. Gonçalves[6] and **Nelson Abrantes**[7], (1)University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Portugal, (2)Department of Life Sciences, University of Coimbra, MARE - Marine and Environmental Sciences Centre / ARNET – Aquatic Research Network, Portugal, (3)Department of Environment and Planning, Department of Environment and Planning & Centre for Environmental and Marine Studies (CESAM), University of Aveiro, Portugal, (4)CESAM - Centre for Environmental and Marine Studies and Department of Biology, University of Aveiro, Portugal, (5)Life Sciences, University of Coimbra, MARE - Marine and Environmental Sciences Centre, Portugal, (6)University of Aveiro, Portugal, (7)Department of Biology, Department of Biology & Centre for Environmental and Marine Studies (CESAM), University of Aveiro, Portugal*

The waterborne copper concentration has been increasing over the decades mainly associated with industrial and agricultural inputs. Remarkably, this metal is one of the most extensively used agrochemicals (both as fertilizer or pesticide) in Europe, employed for the elimination or control of fungi, bacteria, and algae. While copper can be physiologically essential at low concentrations, its toxicity becomes apparent at elevated levels, impacting organisms across the spectrum from primary producers to secondary consumers. Consequently, once introduced into water, copper exhibits persistence and can induce adverse effects on diverse aquatic organisms. Thus, it is crucial to determine lethal and sub-lethal (e.g., biochemical responses) effects of aquatic organisms to predict the impacts of copper on ecosystem's health. Fatty acids (FAs) are molecules that play an essential role in the maintenance of physiological functions of many organisms being for example the major constituent of the cell wall as part of phospholipids. Furthermore, alterations in FAs profile can act as early warning signals of stressing conditions becoming an effective ecotoxicological tool. Hence, this study aimed to assess the effects of sub-lethal copper concentrations on the FAs profile of standard freshwater species (*Raphidocelis subcapitata*, *Lemna minor*, *Daphnia magna* and *Chironomus riparius*). Firstly, the copper EC_x for all species was determined subjecting the organisms to a range of non-lethal to lethal copper concentrations. Considering the values obtained for each species, biochemical bioassays were performed using a concentration below EC_{10} and equal to EC_{10} and EC_{20}, respectively. Results pointed out that *D. magna* is the most sensitive planktonic species to copper, followed by *L. minor* and *R. subcapitata*. Moreover, in this study, the species from different trophic levels exposed to a range of copper concentrations revealed changes in its fatty acid content. There was an increasing of saturated FAs (mainly composed by Palmitic acid) and polyunsaturated FAs (mainly composed by the essential fatty acid α-Linolenic acid – ALA – omega-3, with exception of *C. riparius*) with increasing of copper concentrations, for all species with exception of *R. subcapitata*. FAs proved to be a useful bio-indicator of the healthy status of aquatic ecosystems, providing crucial information about the impacts of copper in the trophic food web.

3.11.P-Mo170 Associations of Heavy Metal Exposure with Dyslipidemia and Elevated Liver Enzymes

***Eun-Hee Lee**[1], Tae-Hyeong Kim[1], Ji-Eun Oh[2], Hyo-Jin Kim[3] and Younglim Kho[4], (1)Graduate School of Health Science, Far East University, Korea, Republic of (South), (2)Biomedical Laboratory Science, Far East University, Korea, Republic of (South), (3)Division of Health Science, Baekseok University, Korea, Republic of (South), (4)Health, Environment & Safety, Eulji University, Korea, Republic of (South)*

Lead and Mercury has permanent adverse effects on human and this exposure has become one of the major public health problems. The purpose of this study was to investigate the association of blood levels of lead(Pb) and mercury(Hg) with dyslipidemia and liver function. Analyses were performed with a total of 2,952 participants in the KNEHS(Korea National Environmental Health Survey) from 2018 to 2020. KNEHS is a cross-sectional study that has calculated national statistical data on the level of exposure to environmentally harmful substances in the body since 2009. The blood lead levels were significantly higher in the dyslipidemia group (n=931, 1.609ug/dL) compared to non-dyslipidemia (n=2014, 1.456ug/dL). Similarly, those with elevated liver enzymes (n=744, 1.780ug/dL) exhibited higher lead levels than the normal group (n=2201, 1.415ug/dL). The blood mercury levels also showed significant elevation in the dyslipidemia group (3.263ug/L vs.2.809ug/L) and elevated liver enzymes group (3.815ug/L vs.2.686ug/L) compared to the control group. In logistic regression analysis, dyslipidemia was significantly associated with blood lead (OR 1.609; 95% CI: 1.243-2.084) and mercury level (OR 1.403; 95% CI: 1.178-1.672). Elevated liver enzymes were similarly associated with blood lead (OR 3.148; 95% CI: 2.350-4.217) and mercury level (OR 2.272; 95% CI: 1.869-2.762). This study showed a strong link between blood levels of lead and mercury, dyslipidemias, and elevated liver enzymes, emphasizing the potential health risks posed by exposure to these heavy metals.

3.11.P-Mo171 Kinetics of Meta-metabolome Response to Cobalt Exposure in Dynamic River Biofilm Communities

***Simon Colas**[1], Benjamin Marie[2], Soizic Morin[3], Mathieu Milhe-Poutingon[1], Pierre Foucault[2], Clementine Gelber[4], Siann Chalvin[1], Patrick Baldoni-Andrey[5], Nick Gurieff[6], Claude Fortin[7] and Séverine Le Faucheur[1], (1)Universite de Pau et des Pays de l'Adour, E2S-UPPA, CNRS, IPREM, France, (2)UMR 7245 CNRS/MNHN « Molécules de Communication et Adaptation des Micro-organismes », Muséum National d'Histoire Naturelle, France, (3)INRAE UR EABX, France, (4)TotalEnergies, Pole d'Etudes de Recherche, France, (5)TotalEnergies, Pole d'Etudes de Recherche de Lacq, France, (6)Rio Tinto, Closure R&D, Australia, (7)Centre Eau Terre Environnement, Institut National de la Recherche Scientifique – Eau Terre Environnement, Canada*

As part of the energy transition away from fossil fuels, the extraction and use of cobalt (Co) has increased significantly in recent decades. Although few studies have investigated its toxicity, it is currently classified as a substance to monitor in rivers in some countries. To provide Co toxicity data needed to assess the ecological risk for aquatic organisms, mature biofilms were exposed for one month in artificial river streams to four Co concentrations (background concentration, 1 x 10^{-7}, 5 x 10^{-7} and 1 x 10^{-6} M). Bioaccumulation, biomass, chlorophyll-*a* levels and the composition and structure of prokaryotic and eukaryotic communities were monitored along with the meta-metabolomic response at different time points (from 1 hour to 28 days). Using an untargeted metabolomic approach, the entire biofilm meta-metabolome was characterized using a new holistic data processing approach based on dose-response modeling, benchmark-dose/time calculation and characterization of response trends. From these results, two ranges of concentrations were observed at each time step. The first range was characterized as a concentration range inducing defense responses (CRIDeR) and the second as a concentration range inducing damage responses (CRIDaR). The initial thresholds of CRIDeR were found to be similar between each exposure time, whereas those of CRIDaR increased as a function of exposure time. This result suggested a community shift toward tolerant species, which was confirmed with the characterization of the prokaryotic and eukaryotic communities. Moreover, we also demonstrated that changes in the meta-metabolome were faster than changes in community composition using a Multivariate Omics Trajectory Analysis. These rapid changes in the meta-metabolome were confirmed by the observation of time ranges inducing defense and damage responses (TRIDeR and TRIDaR) based also on the interpretation of trends in dose-response models of untargeted meta-metabolomic features as a function of exposure time. The initial thresholds of TRIDeR were measured to be a few seconds whereas those of TRIDaR were in the order of 1 day. This study demonstrates that meta-metabolome defenses and damage responses of Co-exposed biofilms are rapidly and continuously impaired, even within resistant and tolerant microbial communities.

3.11.P-Mo172 Accumulation and Effects of Cobalt on Microbial Communities Living in Growing Freshwater Biofilms.
Sarah Gourgues[1], Maria Soledad Goni[2], Patrick Baldoni-Andrey[3], Nick Gurieff[4], Clementine Gelber[5] and ***Séverine Le Faucheur***[6]*, (1)Institute of Analytical Sciences and Physico-Chemistry for Environment and Materials (IPREM), France, (2)Université de Pau et des Pays de l'Adour, E2S-UPPA, CNRS, IPREM, France, (3)TotalEnergies, Pole d'Etudes de Recherche de Lacq, France, (4)Rio Tinto, Closure R&D, Australia, (5)TotalEnergies, Pole d'Etudes de Recherche, France, (6)Universite de Pau et des Pays de l'Adour, E2S-UPPA, CNRS, IPREM, France*
Cobalt (Co) is one of the metals whose use and extraction have increased considerably over the last few decades. As it is likely to find its way into the environment in the near future, it is vital to assess its impact now. Although they are not widely used in chemical risk assessment, prokaryotic and eukaryotic microorganisms play a vital role in the proper functioning of ecosystems. They can develop in the form of biofilms on submerged substrates in rivers. Freshwater biofilms are ubiquitous and dynamic biological systems harboring a wide diversity of microorganisms involved in the cycling of essential elements. Directly exposed to contamination induced by human activities in freshwater, biofilms are indicators of the health of aquatic ecosystems. This study aimed at deciphering how cobalt impacts the biological organization and functioning of aquatic biofilms.

To that end, artificial substrata were placed in mesocosms (TotalEnergies facilities, Pau, France) contaminated with Co (0.1, 0.5 and 1 µM) or containing background Co concentrations (control) to colonize biofilms for 28 days. After the exposure, a period of 5 weeks was further applied without Co contamination to simulate a recovery period. Water and biofilm samples were collected every 7 days during Co exposure. Water was analyzed for its water quality, including Co concentrations. Biofilms were examined for Co bioaccumulation, and their structure and functional potential.

Cobalt bioaccumulation in biofilms was mainly intracellular and well correlated with the concentrations tested. The presence of Co at concentrations of 0.5 and 1 µM increased the abundance of prokaryotes from the 21st day of exposure and their diversity was also impacted since the early stages of colonization. Indeed,*Cyanobacteria* were highly sensitive and not able to colonize the biofilm support from day 7 for concentrations above 0.1 µM. In contrast, *Bacteroidota* appeared resistant all through the biofilm colonization. Microeukaryotic abundance was lower at day 21 for 0.5 and 1 µM of Co as compared to the control, which was accompanied with a change in beta-diversity for exposed biofilms since first days of colonization. Co-occurrence networks between prokaryotic and microeukaryotic communities are under analysis. Finally, functional potential analyses based on prokaryotic communities' composition revealed that Co influenced a number of cellular processes and primary production, a determining process in the biofilm formation.

3.11.P-Mo173 Temporal and Spatial Changes in Water Quality and Phytoplankton Populations in the lower St. Johns River, Florida
Gretchen K. Bielmyer-Fraser[1]*, Adam C Ryan[2] and James Nienow[3], (1)Jacksonville University, (2)International Zinc Association, (3)Biology, Valdosta State University*
The St. Johns River (SJR) is an ecologically and economically important estuarine river system in Florida undergoing extensive anthropogenic change. In this study, a variety of water quality parameters and a suite of metals were measured in water samples collected from eight sites in the lower SJR, in Florida from 2019 to 2022, continuing from previous work that documented these parameters in the river from 2017 to 2019. Aquatic communities such as phytoplankton can be indicative of river health; therefore, phytoplankton were collected from each site, and the diatom component was identified. The total number of taxa in each sample ranged from 60 to 190, with 25 taxa accounting for the majority (64%). Similar to water chemistry, seasonal fluctuations in phytoplankton abundance and diversity were observed, with a relative abundance of *Skeletonema costatum* and *Skeletonema subsalsum* in times of lowered diversity. Furthermore, decreased phytoplankton diversity correlated with increased metal contamination in the lower SJR. Multivariate analyses highlighted significant

interactions among phytoplankton diversity and water chemistry variables. This study provides new information about the impact of human disturbance on biotic communities.

3.11.P-Mo174 Does Cryptic Diversity Within the Eurytemora affinis Complex Show Differential Sensitivity to Lithium Exposure?

Quentin Peignot[1,2], *Gesche Winkler*[2], *Ellia Roy*[2], *Nathalie Giusti-Petrucciani*[1], *Caroline Arcanjo*[1] *and Joëlle Forget-Leray*[1], *(1)Sebio, Le Havre Normandy University (ULHN), France, (2)Institut des Sciences de la Mer de Rimouski, Québec-Océan, Université du Québec à Rimouski, Canada*

A cryptic species complex encompasses morphologically indistinguishable species that are genetically divergent. Some of the most frequently used species in ecotoxicological assessment show evidence of cryptic diversity that may affect the results of a given test. Linking cryptic diversity to sensitivity of chemicals has rarely been investigated. Lithium (Li) is an alkali metal considered as one of the most important emerging pollutants under concern due to high demand for this compound essentially to produce rechargeable batteries. Li environmental concentrations are expected to increase in the next years and its effects on marine and coastal organisms remain relatively unrecognized. Here, we focused on two of six cryptic species of the estuarine copepod complex *Eurytemora affinis*, exposing natural populations on two continents. Our main objective was to characterize the differential sensitivity of these two-field collected *E. affinis* cryptic species (the European and the North-Atlantic clade) to Li using a larval bioassay. Ovigerous females of the North-Atlantic clade were sampled in the St. Lawrence estuary (Canada) and for the European clade in the Seine estuary (France) and incubated to recover early-stage larvae (nauplii). We assessed survival and growth of *E. affinis* nauplii exposed to a gradient of Li concentrations (1, 10, 50 and 100 $mg.L^{-1}$) for 96 h at 5 PSU and 15°C. LC50 were estimated by using log-logistic model. LC50 for the nauplii from North-Atlantic and European clades of *E. affinis* were 243.42 (± 3.56) $mg.L^{-1}$ and 241.41 (± 2.05) $mg.L^{-1}$ at 24 h exposure and 86.31 (± 1.07) $mg.L^{-1}$ and 72.78 (± 1.15) $mg.L^{-1}$ respectively after 96 h. Li inhibit growth rate of nauplii at ≥ 50 $mg.L^{-1}$ with an EC50 at 96 h of 60.19 (± 1.13) $mg.L^{-1}$ for the North-Atlantic clade nauplii. The estimated EC/LC50 values were too high to cause extreme effects at environmental concentrations observed in Northern Hemisphere estuaries. No significant differences were observed in Li sensitivity between the two clades. However, further studies should be performed to test other contaminants, to improve knowledge on sensitivity of the cryptic species *E. affinis* complex to assure routine ecotoxicological tests are appropriate.

3.11.P-Mo175 Challenges of Deriving Environmental Quality Standards for Cerium and Lanthanum

Eva Lauber[1], *M. Carmen Casado-Martinez*[2], *Marion Junghans*[3] *and Alexandra Kroll*[3], *(1)Ecotox Centre, Switzerland, (2)Swiss Centre for Applied Ecotoxicology Eawag (EPFL), Lausanne, Switzerland, (3)Swiss Centre for Applied Ecotoxicology, Switzerland*

Lanthanide compounds, specifically Cerium (Ce) and Lanthanum (La) salts, are relatively new alternatives to other commonly used flocculants in water treatment plants. While their use provides some practical advantages, the impact on aquatic environment also needs to be evaluated. We derived environmental quality standards (EQSs) based on the EU Technical Guidance document No. 27 for EQS derivation under the Water Framework Directive (WFD). This guidance is also used in Switzerland.

Aquatic toxicity, environmental fate and physical-chemical properties data were collected from all publicly available resources and assessed for relevance and reliability according to the CRED (Criteria for Reporting and Evaluating ecotoxicity Data) method.

For La, 101 acute, 50 chronic and 3 sub-chronic effect values were evaluated. For Ce, the evaluation included 50 acute, 17 chronic and 2 sub-chronic effect values. As speciation and bioavailability of Ce and La vary under various physical-chemical conditions, only effect studies reporting measured dissolved concentrations and effects related to these were considered.

Insufficient documentation of scientific studies in terms of specification of experimental and analytical conditions led to the exclusion of most studies from open literature. The scientific and technical issues narrowed down the usable data almost exclusively to studies submitted for REACH registration purposes. However, studies from the database of the European Chemical Agency (ECHA) could not be validated, as the reliability of the presented data is unclear in view of missing and contradictory information. The study summaries are often incomplete and neither the official assessment nor the original study reports are available publicly. In the absence of original study reports, the results could not be verified and only preliminary EQSs could be derived that are in the range of measured background concentrations of Ce and La.

As Ce and La occur naturally in the environment, instead of absolute EQS values, we would recommend the definition of maximum permissible additions (MPA) to the local background concentrations as already in place in the Netherlands.

Improvement towards a more robust scientific outcome can be achieved through analytical verification of exposure and complete documentation of experimental studies as well as better managed databases with access to official assessments and original study reports.

3.11.P-Mo176 Evaluating the Sensitivity of Environmental Threshold Derivation of Cu in Europe to the Use of Geographically Relevant Species

***Charlotte Nys**[1], Karel Vlaeminck[1], Patrick Van Sprang[1], Stephen Lofts[2], Stijn Baken, PhD[3] and Karel De Schamphelaere[4], (1)ARCHE Consulting, Belgium, (2)UK Centre for Ecology & Hydrology (UKCEH), United Kingdom, (3)European Copper Institute, Belgium, (4)Ghent University - GhEnToxLab, Belgium*
Chronic toxicity of Cu is dependent on the physico-chemistry of freshwater environments. More specifically, pH, DOC, Ca, Na and Mg have been shown to influence chronic toxicity to aquatic organisms. Hence, the derivation of environmental thresholds of Cu for the freshwater environment in Europe consider the influence of local conditions using bioavailability models. The derivation of environmental thresholds for Cu in Europe, such as the environmental quality standard, is currently under review. These ongoing revisions consider updates to the chronic Cu toxicity database, and of the bioavailability models. Toxicity databases of many metals are typically data-rich, i.e., they include reliable chronic freshwater data of numerous species. For Cu, high-quality data have been identified for 44 freshwater species and covering 336 individual data-entries. Species sensitivity distribution (SSD) approaches used in the environmental threshold derivation assume that the species in the Cu database represent surrogates for species occurring in natural European ecosystems. The use of species that are not representative for the ecosystem to be protected has previously been criticized in literature, as these may not represent the sensitivity of local species. Some jurisdictions, e.g., Australia, consider the geographical relevance of a species for a specific region as a criterion to collate SSDs.

The Cu freshwater database contains 16 species that occur in Europe. Next to this group, ‘European relevant species’ consider also those non-European species that have a close relative (at the genus-level) occurring in Europe, but for which the genus is not yet represented among the European species in the database (5 in total). The remaining species include several species belonging to genera and/or families that are endemic to non-European regions. In the present study, we evaluate several scenarios that assess the influence of considering only ‘European relevant species’ on the environmental threshold derivation for Cu. This will be done by combining the most recent bioavailability normalization approaches with SSD-techniques (using the Cu bioavailability tool CuBioM) using physico-chemistry databases relevant for European freshwaters. Our testing hypothesis is that the consideration of European relevant species has limited influence on environmental threshold derivation. Our study may improve the geographical relevance of risk and compliance assessments for Cu in Europe.

3.11.P-Mo177 Introducing the geographical relevancy of species to set environmental thresholds of Pb for aquatic environments in Europe

***Patrick Van Sprang**[1], Charlotte Nys[1] and Mohammed Jasim Chowdhury[2], (1)ARCHE Consulting, Belgium, (2)International Lead Association*
Chronic toxicity of Pb is strongly dependent on the physico-chemistry of freshwater environments. More specifically, DOC and pH have been previously shown to influence the chronic toxicity of Pb to freshwater organisms. As such, bioavailability models have been developed to account for the influence of these toxicity modifying factors. Hence, the derivation of environmental thresholds of Pb for the freshwater environment in Europe and many other regions is bioavailability-based. For the marine environment, no specific bioavailability correction has been introduced. Recently, chronic Pb toxicity databases have been updated with published chronic toxicity data for both freshwater and marine species. High-quality toxicity data have been identified for 34 freshwater species covering 191 individual data-entries, and for 36 marine species covering 85 individual data-entries. The species sensitivity distribution (SSD) approach has been used to derive the environmental threshold as it assumes that the species in the Pb database represent surrogates for species occurring in natural European ecosystem. Surrogate species may or may not represent the sensitivity of populations of local species. The use of species that are not representative for the ecosystem to be protected has previously been criticized in literature. The Pb toxicity database contains 26 species that are representative for European freshwaters, and 27 species for European marine waters. In the present study, we evaluate several scenarios that assess the influence of considering only ‘European relevant species’ on the environmental threshold for Pb, by combining the bioavailability normalization approaches with SSD-techniques using physico-chemistry databases relevant for European freshwaters. Consistent to our testing hypothesis, the results reveal that the consideration of European relevant species, which increases the robustness of the assessment, has limited influence on Pb environmental thresholds for freshwater and marine environments.

3.11.P-Mo178 EU-WIDE EXPOSURE ASSESSMENT OF METALS IN MUNICIPAL SEWAGE TREATMENT PLANTS

***Maxime Eliat**[1], Nora Ferencz[1], Marnix Vangheluwe[1], Seth Schittekatte[1] and Hugo Waeterschoot[2], (1)ARCHE Consulting, Belgium, (2)Chemicals Management*
Releases from consumer and professional widespread uses to the aquatic environment are based on default assumptions leading to precautionary assessments in the REACH dossiers. Around 80-90% of urban wastewater is collected and treated in the EU. Hence metal emissions from e.g. consumer use of products via STP effluents are not to be neglected. Emissions from municipal sewage treatment plants (STP) can provide a better estimate, given they collect metal emissions from these combined sources.

Providing a realistic estimate of metal concentrations in the effluent of municipal STPs is part of Eurometaux’s ongoing comprehensive “Metals Environmental Exposure Data gathering” (MEED), covering today’s and tomorrow’s need to comply with the REACH combined effects, Zero Pollution Ambition and biodiversity objectives.

The EU's Urban Wastewater Treatment Directive sets requirements for urban wastewater quality but lacks specific regulations for monitoring metals. As a result, there is no centralized database for metal concentration data in the EU. To address this gap and collect data, environmental and water agencies across EU countries were contacted for metal emission data.

Data sets for 20 metals, covering up to 12 countries (availability of data varied between countries), were compiled, and represented the basis for the derivation of reasonable worst-case STP effluent concentration.

The methodology included an outlier analysis to minimize the impact of extreme local point sources (e.g. due to contamination with small industrial sources) when deriving a representative STP effluent concentration.

The EU PEC_{STP} was represented by the median of all 90th percentile values from the different countries. The comparison of the EU PEC_{STP} value with the $PNEC_{STP}$ was made to derive the risk characterization ratios (RCR) at EU scale.

All RCRs for the individual metals were below 1 for the STP. The RCRs for the subsequent environmental compartments after STP discharge were all below 1 except for two metals with RCRs > 1 for the sediment compartment. When also including the regional background concentrations, a significant portion of the RCRs are larger than 0.2 hence will require an assessment of the combined risk in the EU.

Nonetheless, this does not imply the existence of an actual risk. These values could potentially undergo further refinement by incorporating the bioavailability concept, although such refinement lies beyond the scope of this project.

3.11.P-Mo179 REGIONAL EXPOSURE ASSESSMENT OF METALS IN THE AQUATIC FRESHWATER ENVIRONMENT – SEDIMENT COMPARTMENT

Nora Ferencz[1]*, Marnix Vangheluwe*[1]*, Dagobert Heijerick*[1]*, Violaine Verougstraete*[2] *and Hugo Waeterschoot*[3]*, (1)ARCHE Consulting, Belgium, (2)Eurometaux, Belgium, (3)Chemicals Management*

Environmental release rates of metals can vary over time due to new uses and changes in used/manufacturer volumes, but also due to improvement of emission-reducing technologies and external conditions like climate change. As the sediment compartment serves as the primary environmental sink for most metals, changes in metal emissions to water could have a significant impact. Consequently, previously collected regional ambient concentrations used in a regulatory context (e.g. for exposure scenario development under REACH) may not be relevant anymore for current or future situations. An update of these regional metal concentrations in the sediment compartment is part of Eurometaux's currently ongoing comprehensive "Metals Environmental Exposure Data" (MEED) program, covering today's and tomorrow's expected needs to comply with the REACH combined exposure, the Zero Pollution Ambition and biodiversity objectives.

Most countries do not measure metal concentrations in sediment as part of their regulatory-based monitoring program and, additionally, there is no unified European Union (EU) monitoring database.

The absence of such datasets required a customized approach, involving data collection from diverse sources such as national websites and personal communication.

Data sets for 28 metals from 6 databases were compiled to derive the EU $PEC_{regional}$ sediment value according to EU Guidance Documents. To address inherent biases within the datasets due to increased local monitoring efforts at highly histrorically contaminated sites, the EU $PEC_{regional}$ was calculated based on median concentrations.

When comparing the revised EU $PEC_{regional}$ values with the existing values used for exposure modelling purposes, the revised values are generally lower. However this is mainly due to the slightly different methodology. However, it is worth noting that Co, V, and Zn were clear exceptions hinting towards increasing concentrations. The trend assessment was only possible for metals with previously assessed EU $PEC_{regional}$ values , namely: Ag, Co, Cu, Mo, Ni, Pb, Sb, V and Zn.

In conclusion, the project successfully updated the EU $PEC_{regional}$ sediment values for a large number of metals by utilizing multiple databases and applying a standardized approach to ensure consistency. The revised EU $PEC_{regional}$ values based on monitoring data provide more accurate estimates for risk assessments and exposure modelling to help measuring progress to EU environmental quality ambitions.

3.11.P-Mo180 Updating The European Freshwater Annual Average EQS For Nickel: What Are The Environmental Consequences?

Graham Merrington[1]*, Adam Peters*[1]*, Iain Wilson*[1]*, Elizabeth Middleton*[2]*, Emily Rogevich Garman*[2] *and Christian Schlekat*[2]*, (1)wca environment Ltd., United Kingdom, (2)NiPERA Inc.*

Under the European Water Framework Directive (WFD) Environmental Quality Standards (EQS) for nickel (Ni) have been set to be applied across all of Europe. In 2013, an annual average EQS for nickel of 4 µg L^{-1} was derived to account for bioavailability. However, since this time new chronic ecotoxicity data have become available; in 2013 31 species, and 214 data points, to 56 species and 366 data points in 2023. Furthermore, bioavailability models (Biotic Ligand Models, BLMs) have been updated covering a much greater range of water chemistry conditions (in Europe this increases waters covered from 88% to >98%).

In this study we consider the implications of updating the EQS in line with the best currently available science and European Guidance, using the UK as an example, to evaluate whether there are any important differences between the existing Ni EQS and what would be derived based on the best currently available science.

The key findings of the study are that increasing water chemistry coverage with the new bioavailability-models means including more waters that are sensitive to nickel exposures. A revised Ni EQS in the UK would 3.1 µg L^{-1}, which would be protective of 95% of waters in North West Region (of England), which is a reduction from the current value for the EQS of 4 µg L^{-1}. The European Commission has recently proposed to amend the Ni EQS to a value to 2 µg L^{-1}. Unfortunately, this amended value does not include the ecotoxicity dataset for nickel produced since 2013 (so does not include the new tested species), nor the new BLMs (so does not increase water chemistry coverage), and simply applies an assessment factor of 2 to the existing AA EQS of 4 µg L^{-1}.

Utilizing the best available science, including datasets, models and concepts, and following the existing guidance are imperative for the successful derivation and implementation of metal EQS.

3.11.P-Mo181 Comparison of Copper Dust Exposure Across Multiple Operations in Europe that Process Primary and Secondary Sources of Copper

Michelle Kelvin[1]*, Yamini Gopalapillai*[2]*, Steven Verpaele*[3]*, Scott Brindle*[4]*, Matthew Leybourne*[5] *and Daniel Layton Matthews*[6]*, (1)Queens University/XPS, Canada, (2)International Copper Association, Ltd., (3)Belgian Centre for Occupational Hygiene, Belgium, (4)XPS, (5)Queens University, (6)Queens University, Canada*

Although mined for centuries, copper (Cu) has now been deemed one of many critical minerals due to its important application in transitioning to greener energy sources. With this heighted demand for Cu and the objective to contribute to a circular economy, Cu production is rapidly growing and operations now process a variety of Cu materials from ore (primary sources) to recycled products (secondary). During production, operations are required to monitor Occupational Exposure Limit Values (OELVs) from dust emissions to ensure the health and safety of workers and limit contamination to the environment. The European Commission's Scientific Committee on Occupational Exposure Limits (SCOEL) has recently proposed to reduce the OELV several fold more stringent than existing limits; however, a recent longitudinal health surveillance study of workers at Cu smelters suggest no adverse health effects on lung function with exposure at operating conditions over the last 20 to 30 years. Given the variety of materials that are processed across Europe, exposure to workers will differ between operations. In an effort to understand the relevance of the proposed limit on a multi-operational scale, a characterization study was performed on dust exposed to workers at multiple facilities (smelters and refineries) that process different types of Cu materials (Cu ore and secondary sources of Cu powders containing Cu oxides and hydroxides). Respirable and inhalable dust was sampled from workers performing key dust generating activities around the operations. The dust was characterized using a combination of automated mineralogical analysis and chemical assay. An apportionment of Cu by species was determined for respirable and inhalable fractions. The results show significant differences in the composition of dust generated from feed materials entering the operations, but similar characteristics in composition and particle size around furnace and refining activities. At each operation, only minimal total Cu is present in the respirable dust, and where present in respirable fraction, Cu oxides are the dominant species. These findings show that interpretation of toxicology and health surveillance studies that focus on exposure to Cu oxides are relevant for setting occupational health limits, and will be conservative given that the oxides are considered the most toxic Cu species in respiratory health.

3.11.P-Mo182 Method Development in Elemental Analysis of Graphite from Lithium-ion Battery Recycling Process

*Mihaela Ivan, Dave McCutchion, **Max Derbyshire** and Ka Man Chang, Oxford Analytical Services Limited, United Kingdom*

Recycling is a crucial component of sustainable development and an essential step towards making batteries greener, ethical, and more sustainable and the extraction of raw materials, such as lithium and cobalt has a significant environmental and human impact. Recycling batteries can be achieved by conserving resources, reducing pollution, and contributing to the economy. Battery recycling processes involve the mechanical conversion of cathode and anode raw materials into a single powder known as "black mass" containing high concentrations of graphite processed from the battery anode composed of a copper (Cu) foil coated in graphite.

Our research with clients in the field helps monitor the efficiency of the battery recycling process through elemental analysis. Analysis of trace elements is often challenging to measure in graphite samples and thus are hard to quantify. Such methods traditionally require either the use of pressurised microwave reactors of the use of strong acids such as HF which need specialist sample introduction systems for ICP equipment in addition to strict health and safety precautions. Our research presents a workflow for trace element analyses of complex sample solutions to improve the speed and cost efficiency of the process by improving sample preparation procedures and analysis.

For trace element analysis of graphite-based materials, Inductively Coupled Plasma Optical emission spectroscopy (ICP-OES) requires complete sample digestion to clear solutions free of particulates. We aimed to characterize the elements present in low and trace amounts to improve environmental impact assessments and overcome the analytical challenges. To optimise analysis, we improve the digestion workflow and optimised a 2-step sample preparation process. The First step utilised a triple sulphuric, nitric and hydrochloric acid solution used to partially digest graphite particulates at high temperatures using a hot block. The additional process then aided preparation utilising microwave-assisted acid digestion with additional nitric acid. Samples were diluted and analysed using ICP-OES Agilent 5800 focusing on Fe, Mn, P and environmentally concerning elements like Cu, Co, Cd, Ni, Pb, Al and As. Concentration variations within different lithium-ion batteries generated sampling data used to improve plasma stability and reduce matrix effects within relevant samples. Elemental composition results were used to improve efficiency in the battery recycling field.

3.12.P Ionizable Organic Chemicals - Improving Risk Assessment Accuracy

3.12.P-Tu246 Refining Fluorochemical Protein-Water and Membrane-Water Partition Coefficients from in vitro Experiments with Albumin and Phospholipids

Ruiwen Chen[1], *Derek Muensterman*[2], *Jennifer Field*[2] *and Carla A. Ng*[3], *(1)Department of Civil & Environmental Engineering, University of Pittsburgh, (2)Oregon State University, (3)University of Pittsburgh*

This study aimed to determine the partition coefficients of structurally diverse per- and polyfluoroalkyl substances (PFAS) with biological membranes and proteins using solid-supported phospholipid membranes (SSLM) and human serum albumin (HSA), as a means to enhance our understanding of PFAS distribution in organisms. The results revealed that as the fluorinated carbon chain length increased from C4 to C10, perfluoroalkyl carboxylates (PFCAs) exhibited a 0.42-log unit increase in the phospholipid membrane-water partition coefficient (K_{MW}), while perfluoroalkyl sulfonates (PFSAs) showed a 0.47-unit increase, indicating higher membrane affinity for the sulfonates. However, at longer chain lengths, no further improvement was observed, and the values stabilized to a log K_{MW} between 3 – 5. The highest HSA affinity was observed between C6 and C10, while both short-chain and long-chain PFAS exhibited decreased affinity. A comparison between experimental results and HSA – PFAS molecular docking predictions with AutoDock Vina indicated that the model effectively predicted the affinity of PFAS for HSA, especially for PFAS with lower and intermediate carbon chain lengths. Additionally, this study established a means to compare distribution coefficients between PFAS in phospholipid membranes and HSA at various starting concentrations in the water phase. The results demonstrated that at lower concentrations, PFAS were more likely to bind to HSA, while with increasing concentration, their binding tendency shifted towards the phospholipid membrane.

3.12.P-Tu247 Coarse-Grained Simulations of Passive Partitioning of Ionic Surfactants into Cell Membranes

Eoin Kearney[1], *Mark Miller*[1], *Elin Barrett*[2], *Adriana C. Bejarano, PhD*[3], *Jens Bietz*[4], *Kristin Connors*[5], *James Dawick*[6], *Steven Droge*[7], *Marc Geurts*[8], *Geoffrey Hodges*[9], *Diederik Schowanek*[10] *and Sabrina Wilhelm*[11], *(1)Department of Chemistry, Durham University, United Kingdom, (2)Unilever R&D Colworth, United Kingdom, (3)Shell Global Solutions, (4)Clariant Produkte (Deutschland) GmbH, Germany, (5)Procter & Gamble, (6)Innospec Limited, United Kingdom, (7)Environmental Risk Assessment, Wageningen University & Research (WUR), Netherlands, (8)Nouryon Chemicals B.V., Netherlands, (9)Unilever - Safety and Environmental Assurance Centre (SEAC), United Kingdom, (10)Brussels Innovation Centre, Procter & Gamble, Belgium, (11)BASF Personal Care and Nutrition GmbH, Germany*

The bioaccumulation and ecotoxicity of chemicals are key metrics in assessing environmental hazard and safety. However, for chemicals which are difficult to test such as surfactants these can be challenging to determine. Potential alternative approaches are available which use *in silico* and *in vitro* values combined with a biologically relevant partitioning parameter such as the membrane-water partitioning coefficient (log K_{MW}). Several experimental methods exist for the determination of K_{MW} for surfactants but there are also promising computational methods available. Computational simulations, for example, utilizing free energy calculations offer potential insights, and when coupled with coarse-grained force fields such as Martini, offer the opportunity for high-throughput predictions capable of triaging a large group of molecules for risk quickly. The work described here builds on our group's automatic parameterization program for the Martini force field, cg_kmw, which is then used to calculate log K_{MW}, starting from just the SMILES code of the desired solute. The structures the original cg_kmw generates gave accurate predictions for a range of neutral molecules but struggled with charged species. Recently, the group has expanded this model to the most recent force field release, Martini 3, and tested it for a series of small, charged molecules. The current work outlines methodological developments and validations being performed to implement the full features of Martini 3 in cg_kmw, with the goal of accessing a wider variety of ionized species. Here we present results for a cross section of 12 neutral, anionic, cationic and zwitterionic surfactants, outlining current successes and challenges in comparison to the other computational approaches for log K_{MW} prediction (e.g. COSMOmic). Results indicate that anionic and zwitterionic species perform competitively. Ongoing work is addressing some of the challenges which are identified for ionized cationic species and species with higher numbers of ethoxy groups.

3.12.P-Tu249 Differentiating between baseline and excess toxicity for permanently charged compounds (ionic liquids)

Marta Markiewicz[1], *Eunhye Bae, M.Sc.*[2], *Maria Koenig*[3], *Stefan Stolte*[2] *and Beate Escher*[3], *(1)Institute of Water Chemistry, Technical University Dresden, Dresden, Germany, (2)Institute of Water Chemistry, Dresden University of Technology, Germany, (3)Department of Cell Toxicology, Helmholtz Centre for Environmental Research (UFZ), Germany*

Ionic liquids (ILs) are composed of at least two permanently charged entities of which one or both are usually bulky and organic. Toxicity assessment of ILs so far focused on quantitative prediction of toxicity. Nevertheless, there is an interest in obtaining mechanistic insights into the ILs' toxicity including the understanding of potential modes of toxic action (MOA). We predicted nominal concentration eliciting cytotoxicity in several cell lines with the aim of identifying ILs causing baseline and excess toxicity. To do so, critical membrane concentrations characteristic for baseline toxicants and a mass balance model (assuming lipids and proteins are the mainly responsible for partitioning into cells) were applied.

The general cytotoxicity of many ILs was observed at concentrations up to three orders of magnitude lower than expected by the bioassay-specific baseline toxicity QSARs developed for neutral and ionic/ionizable compounds. The possibility of metabolic activation to more toxic products was investigated but shown to be unlikely cause of higher cytotoxicity. Multiple ILs were tested within ToxCast program yet screening of the database as well as further experimental investigation of potential modes of action indicated that most of the ILs showed only non-specific activation of toxicity pathways.

It seems therefore, that especially ILs containing simple anions, either cause excess toxicity at lower critical membrane concentrations or the mass balance model use to predict cytotoxicity requires adjustment. Besides partitioning into membrane lipids via van der Waals interaction, other features of the cell membrane, e.g. surface charge or lipid composition might play a role in defining the affinity of ILs to cells. It is possible that the K_{mw} derived using POPC (1-palmitoyl-2-oleoylphosphatidylcholine) as surrogate for membranes is not suitable to describe such interactions.

Alternatively, lower concentrations of ILs, compared to other baseline toxicants, could be required to elicit the same effect. In that case the ILs should still be regarded non-specific toxicants (i.e. targeting membranes and membrane proteins as a whole and not a specific receptors).

3.12.P-Tu250 Intrinsic Hepatic Clearances of Selected Pharmaceuticals by Rainbow Trout S9 Fractions and Their Use in Estimating Bioconcentration Factors
***Tea Pihlaja**[1,2], Erkka Järvinen[1], Timo J Oksanen[1], Netta Vinkvist[1] and Tiina Sikanen[1,2], (1)University of Helsinki, Finland, (2)University of Helsinki, Helsinki Institute of Sustainability Science (HELSUS), Finland*
Pharmaceutical residues are ubiquitous, often ionizable, and relatively lipophilic aquatic contaminants, many of which have the potential to bioaccumulate in fish. Besides in vivo testing (e.g., OECD305), there are several in silico methods for prediction of bioconcentration factors (BCF) in fish. However, these predictions rely on lipophilicity ($logK_{ow}$, $logD_{ow}$), and often cannot account for the impact of hepatic clearance on the predicted BCF. The OECD test guidance 319B, for determination of in vitro intrinsic clearance (CL_{int}) using rainbow trout (*Oncorhynchus mykiss*) liver S9 subcellular fractions (RT-S9), lays the basis for inclusion of hepatic clearance in BCF extrapolation. Additionally, the S9 assays enable the study of the clearance routes in fish, whether dominated by phase I oxidoreductive enzyme systems, such as cytochrome P450, or phase II transferases.

In this study, the in vitro hepatic clearances (CL_{int}) of fifteen pharmaceuticals (ataluren, atomoxetine, atorvastatin, azelastine, clozapine, desloratadine, felbinac, flecainide, mycophenolic acid, olaparib, orphenadrine, propranolol, quetiapine, sulpiride, zolmitriptan) were measured individually at 1 µM concentration, using commercial RT-S9 fractions. All pharmaceuticals were tested in duplicate with active and inactivated RT-S9, firstly by including all cellular co-substrates, and secondly by excluding NADPH (the P450 cofactor) to inactivate the phase I oxidoreductive P450 enzyme system and evaluate its impact on the overall clearance rate. Of the test substances, five were not significantly metabolized in RT-S9 in the test conditions used, including clozapine, desloratadine, flecainide, olaparib, and sulpiride. Of the remaining ten substances, the metabolism of atorvastatin, azelastine, and mycophenolic acid in RT-S9 was predominantly catalyzed by phase II transferases, as their in vitro intrinsic clearances were similar with and without NADPH (P450 metabolism), whereas the other seven substances were shown to metabolize primarily via P450 system. Overall, the metabolism pathways in RT-S9 correlated well with human metabolism, although some differences were also observed. The results also demonstrate that accounting for the impact of ionization on the lipophilicity ($logK_{ow}$ vs. $logD_{ow}$) and the measured in vitro CL_{int}, as described in OECD319B, has a significant impact on the predicted BCF in fish, for lipophilic and metabolically cleared pharmaceuticals.

3.12.P-Tu251 Sorption Behaviour of (Ionizable) Organic Micropollutants to Different Sandy (Agricultural) Soils
***Jill April Ramona Soedarso**[1], Gabriel Sigmund[2], Nora B Sutton[3], Huub H.M. Rijnaarts[3], Darrell Tang[4] and Hans Meeussen[5], (1)Wageningen University and Research (WUR), Wageningen, Netherlands, (2)EDGE, Wageningen University & Research (WUR), Netherlands, (3)Environmental Technology, Wageningen University & Research (WUR), Netherlands, (4)Soil Physics and Land Management, Wageningen University & Research (WUR), Netherlands, (5)NRG & Delft University of Technology*
In periods with limited precipitation the indirect reuse of treated municipal effluent via surface water is inescapable in the Netherlands. This is especially the case in the higher sandy soil region of the Netherlands and the agricultural areas therein. However, treated municipal effluent contains organic micropollutants (OMPs) and their fate in the environment is relatively unknown, especially for ionizable organic micropollutants. This study focussed on understanding the chemical and physical interaction between (ionizable) organic micropollutants and sandy soil, to predict the potential risk of these OMPs to groundwater resources.

Around 50 OMPs were selected based on monitoring data from Dutch municipal treated wastewater effluents. The interaction of these highly polar and/or ionizable organic micropollutants with sandy soils was researched in batch bottle experiments based on the OECD 106 guideline using five different concentrations of OMPs starting at 0.5 ug/L and increasing with a log 3-

factor. These experiments were complemented by batch bottle experiments using a single concentration of OMPs but changing the background electrolytes. To understand the different interactions of OMPs with the different soil constituents, six different sandy reference soils were selected, containing different organic matter, Fe- and Al-oxides, and clay content. OMPs were grouped based on similar sorption behavior for subsequent data analysis. These insights and OMP sorption data on sandy soils will be used as a key input to extend an existing modeling framework developed for metal(loid)s (ORCHESTRA). We aim to extend the model's scope towards predicting the mobility of OMPs in sandy soils. In further research, the prediction will be made to fresh sandy soils and later compared to batch experiments with fresh Dutch sandy soils to see where there are still limitations in the prediction model. The development of these predictive approaches will enable an improved risk assessment for wastewater effluent-derived OMPs in research, regulation and groundwater recharge practice.

Keywords: sorption, ionizable organic micropollutants, water reuse, effluent, sandy soils, agriculture

3.12.P-Tu254 Bioconcentration assessment of three cationic surfactants in permanent fish cell lines

Fabian Gerhard Peter Balk[1]*, Juliane Hollender*[2] *and Kristin Schirmer*[2]*, (1)Swiss Centre for Applied Ecotoxicology, Switzerland, (2)Eawag - Swiss Federal Institute of Aquatic Science and Technology, Switzerland*

Cationic surfactants are used in many industrial processes and in consumer products with concurrent release into the aquatic environment, where they may accumulate in aquatic organisms to regulatory relevant thresholds. Here, we aimed to better understand the bioconcentration behavior of three selected cationic surfactants, namely *N*,*N*-dimethyldecylamine (T10), *N*-methyldodecylamine (S12) and *N*,*N*,*N*-trimethyltetradecylammonium cation (Q14), in the cells of a fish liver (RTL-W1) and gill (RTgill-W1) cell line. We conducted full mass balances for bioconcentration tests with the cell cultures, in which the medium, the cell surface, the cells themselves and the plastic compartment were sampled and quantified for each surfactant by HPLC MS/MS. Accumulation of the non-permanently charged amines in/to cells correlated with the surfactants' alkyl chain lengths and their membrane lipid-water partitioning coefficient, D_{MLW}. Cell-derived bioconcentration factors (BCF) of T10 and S12 were within factor 3.5 to *in vivo* BCF obtained from literature, while the cell-derived BCF for Q14 were >100 times higher than the *in vivo* BCF. From our experiments, rainbow trout cell lines appear as suitable conservative *in vitro* screening method for bioconcentration assessment of cationic surfactants and are promising for further testing of cationic surfactants.

3.12.P-Tu255 Deriving Fluorochemical Membrane-Water and Protein-Water Partition Coefficients from in Vitro Experiments with Phospholipids and Albumin

Ruiwen Chen[1]*, Derek Muensterman*[2]*, Jennifer Field*[2]*, Carla A. Ng*[1]*, Markus Hjort*[3]*, Gustavo Guerrero-Limon*[4] *and Eleni Vaiopoulou*[5]*, (1)University of Pittsburgh, (2)Oregon State University, (3)Concawe, Belgium, (4)Water, Soil and Waste, Concawe, Belgium, (5)CONCAWE*

This study aimed to determine the partition coefficients of structurally diverse per- and polyfluoroalkyl substances (PFAS) with membranes and proteins using solid-supported phospholipid membranes (SSLM) and human serum albumin (HSA), as a means to enhance our understanding of PFAS distribution in organisms. The results revealed that as the fluorinated carbon chain length increased from C4 to C10, perfluoroalkyl carboxylates (PFCAs) exhibited a 0.42-log unit increase in the phospholipid membrane-water partition coefficient (K_{MW}), while perfluoroalkyl sulfonates (PFSAs) showed a 0.47-unit increase, indicating higher membrane affinity for the sulfonates. However, at longer chain lengths, no further improvement was observed, and the values stabilized to a log K_{MW} between 3 – 5. The highest HSA affinity was observed between C6 and C10, while both short-chain and long-chain PFAS exhibited decreased affinity. A comparison between experimental results and HSA – PFAS molecular docking predictions with AutoDock Vina indicated that the model effectively predicted the affinity of PFAS for HSA, especially for PFAS with lower and intermediate carbon chain lengths. Additionally, this study established a means to compare distribution coefficients between PFAS in phospholipid membranes and HSA at various starting concentrations in the water phase. The results demonstrated that at lower concentrations, PFAS were more likely to bind to HSA, while with increasing concentration, their binding tendency shifted towards the phospholipid membrane.

3.12.P-Tu256 Biomimetic Chromatography and Associated Models to Predict Biological Partitioning

Derek Muensterman[1]*, Jennifer Field*[1]*, Carla A. Ng*[2]*, Mark J Benotti*[3]*, Ruiwen Chen*[4] *and Klara Valko*[5]*, (1)Oregon State University, (2)University of Pittsburgh, (3)NewFields, (4)Department of Civil & Environmental Engineering, University of Pittsburgh, (5)Bio-Mimetic Chromatography Ltd, United Kingdom*

Biomimetic chromatography has the benefit of directly simulating a biological environment using commercially available high-performance liquid chromatography (HPLC) columns containing Immobilized artificial membrane (IAM) and Human serum albumin (HSA) which act as bio-relevant stationary phases. A rapid-gradient approach allows for the determination of partition coefficients for a wide variety of compounds in a single, gradient-based HPLC run. Each analytical stationary phase must first be calibrated with test mixes comprised of nonfluorinated components, each with a known Chromatographic Hydrophobicity Index (CHI) value. The CHI values for PFAS from C18 column reveals their distribution coefficients (CHI logD) as a function of pH while CHI values on HSA and IAM columns are used to determine human serum albumin binding (log K_{HSA}) and phospholipid binding (log K_{IAM}) coefficients. The CHI values, log K_{HSA}, and log K_{IAM} coefficients will also be determined for suspect PFAS in environmental extracts that do not have analytical standards.

3.12.P-Tu257 New Insights in Defining Analogy to Advance the Science of a Read-Across Framework: Starting with Dreissena spp. Exposed to Psychotropic Drugs

Laure Giamberini[1]*, Marie Zaffino*[1]*, Céline Simon*[1]*, Vincent Felten*[1]*, Maximilien Beuret*[1]*, Céline Passignat*[2]*, Anne Vignet*[2] *and*

Laetitia Minguez[3], *(1)Université de Lorraine, CNRS, LIEC, France, (2)LABÉO, Pôle d'analyses et de recherche de Normandie, France, (3)French National Centre for Scientific Research (CNRS), Paris, France*
Compounds designed to be biologically active at low doses, such as pharmaceutical compounds, raise environmental concern. Despite the amount of literature already published about their (eco-)toxicity, knowledge gaps still remain about their fate in organisms and their mechanisms and modes of action at these low environmental concentrations. Read-across is a technique for filling knowledge gaps in toxicology information by analogy between well-studied and poorly studied chemicals. This technique assumes that substances which are structurally similar will have reasonably similar physical-chemical properties, behave similarly, and elicit similar biological effects across species if their molecular targets are present. However, predictions can be difficult for aquatic invertebrates, as our knowledge on the existence and the functional roles of drug targets in these organisms is often incomplete. While direct read-across between mammals and aquatic invertebrates may be complicated, the same difficulty may exist between species phylogenetically close, since life history strategies and their ecology may influence species tolerance. The objective of our work is to address this issue on two freshwater bivalves commonly used in ecotoxicology, *Dreissena polymorpha* and *Dreissena rostriformis bugensis*. To test this, we expose organisms to different psychoactive compounds at environmentally-relevant concentrations, during 15 and 28 days; and we studied a targeted set of biomarkers, linked to important physiological functions (e.g. neuroendocrine system, energy metabolism and osmoregulation), and bivalve's ecological role (e.g. filtration and mineral contents). These functions are expected to be disrupted in bivalves according to what we already know for humans or other non-target organisms. Potential differences between males and females are also assessed. In overall, our results showed strong differences in the fate and effects of these compounds to the two species, as well as differential sensitivity between males and females. By testing the impact of several confounding factors on our capacity to read-across between psychoactive compounds and between molluscs, we bring new knowledge to improve the environmental risk assessment of pharmaceuticals.

3.12.P-Tu258 Applicability of a Ciprofloxacin Bioavailability Model to Four Antimicrobials: Investigating the Effects of pH and Dissolved Organic Carbon on Ecotoxicity

Qiyun Zhang, Ph.D. candidate[1], *Matteo Ticali*[2], *Karel De Schamphelaere*[1] *and Kristof Demeestere*[3], *(1)Ghent University - GhEnToxLab, Belgium, (2)Bioscience Engineering, University og Ghent, Belgium, (3)Ghent University (UGent), Belgium*
Ciprofloxacin (CIP) belongs to the fluoroquinolone family and is among the most prescribed antibiotics in human and veterinary medicine. Recent studies have shown that the ecotoxicity of CIP is affected by water chemistry factors such as environmental pH and dissolved organic carbon (DOC). In addition, a bioavailability model has been constructed to predict the impacts of the two factors on CIP ecotoxicity by incorporating the chemical speciation of CIP and the binding between DOC and the compound. Specifically, the strength of the CIP-DOC binding is predicted by the light absorption coefficient of natural water at 350 nm (ε_{350}).

This current study aims to acquire more information to expand the above knowledge to other antimicrobials. It uses cyanobacteria growth inhibition test to examines the impacts of pH and DOC on four compounds: fluoroquinolone antibiotics enrofloxacin, nadifloxacin, and moxifloxacin, which share structural similarities with CIP, and antibacterial and antifungal triclosan, which has a distinct chemical structure compared to CIP. The ecotoxicity of the four compounds will be tested on a range of pH conditions with various DOC compounds including (1) the commercial product Suwannee River Organic matter, and (2) unprocessed freshwater DOC with different concentration and compositions. Moreover, this study also investigates if the constructs of the CIP bioavailability model can be applied by other antimicrobials.

3.12.P-Tu259 The impact of pH on the toxicity of ionizable agrochemicals

Anna Huang[1], *Steven Droge*[2], *Evangelia Alexandri*[3], *Laura Buijse*[2] *and Ivo Roessink*[4], *(1)Wageningen Environmental Research (WUR), Netherlands, (2)Environmental Risk Assessment, Wageningen University & Research (WUR), Netherlands, (3)Aquatic Ecology and Water Quality Management Group, Wageningen University & Research (WUR), Netherlands, (4)Wageningen University & Research (WUR), Netherlands*
A wide range of chemicals causing environmental concerns belong to the group of ionizable organic chemicals (IOCs). Among agrochemicals up to one-third are ionizable, particularly herbicides (mostly acids) and fungicides (mostly bases). IOCs can exist in the aquatic environment in two or more forms, changing their form based on pH variations determined by their acid dissociation constants (pKa). The neutral form of IOCs has a higher potential to reach organism target sites and consequently IOCs are often observed to be more toxic in this form. This indicates that part of a ionizable compounds toxicity is pH driven. Yet, while actual European surface water pH may range between 6-9, the European aquatic risk assessment does not require the pH to be fixed for aquatic toxicity tests, and only considers endpoints at a single pH, which may deviate from a worst case pH encountered in the environment. The OECD *Daphnia* guideline 202, a standard test in Tier-1 regulatory testing, usually maintains a default medium pH of 7.5 or does not account for pH variations as long as it remains within pH 6-9.

To address concerns about ionizable agrochemicals and impact of pH on tests with aquatic organisms, we first examined the 48h response of *Daphnia magna* to different buffers in the range of pH 6-9, which indicated >10% adverse effects at the more extreme pH levels of 6 and 9. Secondly, we examined the intrinsic sensitivity of *Daphnia magna* by applying the reference toxicant potassium dichromate across different buffered pH levels (6.5, 7.5, and 8.5). The LC_{50} values for dichromate at these buffers varied 0.27-0.34 mg/L. We then investigated the toxicity of two such IOC chemicals — insecticide teflubenzuron (pKa 9.2) and hericide 2,4-D (pKa 2.73) across the three pH levels.

The toxicity of teflubenzuron showed no significant difference among pH levels (LC_{50} 0.30-0.67 ug/L), as expected because the neutral fraction remains dominant at all tested pH levels. However, it was noted that the chemical dissipated more rapidly at pH 7.5 and 8.5 compared to pH 6.5. The results for 2,4-D were inconclusive; at pH 7.5 and 8.5, the LC_{50} remained comparable at 540 and 370 mg/L, resp., while no effects were observed at pH 6.5 at the highest concentration (100 mg/L), whereas a factor 10 lower LC_{50} was anticipated at this lower pH. Our study underscores the imperative for further investigation into data requirements on intrinsic toxicity of ionizable agrochemicals at different pH levels.

3.12.PC Ionizable Organic Chemicals - Improving Risk Assessment Accuracy

3.13 Latest Science on PMT/vPvM Substances and on Bioavailability in Times of the Pollution Crisis

3.13.T-01 Regulation of Persistent and Mobile substances at the European level: Regulatory developments and CLP Guidance development

*Konstantinos Prevedouros[1], **Kostas Andreou**[1], Jane Caley[1], Romanas Cesnaitis[2], Doris Hirmann[1], Anu Kapanen[1], Aiga Latsone[1] and Simon Uphill[1], (1)European Chemicals Agency (ECHA), Finland, (2)Telakkakatu 6, European Chemicals Agency (ECHA), Finland*

Regulation (EC) No 1272/2008 on the classification, labelling and packaging of substances and mixtures (CLP), was introduced in 2008 in order to ensure a high level of protection of human health and the environment. Industrial, pesticidal and biocidal active substances fall under the scope of CLP that harmonises the classification and labelling of substances and mixtures based on their intrinsic properties by designating them into hazard categories (classes). During the last decade, substances containing the combination of persistent and mobile properties have attracted scientific and regulatory attention, facilitating entry into the water cycle and spreading over distances from local/point sources. Due to the concerns posed by such Persistent, Mobile, Toxic (PMT) and very Persistent, very Mobile (vPvM) substances, the European Commission introduced new hazard classes and labelling requirements into CLP for those substances and mixtures that came into force in April 2023, as well as corresponding scientific criteria to identify them.

The presentation will discuss the regulatory developments and detailed scientific criteria for Persistent and Mobile substances in the context of CLP and detail the development of the associated Guidance on the availability, use and weighing of all relevant information to conclude on each of the P, M and T properties. A specific focus will be placed on Mobility, as this property has just been introduced in such a wide regulatory context, with further elaborations on the relevant test methods and other available information being presented. Importantly, the comparison with the regulatory criteria for PMTs/vPvMs will be detailed, reflecting the comprehensive analysis presented in the respective Guidance, which is envisaged to be published in mid 2024. The SETAC Seville meeting will be the first time that the CLP Guidance on PMTs/vPvMs will be presented to such a wide stakeholder audience. This important communication is envisaged to raise awareness on these regulatory developments and enhance the quality of the information submitted to ECHA by Dossier submitters on such substances and, ultimately, facilitate efficient and cost-effective regulation at the European level.

3.13.T-02 Occurrence of persistent and mobile chemicals in tap water

***Daniel Zahn**[1], Alina H. Seelig[1] and Thorsten Reemtsma[2], (1)Department of Analytical Chemistry, Helmholtz Centre for Environmental Research (UFZ), Germany, (2)Helmholtz Centre for Environmental Research (UFZ), Germany*

Persistent and mobile (PM) substances are able to spread quickly in the water cycle and where thus identified as potentially problematic for the environment and water quality. If also toxic (PMT), or very persistent and very mobile (vPvM) their regulation under REACH as substances of very high concern is foreseen. PM chemicals are a challenge for a circular economy for water as they are difficult to remove from the water cycle. Yet, data on their occurrence in tap water is scarce and consequently the human exposure through drinking water consumption can only be speculated on.

In this study we analysed 33 tap water samples from 12 countries for 67 known or suspected PM chemicals. Of these chemicals 29 were detected in at leat one sample with median concentrations ranging from 240 ng/L (Tetrafluoroborate) to 0.3 ng/L (2-[2-(Dimethylamino)ethoxy]ethanol). Among the detected PM chemicals 15 exceeded 100 ng/L in at least one sample with Melamine and Cumenesulfonic acid having the largest number of detects above 100 ng/L with 9 samples each.

This study shows that PM chemicals do, indeed, occur widely in tap water, in many countries, with different sources of raw water and after different drinking water treatment processes. This highlights the ability of PM chemicals to spread throughout the water cycle and consequently points towards drinking water consumption as a major human exposure pathway.

3.13.T-03 Exploring Organic-Carbon–Water Partition Ratio (KOC) Data for Mobility Hazard and Exposure Assessments Using Big Data Approaches

***Sivani Baskaran**[1], Raoul Wolf[2] and Hans Peter Arp[2,3], (1)Norwegian Geotechnical Institute (NGI), Oslo, Norway, (2)Norwegian Geotechnical Institute (NGI), Norway, (3)Norwegian University of Science & Technology (NTNU), Norway*

Chemical hazard and risk assessments often use physical-chemical properties to categorize and identify chemicals of concern. In Europe, recent legislation regarding the classification, labelling and packaging of consumer products includes new chemical hazard categories, including persistent, mobile, and toxic (PMT) and very persistent and very mobile (vPvM). While persistency and toxicity are currently used in chemical regulation, mobility is a new criterion for chemical hazard classification. As a result, the mobility of thousands of chemicals on the global market must be assessed. Mobility is determined based on the organic carbon–water partition ratio (K_{OC}) or octanol–water partition ratio (K_{OW}) for neutral compounds and the octanol–water distribution ratio (D_{OW}) for ionizable compounds. However, measured K_{OC} values can vary by orders of magnitude depending on the environmental conditions particularly for ionizable compounds.

Ideally such property data is available in machine-readable formats in standardized units with meta data regarding the environmental conditions of the measurement. However, current regulatory databases and experimental datasets have thousands of K_{OC} data values of diverging quality available, and the environmental conditions associated with this data are not easily accessible. Data must be cross-referenced to ensure the name and CAS number associated with a K_{OC} value matches the SMILES used in prediction models. The data must be tidied up to remove duplicated entries and incorrectly reported units.

In this work, we use all available K_{OC} data for chemicals on the global market in a consensus-based approach, which considers the number of K_{OC} values and their individual variability and uncertainty, and source of K_{OC} data. Data sources include the OECD's eChemPortal and QSAR Toolbox, experimental $\log_{10} K_{OC}$ datasets, and multiple K_{OC} prediction models of varying quality and domains of applicability.

With Bayesian statistical inference approaches we aggregate values and their errors from these different sources to derive a probability distribution for the "true" $\log_{10} K_{OC}$ value. The use of probability distributions is advantageous in these instances because we are less concerned about the environmental conditions for which the K_{OC} is measured and can apply mobility classifications based on relative risk tolerance of the uncertainty for a given K_{OC} value.

3.13.T-04 Lowering bioavailability with carbonaceous materials: from science to large-scale applications

***Gerard Cornelissen**[1], Erlend Sørmo[1], Espen Eek[2], Gijs Breedveld[1] and Hans Peter Arp[1], (1)Norwegian Geotechnical Institute (NGI), Norway, (2)NGI, Norway*

In the 90s the discovery was made that organic compounds in soils and sediments could be bound so strongly to the solid matrix that they were hardly desorbed, and showed low available for uptake in plants and organisms, and slow transport into the groundwater. At the end of the decade it turned out that this strong binding was due to the presence of carbonaceous “black carbon” geosorbents, in particular soot and charcoal. Another important consequence in the form of limited biodegradation was revealed.

Gradually the concepts of bioavailability and bioaccessibility entered the policy domain, and technologies such as passive sampling and infinite-sink desorption, as well as bioavailalibility-inclusive models, were developed to include these in risk assessment procedures.

From an engineering perspective, carbonaceous materials were engineered and designed and amended to soils and sediments to reduce bioavailability and thus environmental risk. The most recent innovation is the use of biochar from organic waste materials such as sewage sludge for PFAS, PAH, PCB and dioxin remediation. Waste-based biochars have the additional advantages that they contribute to the circular economy and sequester up to half of the carbon present in the original feedstock.

Having been involved in key developments at all those stages, in the presentation I will go through the whole journey from the initial discovery of limited bioavailability, to the discovery of environmental “black carbon” being responsible for it, to the development of technologies such as passive sampling and Tenax extractions, to large-scale applications in joint-industry projects. Notable projects that will be presented include the pilot remediation of Europe’s largest dioxin contamination in the Grenlandsfjords, where thin layers of carbonaceous materials reduced dioxin bioavailability by up to 90%, as well as the recent discovery that PFAS-contaminated sludge can be turned into clean biochars, that can be used for PFAS remediation of contaminated soils, while sequestering carbon. Reductions in PFAS leaching of > 99% have been found for these sludge-based biochars, and this could open up a whole new industry around the circular handling of current negative-value waste fractions.

3.13.T-05 Translating bioavailability science into practice through technology development and regulatory innovation in the USA

***Upal Ghosh**, University of Maryland, Baltimore County*

Pollutant bioavailability in sediment impacts uptake in the aquatic food web. While the science behind pollutant bioavailability was maturing within the scientific community two decades ago, there was little impact in the practice of sediment risk assessment that was based on total concentrations. Sediment remediation practice largely relied on disruptive sediment removal that often failed to achieve risk reduction goals. We learned from careful observations of nature that black carbon particles natively present in sediments sequestered hydrophobic pollutants rendering them less bioavailable. This observation provided powerful insights that needed to be translated into practice for both risk assessment and for designing remedies. Translation of bioavailability science into practice had to progress on three fronts: 1) testing and development of methodologies to alter pollutant bioavailability in sediments through amendment of strong sorbents, 2) development of reliable metrics of measurement of bioavailability changes in sediments, and 3) regulatory innovation to enable acceptance of the new metric of assessing risk posed by pollutants in sediments and consideration of new approaches for in-situ management of polluted sediments through bioavailability manipulation. This presentation will provide an overview of the developments in the science of pollutant bioavailability in the last 2 decades with a focus on the following aspects: 1) development of the novel sediment remediation technology of activated carbon amendments into sediments to reduce bioavailability that has now become a mainstream approach in the US. 2) development and standardization of passive sampling technology to measure freely dissolved concentrations as a key metric for pollutant bioavailability, and 3) regulatory innovation through active collaboration and dialog among researchers, regulators, and practitioners that enabled creation of a conducive environment where new approaches based on the latest science could flourish.

3.13.P Latest Science on PMT/vPvM Substances and on Bioavailability in Times of the Pollution Crisis

3.13.P-Tu260 An investigation into the infiltration of Persistent, Mobile and Toxic as well as very Persistent very Mobile chemicals in Irish water

***Rebecca Smith**[1], Fiona Regan[2], David O'Connor[3], Susan Hegarty[4] and Alexander Savelev[3], (1)Dublin City University (DCU), Ireland, (2)Water Institute, Dublin City University (DCU) School of Chemical Sciences, DCU Water Institute, Ireland, (3)Dublin City University (DCU) School of Chemical Sciences, DCU Water Institute, Ireland, (4)Dublin City University (DCU) School of History and Geography*

Fear regarding water quality is a growing issue globally. As the negative effects of pollution on both the environment and health are beginning to become apparent, an emphasis is being placed on the control and mitigation of contaminants of emerging concern. Historically, persistent chemicals have been highlighted as major problem contaminants as they remain in the environment for long periods and occur in various forms. Persistent, mobile and toxic as well as very persistent, very mobile chemicals, collectively known as PMT/vPvM chemicals, are the latest persistent chemical group of concern as outlined by the EU’s REACH legislation.

However, limited investigations have been carried out regarding how PMT chemicals behave in the Irish aquatic environment. This is additional interest given Ireland has one of Europe's most decentralised populations, with a large proportion of rural residents dependent on private wells and group water schemes as their primary water source. Human health is particularly at risk in these cases as Irish Water (the Irish water regulation body) carries out no water quality testing whatsoever on these systems, deferring to local governments. Hence, water treatment is not as stringent leading to contaminated groundwater.

The work here will mainly focus on agricultural and pharmaceutical sources of PMT/vPvM chemicals, as these sectors are known to be the most significant polluters. A prioritisation of PMT compounds has been selected from the ‘REACH’ registered substances list based on their potential hazard to both the environment and human health in an Irish context. The major pathways for these selected compounds into Irish waterways will be determined to develop robust monitoring programmes.

GIS modelling (utilising data collected from LC-MS studies) will be employed to better understand the effects of PMT/vPvM compounds on the aquatic landscape. Allowing the creation of water catchment area maps and for watershed analysis. This will provide insight into their mobility in the environment as they travel from their original sources. Various GIS modelling techniques will be used to enhance the gathered data, highlighting vulnerable and at risk areas.

From this research, several recommendations and conclusions will be drawn for future Irish legislation and research planning, creating the most effective PMT/vPvM solution possible.

3.13.P-Tu261 vPvM in Urban Runoff: Barcelona as a Pilot Case

***Francesc Labad Roig**[1], Sergio Santana-Viera[2], Marc Teixidó[3] and Sandra Perez Solsona[1], (1)Onhealth, Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain, (2)Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain, (3)Geosciences, Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain*

Recently, persistent (P), mobile (M) and toxic compounds (PMTs) have gained relevance in environmental research due to their capability to reach freshwater bodies, posing great concern for the quality of potential resources of drinking water [1]. Additionally, following the REACH guidelines, a PMT subgroup based on the very persistency (vP) and very mobility (vM) substances (vPvM) represent PMTs with greater persistency and mobility in the environment. The vPvM substances involve a risk to the quality of water sources due to their vP characteristics, presence for more than 60 days in freshwater, and their vM property, log Koc lower than 3. However, the vast majority of these substances fall in the current analytical gap because of the difficulties of both, extracting and detecting them using conventional analytical procedures such as solid-phase extraction (SPE), where these very polar substances can break through, as well as the reversed-phase liquid chromatography (RPLC), the chromatography per excellence in the last decade, not always useful to retain these kind of substances.

In this study, urban stormwater runoff samples were collected throughout Barcelona. Regarding the enrichment technique consists of the vacuum-assisted evaporation of 10 mL of runoff sample at a bath temperature of 55 ºC, 250 rpm platform orbital rotation and a vacuum gradient reaching a final pressure of 20 mbar. Samples were finally reconstituted into 0.5 mL of a mixture of acetonitrile with water (95:5, v/v) and transferred to glass HPLC vials. Regarding the HPLC-HRMS, the separation of the analytes was achieved using a BEH Amide column (100 × 2.1 mm, 1.7 µm).

More than 100 samples were collected, enriched using a vacuum-assisted evaporation system and processed by LC-HRMS using a hydrophilic interaction liquid chromatography column (HILIC) and up to 27 vPvM were analysed in the urban runoff water of Barcelona. Up to 24 vPvM were detected and concentrations ranged from undetected to 271 µg L^{-1} and acesulfame, ε-caprolactam, melamine and metformin were detected in 100% of the samples (n = 113). Pearson correlation test helped to discern patterns in the analytes of the study, showing interesting relations between compounds such as melamine and ε-caprolactam. Several positives were found, such as melamine, metformin or trifluoromethanesulfonic acid with concentrations up to 7.1, 98.2 and 2.7 µg L^{-1}, respectively.

3.13.P-Tu262 The UBA list with prioritised PMT/vPvM substances in the REACH registration database

***Michael Neumann**[1], Sarah Hale[2], Ivo Schliebner[3] and Hans Peter Arp[4], (1)IV 2.3 Chemicals, German Environment Agency (UBA), Germany, (2)DVGW: TZW, (3)German Federal Environmental Agency (UBA), Germany, (4)Norwegian Geotechnical Institute (NGI), Norway*

The European Green Deal by the European Commission sets an ambitious zero pollution vision for 2050. The overall objective is to reduce pollution to achieve a toxic-free environment. The Chemicals Strategy for Sustainability Towards a Toxic Free Environment contributes towards the achievement of the Zero Pollution Ambition. The Classification, Labelling and Packaging (CLP) Regulation ((EC) No 1272/2008) has the purpose to ensure a high level of protection of health and the environment. On 20th April 2023 the new hazard classes PMT and vPvM entered into force.

In 2019 UBA published the results of a PMT/vPvM assessment for all substances registered under REACH as of May 2017 (UBA TEXTE 126/2019). Here we present the first update of the UBA list of PMT/vPvM substances in the REACH registration database. The underlying PMT/vPvM assessment now includes all substances registered under REACH as of September 2019 (UBA TEXTE 19/2023). Only 1.9 % of the unique chemical structures in the REACH registration database fall in the new CLP hazard classes PMT and vPvM.

There are 259 unique chemical structures (belonging to 360 registered substances) that were assessed as meeting the new PMT and vPvM hazard classes under CLP. The UBA list of PMT/vPvM substances in the REACH registration database is split into three priority categories.

The UBA list of PMT/vPvM substances in the REACH registration database supports registrants and downstream users to immediately act to reduce and minimise emissions throughout the whole life cycle of these substances. Local authorities at the watershed scale should use the UBA list of PMT/vPvM substances in the REACH registration database to contact manufacturers, importers and downstream users of the substances so that they are able to develop "source control" schemes. For Member State Competent Authorities, the European Chemicals Agency (ECHA) and the European Commission (EC), the UBA list of PMT/vPvM substances in the REACH registration database provides candidates for the identification as SVHC under REACH and for classifications using the new hazard classes PMT and vPvM under CLP.

Acknowledgement – This research project was funded by the Federal Ministry for the Environment, Nature Conservation, Nuclear Safety and Consumer Protection (BMUV) with Project No. (FKZ) 3719 65 408 0

3.13.P-Tu263 Should we assess the P&M chemicals from a perspective of the “hazard” or “exposure”?

*Zhizhen Zhang[1], Alessandro Sangion[2], Shenghong Wang[1], Todd Gouin[3], Trevor N Brown, PhD[2], Jon A. Arnot[2] and **Li Li**[1], (1)School of Public Health, University of Nevada, Reno, (2)Arnot Research and Consulting Inc. (ARC), Canada, (3)TG Environmental Research, United Kingdom*

Persistent and mobile (P&M) chemicals are considered emerging threats to the environment and drinking water because they can be transported over long distances, penetrate natural and artificial barriers, and resist removal by traditional water treatment procedures. Current chemical regulatory practices define P&M chemicals based on the presence of chemicals in drinking water and the potential for human exposure. However, when screening the myriad of commercial chemicals for mobility, most existing efforts utilize bright-line criteria based on chemicals’ intrinsic “hazard” properties, such as biodegradation half-lives for P and organic-carbon-water partition coefficients for M. In this work, we compare and contrast the proposed intrinsic “hazard” criteria with chemicals’ concentration in drinking water predicted by a fate and transport model, based on the data of 112,000+ discrete organic chemicals registered in different countries’ chemical inventories. We evaluate the consistency of chemicals prioritized by “exposure” potential (chemicals with the highest concentrations in drinking water sources) and those by “hazard” assessment (chemicals with high P and M scores). We find that while chemicals with high P and M scores tend to possess a high potential to contaminate drinking water, P and M are not the only properties related to a chemical’s potential to contaminate drinking water. An example is the low potential of volatile chemicals to contaminate drinking water, even if they have high scores in P and M. Thus, screening chemicals based on the P and M hazard indicators alone may, unfortunately, lead to “false positives” and “false negatives”. It is therefore not appropriate to evaluate P&M chemicals by using hazard indicators as a proxy. This work addresses the academic and regulatory need for a better understanding of the processes and properties related to drinking water contamination and for developing and evaluating scientifically defensible methods and criteria to identify and potentially regulate chemicals of concern for the safe and sustainable use of chemicals in commerce.

3.13.P-Tu264 Data Science Tools for Mapping, Identification, and Assessment of PMT/vPvM Chemicals
*Adriana Sardi[1], Valeria Dulio[2], **Sandrine Andres**[1] and Pierre Boucard[1], (1)INERIS, France, (2)Institut National de l'Environnement Industriel et des Risques (INERIS), France*
Environmental authorities face an overwhelming challenge in managing and assessing risks posed by numerous manufactured chemicals. Hence, computational ecotoxicology tools like QSARs are essential in evaluating environmental hazards. Yet, for toxicity data prediction to be useful in the regulatory arena, data must be translated into synthesized information. A possible way to do this is by classifying and grouping substances. A regulatory gap exists in REACH criteria for substances with intrinsic characteristics, like PMT or vPvM substances, needing precise classification criteria to prevent potential water contamination. We have mapped over 500 vPvM/PMT suspected substances. The database included information on substances' intrinsic properties, use, tonnage, environmental release routes, process categories, and occurrence or monitoring data. We could identify substance groups that correspond well with previous classifications using standard data science techniques, such as unsupervised k-means clustering. We incorporated data quality into the mapping criteria by employing simple data analysis techniques and filtering the data regarding their origin, *i.e.*, experimental data *vs.* predictive data. Natural Language Processing models helped disentangle complex textual data regarding substance uses and identify the economic sectors in which vPvM/PMT substances occur the most. Finally, we calculated a robustness score based on the weight of evidence available for each substance serving as weights for the final classification. This work is one of the objectives of the EU Horizon 2020 project PROMISCES, which aims to protect natural resources, the environment and human health from PMTs, focusing on preventing PMT impact within the soil-sediment-water system. Mapping results will be part of a decision support framework, conveying a clear message to regulators and users regarding vPvM/PMT impacts in circular economy routes and providing targeted solutions.

3.13.P-Tu265 Enhancing Chemical Hazard Evaluation through Mobility Classifications
***Colleen McLoughlin**, Ziba Hosseini and Don Ward, Toxicology, Enhesa*
The Enhesa Toxicology Team manages a database of chemical hazard assessments (CHAs) with over 300000 substances that have undergone authoritative list screening and approximately 5000 substances that have verified chemical hazard profiles. To date, CHAs include 23 human health (Carcinogenicity, Mutagenicity-Genotoxicity, Developmental Toxicity, Reproductive Toxicity, Endocrine Activity, Acute Toxicity (oral, dermal and inhalation), Sensitization (Respiratory and Dermal), Irritation (Dermal, Eye, and Sensory), Systemic Toxicity, Neurotoxicity, Aspiration Potential), environmental health and fate (Persistence, Bioaccumulation, Acute Aquatic Toxicity, Chronic Aquatic Toxicity, Environmental Transformation Products), and physical endpoints (Reactivity, Flammability). Each chemical receives an overall designation called the hazard category which is derived by a weighing of endpoints and classifications. The hazard categories are represented by a stoplight system where chemicals of high concern (e.g., carcinogens) receive a red and chemicals of low concern (water) receive a green, with intermediates of yellow and yellow/green; and gray for substances of unknown concern. Our toxicology team moves in line with the Chemical Strategy for Sustainability (CSS) towards zero environmental pollution by conducting CHAs. To this end, the current works are to include mobility assessment in the chemical hazard assessments and the hazard category score. The authors identified overlapping substances between the verified substances and the work by Arp and Hale which was 1287 substances. The mobility classifications from Arp and Hale's work, (using the Registration, Evaluation, Authorisation and Restriction of Chemicals (REACH) criteria and three-tiered priority levels) are being incorporated into the chemical hazard assessments. For the remaining approximately 3700 chemicals with verified hazard profiles in the database that were not analyzed in Arp and Hale's paper, we are in the process of identifying the chemical characteristics (organic vs. inorganic; types of organic structures and polarities; SMILES, etc.) to identify the chemicals and relevant information to conduct mobility assessments. The authors will present the mobility assessment conclusions, identification of PMT/vPVM substances, how the mobility assessments will be included in the hazard category, as well as the total number of chemicals that reach a red hazard category by the addition of the mobility endpoint.

3.13.P-Tu266 Fate and Exposure Modeling of PMT/vPvM Substances using PROTEX
*Zhizhen Zhang[1], Alessandro Sangion[2], Shenghong Wang[1], Trevor N Brown, PhD[2], Jon A. Arnot[2] and **Li Li**[1], (1)School of Public Health, University of Nevada, Reno, (2)Arnot Research and Consulting Inc. (ARC), Canada*
PMT/vPvM substances have been perceived as an emerging threat to aquatic environments and human health because they have the potential to penetrate natural barriers and contaminate various drinking water sources, such as groundwater and riverbank filtrate. For this reason, it is essential to understand and characterize the environmental fate, human and ecological exposures, and potential risks for PMT/vPvM chemicals. Environmental fate and exposure models are cost-effective tools to achieve this goal, with one of the examples being PROduction-To-EXposure (PROTEX), a generic comprehensive fate and exposure model that supports modeling the fate and transport of organic contaminants in a regional multimedia environment and resulting human multi-pathway exposures. Different from "legacy" environmental pollutants, which are largely non-ionizable and hydrophobic like organochlorines and organobromines, most PMT/vPvM substances are polar or ionizable. In this presentation, we report our efforts to upgrade and evaluate PROTEX to allow for fate and exposure modeling for PMT/vPvM substances. Specifically, the latest version of PROTEX integrates more sophisticated characterization of (i) water compartments (freshwater, shallow and deep groundwater, and estuarine water) and hydrological water balance, (ii) multimedia partitioning of ionizable chemicals, and (iii) sorption of chemicals onto multiple geosorbents (amorphous organic

matter, carbonaceous organic matter, and minerals). For illustrative purpose, we apply the updated PROTEX model to predict concentrations of perfluorooctanoic acid (PFOA) in surface water, riverbank filtrate, and deep groundwater. The result shows that PFOA concentration in surface water is responsive to cessation of emissions, whereas it takes time for PFOA to be transported to and accumulated into shallow and deep groundwater. Such a time-lagging effect highlights the irreversibility of historical contamination of PMT/vPvM chemicals. By using the updated PROTEX model, one can predict the time-dependent chemical concentration in different environmental compartments. In this case, regulatory efforts can leverage this information to understand the temporal accumulation of PMT/vPvM chemicals and the irreversibility of historical contamination of PMT/vPvM chemicals. This work provides a holistic computational method to predict the environmental fate and human and ecological exposure to PMT/vPvM chemicals.

3.13.P-Tu267 Application of a multimedia activity model for evaluating the fate of persistent and mobile chemicals in soils: The influence of media-specific volume fractions

Todd Gouin[1]*, Li Li*[2]*, Shenghong Wang*[2]*, Zhizhen Zhang*[2] *and Mick Whelan*[3]*, (1)TG Environmental Research, United Kingdom, (2)School of Public Health, University of Nevada, Reno, (3)School of Geography, Geology and the Environment, University of Leicester, United Kingdom*

In recent years, there has been a growing focus on screening and prioritizing chemicals used in commerce for their potential to contaminate drinking water sources. The European Union, particularly the German Environment Agency (Umweltbundesamt – UBA), has proposed screening criteria to identify chemicals that may pose hazards to drinking water. These criteria aim to pinpoint chemicals that are both persistent and mobile (PM) or very persistent and very mobile (vPvM) under the EU's REACH chemical regulation.. These chemicals are prevalent in various industrial sectors, making it essential to develop effective assessment tools for their environmental fate and transport. This study summarizes the development of a multimedia environmental fate and transport model, which supports simulations in a variety of scenarios, including under steady-state, equilibrium and non-steady-state and non-equilibrium conditions. The developed model includes multilayer soil and aquifer compartments (unsaturated and saturated) which is used to enable a screening level estimate of exposure of PM chemicals in coupled groundwater and surface-water systems (which might be used for water supply via “bank filtration”). Model results demonstrate the relative importance of including a saturated compartment when estimating the concentration of PM chemicals in groundwater that might be used for drinking water.   The comprehensive approach developed here, thus, aims to enhance confidence in the model's performance and its utility in screening and estimating exposure to PM chemicals, which will ultimately encompass various exposure routes, including drinking water and food.

3.13.P-Tu268 What next for Persistent, Mobile and Toxic (PMT) substances – The plant protection products regulation as a case study for ensuring safe use concerning drinking water sources

Philip R Branford[1]*, **Bernhard Jene***[2]*, Stuart Leslie*[3]*, Andrew Eatherall*[4]*, Dieter Schaefer*[5]*, Dragan Jevtic*[6] *and José Luis Gomez-Eyles*[7]*, (1)ADAMA Agricultural Solutions, United Kingdom, (2)BASF SE, Germany, (3)FMC Agricultural Solutions, United Kingdom, (4)Corteva Agrisience, United Kingdom, (5)Bayer AG - Crop Science Division, Germany, (6)Bayer AG, Germany, (7)Syngenta Ltd, United Kingdom*

PMT and vPvM have been established as new hazard classifications for CLP to indicate chemicals with potential to reach drinking water sources bypassing natural barriers like soil or riverbank sediments.

Under the new criteria for mobility the Koc-value is used as the primary metric to decide on mobile (M) or very mobile (vM) classification. However, sorption alone can only be considered a measure of the potential for a substance to be mobile, particularly if sorption is studied only in a basic laboratory test.

Many plant protection product (PPP) active substances and/or their degradation products may be considered to have the potential to be mobile or very mobile based on their Koc alone. But long standing authorisation procedures in the European Union (EU) have established comprehensive data requirement and risk assessment frameworks to ensure that active substances are only approved where they can be shown to be safe concerning human health and the environment.

True mobility is dependent on many factors such as the intrinsic properties of the molecule, the location and type of emission as well as the local environmental conditions. Therefore consideration of all available data and applying a “weight of evidence”, which is explicitly mentioned in the regulation, is essential and needs to be adequately addressed in the corresponding guidance under development.

For context a comparison has been performed of selected PPPs showing examples where a conclusion of M or vM within the CLP assessment based on basic lab sorption data is not consistent with true mobility as observed in the field.

The presentation will demonstrate that when used according to authorised use patterns supported by comprehensive data requirements and risk assessment, substances with potential mobility might not show true mobility under appropriate environmental conditions of use. Therefore, these assessments can be considered to represent an appropriate Weight of Evidence approach in the context of the mobility assessment. However, if such processes are not included in the mobility assessment, then the regulation of PPP may act as a case study to demonstrate that, when used according to authorised regulated methods, substances identified as M or vM may be safely used.

3.13.P-Tu269 Adsorption as a Counterpart to Bioavailability: Investigating Hydrophobic Organic Compound (HOC)–Clay Mineral Interactions to Improve Understanding of the Environmental Fate of Halogenated Pollutants

Leonard Böhm[1], *Peter Grančič*[2], *Lilli P Butzke*[1], *Jan Siemens*[1], *Daniel Tunega*[2] *and Martin H Gerzabek*[2], *(1)Institute of Soil Science and Soil Conservation, Research Centre for BioSystems, Land Use and Nutrition (iFZ), Justus Liebig University Giessen, Germany, (2)Institute for Soil Research, Department of Forest and Soil Sciences, University of Natural Resources and Life Sciences (BOKU), Austria*

Hydrophobic organic compounds (HOCs), such as halogenated aromatic hydrocarbons, can be very persistent in the environment and lead to adverse effects on humans and other biota. Sorption processes are highly relevant for the assessment of their environmental fate and risk, which is highly depending on the bioavailability of contaminants. In this context, especially the interactions between HOC and organic matter are intensively studied. However, significant adsorption of HOC can also take place on mineral phases [1].

For further mechanistic elucidation of HOC interactions at water/mineral interfaces, adsorption experiments with different HOC–mineral systems were performed. Five halogenated benzenes (log K_{OW} 2.6–6.5) were used as HOC representatives and 20 smectite-rich bentonites were used as mineral phases.

Results showed a large mutual influence of the characteristics of HOC and clay minerals on the extent of sorption. The determined solid-liquid adsorption coefficients K_d varied over several orders of magnitude for specific HOC–mineral interactions. The hydrophobicity of the HOC played a relevant role for the level of adsorption, but to a lesser extent than the mineral properties. This can be illustrated by the example of two selected HOCs (A: log K_{OW} 2.6 and B: log K_{OW} 5.6), whose adsorption varies depending on the clay minerals by up to a factor of 5 for substance A (log K_d 1.8–2.5), but by up to a factor of 90 for substance B (log K_d 2.1–4.0).

The interpretation of results is based on various clay mineral characteristics. In terms of particle morphology, especially the pore size distribution is discussed as factor for the interaction of HOCs with clay minerals. The sorption processes are further interpreted on the basis of molecular simulations [1,2].

The results indicate the general influence of clay minerals on the adsorption of HOCs and suggest a great influence of specific HOC–clay mineral interactions on the environmental distribution behavior of HOCs with potential relevance for the fate and transport of HOCs in the environment, i.e., for both assessing bioavailability and long-term source/sink phenomena in soils and sediments. The elucidation of the fundamental processes is also critical for the use and modification of adsorbents with respect to potential remediation treatments.

3.13.P-Tu270 On-site solid-phase extraction of polycyclic aromatic compounds (PACs) from biochar-amended contaminated soil.

Ayan Au Musse[1], *Anja Enell*[2], *Ulrika Eriksson*[3] *and Maria Larsson*[4], *(1)MTM Research Centre, Oerebro University, Sweden, (2)Swedish Geotechnical Institute, Sweden, (3)Örebro UniversitySchool of Science and Technology, Oerebro University, Sweden, (4)MTM Research Centre, Orebro University, Sweden*

Soil has the potential to act both as a sink and as a secondary source for contaminants in the environment. This is due to sorption processes (ad/absorption and desorption) and the possibility of contaminants to desorb from the soil constituents to soil porewater and be further leached out to groundwater and surface water. This leachability is, however, dependent on different parameters, e.g., physio-chemical properties of the compounds, soil type, and contamination age. Furthermore, the soil's content of organic matter has an impact on the leaching as dissolved organic carbon (DOC) may serve as contaminant carrier and thereby increase the contaminants' mobility and make them more (bio)available. Therefore, soil porewater can be a useful matrix to study the leachability of environmental contaminants like polycyclic aromatic compounds (PACs) from contaminated soil.

PACs are often present at trace levels in water samples (e.g., groundwater, surface water, soil porewater) taken at/near historical contaminated sites, requiring sampling of large volumes of water to exceed the detection limit. Besides the large volumes required, these samples should preferably be collected in glass vessels (to minimize losses of analytes due to ad/absorption) which can make the transport and storage of samples cumbersome; additionally, PACs have also been observed to adhere/sorb to glass surfaces making conventional water sampling in glass vessels problematic.

In this study, a field study was set up to investigate biochar's ability to immobilize PACs in biochar-amended contaminated soil. For sampling soil porewater as a measure of the leachability and thus the (bio)availability of PACs, an on-site solid-phase extraction (SPE) sampling technique was evaluated. The soil porewater was sampled using a PRENART stainless steel lysimeter embedded into the soil and enriched onto an Waters^{TM} HLB SPE cartridge. Additionally, a laboratory study was conducted to validate the robustness (i.e., examining whether increased DOC and PAC concentrations as well as increased volume passed through impacted PACs' sorption on the SPE sorbent) of the on-site sampling method. The findings from this study will emphasize the advantages of utilizing an on-site SPE sampling method, e.g., simplifying transport and storage and minimizing loss of PACs as they are already enriched onto the SPE sorbent.

3.13.P-Tu271 Scrutinising Soil: A Cost-Effective, Scalable Approach to Investigate the Behaviour of Small Molecules in Soil Ecosystems Using Chemical Sampling Probes

Abdullah Shahid[1], *Christopher Sweeney, PhD*[2], *Leon Barron Dr*[3], *Helene Fain*[4] *and Will Pearse*[5], *(1)Environmental Research Group, Imperial College London, South Kensington,, United Kingdom, (2)Syngenta Ltd, Bracknell, Berkshire, United Kingdom, (3)Environmental Research Group, Imperial College London, United Kingdom, (4)Syngenta, United Kingdom, (5)Imperial College London, United Kingdom*
A major source of pollution in soil comes from anthropogenic organic contaminants, often via point sources, like direct application of chemicals and non-point sources such as irrigation and fertilization. Their chemical properties, environmental conditions, and soil type affect the exposure and fate of these pollutants. Providing a diagnostics tool that can characterise the chemical and biological mechanisms affecting soil health will contribute towards understanding and remediating soil efficiently.

Passive sampling devices (PSD) have been manufactured using 3D printing for use in environmental matrices like air and water but have not yet been utilised in soil. The presented work provides a proof-of-concept methodology that uses 3D-printed PSDs to characterise the transport behaviour of contaminants of emerging concern (CECs) in soil, after wastewater (WW) exposure. Finally, the effects of WW on soil microbial activity were investigated using a cotton strip assay. The PSDs were assembled with five individual 9 mm hydrophilic-lipophilic balanced (HLB) sorbent disks and a protective PES membrane, buried in the soil (LufaSpeyer 2.2, Germany) and sprayed with periodic doses of WW (10ml/3hrs). Contaminant uptake, for 17 compounds, onto the HLB sorbents was determined using a targeted direct-direct-injection rapid liquid chromatography-mass spectrometry (LC-MS/MS) method; reducing the need for pre-treatment such as complex soil extraction and clean-up analytical techniques.

From the 160 target compounds, 33 (27 quantified) were detected in the WW influent sample. Benzoylecgonine (BZE) was detected at the highest concentration at 8,863 ±23 ng/L. Seventeen CECs were quantified in the PSD extracts, the highest concentrations were found for carbamazepine(cbz)-10,11-epoxide at 9.2 ±0.50, followed by BZE at 5.9 ±0.25 ng/disk. Soil leachate samples were also analysed, 11 CECs were detected the highest being BZE at 346 ±4 ng/L. Cbz-epoxide was detected only on disk, whereas haloperidol and nortriptyline were detected in WW and on disk but not in leachate. The cotton strip assays showed faster degradation of the strip when the soil was exposed to WW after two weeks compared to non-dosed soil. The use of 3D-PSDs for soil sampling represents a new method which can be rapidly upscaled for large monitoring programmes for chemical transport and fate studies.

3.13.P-Tu272 Soil amendement with Sargasso biochar: a way to secure animal production in the antillean chlordecone contamination context?

Matthieu Delannoy[1], ***Perrine Stephan***[1], *Sarra Gaspard*[2], *Maguy Dulormne*[3], *Markens Francoeur*[2], *Stacy Narayanin*[2], *Paméla Hartmeyer*[1] *and Guido Rychen*[1], *(1)Urafpa, Université de Lorraine, France, (2)Covachim M2E, Université des Antilles, France, (3)UMR EcoFog, Université des Antilles, France*
The French West Indies faces two major environmental and health problems: on the one hand soil and food products chlordecone pollution, a pesticide widely used from 1970 to 1993, and on the secondhand arrivals of invasive brown algae, Sargassum spp. One way to manage the abundance of this biomass, as well as to limit the transfer of the CLD still present in the soils, can be the addition to these soils of biochar (BC) or activated charbon (AC) made from Sargasso. This study purpose is to evaluate the reduction of CLD transfer from soil to animal following soil amendment by BC of Sargasso (BCS) or AC DARCO (ACD, a matrix known for its sequestration power). Oral bioavailability measurements were carried out on laying hens and piglets fed respectively with granules containing a fraction of contaminated soil with or without BCS or ACD amendment. After a contaminated period of 10 and 21 days for the piglets and the laying hens respectively, the animals were anaesthetized by electronarcosis and target organs, liver, fat and muscle, were collected and analyzed. For piglets, only liver data revealed significant reductions in bioavailability between modalities for both soils. For the liver the most important reductions were obtained in Andosol and were of the order of 41% with the BCS and 65% with the ACD. For Nitisol a smaller reduction, at the limit of the significance, is observed with the BCS (10%) while with the ACD one obtains a reduction around 57%. In laying hens, liver, egg yolk and muscle analyses showed similar rates of bioavailability reduction by modality. Thus, with BCS reductions of 26 to 31% were observed and with ACD the reductions were higher, in the order of 56% to 59%. The difference between the two soils can be explained by much higher CLD concentration in Nitisol than in Andosol, which can limit the effectiveness of Sargasso biochar by saturation. The variations of physico-chemical characteristics that exist between the two matrices tested, resulted from the additional activation phase for DARCO. It may explain the difference in efficiency between the two matrices tested. This experiment is considered as a first step to judge the relevance of this rehabilitation technology in the case of the French Antilles. These promising results toned to be tested in situ in order to verify the feasibility and the reduction levels obtained in real Caribbean conditions.

3.13.P-Tu273 The Challenges of Validating and Implementing Methods for Characterising Non Extractable Residues in Soils

***Avril Crowe**, Metabolism, Labcorp, United Kingdom*
According to IUPAC the definition of Non Extractable Residues (NER) in soils is species originating from chemicals that remain unextracted by methods which do not significantly change the chemical nature of the parent substance or its degradates or the structure of the matrix. Regulatory opinion on NER formation differs considerably. Pesticide regulations have historically considered NER to be irreversibly bound degraded residues of no environmental concern. However, ECHA

considers NERs as potentially bioavailable, non-degraded residues (parent substance) unless it has been demonstrated that the chemical is completely degraded or irreversibly bound.

There has been some discussion about the methods of extraction which should be employed prior to quantifying the amount of NER remaining in the soil. Some of these methods can be considered harsh and may not conform to the recommendation not to alter the nature of the chemical or matrix.

Where the amount of NER is 10% of the applied radioactivity or more ECHA considers that it should be further characterised by separating it into Type I, Type II and BioNER:

- Type I NER is considered to be physically entrapped or non-covalently bound and potentially bioavailable.
- Type II NER is considered to be covalently or irreversibly bound.
- BioNER (Type III) is considered to be incorporated into the soil biomass and of no concern.

Methods for differentiating Type I NER using silylation and EDTA extraction have been proposed. In order to determine the amount of Type II NER it is necessary to quantify the BioNER by concentrated acid hydrolysis followed by calculation of the difference. However, there are currently no suitable standardised methods for quantifying the amount of NER or the different types of NER for use in regulatory studies.

The poster will discuss the challenges associated with developing and validating methods that might be suitable for use in regulatory studies.

3.13.P-Tu274 Uptake and elimination of per- and polyfluoroalkyl substances in earthworms exposed to a fortified sandy loam soil

Guilherme R. Lotufo[1]*, Robert Boyd*[1]*, Michael Simini*[2] *and Roman Kuperman*[2]*, (1)U.S. Army Engineer Research and Development Center, (2)U.S. Army DEVCOM Chemical Biological Center*

We investigated the uptake and elimination kinetics of per- and polyfluoroalkyl substances in earthworms exposed to amended artificial soil to derive bioaccumulation factors (BAF). Uptake kinetics was determined at two concentrations, 0.01 and 1 mg/kg, of each of 18 PFAS relevant to the DoD (8:2 FTS, PFBA, PFBS, PFDA, PFHpA, PFHpS, PFHxA, PFHxS, PFNA, PFOA, PFOS, PFOSA, PFPeA, PFTeDA, PFTrDA and PFUdA). Exposed earthworms were sampled in triplicate after 1, 3, 7, 14, 21 and 28 d. The concentration of PFAS remained relatively unchanged during the exposure and rates of uptake were estimated for most individual PFAS. For the 0.01 mg/kg treatment, steady state was reached (based no significant difference between the last three endpoints) for all PFAS except PFHpS, PFHxS, PFOS, PFTeDA (most tissue samples below detection), and PFTrDA. For the 1 mg/kg treatment, steady state was reached for all PFAS except 8:2 FTS, PFDA, PFTeDA, and PFUdA. Reliable rates of uptake were obtained from all PFAS except for PFHxA and PFPeA. Uptake rates were lower for the 1 mg/kg (typically by a factor of 3 to 4) for all individual PFAS except 8:2 FTS, likely because of sublethal physiological impairment caused by the exposure to a high concentrations of sum PFAS (i.e., approximately 10 mg/kg) in the exposure soil. For the 0.01 mg/kg treatment, BAFs ranged from 4 to 49 for most PFAS, but were higher for PFHxS (72), PFTeDA (271), and PFUdA (299). BAFs were lower for the 1 mg/kg treatment for all individual PFAS, typically by a factor ranging from 3 to 16. The elimination kinetics experiment will also be derived. Elimination rates were used to calculate kinetically derived BAF values as the ratio of uptake and elimination rate constants.

3.13.P-Tu275 Assessment of the Persistence, Bioaccumulation, Mobility and Toxicity of cosmetic ingredients in the COSMETICK database: a preliminary analysis of regulatory evolution

Juliette Guerineau, Clarisse Bavoux, Cyril Durou, Faizan Sahigara and ***Kevin Georges Antoine Bonnot****, Consultancy for Environmental & Human Toxicology and Risk Assessment (CEHTRA), France*

Faced with growing environmental challenges, regulations on cosmetic ingredients are evolving. The assessment of the environmental and ecotoxicological impact of these products has become essential. The COSMETICK tool marks a significant step forward in the toxicological and ecotoxicological assessment of cosmetic products. By integrating over 800 ecotoxicological profiles, this tool aims to fill the gap in the assessment of the ecotoxicological impacts of cosmetic ingredients, often underestimated in cosmetic regulations. It assesses these substances using the criteria of PBT (Persistence, Bioaccumulation, Toxicity) and PMT (Persistence, Mobility, Toxicity), reflecting an approach similar to regulation evolution under the EU Chemicals Strategy for Sustainability, anticipating the application of PBT/PMT assessment in regulation such as EU REACH and CLP.

The first part of the study involves a descriptive statistical analysis, sorting ecotoxicological data and visualization to extract maximum information. Based on complete datasets of ecotoxicological criteria, analysis of the distribution of ingredients according to these PBT and PMT criteria, reveals the proportion of ingredients failing to pass one or all of the criteria. In the second part, we introduce an innovative hierarchical classification method on principal components (HCPC), based on chemical families. It uses the clustering of molecular fragments (qualitative data) and 2D descriptors (quantitative descriptors) and is enriched by unsupervised statistical analysis methods, such as PLS regression. This approach results in a chemical mapping of cosmetic compounds, establishing a correlation between molecular structure and ecotoxicological alert levels.

This study provides a unique perspective on the environmental impact of a broad spectrum of cosmetic compounds and ingredients of varying quality. By focusing on molecular structure, it enables the ecotoxicological impact of substances to be predicted qualitatively. From the clusters created and the descriptors and fragments characterizing these groups, we will also be able to identify ranges of molecular descriptors critical for ingredient assessment. Such information is essential for effective and proactive environmental assessment and green formulation in the cosmetics industry.

3.14 Lower Micron and Nanosize Plastics: Challenges, Analytical Methods, Occurrence, Composition, Local Sources, Long-Range Transport and Human Exposure

3.14.T-01 Beyond the Horizon: Unveiling Transport Mechanisms and Residence Times of Atmospheric Micro- and Nanoplastics

Marianne Seijo[1]*, Mick Whelan*[2]*, Todd Gouin*[3] *and Antonia Praetorius*[4]*, (1)University of Amsterdam (UVA), Netherlands, (2)School of Geography, Geology and the Environment, University of Leicester, United Kingdom, (3)TG Environmental Research, United Kingdom, (4)Institute for Biodiversity and Ecosystem Dynamics, University of Amsterdam, Netherlands*

Plastic pollution, a pervasive global challenge, necessitates a nuanced understanding of the atmosphere's micro- and nanoplastics (MNP) transport dynamics to predict residence times and assess their potential for long-range atmospheric transport under different meteorological conditions. This study intricately examines MNPs transport mechanisms and residence times, accounting for diverse compositional, dimensional, and meteorological variables. From 1 nm to 5 mm, MNPs present unique complexities, particularly in tropospheric transport and deposition. MNPs demand dedicated or adapted equations and parameters, a necessity heightened by non-spherical shapes and complexities arising for aggregated MNPs.

Addressing the density, size and shape spectrum of MNPs, this study theoretically investigates and advances the description of different deposition processes: dry settling, resistance deposition near surfaces, and wet deposition during precipitation events.

For each process, the impact of MNPs size, density, and shape is assessed and compared to meteorological or other environmental influences (e.g. wind speed, rain intensity, deposition surface properties):

- Dry Settling: Exploring dry settling reveals size, density, weathering, shape, and aggregation impact MNPs' behavior.
- Dry Deposition: With a specific impact of land surface characteristics and atmospheric stratification on the MNPs deposition.
- Wet Scavenging: Scrutinizing below-cloud and in-cloud processes, these investigations unravel intricate mechanisms of particle captured.

Finally, we combine the above processes to determine the total residence times of MNPs in the atmosphere under selected meteorological scenarios. This research augments current theoretical frameworks for predicting the atmospheric transport of MNPs, providing valuable process descriptions for environmental fate models and directives for monitoring efforts. A systematic exploration of MNPs characteristics and environmental conditions enhances our scientific comprehension of atmospheric MNPs transport, supplying essential insights for refining transport models and steering future investigations.

3.14.T-02 A realistic nanoplastics test material: accelerated ageing, production and phys-chem characterization

Francesco Fumagalli[1]*, Gabriella Schirinzi*[2]*, Dora Mehn, PhD*[3]*, Justin M. Gorham, PhD*[4]*, John M. Pettibone*[4]*, Eric S. Windsor*[4]*, Li-Piin Sung*[4]*, Katherine Shaw*[4]*, Jennifer Lynch, PhD*[4] *and Andrea Valsesia*[1]*, (1)European Commission - Joint Research Center (JRC), Italy, (2)Joint Research Centre (JRC) - European Commission, Italy, (3)European Commission - Joint Research Centre (JRC), Italy, (4)National Institute of Standards and Technology (NIST)*

Research on Nanoplastics (NPs) has still many knowledge and methodological gaps, mainly due to the lack of standards and realistic test materials which negatively influence development of analytical techniques for the detection and quantification of NPs in environmental, food and human samples. Moreover, toxicological and ecotoxicological studies cannot be conducted in an appropriate way. In literature, there are still very few cases of NPs isolated, detected and quantified in environmental and human samples. Most of the work related to NPs done so far has been done using polystyrene latex beads. Unfortunately, these particles are not representative of realistic NPs mainly because secondary NPs generated from fragmentation are subjected to different stressors, modifying the original structure and composition of the polymer, as well as their surface properties, influencing their stability, protein corona formation and consequently, their fate in the environment and in the human body. Moreover, latex beads are colloidal dispersions stabilized with surface charge moieties and surfactants, while realistic NPs are fragments that could be stabilized by natural processes. Several researchers attempted to produce environemntally relevant NPs using both top-down approaches (by the degradation of larger plastic particles) and bottom-up via direct NPs synthesis . Reference particle models are essential to obtain an accurate perspective of how environmental nanoplastics (NPs) behave in natural systems and to generate data on their environmental fate and impact on living organisms. However, although the current available models are particularly important for filling the initial knowledge gaps on nanoplastics, they do not demonstrate enough diversity to represent the actual heterogeneity of the physical and chemical properties of environmental nanoplastics. In this contribution, the research activities about model environmentally relevant neoplastic materials synthesis and characterization are presented concerning identification of a novel strategy for high throughput production of model nanoplastics with properly engineered surface chemistry and morphology that could mimic naturally occurring NPs. Artificially aged plastic litter (UV exposure + Cryomilling) is discussed with specific insight into the surface chemistry modifications engineered in order to mimic external stressors influences on nanoplastics objects as they are exposed to the environment.

3.14.T-03 Automated Microplastics Identification (<500nm to mm's): Particle Shape/Size Artefact-Free Submicron IR & Simultaneous Raman with Nile Red Fluorescence Imaging to Pre-Scan Samples for Increased Speed

*Mustafa Kansiz[1], Christoph Krafft[2] and **Miriam Unger**[3], (1)325 Chapala St, Photothermal Spectroscopy Corp., United States, (2)Leibniz Institute of Photonic Technology, Germany, (3)Photothermal Spectroscopy Corp, GmbH, Germany*

Microplastic (MP) contamination have been recognized as a global environmental problem. MP particles are found globally in water, air, soil and regularly ingested by marine life. MPs can enter the human body by via contaminated water, beverages, and food, and by breathing airborne particles. The MP research community has grown quickly to address questions related to environmental/health risks. Spectroscopic analysis is frequently used to characterize populations of MPs, but most IR microspectroscopic analyses have been limited to >20 um particles. Better spatial resolution techniques such as Raman microscopy exist, but often suffer from limited sensitivity and/or autofluorescence issues. This has left a critical unmet need in the analysis of micron scale MP particles, which are of particular concern for human and animal health, because these particles are able to pass through the gut wall to accumulate in tissue with potential impact to organ function.

We have developed an optical microscopy based platform with automated capability for the measurement and analysis of micron scale MP particles based on Optical Photothermal Infrared Spectroscopy (O-PTIR) and complementary and simultaneous Raman spectroscopy. Preparations of microplastic particles can be automatically screened via optical microscopy (or Fluorescence imaging with Nile Red) to identify particles of interest and then automatically measured by O-PTIR and/or Raman. While conventional infrared spectroscopy (and even Raman) can struggle to spectroscopically identify micron scale MP particles, the O-PTIR approach overcomes the spatial resolution limits of conventional infrared spectroscopy by using a photothermal detection mechanism that employs a separate visible probe beam to detect infrared absorption. Because of the smaller wavelength or the probe beam, O-PTIR can achieve spatial resolution 10-30X smaller than infrared diffraction limits, while also avoiding size and shape dependent scattering artifacts that often limit the repeatability of traditional FTIR/QCL based techniques.. O-PTIR is also insensitive to autofluorescence which can be problematic with Raman.

This presentation will review O-PTIR technology and operating principles and then discuss the automated measurement and analysis of arrays of MP particles whilst providing key measurement performance metric

3.14.T-04 Differentiating Microplastics from Natural Particles in Aqueous Suspensions using Flow Cytometry with Machine Learning

***Denise M Mitrano**[1], Xinjie Wang[2], Yang Li[3] and Alexandra Kroll[4], (1)Environmental Systems Science, ETH Zurich, Switzerland, (2)Department of Environmental Systems Science, ETH Zurich, Switzerland, (3)Beijing Normal University, China, (4)Swiss Centre for Applied Ecotoxicology, Switzerland*

Microplastics (MPs) in natural waters are heterogeneously mixed with other natural particles, including algal cells and suspended sediments. An easy-to-use and rapid method for directly measuring and distinguishing MPs from other naturally present colloids in environmental samples would expediate analytical workflows. Developing such an approach would be indispensable for both screening for the presence of MPs and quantitatively identifying and enumerating them, contributing to a better understanding of their presence in environmental and technical systems. This is particularly relevant for small sized MPs (e.g., < 20 µm), which are not routinely measured by analytical approaches used in the field today, such as µFTIR. In this study, we established a database of MPs scatter and fluoresces properties, either alone or in mixtures with natural particles, by stain-free flow cytometry. The resulting high-dimensional data were analyzed by machine learning approaches, either unsupervised (e.g., visual stochastic network embedding) or supervised (e.g., random forest algorithms). We assessed our approach in identifying and quantifying model MPs of diverse sizes, morphologies and polymer compositions in various suspensions including phototrophic microorganisms, suspended biofilms, and sediments. We could precisely quantify MPs in microbial phototrophs and natural sediments with high organic carbon by both machine learning models, although it was not possible to distinguish between different MPs sizes or polymer compositions. By testing the resulting method in environmental samples through spiking MPs into freshwater samples, we further highlight the applicability of this approach to be used as a rapid screening tool for MPs. Collectively, this workflow can be easily applied to a diverse set of samples to assess the presence of MPs in a time-efficient manner.

3.14.T-05 Analysis of microplastics in underground waters and drinking waters down to 5µm

***Lauriane Barritaud**, Scientific & Technological Expertise Department, Veolia Group, France*

“Human beings ingest 5 grams of plastic per week”. The press reported this statement even before the WWF-funded study was published. It turns out this figure corresponds to the worst-case scenario, hardly representative of reality! Many press articles highlight microplastics contamination of bottled water but also in tap water and point out a potential risk to human health. However, occurrence of microplastics in underground waters and the efficiency of drinking water treatment plants (DWP) are not well known yet.This study focuses on two French DWPs with underground waters as resources. The first plant has a 6 m deep resource influenced by a close-by river. For the second plant, two protected resources (70 m and 14 m depth), were analysed. A dedicated filtration system was used to sample large volumes of water (>500 L) on 5 µm mesh-size stainless steel filters and is presented. This system includes a filter dedicated for the field blank sample. Microplastics were quantified with state of art technique, namely imaging µFT-IR with a 3.3 µm pixel resolution at Aalborg University (Simon et al., 2018, Kirstein et al. 2021). Results show small amounts of microplastics in both underground waters and drinking waters. Drinking waters present a contamination of microplastics >6.6 µm below 1 MP/L. Underground water influenced by the river (inlet DWP1) had a higher amount of microplastics compared with inlet waters from DWP2: 2 MP/L versus 0.3 MP/L, respectively.

3.14.P Lower Micron and Nanosize Plastics: Challenges, Analytical Methods, Occurrence, Composition, Local Sources, Long-Range Transport and Human Exposure

3.14.P-Mo183 Overcome the Obstacle of NP Analysis – A Concept of Artificial Intelligence Combined with Chemical/Microscopic Methods

Alexandra Foetisch*, Collin Weber and Moritz Bigalke, Technical University Darmstadt, Germany*

Numerous studies have shown the potential risk that nanoplastic (NP) represents for the living organisms in the different ecosystems. However, the amount and characteristics of NP present in the environment are still unknown in its full extent. Even if several methods have already managed to quantify or characterize environmental NP, none, to our best knowledge, could yet provide a complete characterisation over the full nanoscale range combined with a high sample throughput.

The present work tackles the challenge of NP full characterisation in a wide range of media (air, water, soil) by testing an innovative combination and alignment of µ Raman spectroscopy (RS), scanning electron microscopy coupled with energy dispersive x-ray spectroscopy (SEM/EDX), pyrolysis gas chromatography mass spectrometry (Py-GC/MS) and artificial intelligence (AI). The aim is to use the RS and Py-GC-MS data to train an AI model to be able to automatically characterise NP in environmental samples using SEM/EDX data. Since this project is in its infancy, only the concepts are presented here.

The method is tested and optimized using sample types of increasing complexity, starting with pure NP, mixed NP, spiked media and, finally, environmental samples. First, NP chemical information is acquired down to a ~500 nm size using RS and NP quantification, size and surface characteristics are obtained using SEM/EDX down to a ~20 nm size. Based on the RS and SEM data, the total mass of each polymer present in the sample is extrapolated and then cross-validated by performing a Py-GC/MS analysis on the same sample. Monte Carlo simulations are then used to model the error of the extrapolation based on the 2 and 3D data provided by the RS and SEM data.

Finally, the dataset acquired with RS and SEM/EDX on >500 nm NP is divided into a training and testing set to build a convolutional neural network (CNN) allowing the differentiation between NP and non-NP particles present in a sample. The aim of this model is then to allow the identification and characterisation of <500 nm NP present in a sample using SEM/EDX data and AI and cross validation with Py-GC-MS data.

In case of success, this model would provide for the first time a full characterisation of environmental NP with a high sample throughput. This methods combination could then provide a more accurate assessment of the NP pollution in the environment.

3.14.P-Mo184 Development and validation of a pyrolysis - gas chromatography – high resolution mass spectrometry method for the determination of nano- and microplastics in river water and sediment samples

***Eva of Amsterdam - Institute of Biodiversity and Ecosystem de Rijke**[1], Samira Absalah[2], Annemarie van Wezel[3], Rachel Addoquaye[4] and Tristan Jansen[5], (1)University of Amsterdam (UVA), Netherlands, (2)Triskelion, Netherlands, (3)University of Amsterdam, Institute for Biodiversity and Ecosystem Dynamics (IBED), Netherlands, (4)BERLIN-CHEMIE Menarini, (5)IBED UvA*

Micro- and nanoplastics (MNP) are a class of emerging contaminants in the environment. Measuring concentrations and sizes of micro- and nanoplastics in the environment is essential to assess the risks plastic particles could pose. Microplastics have been detected globally in a variety of ecosystems. Their determination, however, is still challenging. Recently, pyrolysis gas chromatography to mass spectrometry (Py-GCMS) was introduced for mass related quantification of microplastics. Under high temperature and oxygen-free conditions thermal breakdown of polymers takes place and characteristic volatile pyrolytic products are generated. Under reproducible pyrolysis conditions following gas chromatographic separation and mass spectrometric detection, individual polymer types can be quantified. Pyrolysis GC-MS has shown to be promising for the detection of MNP in environmental samples and can give information on the different polymer types and quantities. In this study, different commonly occurring MNP polyethylene (PE), polypropylene (PP), polystyrene (PS), polymethylmetacrylate (PMMA), polybutylmetacrylate (PBMA), polyvinylchloride (PVC), polyethylene terephthalate (PET), polytetrafluoroethylene (PTFE) were investigated. The preparation of standards was optimized by comparing cryo-milling with quartz sand and dissolution in various solvents. A low resolution pyrolysis GC-MS method was developed and transferred to a py-GC-HRMS Orbitrap system. Both methods were validated. Furthermore, a double-shot method was developed to qualitatively determine volatiles additives present in the MNP. As an application, pre-concentrated nanoplastics from aqueous environmental samples (surface water and river sediment) were qualitatively and quantitatively investigated with the optimized methods. For all MNP except PP three indicator pyrolysis products were found and limits of detection were below 0.02 ng absolute in all cases, with R^2 values ranged between 0.990 and 0.999. With the optimized py-GC-HRMS method PS an PE were successfully identified in sediment samples and PET in the water samples.

3.14.P-Mo186 Development of Semi-automatic Analytical Methods for Fine Microplastics larger than 1 µm in Surface Water by Raman Imaging Microscopy

***Yutaka Kameda**, Chiba Institute of Technology, Japan*

It is a matter of great concern that ultra-fine microplastics (UFMPs), ranging from 1µm to 20 µm, may have adverse effects on human health and wildlife. The occurrence of UFMPs in the ocean poses issues that should be addressed in the context of ecological risk assessments in aquatic environments and environmental behaviors in marine settings. However, quantifying and identifying UFMPs in water samples is challenging because each particle must often be individually identified by operators, requiring a significant amount of time and effort. In addition, Raman spectroscopy is not suitable for observing a wide range of areas to quantify and identify all UFMPs in samples, leading to high extrapolation for estimating UFMP concentrations and their upper limits of detection. Pretreatment processes for UFMPs with minimal contamination are also necessary. This presentation introduces semi-automatic analytical methods for UFMPs in the surface water of Tokyo Bay, including pretreatment methods. The pretreatment process for the water samples consists mainly of three crucial steps. The first step involves removing organic fluorescent matrices from glass apparatus and two types of membranes, achieved by heating them at 450 degrees Celsius for 2 hours. Subsequently, surface water samples were passed through a silver membrane to collect UFMPs, which are then gathered on a nickel membrane. The second step involves a digestion process using the Fenton reaction in a centrifuge tube. Following this, sodium iodide is added to the tube for density separation. The third step aims to remove excess sodium iodide and other salts in supernatants from the tube, obtained three times after centrifugation. The pooled supernatant is filtered by a nickel membrane, and hydroperoxide and hydrochloric acid are added to dissolve excess salts. Finally, the washed solution, including FHMPs, is passed through an area with a 4 mm diameter of a silicon membrane. UFMPs on the membrane can be analyzed using the DXR3xi Raman Imaging Microscope (Thermo Fisher Scientific). The Raman microscope has ultra-fast chemical imaging capabilities, making it possible to analyze UFMPs across more than 63.7% of the total area for 32 hours. Using this analytical method, microplastics as small as 0.3 µm could be detected. The poster will also show recovery tests conducted in our laboratory, as well as monitoring results of UFMPs in Tokyo Bay.

3.14.P-Mo187 Validation of Nanoplastic Extraction from Compost by Advanced Techniques and Screening Techniques to Enable Nanoplastic Identification and Quantification by Nanoscale Infrared Imaging

***Patrizia Pfohl**[1], Svetlana Guriyanova[1], Iban Amenabar[2], Denis Botin[3], Christian Roth[1], Sebastian Mueller[1], Rainer Hillenbrand[2] and Wendel Wohlleben, Dr.[1], (1)BASF SE, Germany, (2)CIC nanoGUNE, Spain, (3)Analytical and Material Science, BASF SE, Germany*

Environmental aging of macro- and microplastics might lead to formation and release of nanoplastics. However, current extraction protocols established for microplastics are not suitable for nanoplastics because of (hetero)agglomerate formation and longer flotation times during density separation. In addition, common microscopy counting techniques for microplastics (Raman, IR, Fluorescence) are not applicable to nanoplastics, and the mass-based detection limit of techniques such as thermogravimetric analysis (TGA) or pyr-GCMS corresponds to an unsatisfyingly high number concentration of nanoplastics that would remain undetected, if present. Consequently, there is a knowledge gap on nanoplastic presence and quantity in different environmental compartments.

Here we present an extraction process developed for polyamide nanoplastics from compost, which is based on deagglomeration and fractionation by size to isolate the nanoplastics from compost components, which are then enriched by a stacked density-separation. The extraction protocol was validated by different advanced and screening techniques, using spherical fluorescent polystyrene (PS) beads (0.91 µm) for visual inspection in a first approach, then gravimetrical approaches including TGA for polyamide (PA) nanoplastics and finally analytical ultracentrifugation during density gradient separation. Each step of the extraction protocol was validated separately to identify and improve the most critical steps. For demonstrating the recognition of individual nanoplastics via infrared nanoimaging using Scattering-type Scanning Near-field Optical Microscopy (s-SNOM), we spiked polydisperse, non-spherical pristine and UV-aged PA nanoplastics into compost < 20 µm and extracted them with stacked density separation. Imaging was performed at few specific IR frequencies, which were obtained from spectra of the reference materials (PA and compost particles). The reference spectra were recorded by Fourier transform infrared nanospectroscopy (nano-FTIR). Based on the IR images, the individual nanoparticles were identified and counted using special data and image processing.

3.14.P-Mo188 Capillary Electrophoresis as a Promising Technique Towards a Universal Analytical Tool for Separation and Detection of Nanoplastic Particles

***Carlos Adelantado Sánchez**[1], Blanca H. Lapizco Encinas[2], Jan Jordens[3], Stefan Voorspoels[3], Milica Velimirovic[3] and Kristof Tirez[3], (1)Flemish Institute for Technological Research (VITO), Mol, Belgium, (2)Microscale Bioseparations Laboratory and Biomedical Engineering, Rochester Institute of Technology, (3)Flemish Institute for Technological Research (VITO), Belgium*

Nanoplastics are released throughout the entire life cycle of plastic consumer products. Nanoplastic size is small enough to avoid plastic removal procedures and to penetrate biological barriers, increasing the possibility of inherent toxicity and toxin transportation to organisms. Due to reactivity with other environmental materials, nanoplastic quantification in natural items becomes more difficult.

In the framework of the EU-funded CE4Plastics project, capillary electrophoresis is the main technique for the nanometrological approach herein described, in which separation of differently sized nanoplastic particles is reported.
A separation methodology for polystyrene nanoparticles with particle diameters ranging from 30 to 300 nm has been

developed, making use of a buffer containing 5 mM sodium phosphate in conjunction with 5 mM sodium dodecyl sulphate in alkaline medium (pH=8.9), through a bare fused silica capillary and ultraviolet detection. The proposed strategy was also assessed for polymethyl methacrylate, polypropylene, and poelythylene nanoparticles, finding that stronger alkaline conditions, employing an ammonium hydroxide buffer (7.5%, pH=11.9), enabled the separation of these polymers for the first time by means of electrophoresis for particle diameters below 200 nm. Detection limit was found to be in the concentration region of 10^{11} particles mL^{-1}, whilst repeatability obtained for migration time and peak area had variations in all cases below 10%.

Data on nanoparticle effective electrophoretic mobility show an increasing absolute value from the smaller to the larger sizes. In contrast, the absolute value of particle surface-charge density is decreasing with the increasing particle size. This phenomenon aligns with shorter migration times revealed by the smaller particles, whilst the larger particles migrate later due to their smaller absolute value of surface-charge density and higher absolute value of effective electrophoretic mobility. It is believed that the separation mechanism involves a combination of linear and nonlinear electrophoretic effects. This work is the first report on the quantification of nonlinear electrophoretic effects on nanoplastics in an electrophoresis system and presents an interesting contribution in nanoplastic research by electrophoresis.

This project has received funding from the European Union's Horizon Europe research and innovation programme under the Marie Skłodowska-Curie grant agreement No 101059423.

3.14.P-Mo189 Navigating Nanoplastics: Challenges and Approaches in Producing Standardized Materials

Milica Velimirovic[1], *Xiaoyu Zhang*[1], *Carlos Adelantado Sánchez*[2], *Géraldine Dumont*[1], *Kristof Tirez*[1] *and Stefan Voorspoels*[1], *(1)Flemish Institute for Technological Research (VITO), Belgium, (2)Flemish Institute for Technological Research (VITO), Mol, Belgium*

Plastic is considered one of the most practical inventions of the 20th century, yet today it represents one of the greatest potential threats to the environment and human health. The low production cost of plastics, as well as their very favourable characteristics, including light weight, durability, inertness and resistance to corrosion and degradation, have led to significant technological and social progress. Although concerns regarding the environmental impact of microplastics (MPs) surfaced in the 1970s, the scientific community has recently recognized the pressing urgency of the issue, particularly concerning nanoplastics (NPs). Detection, quantification, and source identification of nanoplastics (NPs, 1-1000nm) in different matrices is still one of the largest challenges in this context due to the lack of adequate sample preparation procedures and straightforward analytical techniques for their characterization and quantification. In addition, design and fabrication of relevant reference and standard plastic particles within targeted nano-size ranges is of crucial importance for developing straightforward analytical techniques.

In the framework of the research project MS4Plastics (H2020-MSCA-IF-2020 - Grant Agreement No 101023205) different approaches such as high-energy grinding, extensive sonication, and exposure to ultraviolet (UV) light to initiate photochemical reactions leading to the breakdown of plastics were employed to degrade or fragment different plastic materials (e.g., a surgical face mask, polymer pellets, rubber dust, and plastic powders) into NPs. For detection and size determination of NPs formed after employing different approaches for plastic fragmentation dynamic light scattering was used. Finally, the possibility of using asymmetric flow field-flow fractionation (AF4) hyphenated to multi-angle light scattering (MALS) as a tool for characterization of a subset of the produced NPs samples was investigated.

3.14.P-Mo190 Machine Learning to help identifying polymers

Patrick Bauerlein[1], *Xin Tian*[1], *Frederic Béen*[1,2], *Yiqun Sun*[3] *and Peter van Thienen*[1], *(1)KWR Water Research Institute, Netherlands, (2)Vrije University Amsterdam, Netherlands, (3)School of Earth Sciences and Engineering, China*

Monitoring microplastics is important for science as well as for environmental and water authorities. Therefore, rapid and accurate detection and identification of these compounds is critical. Recent research has shown that machine learning can help to identify microplastics larger than 10 um reliably, using simple models such as knn and more sophisticated ones such as three different Convolutional Neural Network (CNN) models. The next step would be to test these models on smaller particles. As particles are getting smaller there infrared spectra will get more difficult to interpret. Here machine learning can be a very useful tool.

Microplastic samples were analyzed using the quantum cascade laser (QCL)-based Agilent chemical imaging LDIR system. A database with spectra from commercially available and recorded data in the laboratory was used to train the models. In a first step to increase the database, N synthetic samples per polymer class were generated on the basis of data augmentation. Specifically, we resampled the replicate spectra by (i) randomly picking two observed spectra of the same specific polymer, V1 and V2, (ii) setting two random weights, w1 and w2 (s.t. w1 + w2 = 1), (iii) calculating the weighted sum, w1V1 + w2V2, as the new spectra, and (iv) repeating the first three steps N times.

Afterwards, two different types of models were tested using this database. Performance of the models is evaluated using three performance indicators, namely accuracy, precision and recall. Also the model training time is compared. For the knn model the numerical spectral data (cartesian coordinates) from LDIR was used as is, whereas for the CNN models the data was first transformed from cartesian coordinates into polar coordinates and afterwards into a picture.

Conclusion: The most rudimentary model can still prove effective. In our research, a basic sub-KNN model yielded superior results when compared to the three CNN models, with the added advantage of being quicker to train. The amount of high-quality samples available is vital in the model training process. Taking into account our limited dataset, the proposed data augmentation approach led to a significant enhancement in performance. While the 2D-CNN models may not be optimal for this case study, they appear to be more effective in handling multidimensional spectroscopic signals. Further research will explore their potential usefulness.

3.14.P-Mo191 Analysis of microplastics under 20 µm in road dust- A case study in Seoul, South Korea

Dana Fahad Mohamed*, Inae Jeon and Jung-Hwan Kwon, Korea University, Korea, Republic of (South)*

The widespread occurrence of microplastics (MPs) in road dust raises substantial concerns for both the environment and human health. Analyzing MPs smaller than 20 µm is crucial due to their heightened risk of ingestion, respiratory exposure, and potential transport of harmful substances. However, current methods have limitations in detecting MPs smaller than 20 µm, making the analysis time-consuming and challenging. In this study, road dust samples were collected from 30 different locations in Seoul, South Korea. An in-depth analysis of microplastics (<20 µm) in road dust using Confocal Laser Scanning Microscopy (CLSM) and Pyrolysis Gas Chromatography-Mass Spectrometry (Py-GCMS) was conducted. CLSM was used to quantify the number of plastic particles. A counter staining technique using Nile red and calcofluor white was used to exclude any false positives from the sample. The number of particles ranged from 16-1960 MP particles/mg sample. Py-GCMS was used to determine the mass of microplastics in road dust. The mass of microplastics in road dust ranged from 0.342 to 2.96 µg plastics/ sieved sample. The findings not only provide a comprehensive understanding of microplastic distribution in road dust around Seoul but also underscore the importance of employing advanced methodologies to overcome measurement limitations associated with smaller particles.

3.14.P-Mo192 Cascade Filtration for Multi-technique Characterization of Micro-Nanoplastics in Environmental and Human Samples

Sepideh Hadidimasouleh[1]*, Adriaan Duijndam*[2]*, Marthinus Brits*[3]*, Marja Lamoree*[4] *and Florian Meirer*[5]*, (1)University of Amsterdam (UVA), Netherlands, (2)Utrecht University, Inorganic Chemistry and Catalysis, Department of Chemistry, Netherlands, (3)Amsterdam Institute for Life and Environment (A-LIFE), Vrije University Amsterdam, Netherlands, (4)Vrije University Amsterdam, Netherlands, (5)Chemistry, Utrecht University, Netherlands*

Micro-Nanoplastics (MNPs) are defined as plastic particles smaller than 5mm and have become ubiquitous environmental pollutants due to the widespread use of plastic materials. Their presence in various environmental compartments, including water, sediment, soil, and even the human body, raises concerns about their potential adverse effects on ecosystems and human health. However, comprehensive characterization of MNPs remains challenging due to their small size, complex composition, and the presence of natural and synthetic fibers that can interfere with their identification and quantification. To address these challenges, we have used a novel cascade filtration method using silicon (Si) and alumina (Al_2O_3) filters to enhance the combined characterization of MNPs in environmental and human samples. The optimized filtration system effectively captures MNPs across a broad size range while minimizing losses and cross-contamination. The Si filter effectively removes larger MNPs (larger than 800nm), while the alumina filters efficiently capture smaller MNPs (800 nm – 90nm). This sequential filtration process ensures the recovery of MNPs across a wide size range, preventing the loss of smaller MNPs that often go undetected in conventional filtration methods. The separated MNPs are then subjected to further characterization using microscopy, spectroscopy, and pyrolysis-gas chromatography/mass spectrometry techniques to gain insights into their polymer type. Cascade filtration, coupled with advanced analytical techniques, provides a powerful tool for comprehensive microplastic characterization, enabling a better understanding of their sources, distribution, and potential impacts.

3.14.P-Mo193 Detection of microplastic particles (1-10µm) in soil matrices

Ralf Kaegi[1]*, Matthias Philipp*[2] *and Thomas D. Bucheli*[3]*, (1)Process Engineering, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (2)Eawag - Swiss Federal Institute of Aquatic Science and Technology, Switzerland, (3)Environmental Analytics, Agroscope, Switzerland*

Quantifying the number of microplastic particles (MP) < 20 µm remains a challenge. Electron microscopy provides sufficient resolution, allows for an elemental analysis of light elements and comes with a high degree of automation. In this study, we, therefore, explored to potential of automated scanning electron microscopy (SEM) to assess MP between 1 and 10µm. We spiked Lufa 2.4. soil sieved to 0.45-10 µm with polyethylene (PE) and polyvinyl chloride (PVC) MPs of similar sizes to mimic a contaminated soil. The mixtures were suspended in 100% ethanol or isopropanol and filtered through gold-coated membrane filters (Nuclepore, Whatman). For imaging, we used an backscattered detector and the particles were detected based on their density contrast relative to the Au coating. The operational conditions (acceleration voltage of the SEM (3kV) and the thickness of the Au coating (40 nm)) were derived from Monte Carlo simulations of the interaction of the electron beam with solid materials using the software code CASINO (v. 3.3.0.4) [1]. The particle detection was automated using the software code 'feature' (Oxford Inst.). The classification of detected particles was based their elemental signatures recorded with a windowless energy dispersive x-ray (EDX) analysis system (X-TREME, Oxford Inst.). PVC particles filtered from pure suspension sample resulted in a correct identification of 70% of all particles, whereas 15% of the particles were identified as PE and soil particles, each. In PE samples, 85% of all particles were identified as PE and 15% as soil particles and in the pure Lufa 2.4. soil sample, 93% of the particles were classified as silicates and 7% as PE. The somewhat lower detection rate of PVC is most likely due to the volatility of chlorine under the electron beam. To assess the potential of the developed method to identify different types of MPs in complex matrices, mixtures of PE, PVC and Lufa 2.4. soil in a 1:1:2 ratio were filtered on

Au coated Nuclepore filters. In total, 243 PE, 213 PVC and 508 soil particles were detected on a subset of 35 images corresponding to an area of 0.25 mm^2. These particle number translate into number based ratios of PE:PVC:SOIL of 1:0.9:2.1 corresponding well to the expected ratio and demonstrate the potential of our approach.

3.14.P-Mo194 Exploring Oil-Based Extraction for Nanoplastic and Microplastic Analysis in Solid Matrices using a New Type of Reference Material

Kathrin Harre[1], *Lucas Kurzweg*[2], *Jann Schneider*[3], *Luise Elisabeth Lindner*[3], *Maurice Hauffe*[4], *Oliver Kretschmar*[5] *and Thomas Himmer*[6], *(1)Faculty of Agriculture, Environment, Chemistry, University of Applied Sciences Dresden, Germany, (2)Faculty of Agriculture/Environment/Chemistry, University of Applied Sciences Dresden, Germany, (3)Agriculture/Environment/Chemistry, University of Applied Sciences Dresden, Germany, (4)Mechanical Engineering, University of Applied Sciences Dresden, Germany, (5)Agriculture/Environment/Chemistry, University of Applied Sciences Dresden, (6)Mechanical Engineering, University of Applied Sciences Dresden*

The analysis of nanoplastic (NP, size < 1µm) in any matrix is still challenging. Expecially in solid particulate sample NP analysis is hampered by its low concentrations and a significant lack of extraction methods. In environmental samples NP is expected to be present together with microplastic (MP) loads. However, knowledge about NP and MP concentration would be important i.e. in soils, compost, sewege sludge, or filter sludge. One promissing method would be the oil-based extraction (OBE) of NP due to the lipophilic properties of polymers. However, OBE was only applied to samples with limited particle sizes and no OBE of NP is reportet yet.

To enhance NP analysis, we're developing precise NP and microplastic (MP) reference materials using innovative methods. These materials mimic specific characteristics, allowing controlled experimentation. We're exploring OBE adaptations by varying experimenteal conditions, aiming for efficient particle extraction. Extinction measurements show potential for fast NP concentration determination.

Our NP reference materials demonstrate 180 nm diameter, while our monodisperse MP materials vary between 100 and 500 µm with uniform disk-like shapes. Initial small batch experiments revealed low NP extraction rates using stirring and shaking methods, prompting investigations into more effective mixing techniques. Large batch experiments with cryo-grinded MP particles yielded a 44% recovery rate.

Challenges persist in OBE for NP and MP extraction from solid matrices, demanding optimization of process parameters and addressing analytical hurdles. However, OBE's advantages, like non-use of hazardous chemicals and size-independent efficiency, make it promising for environmental sample analysis.

Furthermore, our approach introduces a novel method for producing MP reference materials with defined properties, offering scalability and the potential for materials with fluorescence or magnetic properties. This innovation could revolutionize reference material production and properties, aiding in diverse research avenues.

3.14.P-Mo195 Sensitive Analysis Method for Microplastics Using Wavelength Tunable Quantum Cascade Laser and Photoacoustic Detection

Ana Rita Correia Fernandes[1], *Sudatta Das*[2], *Blaz Hrovat*[3], *Roberto Martins*[4], *Arto Koistinen*[3], *Carlos Marques*[1], *Juho Karhu*[5], *Erkki Ikonen*[6] *and Juha Toivonen*[7], *(1)CICECO – Aveiro Institute of Materials & Department of Physics, University of Aveiro, Portugal, (2)Metrology Research Institute, Aalto University, Finland, (3)University of Eastern Finland, Department of Technical Physics, Finland, (4)CESAM-Centre for Environmental and Marine Studies and Department of Biology, University of Aveiro, Portugal, (5)Metrology Research Institute, Aalto University, Espoo, Finland and Department of Chemistry, University of Helsinki, Finland, (6)Metrology Research Institute, Aalto University, Espoo, Finland and VTT MIKES, VTT Technical Research Centre Finland, Finland, (7)Photonics Laboratory, Physics Unit, Tampere University, Finland*

Human activities are responsible for introducing microplastics (MPs) into freshwater and marine environments. The real impact of MPs remains largely unknown due to their slow degradation, allowing them to persist in the environment for many years. There is an urgent need to enhance our understanding and develop innovative methodologies for their real-time, rapid, and efficient detection across different matrices and environmental compartments. This is crucial for comprehending the ecotoxicological effects on different biological levels and implementing effective removal strategies.

This study proposes a novel microplastic detection method utilizing a wavelength-tunable quantum cascade laser as a light source and a photoacoustic sensor for detection. The method relies on spectrally dependent light absorption by plastics, like the well-established Fourier-transform infrared (FTIR) spectroscopy method. Aqueous dispersions of polystyrene (PS) and polyvinyl chloride (PVC) MPs sized between 25 and 70 µm were prepared in ultra-pure water, followed by manual agitation for one minute until homogenous dispersion. MPs were then extracted by filtrating the solution through a gold-coated filter. Key components of the detection system include a source of energy, a chopper that has a crucial role in modulating the laser beam, and an extremely sensitive cantilever microphone that is a highly sensitive device that measures sound and allows the detection of very weak signals coming from the plastic particles, enabling the identification and quantification of MPs based on their unique spectral fingerprints. The wavelength range in the data is from 8.9 to 10.3 µm, which is limited by the tuning range of the quantum cascade laser model used in this work. All the recorded spectra are compared against the reference FTIR spectra existing in the siMPle library. The obtained data has a good correspondence with FTIR database spectra. This photoacoustic sensor offers several advantages over the already existing techniques, including high sensitivity and specificity, being able to detect and identify MPs samples containing only a few particles in the filter. This research not only addresses the urgent need for reliable MPs detection methods but is also a breakthrough for future applications in related fields such as polymer characterization and environmental impact assessment**.**

3.14.P-Mo197 Pyrolysis-Gas chromatography-Mass spectrometry : Way Forward To The Low-µm and nm Range Plastics Analysis

Géraldine Dumont[1,2]*, Milica Velimirovic*[1]*, Jan Jordens*[1]*, Pierre-Hugues Stefanuto*[2] *and Jean-François Focant*[2]*, (1)Flemish Institute for Technological Research (VITO), Belgium, (2)Chemistry, University of Liège, Belgium*

In recent years, the microplastics and nanoplastics pollution has gained an important interest but methods to identify and quantify them still need to be standardized. The use of pyrolysis-gas chromatography/mass spectrometry for the analysis of low-µm and nm range plastics is a promising approach as the obtained results are mass-based and not based on particles number.

This study aims to contribute to the understanding of plastics analysis by investigating the impact of particle size on the chromatographic outcomes. To achieve this, four distinct polymers, including polystyrene, polyethylene, poly(methyl methacrylate) and polypropylene, each characterized by varying particle sizes, along with a microplastics mix, were subjected to thorough analysis using Py-GC-MS. By exploring the obtained chromatograms, this research seeks to provide valuable insights into the efficacy of Py-GC-MS in elucidating the complexities of plastics at the low-µm and nm ranges.

The analysis of different sizes, ranging from micro to nanometer, of differrent polymer standard particles show an impact of the particle size on the obtained chromatogram. Indeed, a change in ratios between peak areas is observed depending on the polymer size. These results will have to be taken into account while analyzing environmental samples. As such, one of the possible solutions is a size separation step during the sample preparation procedures. Another solution could be to build two different types of calibration curves or a calibration curve based on a mix of different particle sizes in order to represent as much as possible what can be found in the environment.

To conclude, due to its mass-based detection, the Py-GC-MS seems to be a interesting tool in the analysis of nanoplastics. However, extensives studies have still to be carry on nanoplastics to assess the deviation compared to microplastics in order to achieve a reliable quantification in environmental samples.

Acknowledgement - M.V. acknowledges EU-funded project MS4Plastics (H2020-MSCA-IF-2020—Grant Agreement No. 101023205).

3.14.P-Mo198 Microplastic Characterization and Screening by Combining DART and High-Resolution Mass Spectrometry

Arnd Ingendoh[1]*, Carsten Baessmann*[2]*, Kushal Modi*[3]*, William Fatigante*[3] *and Mark Arnould*[3]*, (1)Bruker Daltonics GmbH & Co. KG, Bremen, Germany, (2)Bruker Daltonics GmbH, Germany, (3)Bruker*

Microplastic particles result from commercial product development and the breakdown of plastics and are abundant in our environment from a variety of commercial sources like cosmetics, textiles and other pieces of plastics such as water bottles that breakdown with radiation. Microplastics have been detected at an alarming level in our marine life and drinking water. Direct Analysis in Real Time - High Resolution Mass Spectrometry (DART-HRMS) allows for rapid fingerprinting of environmental microplastics, e.g. for the identification of their origin. Typical samples of interest are polymers found in the environment like virgin pre-production pellets, microbeads from personal care products, microplastics found in the aquatic environment, and synthetic fibers.

DART was coupled to an impact II VIP QTOF (both Bruker, Germany). While traditional GC/MS methods require sample preparation (10-20 min) and long analysis times (> 20 min), this new method allows for rapid polymer analysis (< 5 min) without sample preparation. A small sample sliver is cut and placed in a copper pot of a thermal desorption system (IonRocket, Biochromato Inc., Japan) which delivers temperature gradients from ambient to 600 ºC with ramp rates of 150 ºC/min. When the thermal program is started, the QTOF collects MS spectra at 5Hz data acquisition speed for the entire run.

The resulting mass spectra display thousands of discrete peaks. Depending on the temperature, different additives, the polymeric basis as well as degradation products are released and detected at different time points during the run. Distinct m/z signals and general signal patterns of a microplastic material found in water were compared with standard plastic samples such as a soda bottle, a trash bag and packaging material. While the soda bottle turned out to be made of PET, the microplastic clearly had PE as a basis. PE as an insoluble polymer is difficult to analyze with other MS-based methods like MALDI. The microplastic material showed most similarity with the trash bag, regarding both certain distinct marker m/z values as well as the general pattern released by the temperature gradient, so it can very likely be traced back to that origin.

3.14.P-Mo199 Additive manufacturing of 3D-printed monodisperse microplastic standard particles as an internal standard and for calibrations in microplastic analysis

***Maurice Hauffe*[1]*, Kathrin Harre*[2]*, Thomas Himmer*[3] *and Lucas Kurzweg*[4]*, (1)Mechanical Engineering, University of Applied Sciences Dresden, Germany, (2)Faculty of Agriculture, Environment, Chemistry, University of Applied Sciences Dresden, Germany, (3)Mechanical Engineering, University of Applied Sciences Dresden, (4)Faculty of Agriculture/Environment/Chemistry, University of Applied Sciences Dresden, Germany*

The analysis of microplastics has made enormous progress in recent years and affects almost all environmental compartments from soil, air and water. The EU Directive (DIRECTIVE (EU) 2020/2184) obliges all EU countries to introduce a methodology for measuring the microplastic content in drinking water. For analysis it is often necessary to calibrate, approve or validate the methods with known standard material. There is also a need for microplastic particles with defined properties to investigate the behavior of microplastics in different environmental compartments, e.g. to investigate the influence of polymer type and particle size on transport properties.

So far, microplastic standards have been produced mainly by cryogenic grinding and screen fractionation. This is associated with high costs for liquid nitrogen and only leads to dispersed microplastics with a particle size distribution within the limits of the sieves used.

Monodisperse particle standards are therefore not possible. Due to the particle size distribution, the exact number of particles cannot be deduced from the mass of the fraction. If an exact number is required, this must be counted at great expense of time.

Here we present our new approach, which enables piece-count accurate additive manufacturing of single microplastic dots in the 3D printer. Monodisperse particles are deposited on a printing surface within only a few minutes. Furthermore, this method is cost-effective and can be realized with almost any thermoplastic, including biodegradable plastics.

In terms of environmental friendliness and sustainability this method has further advantages. Cryogenic grinding and screening also result in additional fractions of microplastics of other size classes. With the new manufacturing method, the excess of microplastic produced is reduced to a minimum.

A patent is pending for the process under patent number PCT/DE2023/100515. So far, particles with a size dimension of approx. 100 µm have been successfully produced. Specially manufactured nozzles with diameters of 80 down to 10 µm were tested in first polymer extrusion-tests and promise smaller particles in the future. The materials tested so far are PLA, fluorescent PLA and PCL. We currently also produce our own filament from PE, PET and blends using our own extruder system.

The microplastic standards produced are used for experiments on microplastic enrichment from sediment-rich matrices by means of electro-, density- and oil separation.

3.14.P-Mo200 Production and Analysis Methods for more Environmentally Relevant Small Microplastic and Nanoplastic Test materials

***Andy Booth, PhD*[1]*, Matthias Gerace*[2]*, Christelle Denonville*[3]*, Stine Kylling Mauring*[4] *and Lisbet Sorensen*[1]*, (1)SINTEF Ocean, Norway, (2)Norwegian University of Science & Technology (NTNU), Norway, (3)SINTEF Industry, Norway, (4)NTNU, Norway*

Microplastic (MP; 1-5000 µm) and nanoplastic (NP; <1 µm) particles observed in the natural environment are typically (i) irregular-shaped, (ii) partially degraded, (iii) a wide range of polymer types, (iv) a continuum of sizes, shapes and densities, and (v) a reservoir for complex mixtures of plastic-associated chemicals. There is a need for environmentally relevant MNP test materials for assessing fate and effects. Small MP (sMP; <50 µm) and NP are thought to be the highest risk size ranges, but cryomilling struggles to produce meaningful yields. Here, we present the results from an assessment and optimisation of three previously reported strategies for producing sMP and NP [1,2]. Strategy #1 used pre-cryomilling, thermal treatment, UVC irradiation and probe sonication of PS, PE and PET materials. Strategy #2 involved the testing of different mechanical degradation processes after pre-cryomilling, including bath sonication, probe sonication and wet grinding (Ultra-Turrax). Strategy #3 investigated the suitability of partial solubilisation with a long chain alkane.

Strategy #1 was viable for producing PS, PE and PET sMPs. A measurable increase in the yield of particles in the range 1-10 µm was observed, with the percentage mass yield increasing from ~0.01% to ~0.7% for PS, from ~0.5% to ~3% for PE and from ~0.1% to ~2.5% for PET. However, overall yields remained very low and there was no measurable increase in the amount of NP. Strategy #2 resulted in no change in the average particle size (z-ave) for cryomilled PE under any of the treatments, with high PDIs indicating a broad particle size distribution. Some reduction in z-ave was observed for cryomilled PET, with probe sonication and wet grinding the most effective treatments, reducing the z-ave from ~6000 nm to ~1800 nm and ~2000 nm, respectively. The PDI was correspondingly reduced, but there was no increase in the proportion of NPs.

Strategy #3 resulted in PE particles with z-ave of ~650 nm and a high PDI. The z-ave of PET, PA, PAN and wool ranged from ~200-300 nm, with reduced PDI values suggesting a narrower particle size distribution. Full physicochemical characterisation is currently being completed. The alternative top-down methods evaluated in this study for producing environmentally relevant sMP and NP test materials show potential. Partial solubilisation appears promising for producing, but more characterisation of the resulting materials is need to confirm their environmental relevance.

3.14.P-Mo201 Multi-modal Imaging as a Tool to Decipher the Biological Response of Nanoplastic Exposure
Yu Elkan Lau[1]*, Daniele De Maria*[2]*, Melanie Bailey*[1]*, Matthew Parker*[1] *and Maya Al-Sid-Cheikh*[3]*, (1)University of Surrey, United Kingdom, (2)Physics, ETH, Switzerland, (3)Department of Chemistry, University of Surrey, United Kingdom*
Since the conception of plastic polymers in the 1950s, plastic production has skyrocketed to meet the ever-increasing demand. With estimates of over 14 million tons of microplastics (MPs) in the environment, the fragmentation of larger plastics into MPs is widely understood. However, the further fragmentation of MPs into nanoplastics (NPs, dimensions < 1µm) presents a new area of study in the field. In fact, NPs have been said to be one of the most hazardous components of marine litter. As a direct result, there has been a steady increase in scientific interest pertaining to the potential adverse effects of NPs. The inherent analytical challenges of identifying carbon-based polymers in biological matrices necessitate a novel suite of analytical methods. The use of multi-modal imaging techniques unlocks the capability of co-locating NPs and their associated biological effects, furthering our understanding of the biological response triggered by these NPs. Ultimately, we aim to investigate not only the distribution and biological effects of NPs but also adsorbed co-contaminants on NPs, evaluating the capacity of NPs as a vector for other legacy Persistent Organic Pollutants (POPs).

Here, we developed a spatially resolved omics analysis using Particle-Induced X-ray Emission Spectroscopy and Matrix-Assisted Laser-Induced Desorption Ionization Mass Spectrometry. By doing so, we aim to identify chemical changes in the tissues surrounding plastic particles. Zebrafish (Danio Rerio) embryos were exposed to nano-polystyrene (*n*PS) at environmentally realistic concentrations via media and microinjection. The embryos were euthanized at 4 days post-fertilization, sectioned to 20µm, and analyzed. Changes in elemental and chemical distribution were observed in several vital organs, including the heart. This study provides insight into the biological effects of NPs and paves the way for more focused studies on the specific mechanisms triggered by NPs. Additionally, the potential impact of this research extends to informing environmental policies and practices, contributing to the development of sustainable solutions for managing plastic pollution in aquatic ecosystems. There is ongoing research to couple this analytical workflow with intrinsically tracking the exposed NPs in biological tissue.

3.14.P-Mo202 Investigating (Hetero-) Agglomeration of Nanoplastics using Particle Tracking Analysis
Maximilian J. Huber *and Natalia P. Ivleva, School of Natural Sciences (Dep. Chemistry), Technical University of Munich, Chair of Analytical Chemistry and Water Chemistry, Institute of Water Chemistry, Germany*
A comprehensive analysis of nanoplastics (plastic particles < 1 µm) in the environment usually requires many different properties of these particles to be characterized. This makes it a challenging task with different techniques that must employed. With regards to this, also fate and transport of nanoplastics must be understood well for representative sampling. One major factor influencing the transport properties of such particles is (hetero-) agglomeration. The interaction of nanoplastics especially with inorganic particles found in the environment can play a critical role in their fate and transport behavior. Particle Tracking Analysis (PTA) is a light scattering based technique to gain information on individual particles and agglomerates. It can be used to study particle size and concentration over time and thus indicate agglomeration. Additionally, the zeta potential can be characterized as the surface charge plays an important role in the interaction of particles. For strongly agglomerating samples cryo-scanning electron microscopy (SEM) can be used for further characterization. Conventional sample preparation for SEM has the disadvantage that particles start agglomerating during the drying process. Thus, the suspension is frozen using liquid ethane and then analyzed at low temperatures to maintain the structure of the sample. In this study, a wide size range of plastic particles (60 – 600 nm, including polystyrene, polyethylene and poly(methyl methacrylate)) will be employed and mixed with inorganic particles consisting of TiO_2, SiO_2 and iron oxide. In a further step, organic substances, like humic acids and proteins, can be added to evaluate their influence on particle agglomeration in a controlled matrix. At last, an environmental sample will be spiked with plastics and their agglomeration will be investigated. In further studies PTA can be online-coupled to separation techniques like field flow fractionation (FFF) to achieve even higher resolution over a broader size range and more detailed information on complex mixtures. In hyphenation with Raman microspectroscopy also chemical information about suspensions could be achieved. Overall, a more detailed insight into particle agglomeration of nanoplastics will greatly benefit the understanding of transport and fate of this complex analyte. This would not only improve sample preparation for quantitative measurements, but also support toxicity studies and targeted measures to remove these particles.

3.14.P-Mo203 µ-Raman analysis of a candidate microplastics' reference material – a proof of concept
Oliver Jacob[1]*, Elzbieta Stefaniak*[2]*, John Seghers*[2]*, Rita La Spina*[3]*, Gabriella Schirinzi*[4]*, Andrea Held*[2]*, Konstantinos Chatzipanagis*[2]*, Hakan Emteborg*[2]*, Martin Elsner*[5] *and* ***Natalia P. Ivleva***[5]*, (1)Chair of Analytical Chemistry & Water Chemistry, Institute of Water Chemistry (IWC)), Technical University of Munich (TUM), Germany, (2)Joint Research Centre (JRC) - European Commission, Belgium, (3)European Commission - Joint Research Centre (JRC), Italy, (4)Joint Research Centre (JRC) - European Commission, Italy, (5)Chair of Analytical Chemistry & Water Chemistry, Institute of Water Chemistry (IWC), Technical University of Munich (TUM), Germany*
Microplastics (MPs, synthetic polymer fragments in the size range 1 µm–5 mm) are found in the environment all around the

globe (in the water, soil, biota, etc.) as well as in drinking water and food, thus raising concerns about their impacts on the environment and human health. Therefore, reliable size-resolved identification and quantification of MPs in different samples, that can be only achieved by application of validated methods is needed. However, validation of analytical methods for measurements of MPs is currently hampered because of a general lack of reference materials.

To tackle this problem, a candidate reference material has been developed by EC JRC, consisting of polyethylene terephthalate (PET) particles and a water matrix. It is based on the concept presented elsewhere (PET particles embedded in a layer of NaCl, which must be reconstituted into water using a surfactant solution), but with a low PET particle number concentration. According to the definition, RM must be sufficiently homogeneous and stable with respect to one or more specified properties. In case of this analyte (PET particles of a defined size range), the analytical method needed for the assessment, to comprise the automated counting of particles, their size determination and confirmation of chemical identity. This has been done, for the first time, by Raman microspectroscopy (µ-Raman) combined with a tailor-made software. Several units of the candidate RM allocated to homogeneity, stabilty and verification of a small size particle content were analysed by µ-Raman.This technique is a suitable tool for the chemical identification and quantification of MPs down to 1 µm. Automed µ-Raman analysis has been performed using recently developed open-source program *TUM-ParticleTyper 2*. The latter enables the automated detection, quantification, and morphological characterization of (plastic) fragments in images of optical microscopy, followed by the automated µ-Raman-based identification of MPs and non-plastic fragments. This approach allows for analysis of up to 7000 particles down to 10 µm, randomly selected on the entire filter. For the analysis of particles down to 1 µm an improved strategy, including subsampling with random windows, and a bootstrap method for estimating the quantification error was used. In this presentation we will discuss a suitability of the applied approach and the tailor-made software to fully evaluate a candidate RM with microplastics as a proof of concept.

3.14.P-Mo204 A Chemometric Approach to Improve the Identification and Quantitation of Plastic Particles in Human Blood Using Pyrolysis-GC-MS
*Wilco Nijenhuis[1], Marthinus Brits[1], Martin van Velzen[2], Sicco Brandsma[3], Marja Lamoree[3] and **Frederic Béen**[4], (1)Amsterdam Institute for Life and Environment (A-LIFE), Vrije University Amsterdam, Netherlands, (2)A-Life, Vrije University Amsterdam, Netherlands, (3)Vrije University Amsterdam, Netherlands, (4)KWR Water Research Institute, Netherlands*
Accurate quantitative methods are crucial to assess human exposure to micro and nano plastics (MNPs). Quantitative pyrolysis-gas chromatography-mass spectrometry (Py-GC-MS) has recently been used for quantifying MNPs in human blood. However, pyrolysis introduces complex effects, including potential secondary reactions between matrix compounds and polymers, impacting current quantification methods based on single markers.

This study uses a chemometric approach to enhance the identification and quantification of MNPs in human blood. A non-targeted approach was used to investigate all thermal degradation products and study their behaviour. Blood samples spiked with MNPs were analysed to identify effective markers for various polymer types while addressing co-pyrolysis and matrix effects. Comprehensive multivariate analysis is first applied to polymer standards' reference data and then extended to an in-matrix study.

Based on the method by Leslie et al. (2022), human whole blood was spiked with varying PET, PE, and PVC concentrations and was analysed using Py-GC-MS. Utilizing the PARAFAC2 algorithm in PARADISe, data was extracted for an untargeted analysis of all pyrolysis products. Multivariate quantification, employing random forest and PLS-regression was compared to single-variable linear regression.

The multivariate quantification (using 416 features) outperformed single-variable regression, especially for PVC analysis. Recursive Feature Elimination was used to select a subset of optimal features and showed more than 15% decrease in quantification error compared to single-marker quantification. The pyrolysis of PE and PVC is identical in blood, while PET appears to exhibit complex interactions with the matrix, resulting in newly formed compounds and expected markers being reduced. However, the affected compounds are able to quantification PET, while reproducibility can be doubted. Additionally, the presence of PE appears to increase PAH formation during the pyrolysis of PVC, causing overestimations in PVC concentrations.

In conclusion, this study highlights the importance of considering secondary effects in pyrolysis, proving the value of a multivariate approach for the identification and quantification of MNPs in blood. Markers are identified, and the importance of understanding potential interferences and secondary reactions is highlighted, emphasizing awareness of the present polymer types and matrix compounds during pyrolysis.

3.14.P-Mo205 Human Exposure to Airborne Micro and Nano Plastics in Indoor Areas
***Aala Azari**[1], Jeroen Vanoirbeek[2], Manosij Ghosh[2] and Peter Hoet[2], (1)KU Leuven, Leuven, Belgium, (2)Environment and Health, Department of Public Health and Primary Care, KU Leuven, Belgium*
Background: Micro and nano plastics (M/NPs) are even detected in remote areas, raising significant health concerns. While much research focused on marine and soil environments, the underestimated threat of exposure to airborne M/NPs (aM/NPs) is

concerning. Their low density and small size, pose potential health risks through inhalation and ingestion. Accurate sampling, measurement, and analysis of aM/NPs are complex challenges that require a critical evaluation of existing techniques. Consequently, we conducted a trial experiment to assess indoor aM/NP exposure, considering human activity intensity.

Materials and Methods: MP deposition samples were collected from 3 types of rooms in a laboratory in Leuven, Belgium using glass funnels attached to Erlenmeyer flasks over 10 working days. This experiment was conducted during 4 different periods: Low activity/Cold season, High activity/Cold season, Low activity/Warm season, and High activity/Warm season. Environmental factors including CO_2 concentration, flow rate, relative humidity, and temperature were measured. Macro imaging and ImageJ software were used for quantification purposes, while morphological characteristics were analyzed with a stereomicroscope. For chemical identification reference materials were used for optimization of qualitative analysis by μ-Raman, Pyro-GC/MS, and high spectral imaging and then the chemical characteristics of the collected sample will be done using these techniques.

Results and Discussion: Our prior study highlighted the importance of careful consideration in five critical steps: pre-sampling, sampling, post-sampling, analysis, and contamination control, ensuring precise results for human exposure to aM/NPs. Our findings consistently showed the highest M/NP concentrations in the kitchen and dining area across all seasons, with notably higher counts during the cold season. During this season, human activity primarily contributed to aM/NP levels in offices, kitchens, and dining areas, while in the warm season, external sources, along with human activity, contributed to increased particle counts. Laboratories consistently experienced primary exposure from human activity.

Conclusions: A comprehensive assessment of aM/NPs necessitates diverse techniques and contamination control measures. Human exposure to particles is influenced by factors such as human activity, cleaning schedules, and air quality.

3.14.P-Mo206 A Novel Sampling Approach for Airborne Microplastics: In Situ Sampling and Extraction

Fatma Nur Eraslan *and Eftade Emine Gaga, Environmental Engineering, Eskisehir Technical University, Turkey*

Many analytical difficulties are encountered when determining micro/nano plastics in air using conventional atmospheric particulate matter sampling methods such as high-volume air samplers or impactors. The small size and very large number of microplastics (MPs) in the air make it difficult to use extraction methods used in the literature for other environmental matrices in air samples. The aim of this study is to design and develop a novel sampler to collect and extract airborne MPs from atmospheric particles in situ. For this purpose, two separation funnels were connected in series to an air pump. While atmospheric particles settled to the bottom of the separation liquid due to their higher density and coarse structure, airborne MPs were collected on the surface of the separation liquid due to their lower density. Two salt solutions with different densities (NaCl: 1.2 g/cm^3 and $ZnCl_2$: 1.6 g/cm^3) in all possible combinations were put in separation funnels connected in series for in situ sampling of MPs from the air. The air was sucked with a flow rate of 5 L/dk, and both fractions were filtered onto a Polycarbonate filter and then visually analyzed using a stereomicroscope. According to preliminary findings, the percentage of total MP collected on the solution surfaces was for NaCl-NaCl, NaCl-$ZnCl_2$, $ZnCl_2$-NaCl, and $ZnCl_2$-$ZnCl_2$ combinations, 75.69%, 51.28%, 81.56%, and 85.80%, respectively. Despite some minor settling of MPs, the presence of $ZnCl_2$ solution in both separation funnels proved to be more effective in collecting and separating than other alternatives. Fibers were the most prevalent form of MPs in all samples and the most abundant MPs were observed in blue, transparent, and yellow colors, with the most abundant range of MPs were 100-500 μm. This new MPs sampler presents a practical approach for the efficient collection of airborne MPs and a pioneering idea to avoid positive and negative contamination from pre-treatments.

Keywords: Active sampling, Airborne microplastics, Method development, Novel sampler for MPs

3.14.P-Mo207 Impact of Microplastic Air Pollution From Intensive Agriculture in South-Eastern Spain

Adrián Rosa García[1]*, Laura Cortés Corrales*[1]*, Victor Manuel Cutillas*[1]*, Alfredo Alcayde-García*[2]*, Maria Jesus Martinez Bueno*[1] *and Amadeo Rodriguez Fernández-Alba*[1]*, (1)Chemistry and Physics Department, University of Almería, Spain, (2)Engineering Department, University of Almería, Spain*

The atmosphere is currently recognized as a major vector of long-distance microplastics (MPs) transport. The major sources of airborne MPs are the synthetic clothing, furniture, building materials, abrasion of rubber tires and city dust. However, the knowledge about the concentrations of airborne MPs worldwide is still limited, due to the lack of data and standardized protocol for their extraction and quantification.

On the other hand, during the last 20 years, the production of vegetables in a protected environment has contributed importantly to the national economies in Mediterranean regions, especially in the Spanish province of Almería, which has the largest area covered by greenhouses in the world. The construction of greenhouses requires the use of many synthetic materials, which are used for roofing, mulching, ropes, and clips to hold plants, among others. This has led to the production of large amounts of plastic residue. Thus, the main objective of this work was evaluating the impact of plastic pollution due to intensive agriculture in this area.

For that, a MP passive sampler was developed to give a more comprehensive information about the presence of MPs in the atmosphere around greenhouses. The device consisted of a funnel constructed by a 3D printer containing a stainless-steel filter of 25 µm and 30 cm of diameter. A continuous record of the air flow adapter to a flowmeter provided an accurate estimation of the concentration of the MPs per m^3. Air samples were taken inside and outside a greenhouse, as well as at an altitude of 100 m to compare the extent to which intensive greenhouse agriculture affects to the airborne MP content. A stereomicroscope and a micro-FTIR were used to identify the number of MPs and classify them in terms of morphology, color, and type.

The results revealed that the number of plastic particles was lower at 100 m height than at ground level (36 items/m^3 and 70 items/m^3, respectively). The average total area of MPs was around 140 µm^2/m^3 at 100 m altitude and 310 µm^2/m^3 at greenhouse level. Fragments were the most detected particles, followed by fibres, and films. The main colours found were blue, black and red. Up to a total of 9 different synthetic polymers were identified by FTIR analysis. PP, PA, and PE were the most frequent polymers detected in the samples analysed.

3.14.P-Mo208 Arctic Airborne Pollution: Tracking Microplastics and Plastic-Associated Contaminants in Canadian Snowfall

Alejandra Granados Galvan, Ph.D. Student[1], *A H M Enamul Kabir*[2], *Amila O. De Silva*[3], *Liisa Jantunen*[4], *Derek C.G. Muir*[5], *Huixiang Xie*[2], *Youssouf D. Soubaneh*[6], *Peter Amarualik*[7] *and Zhe Lu*[2], *(1)Institut des Sciences de la Mer de Rimouski, University of Quebec at Rimouski (UQAR), Rimouski, Canada, (2)Institut des Sciences de la Mer de Rimouski (ISMER), University of Quebec at Rimouski (UQAR), Canada, (3)Aquatic Contaminants Research Division, Environment and Climate Change Canada, Canada, (4)Atmospheric Science and Technology, Environment and Climate Change Canada, Canada, (5)Air Quality Processes Research Section, Environment and Climate Change Canada, Canada, (6)Département de Biologie, Chimie et Géographie, University of Quebec at Rimouski (UQAR), Canada, (7)Resolute Bay, Canada*

Plastic pollution produces adverse impacts caused by plastic pieces, additives, and chemicals adsorbed on plastics in the environment. Atmospheric deposition, particularly through snowfall, facilitates the infiltration of airborne microplastics (1 µm - 5 mm) and plastic-associated contaminants into soil and aquatic ecosystems. However, little is known about how microplastics and plastic-associated contaminants deposit into the Canadian Arctic via atmospheric deposition. Therefore, this study investigated the occurrence and distribution of microplastics and three groups of plastic-associated contaminants: organophosphate esters (OPEs), per- and poly-fluoroalkyl substances (PFASs), and benzotriazole UV stabilizers (BZT-UVs) in Canadian Arctic snow. Samples were collected between February 2020 and May 2021 from Little Fox Lake (Yukon; n=6), Yellowknife (Northwest Territories; n=5), Cornwallis Island (Nunavut; n=9), and Alert (Nunavut; n=15). We employed filtration (>20 µm), microscopic visualization, and FTIR for microplastic analysis. Plastic-associated contaminants were extracted by solid phase extraction and analyzed by liquid chromatography-tandem mass spectrometry or gas chromatography coupled to triple quadrupole mass spectrometry. The microplastic abundances were as follows: Cornwallis Island (50 ± 10 n/L) (counts per L, mean ± S.E.), Alert (25 ± 7 n/L), Little Fox Lake (17 ± 8 n/L), and Yellowknife (12 ± 3 n/L). Prevalent shapes included fibers (48%), fragments (42%), and films (9%), with an average length of 695 ± 56 µm (mean ± S.E.). Analysis revealed 22 plastic polymers, with polypropylene (30%) and polyester (25%) as dominant. Microplastic deposition flux estimated at Alert was 57±9 microplastics/day/m^2 between February 2020 and May 2020. Yellowknife and Cornwallis Island samples were analyzed for OPEs and PFASs. OPEs and PFASs were frequently detected (>75%) in the samples, with a mean concentration of Σ_{26}OPEs 97 ± 5 ng/L and Σ_{23}PFASs 3.5 ± 0.3 ng/L. Preliminary findings showed a negative correlation between total microplastics and dissolved triethyl phosphate concentration, but no correlation was observed with other analyzed OPEs or PFASs. The analysis of BZT-UVs is currently underway. Upon completion of data analysis, our study will examine relationships among microplastics, OPEs, PFASs, and BZT-UVs, increasing baseline knowledge on the transport of microplastics and plastic-associated contaminants into the Canadian Arctic.

3.14.P-Mo209 Small microplastics (<100 µm) in the urban atmosphere: a comparison between aerosol and wet- dry depositions

Beatrice Rosso[1], *Elena Gregoris*[2], *Barbara Bravo*[3], *Carlo Barbante*[2], *Andrea Gambaro*[1] *and Fabiana Corami*[4], *(1)Department of Environmental Sciences, Informatics, and Statistics, Ca' Foscari University of Venice, Italy, (2)National Research Council (CNR), Institute of Polar Science (ISP), Italy, (3)Thermo Fisher Scientific, Italy, (4)Italian National Research Council (CNR), Italy*

MPs (microplastics) have been found widely in terrestrial to aquatic ecosystems; however, only recently has greater scientific attention been focused on the presence of MPs in the atmosphere and their potential role in human health implications. Hence, the atmosphere is considered one of the most important pathways for the transport of emerging contaminants, including the smallest size of MPs (SMPs <100 µm), since they are easy to be transported through the air circulation and inhaled by humans and biota. However, the SMP fluxes from aerosol to the ground due to the wet and dry depositions are still unknown. In our study, we provide an entire SMP dataset for aerosol and wet/dry depositions collected in an urban area to understand better their fluxes in an urban atmospheric system, employing the same methodology with a QA/QC (Quality assurance and quality control) protocol. Aerosol and wet/dry deposition samples were collected in three different campaigns from winter 2021 to winter 2022 near Venice, Italy. The sampling was carried out on the roof of the scientific campus of Ca' Foscari University of Venice in Mestre City. Then, a pre-treatment procedure for each matrix was performed using an oleo-extraction method and a quantification and chemical identification of SMPs was carried out using a MicroFTIR. The SMP's complete database of abundance, weight, aspect ratio, polymer typology and size was obtained for each matrix in different seasons employing the same method. Different urban source inputs involved in the atmosphere were hypnotized analyzing the polymer typologies in each matrix. Regarding the seasonality evaluation trend, the SMPs occurrence was always higher in winter periods than in summer for both aerosol and wet/dry depositions. The majority of SMPs were confirmed to be less than 100 µm, Further, it was observed a decrease in airborne SMP abundance after each rainfall event. Hence, comparing wet and dry depositions, the most contribution derives properly from wet deposition, confirming their potential role in SMP removal due to the scavenging effect, greater than in dry periods. Also, even precipitation with a low intensity would facilitate the deposition of airborne SMPs from the atmosphere by wet depositions. Hence, the contribution of SMPs in the atmosphere was confirmed to be an important pathway that contributes to their transport in terrestrial and aquatic compartments, with potential implications for all ecosystems.

3.14.P-Mo210 Control of Microplastic Pollution Though Beehive Colonies

Laura Cortés Corrales[1]*, Jose Javier Flores Morales*[1]*, Adrián Rosa García*[1]*, Jozef van der Steen*[2]*, Flemming Vejsnæs*[3]*, Maria Jesus Martinez Bueno*[1] *and Amadeo Rodriguez Fernández-Alba*[1]*, (1)Chemistry and Physics Department, University of Almería, Spain, (2)AlveusAB, Netherlands, (3)Danish Beekeepers Association, Denmark*

Recent scientific papers have reported on the usefulness of honeybee hives as biological samplers for xenobiotic pollutants monitoring such as pesticides as they bring back these pollutants to the hive from forage areas. However, their use for the control of microplastics (MPs) has not yet been addressed.

In this study, several modes of MPs sampling, such as bees and pollen, have been evaluated together with a novel in-hive passive sampler, called APITrap (Apiarian-Trap). API-Trap basically consist of a rigid plastic polyethylene with a polyvinyl acetate adhesive, protected by a metallic net of 2 mm, where the MPs present in the hive are trapped. The evaluation of the different sampling modes for MPS were performed on groups of 25 bees, 2 grams of pollen, and APITrap device after two weeks placed inside the hive. Four surveillance programmes were carried out in five different apiaries in Denmark. The samples were analysed by stereomicroscopy for identifying the number of MPs and classify them in terms of morphology, color, and type (fibre, fragment, film). After morphological identification, a micro-FTIR was used to classify and identify the polymer types.

The results demonstrated a better reproducibility of the APITrap sampler compared to the analysis of honeybee and pollen samples. The average number of MPs detected over four monitoring studies ranged from 39 to 79 items in APITrap, from 6 to 9 in bees and from 1 to 4 in pollen samples. Fibres were the most detected shape, with mean detection frequency of 92%, followed by fragments (~5%) and films (~3%) in APITrap. Black, blue, green and red were the main colours of the MPs detected. FTIR analysis confirmed the presence of up to seven different synthetic polymers, been the most frequent polyethylene terephthalate (PET), followed by polypropylene (PP), polyethylene (PE) and polyacrylonitrile (PAN).

3.14.P-Mo211 Tracking Urban Sources of Microplastic Contamination: Insights From the City of Modena, Italy

Elisa Bergami[1,2]*, Giorgio Veratti*[3]*, Valentina Ferrari*[1]*, Marco Scaramelli*[1,2]*, Alessandro Bigi*[3]*, Sergio Teggi*[3]*, Grazia Ghermandi*[3]*, Sara Righi*[1]*, Roberto Simonini*[1] *and Daniela Prevedelli*[1]*, (1)Department of Life Sciences, University of Modena and Reggio Emilia, Italy, (2)Nbfc, National Biodiversity Future Center, Italy, (3)Department of Engineering “Enzo Ferrari”, University of Modena and Reggio Emilia, Italy*

Urban settings are densely populated areas that may act as a significant source of microplastics (MP, < 5 mm), such as tire wear particles (TWP) and textile microfibers. Notwithstanding, evidence on airborne MP in urban outdoor environments is confined to a handful of reports, limiting the application of MP dispersion modelling as well as environmental risk assessment. This study aims at investigating the occurrence and small-scale transport of airborne MP in Modena, a model mid-sized city located in the Po Valley (Italy).

Active and passive sampling was conducted at two sites (comparing traffic *vs* background conditions), during wintertime and summer. In the two periods, daily active measurements were taken for 1 week using low volume active pumped samplers (size cut-off <10µm). Sub-samples (10x10mm^2) of the active filters were examined using different techniques as Scanning Electron Microscopy Energy Dispersive X-ray (SEM-EDX). Passive deposition samples were collected using stainless steel funnels equipped with glass bottles. After 14 days, passive samples were concentrated and treated to remove organic matter. Finally, samples deposited onto glass-fiber filters were examined under optical digital microscope for semi-automatic MP count and measurement. Sub-samples were further analysed by Raman microscopy (µRaman) for the polymer identification. In parallel to MP analysis, atmospheric dispersion simulations of tire wear were conducted at the city scale to estimate the spatial distribution of TWP concentrations and deposition.

In active samples, SEM-EDX confirmed the contribution of TWP in the PM_{10} fraction in Modena. Likewise, in passive samples, a prevalence of TWP was found. Other MP retrieved from passive samples in the winter campaign mainly included fibers (76%) and fragments (34%). µRaman showed that petroleum-based and (semi)synthetic textile polymers dominated the MP cont. Other urban emission sources identified were building materials, as shown by the presence of varnish fragments. As 26% of the initial MP candidates resulted of cellulose, further processing of passive samples resulted crucial to minimize matrix effects at µRaman. Ongoing analyses on active and passive samples from the summer campaign will allow to compare MP deposition rates and abundances at the two sites and time periods. Findings from the MP dispersion modelling will inform strategies to reduce MP emissions in urban environments.

3.14.P-Mo212 Transfer of Micro- and Nanoplastics via Sea Spray Aerosols and Estimate of Human Exposure

*Silke Lambert[1], Maaike Vercauteren, PhD[2], **Ana I Catarino**[3], Yunmeng Li[1,4], Josefien Van Landuyt[5], Nico Boon[5], Gert Everaert[3], Maarten De Rijcke[4], Colin Janssen[1,6] and Jana Asselman[1], (1)Blue Growth Research Lab, Ghent University (UGent), Belgium, (2)Ghent University (UGent), Belgium, (3)Ocean & human health, Flanders Marine Institute (VLIZ), Belgium, (4)Flanders Marine Institute (VLIZ), Belgium, (5)Center for Microbial Ecology and Technology (CMET), Ghent University, Belgium, (6)GhEnToxLab, Ghent University (UGent), Belgium*

Little information is available on the possibilities of micro- and nanoplastics (MNPs) to be introduced in the atmosphere via sea spray aerosols (SSAs) and more specifically about the effects plastic characteristics have on this aerosolization process. Currently, the importance of the transport of MNPs via SSAs as a possible new exposure route for human health is unknown. Therefore, the aim of this explorative study was two-fold: (1) to examine if the polymer types, sizes and concentrations of MNPs affect the aerosolization process, (2) to perform a preliminary exposure assessment for humans based on the results of the aforementioned experiment.

This study used a laboratory-based bubble bursting mechanism, simulating the aerosolization process in the sea. Four different series of experiments were set up, to study the influence of plastic size, polymer type, plastic concentration and seawater characteristics on the aerosolization process. To determine the potential human exposure to microplastics via inhalation of SSAs, the results of the experiments in the lab were extrapolated to the field using the concentration of plastics in the sea and the volume of inhaled aerosols.

Our results indicate an enrichment of MNPs in SSAs compared to surface and bulk seawater. Aerosolization increased with decreasing plastic size and with decreasing concentration, and was higher for the higher density polymer type. Besides, the use of surface seawater instead of bulk seawater seemed to influence the aerosolization process. Our human exposure estimate shows that in comparison with reported inhaled concentrations in urban and indoor environments, this exposure route seems negligible for microplastics. Following the business as usual scenario on plastic pollution, the daily inhalation in 2100 is estimated to increase but still be far below 1 particle per day. A variation in exposure concentration can be seen due to weather conditions influencing the aerosol formation. Currently, due to the lack of environmental concentrations of nanoplastics, it is impossible to do a similar extrapolation for nanoplastics.

This study shows that aerosolization is a new plastic transport pathway to take into account, but seems negligible for microplastics in terms of human exposure. An estimation is needed for nanoplastics as a higher aerosolization and a higher exposure is expected.

3.14.P-Mo213 Having Fun and Raising Awareness: Italian Students Monitor Airborne Microplastic in Indoor and Outdoor School Environments

***Elisa Bergami**, Sara Righi, Valentina Ferrari, Marco Scaramelli, Fabiana Cancello and Daniela Prevedelli, Department of Life Sciences, University of Modena and Reggio Emilia, Italy*

Densely populated areas are a significant source of microplastics (MP, < 5 mm), for example considering tire wear particles and textile fibres, easily dispersed through the air. However, public perception on MP as an environmental issue is still confined mostly to seas and oceans. Thus, while it is urgent to increase MP monitoring effort in urban environments to estimate MP levels and identify major sources and pathways, it is also important to inform the public about our own role in spreading MP contamination. To fulfil these objectives, we present the activities carried out by the University of Modena and Reggio Emilia (UNIMORE) at a local scale, which allowed to both collect scientific data on airborne MP in urban environments and raise awareness among young people.

The perception, knowledge and attitude of the public on MP contamination was initially assessed through the administration of a voluntary-based online survey (October 2022) in the area of Modena (Italy), involving young people, firms, academia and environmental associations. The educational program «Taking microplastics into the class» was then launched in collaboration with the scientific high school in Applied science in Modena to collect data on MP passive deposition in indoor and outdoor sites at the school, estimate MP exposure in high school students and promote sustainable and pro-environmental behaviours. The program included seminars about plastic pollution and an active participation of the students in MP monitoring at school through: clean-up activities, air passive sampling, sample processing (filtration) and analysis (MP count and classification using ImageJ) and presentation of the results. UNIMORE researchers coordinated field and laboratory activities, stressing the importance of quality control measures (using field and laboratory blanks) and performing additional analyses when needed (e.g., sample oxidative treatment, acquiring MP images and identifying polymers through Micro-Raman spectroscopy).

In the questionnaire, 92.8% of the 523 respondents expressed high level of concern about MP contamination, but a lack of knowledge about MP sources in urban areas was found. The activities carried out in the high school allowed to collect first data on MP level, types and polymers found in indoor (1 site) and outdoor (2 sites) school environments, in comparison, and promoting public awareness in young citizens about the manifold MP sources and their transport in urban environments.

3.14.P-Mo214 Atmospheric Microplastic in the Arctic and Mainland Norway; occurence, composition and sources

Dorte Herzke[1]*, Natascha Schmidt*[2]*, Sabine Eckhardt*[1]*, Dorothea Schulze*[2] *and Nikolaos Evangeliou*[1]*, (1)Norwegian Institute for Air Research (NILU), Norway, (2)Climate and Environmental Research Institute NILU, Norway*

The majority of studies on the transport of microplastics to the Arctic have focused on ocean pathways. Ocean currents originating in the south of Europe have been proposed to function as major transport routes, carrying microplastics from the more densely populated southern areas in Europe to the Arctic (Cózar et al., 2017; Tekman et al. 2020). However, given the limited empirical data and lack of harmonized methodologies for sample collection, it is not yet possible to estimate the magnitude, composition and sources of atmospheric microplastics transported to the Arctic.

Here we present the outcomes of a study applying passive and active air-samplers for wet and dry deposition on two remote monitoring stations, Ny Ålesund (Svalbard) in the High Norwegian Arctic, and at Birkenes in mainland Norway in 2022 and 2023. We complement the results with active airsamples collected on cruises along the East- and Westcoast of Svalbard in 2021 and 2023, representing Arctic offshore samples.

All samples were handled under strict QA/QC requirements, with all sample treatment occurring in controlled conditions of clean rooms and laminar flow cabinets. After filtration on a GF/F filter, polymer determination was performed by pyr-GC/MS. The analytical method, adapted from Ishimura et al. and Matsueda et al., uses calcium carbonate as a catalyst for the simultaneous quantification of 10 different polymers and SBR rubber, originating from tires. With this adapted method it is possible to quantify PMMA (poly(methyl methacrylate)), Nylon-6 (polycaproamide), Nylon-6,6 (poly(hexamethylene adipamide)), PP (polypropylene), PVC (poly(vinyl chloride)), PC (polycarbonate), PET (poly(ethylene terephthalate)), PE (polyethylene), ABS (acetonitrile-butadiene-styrene copolymer) as well as PS (polystyrene) and PTFE (polytetrafluoroethene). All samples were accompanied with field and procedural blanks.

Results were further analysed with respect to their spatial origin and long-range transport using the Lagrangian particle dispersion model FLEXPART. Rubber from car tires and Nylon dominated most samples, followed by PMMA and PVC. The estimated concentrations were fitting well on most timepoints, with some underestimation, indicating some missing sources in the model.

3.14.P-Mo215 Atmospheric Pathways: A Global Comprehensive Study on Microplastic Deposition

Perrine Julie Florent[1]*, Benjamin I Collins*[2]*, Martine Graf*[3]*, Michaela Reay*[4]*, David R Chadwick*[2] *and Davey L Jones*[2]*, (1)Bangor University, United Kingdom, (2)School of Environmental & Natural Sciences, Bangor University, United Kingdom, (3)School of Natural & Environmental Sciences, Bangor University, United Kingdom, (4)Organic Geochemistry Unit, School of Chemistry, University of Bristol, United Kingdom*

Microplastic contamination is a pressing environmental concern with repercussions for ecosystems and human well-being. This study conducts a thorough analysis of atmospheric microplastic (MP) deposition, providing valuable insights into the dynamics of this emerging pollutant. While aquatic compartments have been extensively studied for MPs, their presence in the atmosphere remains underexplored. This research aims to bridge this gap by evaluating atmospheric MPs, enhancing our understanding of their distribution and transport. The main objective is to assess the characteristics and prevalence of MPs in the atmosphere in North Wales, UK. Concurrently, the study identifies MPs in the soil, facilitating a comprehensive comparison between the two environments. This analysis contributes to conclusions about potential atmospheric MP deposition onto the soil, offering insights into their transport dynamics. The sampling approach involves collecting both rainfall and soil samples over a year, with fluorescence microscopy assessing the quantity, shape, and size of MPs, and Laser Direct Infrared Imaging (LDIR) identifying their polymer composition. Our preliminary findings indicated a notable prevalence of small MPs (20-40 microns), with the abundance diminishing as the MP size increased. The temporal variations of MPs primarily aligned with the rainfall pattern, though wind emerged as a crucial factor during periods of low-intensity precipitation. In addition, the presence of MPs in the soil is anticipated to be primarily affected by vegetation coverage, and the deposition is expected to rise with increased precipitation. This comprehensive examination enhances our understanding of the environmental fate of MPs, advancing knowledge of atmospheric MP pollution and emphasizing the need for a thorough approach. In addition, this research involves global partnerships (China, Vietnam, Egypt, India, and Sri Lanka) to enable the comparison of atmospheric MP deposition across different climate zones. This collaborative effort expands the study's scope, allowing for insights into how atmospheric MPs vary globally. By fostering international cooperation, the research aims to contribute valuable data for a more nuanced understanding of the impact of atmospheric MPs on diverse environments.

3.14.P-Mo216 Human exposure to airborne microplastics in Australian indoor air

Kushani Perera[1]*, Shima Ziajahromi*[1]*, Susan Bengtson Nash*[2] *and Frederic Leusch*[1]*, (1)Griffith University, Australian Rivers Institute, School of Environment and Science, Australia, (2)Centre of Planetary Health and Food Security, Griffith University, Australia*

People spend more than 90% of their time indoors, where they can be exposed to atmospheric microplastics (AMPs). Despite the importance of indoor air quality, little is known about human exposure to AMPs in indoor environments. Hence, it is crucial to identify and characterize AMPs in indoor air to understand possible human exposure levels and any associated health impacts. This study used an active sampling approach to collect AMPs (20 – 5000 µm) from seven different indoor locations across Southeast Queensland, Australia, where people spend most of their time. The annual human exposure levels to AMPs were calculated using scenario-specific activity levels. These activity levels were used as human exposure to AMPs varies among individuals as they spend their time in different indoor locations with different activity levels and experience different inhalation rates. The results revealed that a childcare site had the highest AMP concentration (2.25 ± 0.38 particles/m^3), followed by an office (1.20 ± 0.14 particles/m^3) and a school. Of the selected indoor locations, the vehicle had the lowest indoor MP concentration at 0.20 ± 0.20 particles/m^3. 98% of AMPs were fibers ranging from 71 to 4950 µm in length, and the remaining were fragments. Polyethylene terephthalate (PET) was the most prominent polymer type found across different sites. Our findings also showed that males aged 18 to 64 had the highest AMP exposure at 3187 ± 594 particles/year, followed by males ≥ 65 years. The females between the ages of 5 and 17 obtained the lowest exposure of 1928 ± 549 particles/year. This study is the first to report AMP concentrations in Australian indoor locations where people spend most of their time. Our findings highlight direct human exposure to MPs via indoor air. Further research should evaluate possible human health risks upon inhalation of AMPs.

3.14.P-Mo217 Extraction of Microplastics at High Temperature and Pressure for Subsequent Analysis of Atmospheric Aerosol by Pyrolysis Gas Chromatography–Mass Spectrometry

*Giulia Vitale[1], **Beatrice Rosso**[1], Andrea Gambaro[1], Fabiana Corami[2] and Elena Gregoris[2], (1)Department of Environmental Sciences, Informatics, and Statistics, Ca' Foscari University of Venice, Italy, (2)National Research Council (CNR), Institute of Polar Science (ISP), Italy*

Microplastics (MPs) are emerging pollutants of great concern since they are widely distributed in the environment. Nevertheless, their occurrence, concentration and distribution in the atmospheric aerosol is understudied.

One of the main issues related to the identification and quantification of MPs in the environment is the absence of standard methods, neither for the instrumental analysis nor for the pre-treatment procedures. Specifically, pre-treatment is crucial to produce a suitable sample to undergo subsequent analysis. The analysis of MPs by pyrolysis gas chromatography-mass spectrometry (Py-GC/MS) has the advantage of not requiring the maintenance of the morphological characteristics of ambient MPs during the pre-treatment. A possible way for isolating MPs from aerosol filters could be an extraction with organic solvents at high temperatures and pressure. This technique has been proposed by a few studies but has not been deeply investigated.

The aim of this work is to assess the feasibility of solvent extraction as a pre-treatment procedure for the analysis of MPs in atmospheric aerosol by using Py-GC/MS, avoiding the problem of the low solubility of plastics by reaching high temperatures (about 180°C).

The accelerated solvent extractor Thermo ASE 350 was used in this work. The extraction was conducted in dichloromethane, varying the extraction parameters, such as the extraction temperature, the static time, and the number of extraction cycles, to get information about their effect – alone or interacting with each other – on the extraction yield of plastics.

The preliminary results obtained with standard polyethylene showed a higher effect of the temperature on the extraction yield than of the other parameters; the static time seemed not to produce a yield enhancement, while the effect of the cycle number is strictly related to the other parameters (i.e. the effect of cycle number is higher at low temperatures, nearly absent at high temperatures). These results suggested that it is not necessary to conduct the extraction for a long time or with a high number of cycles - with subsequent solvent consumption and waste production - to get a satisfying yield, but a fast extraction at high temperatures may be preferable.

These findings shed light on which could be the best conditions for extracting microplastics with organic solvents and contribute to the development of a method for MP analysis in the atmospheric aerosol by using Py-GC/MS.

3.14.P-Mo218 Assessment of the impact of local human activity on microplastic atmospheric deposition

***Max Beaurepaire**[1], Rachid Dris[2], Mathieu Goriaux[3], Ngoc-Nam PHUONG[3], Sophie Ricordel[3], Bruno Tassin[2] and Johnny Gasperi[3], (1)Water Environment and Urban Systems Laboratory (LEESU), France, (2)Leesu, Ecole des Ponts ParisTech, Université Paris Est Créteil, France, (3)Gustave Eiffel University, France*

The study of microplastic transfer in the atmospheric compartment is gaining traction as a scientific field, as it is likely to represent a major transport vector for microplastics into the environment. In this work, atmospheric deposition of microplastics was monitored following the same methodology at four different sampling sites characterized by varying levels and types of human activity. Two sampling sites were located in urban environments, while the other two were surrounded by agricultural activities. Two sampling sites were close to the Paris urban area and were monitored for 5 months, while the other two were close to the metropolis of Nantes, west of France and were monitored for 12 months.

After collection, all samples underwent a treatment consisting of a density-based separation and an oxidative digestion, before they were analysed using an automated µFTIR imaging analysis with a Nicolet iN10 by Thermo Scientific, identifying particles down to a size of 25 µm.

Median microplastic deposition rates of 60.2 and 29.2 MP m^{-2} d^{-1} were measured in the urban sites, against medians of 40.3 and 14.3 MP m^{-2} d^{-1} in the rural sites. In each metropolitan area, lower deposition rates were measured at rural sites than at urban sites, regardless of the sampling period. The polymer types were similar between sites, dominated by polypropylene, polyethylene and polystyrene. Smaller particles represented the majority of the identified microplastics. Differences were however noted between sites, with PE more present in rural sites and a higher diversity of microplastics in the urban sites.

No clear impact of precipitations or wind direction on microplastic deposition was found, suggesting the differences in human activity were the dominant factor.

3.14.P-Mo219 Microplastics Reference Materials: Advancing Environmental Monitoring and Research
Jon Eigill Johansen[1]*, Marie-Luoise Tambo Magni*[1]*, John Magnus Cotton Breivik*[1]*, Craig McKenzie*[1]*, Elena Martinez-Frances*[2]*, Bert van Bavel*[2] *and Huiling Liu*[1]*, (1)Chiron AS, Norway, (2)Norwegian Institute for Water Research (NIVA), Norway*
Microplastic pollution has emerged as a global environmental concern, posing potential risks to human health and ecosystems. Accurate and reliable analytical methods are essential for assessing the extent, fate, and effects of microplastic contamination in the environment. Microplastics reference materials play a crucial role in ensuring the quality and consistency of analytical measurements, enabling researchers to confidently evaluate microplastic concentrations and compare results across studies.

Chiron, a leading provider of microplastics reference materials, offers a comprehensive range of neat microplastic particles and tablets covering a variety of commonly encountered microplastic polymers. These reference materials are rigorously characterized and validated to ensure their authenticity, size, and composition, providing researchers with the tools they need to confidently interpret their analytical data.

This presentation will showcase Chiron's commitment to advancing environmental monitoring and research through the development of high-quality microplastics reference materials. We will discuss the production process, characterization methods, and validation procedures for our reference materials, highlighting their importance in ensuring reliable and comparable microplastic measurements.

3.14.P-Mo220 Deposition of Atmospheric Microplastics in an Urban Environment
Mine Sağdıç Ulusoy *and Eftade Emine Gaga, Environmental Engineering, Eskisehir Technical University, Turkey*
Atmospheric scavenging is known to play an important role in the transport and fate of atmospheric pollutants. Studies have shown that atmospheric microplastics are effectively washed out of the atmosphere by wet deposition. However, dry deposition of microplastics, which is another effective mechanism for the transport of atmospheric MPs, is much less common in the literature. Deposition samples were collected from the urban catchment of Eskişehir, Turkey, using a wet-only sampler. A certain amount of the collected samples was taken for analysis. Centrifugation and oxidative extraction methods were used to remove organic materials in the pre-treatment of the samples. Samples filtered through the polycarbonate filter after pre-treatment were analyzed using a stereomicroscope. MPs were identified and sorted using ImageJ software based on their quantity, size, shape, and color. In preliminary studies, the average dry deposition flux according to the stereomicroscope results was 6310 MP/m^2/d for all suspected particles and 995 MP/m^2/d for fiber particles. It was observed that the amount of MPs varied between the samples. The subsequent phases of the study will involve the chemical characterization of the MPs in deposition samples that have been visually analyzed. The characterization of the MPs will be used to investigate the scavenging of the MPs by wet and dry deposition.

Keywords: *Atmospheric Microplastics, Dry Deposition, Scavenging, Precipitation, Urban*

3.14.P-Mo221 Atmospheric Microplastics in Two Norwegian Cities, Composition and Temporal Trends
Natascha Schmidt[1]*, Dorte Herzke*[2]*, Dorothea Schulze*[1]*, Sam Celentano*[1] *and Xinyi Zeng*[3]*, (1)Climate and Environmental Research Institute NILU, Norway, (2)Norwegian Institute for Air Research (NILU), Norway, (3)College of Environmental Science and Engineering, Tongji University, China*
Small microplastic (MP) particles can be subject to atmospheric transportation or wash out of the atmosphere during precipitation. A growing amount of evidence suggests that MPs are ubiquitous in the air as they are in other environmental compartments, such as the marine environment. However, little is known on local sources and temporal trends.

Here, we present data on the occurrence and composition of atmospheric microplastics in two Norwegian cities, Oslo and Tromsø. Samples were collected in summer/autumn 2023 and include active air samples as well as passive (deposition) samples, with each sampling period covering 14 days. Samples were analyzed for 10 polymers using pyrolysis-gas chromatography–mass spectrometry (Py-GC/MS). Styrene-butadiene rubber (SBR) was the dominant polymer in samples from both cities, representing 80-90% by mass of detected polymers in all samples. This suggests that car traffic is the predominant source of airborne microplastic contamination in urban areas, independent of the longitude of the study area. The population size of Tromsø is roughly 10 times less than the population size of Oslo, but SBR concentrations were similar or only slightly lower in samples from Tromsø. Possible explanations might be bad road conditions in Tromsø (as typical for cold climate regions) leading to a higher production of tire and road wear particles (TRWP) or a higher availability and use of public transportation in the capital.

3.14.P-Mo222 Investigating the Case of Microfibre Pollution in Air: Which Fibres are Guilty?

***Chimdia KeChi-Okafor**[1], Kelly J Sheridan[1], Neil L Lant[2], John R Dean[3] and Anil Namdeo Prof[1], (1)Northumbria University, United Kingdom, (2)Procter & Gamble, Newcastle Innovation Centre, United Kingdom, (3)Department of Applied Sciences, Northumbria University, United Kingdom*

The increasing demand for fast fashion, characterised by rapid manufacturing cycles and disposability, has ushered in a culture in which garment care has become a significant determinant of the industry's environmental footprint. Emissions from drying processes, which release microfibres (MFs) into the air, have consequences for both indoor and outdoor environments, altering air quality indices and impacting human health. In contrast to the extensively researched field of washing machines, there is paucity of study in cloth dryers' impact. This study therefore aimed at assessing the effectiveness of MF capturing devices built internally within tumble dryers or added during drying process and the role of laundered garments in the prevalence of MF in air when more than one garment type is tumble dryed together.

10 garments made from 100% cotton and 10 garments made from 100% polyester were all washed and subsequently dried together in a tumble dryer. The efficacy of lint filters (components of tumble dryers) of varying pore sizes and dryer sheets (external MF capturing device) was determined. In all the experiments, cotton MFs were released significantly more than polyester MFs.

This study evidences the contribution of vented tumble dryers to airborne MF pollution whilst highlighting that a garment's construction is a major determinant to the release of MFs available for polluting the air. Therefore, discussions around airborne MF pollution ought not be centred on synthetic fibres alone as any garment has the potential to contribute to this form of pollution which can be excerbated by the way it is constructed. Recommendations and new developments in the field based on an ongoing study through the IMPACT+ Network would be presented at the conference.

3.14.P-Mo223 Invisible Footprint of Climbing Shoes: Data From Indoor Facilities Reveal Unprecedented Exposure to Rubber Additives

***Thibault Masset**[1], Anya Sherman[2], Lukas Wimmer[2], Lea Ann Dailey[2], Thorsten Huffer[2], Florian Breider[3] and Thilo Hofmann[2], (1)EPFL, Switzerland, (2)University of Vienna, Austria, (3)Central Environment Laboratory, Ecole Polytechnique Fédérale de Lausanne – EPFL, Switzerland*

There is increasing research focused on rubber-derived chemicals (RDCs), predominantly originating from tire and road wear particles. Other consumer products also contain RDCs, but the overall human exposure to these compounds remains unknown. The soles of climbing shoes are highly engineered for specific properties, such as softness, flexibility, stiffness, and durability. Therefore, climbing shoes could be a contributor to human indoor exposure to RDCs, including potentially harmful substances such as benzothiazoles, p-phenylenediamines (PPDs), and PPD-quinones. In 2018, an estimated 1.5% of UK population, and about 4.4% of the US population visited indoor climbing halls. Therefore, indoor climbing halls might be a relevant but previously overlooked micro-environment where a noteworthy portion of the population, including employees, is exposed to inhalable rubber particles and the organic RDCs they contain. We show that shoes samples (n=30) contain high but variable concentrations of RDCs (mean 711 µg/g). In indoor climbing halls, abrasion particles from these shoes can be suspended in the air. Dust (n = 5) and air samples (n = 2) were collected in two climbing halls and particulate matter in the inhalable and respirable fractions were analyzed for 15 RDCs. Mean PM concentrations were 1295 $\mu g/m^3$ in the inhalable and 970 $\mu g/m^3$ in the respirable fractions, which exceed WHO guidelines for indoor PM10 concentrations of 50 $\mu g/m^3$. Concentrations in dust (16 to 43 µg/g) and particulate matter (23 to 35 ng/m^3) exceed those reported from other environments. For most RDCs, estimated daily intake via inhalation (EDI_{inh}) for adults visiting or working in these facilities exceeds the EDI from other sources. This highlights the potential concerns with using large amounts of rubber additives in consumer products. RDCs profiles in shoe samples differed from those in dust and particulate matter, indicating that RDCs are chemically transformed in airborne rubber particles, which we confirmed by performing lab-controlled oxidation experiments. This finding has broader implications as similar transformations are likely to occur in airborne tire wear particles. Future research should address the leaching and bioavailability of RDCs within the human body as well as the toxicological risk that RDCs pose in the respiratory and gastrointestinal tracts.

3.14.P-Mo224 Occurrence and backtracking of microplastics in Northern Atlantic Air

*Isabel Goßmann[1], Dorte Herzke[2], Andreas Held[3], Janina Schulz[4], Vladimir Nikiforov[2], Christoph Georgi[5], Nikolaos Evangeliou[2], Sabine Eckhardt[2], Gunnar Gerdts[6], Oliver Wurl[7] and **Barbara Scholz-Boettcher**[1], (1)University of Oldenburg, Institute for Chemistry and Biology of the Marine Environment, Germany, (2)Norwegian Institute for Air Research (NILU), Norway, (3)Technical University Berlin, Chair of Environmental Chemistry and Air Research, Germany, (4)Institut for Chemistry and Biology of the Marine Environment, University of Oldenburg, Institute for Chemistry and Biology of the Marine Environment, Germany, (5)Bayer AG - Crop Science Division, Germany, (6)Alfred Wegener Institute Helmholtz-Center for Polar and Marine Research, Germany, (7)Carl von Ossietzky University of Oldenburg, Center for Marine Sensors, Institute*

for Chemistry and Biology of the Marine Environment (ICBM), Germany
By now microplastic (MP) pollution is shown to be omnipresent and background knowledge on their dispersion and enrichment behavior are of great interest. Meanwhile, the database for many environmental compartments is gradually becoming solid, except for remote areas such as the oceans when air masses become into focus. While sampling on land is comparatively easy to realize, areas, especially over the oceans, are difficult to access. To date, little is known about the pollution of the marine atmosphere with microplastics and tire wear particles. The very few studies available and they are almost exclusively particle-based. Mass-based ones are extremely rare and incomplete. The presented study is embedded in the JPI-Oceans FACTS project dealing with occurrence and transport of MP up to northern waters. During a research cruise in 2021 seven transects along the Norwegian coast up to Bear Island were actively sampled on the observation deck during steaming to prevent any ship based secondary contamination. The performance of two different sampling devices was evaluated. MP analysis and mass quantification was conducted using a by now established Py-GC/MS method referring to defined base polymer clusters (C-) related to specific base polymer building blocks. With careful reference to available field and laboratory blank values, MP was detected even in remote Artic areas with concentrations up to 37.5 ng MP m^{-3} air and a clear predominance of the PET cluster. In addition, car tire tread, and clusters of PS, PP, and PUR were detected more often. Using two independent "backtracking" models (HYSPLIT and FLEXPART) an attempt was made to reconstruct the origin of the air masses and to gain information about the origin of the measured MP from it. In addition to the more obvious aeolian transport of MP particles, the re-emission of MP from the ocean into the overlying air layers appears to be a relevant source in this context. Likewise, in particular the long-range transport of C-PET particles appears to be substantial. The range of detectable polymers, but also the risk of sample contamination, was closely linked to the particular sampling method used [1].

[1] Goßmann I., Herzke D., Held A., Schulz J., Nikiforov V., Georgi C., Evangeliou N., Eckhardt S., Gerdts G., Wurl O., Scholz-Böttcher B.M. 2023. Nature Communications (2023)14:3707, doi10.1038/s41467-023-39340-5.

3.14.P-Mo225 Extraction of Aged Bio-Microplastics from Compost Matrices: Method Development

***Sevil Vafadar Afshar**[1], Fabiana Corami[2], Beatrice Rosso[3] and Nanna B. Hartmann[1], (1)DTU Sustain, Technical University of Denmark (DTU), Denmark, (2)Italian National Research Council (CNR), Italy, (3)Department of Environmental Sciences, Informatics, and Statistics, Ca' Foscari University of Venice, Italy*
Biodegradable plastics have been seen as a promising alternative to conventional plastics, offering the potential to mitigate the environmental burdens associated with the latter at multiple stages of their lifecycle. Biodegradable plastics are often designed to be degradable in industrial waste management settings. However, current test methods to assess their degradability (e.g., during industrial composting) do not consider the potential for microplastic production if complete degradation is not reached. While extensive research has explored the presence and impact of microplastics from conventional plastics in various environments, a significant challenge lies in extracting and assessing microplastics originating from biodegradable plastics (bio-microplastics). Current methods for microplastic extraction employ chemicals that can be destructive to bio-microplastics, especially if they are aged. This challenge necessitates the development of specialized methodologies tailored to extract and quantify aged bio-microplastics. Detecting and analyzing bio-microplastics is crucial to understanding further biodegradable plastics' environmental fate and potential negative impacts. This study introduces the development of a novel method for extracting aged bio-microplastics from compost matrices. Utilizing the oleophilic nature of plastics, this method employs oil to extract microplastics. During the method development, varying parameters, including sample amount, amount of hydrogen peroxide (H_2O_2) used for the pretreatment, and oil type, were explored alongside pretreatment without H_2O_2. The quantification and simultaneous chemical characterization of microplastics were performed via µ-FTIR. The study aimed to provide methodological guidance on future procedures for isolating and analyzing bio-microplastics from complex matrices, such as compost. By addressing the limitations of existing microplastic extraction procedures, the study aims to shed light on the often-overlooked aspect of biodegradable plastic degradation and its potential contribution to microplastic pollution.

3.14.P-Mo226 What is in specks of highway road dust? Quantification and Chemical Characterization of Small microplastics (<100 µm) and Plastic additives

*Fabiana Corami[1], **Beatrice Rosso**[2], Barbara Bravo[3], Elena Gregoris[4], Carlo Barbante[4] and Andrea Gambaro[2], (1)Italian National Research Council (CNR), Italy, (2)Department of Environmental Sciences, Informatics, and Statistics, Ca' Foscari University of Venice, Italy, (3)Thermo Fisher Scientific, Italy, (4)National Research Council (CNR), Institute of Polar Science (ISP), Italy*
Highway road dust (HWRD) continuously accumulates on highways due to the traffic of vehicles; it is a composite miscellany of particles, and it is considered one of the primary sources of microplastics (MPs) in the atmosphere The wear of tires, bitumen, road marking paints used in road pavement, brake wear, vehicle emissions, soil from construction sites, atmospheric deposition, plastic or other materials debris, and road pavement made of recycled plastics are generally deposited in the HWRD.

In this study, a simultaneous quantification and chemical characterization of additives, plasticizers, natural and non-plastic synthetic fibers (APFs), and small microplastics (SMPs, <100 µm) in HWRD will be performed. The sampling procedure was optimized, as well as pretreatment (extraction, purification, and filtration) and analysis via Micro-FTIR. HWRD samples were collected during dry periods (at least 2 weeks after a rainfall event) from winter 2021 to winter 2022 from a trafficked highway in Italy.

A detailed protocol was designed to minimize potential plastic contamination of samples during sampling, transport of samples, pretreatment, and analysis. The pre-treatment procedure (oleoextraction, purification, and filtration) was optimized according to the one previously developed. The filters were then analyzed via Micro-FTIR, where identification and quantification via microscopic counting were performed simultaneously.

Among the polymers characterized and quantified, vinyl ester and polytetrafluoroethylene were predominant. Lubricants and plasticizers are the two most abundant categories, followed by vulcanizing agents, accelerators, and pre-vulcanizing retarders derived mainly from tires. A potential relation between APFs and SMPs in the different seasons was observed, as their concentration was lower in summer for both and higher in winter 2022.

Data from this study will be relevant in assessing the load of SMPs and APFs from highways, which is urgently necessary for a more accurate inclusion in emission inventories, receptor modeling, and health protection programs by policymakers, especially in air and water pollution policies, to prevent risks for human health.

3.14.P-Mo227 Tire Particles and Microplastics in Urban Road Dust: A Double Shot Pyrolysis-Gas Chromatography-Mass Spectrometry Analysis for Identification, Characterization and Quantification

V Fernández-González, C Moscoso-Pérez, E Concha-Graña, P López-Mahía and ***S Muniategui-Lorenzo****, Universidade da Coruna, Spain*

Road dust consists of a combination of organic and inorganic particles, among which Microplastics (MPs) were found to contribute up to 0.06% of dry mass within an urban city environment. MPs have been detected in road dust worldwide and their presence has been mainly attributed to the vehicle traffic, resulting in the fragmentation of large pieces of roadside debris, including plastic food containers and packaging as well as asphalt and other construction materials, soils and organics.

The identification of MPs in environmental samples is complex; current analytical methods vary greatly in sampling techniques as well as extraction and analysis protocols. It is believed that the microplastic pollution in road dust has been underestimated, due to inefficient detection methods, especially for tiny MPs. Spectroscopic techniques may be used to identify MPs, such as Raman or Fourier Transform Infrared (FTIR) spectroscopy, nevertheless only chromatographic techniques coupled with pyrolysis-gas chromatography allow the mass quantification of tire particles and MPs independently of their size.

A double shot (thermodesorption and pyrolysis) TD/PY-GC-MS method was applied to urban dust samples to identify and quantify, very selectively, tire particles and MPs, in addition to performing a qualitative analysis of other plastic additives and organic contaminants present in the sample.

The sample is sieved into different fractions, 63, 125, 250, 500, 1000 and 2000 µm and each of these fractions is introduced directly into the pyrolyzer, without any pre-treatment. Several polymer-specific markers are used to confirm the presence of tire particles and MPs, and the different polymers present in each of the fractions are identified and quantified.

Polymers such as PS, PVC, PC, PMMA and tire particles were found in the smaller particle fractions. However, PE and MDI-PUR were found only in the larger particle fractions. Furthermore, compounds such as octylphenols, PAHs, benzothiazols, phthalates, alkyl citrates, fatty acids, squalene or levoglucosan were identified thanks to the thermodesorption method.

3.14.P-Mo228 Fabrication and Analysis of Microplastics Reflecting Weathering Characteristics

Chaehwa KIM[1,2]*, Shin Ae Song*[3] *and Tae Hee Kim*[2]*, (1)Jeonbuk National University, Jeonju-si, Korea, Republic of, (2)Advanced Textile R&D, Korea Institute of Industrial Technology (KITECH), Korea, Republic of (South), (3)Digital Transformation R&D, Korea Institute of Industrial Technology (KITECH), Korea, Republic of (South)*

Microplastics, due to their extremely small size and long-lasting presence in the environment, are globally recognized as a significant concern with potentially harmful impacts on ecosystems and human health. Despite widespread research on the human and environmental toxicity of microplastics, much of the currently utilized microplastics in studies often fail to accurately reflect the characteristics and forms of microplastics detected in the environment. Microplastics exist in altered states, with changes in shape and surface properties, resulting from physicochemical weathering. The majority of research relies on commercially available, limited-sized spherical polymer particles. Therefore, there is a need for studies focused on weathered microplastics that actively reflect the features of microplastics prevalent in actual marine environmental pollution. In this study, various polymeric materials were milled, powdered, and fractionated to produce samples of different sizes and shapes for toxicity assessment. Due to the inherent ductility of polymers and melting issues during milling, a cryogenic grinding method was employed for sample preparation. Electron beam irradiation was conducted as a preprocessing step to obtain particle sizes in the range of several micrometers, confirming the effectiveness of electron beam irradiation in particle size reduction. Through cryogenic milling and precise classification processes, uniform particle sizes ranging from less than 20 μm to more than 150 μm on average were produced. The developed microplastic model samples are being utilized in assessing environmental behavior and toxicological impacts. With the capability to produce samples reflecting actual weathering characteristics, this advancement is expected to significantly enhance the scientific reliability of microplastics research.

3.15.A Measuring and Modelling the Environmental Fate and Exposure of Pesticides

3.15.A.T-01 Weight-of-evidence approach for correlation of degradation and/or sorption parameters with soil pH

Michelle Morris Dr.[1]*, James A. Hingston Dr.*[2] *and George P. T. Roddy*[2]*, (1)Chemicals Regulation Division, Health & Safety Executive, United Kingdom, (2)Health and Safety Executive (HSE) - Chemical Regulation Division, United Kingdom*

The FOCUS kinetics guidance (2014) provides a harmonised approach to consider degradation of parent pesticide compounds and breakdown products to determine key regulatory endpoints (DT_{50}, DT_{90} and formation fractions) to support pesticide risk and hazard assessments. OECD guideline 106 provides guidance on the conduct and interpretation of adsorption/desorption studies also used to determine key regulatory endpoints ($K_{foc,}$ 1/n). However, when considering potential correlation of degradation or sorption parameters with soil pH, there is no specific EU guidance available on how to investigate and demonstrate such a relationship, as noted in the EFSA scientific report on surface water repair (EFSA, 2020).

Through extensive experience of evaluating many active substance packages, HSE's Chemicals Regulation Division (CRD) have developed a weight-of-evidence approach to help concluding on correlation of degradation and/or sorption parameters with soil pH. The approach recommended here is split into two steps to ensure that a consistent and robust conclusion is reached. First, a review of all relevant information should be undertaken to establish if there are good scientific or mechanistic reasons to suspect that a correlation exists. Second, the significance of the correlation is investigated via adequate statistical tests. When supported by the outcome of steps 1 and 2, the exposure assessment should be performed accounting for any significant correlation.

Due to the complexity of interactions in soils and the typically limited nature of regulatory datasets it is possible that a number of different and potentially contradictory outcomes will result from Steps 1 and 2. Where a high degree of uncertainty exists, consideration should be given to ensuring that a conservative assessment is conducted at the first tier based on the evidence supporting a clear mechanistic basis for a relationship to be expected.

3.15.A.T-02 Uncovering the Spray Drift in Unscrewed Aircraft Spray Systems Through Intensive Field Studies

Qianwen He[1]*, Jerome Goulet-Fortin*[2]*, Francis P. Donaldson*[3]*, Bernhard Gottesbueren*[4]*, Beibei Gao*[5] *and Volker Laabs*[2]*, (1)BASF SE, Research Triangle Park, United States, (2)BASF SE, Germany, (3)BASF Corporation, (4)Make-Sense consulting, Germany, (5)BASF (China) Co. Ltd., China*

Uncrewed Aerial Spray Systems (UASs) have emerged as a promising technique for the application of crop protection products, offering potential benefits for agricultural efficiency and sustainability. However, off-field deposition, known as spray drift, poses risks to crops, the environment, and humans. This study presents the results of 114 UASs drift trials conducted in China in 2022. The analysis focuses on quantifying the spray drift of UASs and investigating the impact of environmental factors, including wind conditions, air temperature, relative humidity, as well as UAS flying altitude and speed. The study found that UASs drift magnitude falls within a similar range to the one of air blast application measured for orchards in the EU. Under the experimental setups, the study demonstrates a higher drift when the UASs was flying at 5m/s speed and at 5m altitude, compared with 3m/s speed and 3m altitude. Results of an ANOVA test indicate that environmental variables have a more significant impact on drift values than spray system parameters adopted by the experimental setups. The study highlights the importance of considering multiple factors when analysing drift behaviour and provides valuable insights for risk assessment and responsible use of UASs applications of crop protection products in agriculture.

3.15.A.T-03 Appropriateness of the Soil Organic Matter Map contained within PERSAM: Exploring Options in a Dynamic and Evolving GIS Data Landscape

Fabrizio Rama[1]*, Gregor Spickermann*[2]*, Shanghua Li*[3]*, David Patterson*[4]*, Dieter Schaefer*[5]*, Klaus Hammel*[6] *and Bernhard Jene*[7]*, (1)Syngenta, UK, (2)ADAMA Deutschland GmbH, Germany, (3)Product Safety (ES EAME), Syngenta, Switzerland, (4)Science Strategy, Syngenta, United Kingdom, (5)Bayer AG - Crop Science Division, Germany, (6)Bayer AG, (7)BASF SE, Germany*

The EU soil risk assessment for the approval of plant protection products (PPPs) is under revision (EFSA, 2017). European-wide GIS data layers and analytical equations implemented through the PERSAM tool are proposed to calculate predicted environmental concentrations in soil (PECsoil). PECsoil values at all tiers are significantly impacted by soil Organic Matter (OM) content, as soil Bulk Density (BD) is derived from OM content with an empirical equation, and thereby the OM GIS layer is a critical driving factor in the proposed modelling scheme. European-wide soil OM GIS layers generated using various approaches are increasingly available. However, all such layers include inaccuracies and biases when compared to real-world measurements. For example, the EFSA OM map available with the PERSAM software, exhibits significant biases in arable land areas. Nonetheless, an EU soil risk assessment based on flawed data may result in safe PPPs being inappropriately removed from sale. Thus, to evaluate the representativeness and PECsoil impact, a systematic analysis of available European soil OM data layers (e.g. EFSA 2012 OM map, de Sousa et al. 2022) has been performed, comparing them with measurements of real soil OM on arable land in Europe, obtained from LUCAS (2018) database. Arable land was defined as the spatial union of three classes (i.e. "Annual crops", "Permanent crops" and "Rice") of the CORINE Land Cover (CLC) 2012 layer. The comparison with LUCAS 2018 OM measurements confirmed significant inaccuracies within the EFSA 2012 OM map used in PERSAM. Analysis of the EFSA 2012 dataset also demonstrates agronomically unrealistic soil conditions with OM content exceeding 10% in most cases, with maximum values of 20% in the Northern Registration Zone. The analysis also suggests EFSA 2012 may be in general the least accurate European OM dataset among those currently available. The authors hope this work may favour a scientific and regulatory discussion around the digital mapping of OM in Europe, to implement a robust GIS layer of OM based on the best science available, using updated sources and comprehensive datasets. To conform with the EC "FAIR" commitment to guarantee findable, accessible, interoperable and reusable data, a traceable and well-defined procedure should be also defined to periodically update and check the spatial layers which form part of the EU PPP registration process.

3.15.A.T-04 Harmonised Framework for the SETAC Spatially Distributed Leaching Modelling of Pesticides Initiative: 2024 update

Aaldrik Tiktak[1]*, Anton Poot*[2]*, Bernhard Jene*[3]*, Gerco Hoogeweg, PhD*[4]*, Maarten Braakhekke*[5]*, Louise Wipfler*[6]*, Abdul Ghafoor*[7]*, Judith Klein*[8]*, Michael Stemmer*[9]*, Amy Ritter*[10]*, Robin Sur*[11]*, Gregor Spickermann*[12]*, Gerard Heuvelink*[13]*, Gregory Hughes*[14]*, Stephan Marahrens*[15]*, Stefan Reichenberger*[16]*, Nicoleta Suciu*[17] *and Michelle Morris Dr.*[18]*, (1)PBL Netherlands Environmental Assessment Agency, Netherlands, (2)Board for the Authorisation of Plant Protection Products and Biocides (Ctgb), Netherlands, (3)BASF SE, Germany, (4)Corteva Agriscience, (5)Environmental Risk Assessment, Wageningen Environmental Research (WUR), Netherlands, (6)Environmental Risk Assessment, Wageningen University & Research (WUR), Netherlands, (7)KEMI, Sweden, (8)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (9)Austrian Agency for Health and Food Safety (AGES), Austria, (10)Waterborne Environmental, Inc., (11)Environmental Safety, Bayer AG - Crop Science Division, Germany, (12)ADAMA Deutschland GmbH, Germany, (13)ISRIC, Netherlands, (14)GeoSpatial Analytics Ltd, United Kingdom, (15)German Environment Agency (UBA), Germany, (16)knoell France SAS, France, (17)Universita Cattolica del Sacro Cuore, Italy, (18)Chemicals Regulation Division, Health & Safety Executive, United Kingdom*

Spatially distributed leaching modelling (SDLM) of pesticides is a methodology to estimate the leaching potential over a large spatial extent such as national or European scale. It is described in the FOCUS groundwater report and foreseen to be used as higher tier leaching risk assessment as well as supporting groundwater monitoring studies. At the SETAC Europe 2020 meeting, the initiative was officially formalised as a SETAC working group, consisting of a triad of members from regulatory agencies, academia, and the private sector. As the SDLM team continues to work, this presentation provides an update to interested parties.

The group has now developed a first version of the framework. The process-based leaching models PEARL and PELMO will form the core of the framework. The model will run for approximately 10,000 scenarios, which are unique combinations of land-cover, climate and soil data. The scenarios were created from the geodata using a *k*-means clustering procedure, which aims to minimise within-cluster variances. The group has selected datasets that cover the entire EU and UK. The framework will use soil data from the SoilGrids database. Because the soil organic matter content depends on land-use, a map specific for arable soils was developed. For this, machine learning algorithms were applied using the available data in the SoilGrids database. The group paid a lot of attention to the harmonisation of pedotransfer functions. For this, available pedotransfer functions for soil bulk density and soil hydraulic properties were reviewed.

The framework will be tested using several test substances. Specific attention will be given to the plausibility of the predicted leaching maps. Furthermore, the 90th overall percentile leaching concentration for the nine FOCUS zones will be calculated and compared with results from the nine FOCUS scenarios that are used in Tier-1.

The work so far demonstrates that the development of a framework involves expert judgements that need to be thoroughly checked and documented. A plausiblity check and a comparison of different frameworks is therefore part of this project. However, in the long run, a monitoring network consisting of mulitple field sites would be helpful to further gain confidence in the modelling tools.

3.15.A.T-05 Preparing to revise the Guidance Document on risk assessment for non-target arthropods to pesticides: off-field exposure characterisation

Laura Padovani[1]*, Pauline Iris Adriaanse*[2]*, Henk Jan Holterman*[3]*, Mechteld ter Horst*[4] *and Bas Buddendorf*[2]*, (1)European Food Safety Authority (EFSA), Italy, (2)Environmental Risk Assessment, Wageningen University & Research (WUR), Netherlands, (3)Agrosystems Research, Wageningen University & Research (WUR), Netherlands, (4)Wageningen University & Research (WUR), Netherlands*

The EU legislative framework on Plant Protection Products (PPPs) underscores the significance of conducting thorough risk assessments for active substances to protect Non-Target Terrestrial Organisms (NTTOs). The focus has recently been on revising guidance documents for bees, birds and mammals. Now, there is a high priority emphasis on Non-Target Arthropods (NTAs). In this remit, EFSA set up a Framework Partnership Agreement with Wageningen University and Research with the aim to contribute to the development of concepts and methods for the environmental exposure assessment of NTTOs to pesticides. The project is structured to address key steps in this assessment. One pivotal aspect is the definition of the strips/areas surrounding pesticide-treated fields where crops are grown. It is recommended to focus on three defined exposure strips: the in-crop area, the in-field off-crop strip, and the off-field strip. These serve as the foundation for Specific Protection Goals (SPGs), which are critical in determining which ecosystem services need protection. Another crucial step involves outlining environmental exposure routes for off-crop NTTOs, with special focus to spray drift depositions. The project also proposes a structured approach to develop higher tier exposure scenarios for NTAs. The outcomes of the project stress the importance of clear definitions and identify data gaps, such as the lack of spray drift deposition data on in-crop or off-crop plants as 3-dimensional (3D) structures. The valuable role of this work is highlighted in jump-starting scientific initiatives for the development of exposure scenarios for NTAs and for the plausibility check exercises conducted with existing spray drift models to verify if they can be effectively used across EU regions. In conclusion, the collaborative efforts aim to establish a comprehensive and harmonised framework for assessing the environmental risk of pesticides on NTTOs, providing a solid foundation for future regulatory guidance.

3.15.B Measuring and Modelling the Environmental Fate and Exposure of Pesticides

3.15.B.T-01 Improving the procedure for fitting degradation rates in water sediment studies

Sevil Payvandi[1]*, David Patterson*[2]*, Ian Hardy*[3] *and Wenlin Chen*[4]*, (1)Syngenta Ltd, United Kingdom, (2)Science Strategy, Syngenta, United Kingdom, (3)Battelle, United States, (4)Syngenta Crop Protection*

In aquatic risk assessment studies it is typical to determine total system degradation and/or dissipation half lives from water-sediment experiments rather than individual degradation rates of the water and sediment phases. The disadvantage of this is that the use of total system half lives or dissipation half lives may mischaracterise the environmental fate processes in aquatic systems.

The reason that compartment-specific degradation rates are often not used in aquatic risk assessments is that it is difficult to obtain statistically robust estimates of these rates in the experimental system (e.g. excluding the initial mass, M0, 4 rate parameters need to be fitted from approximately 8 - 12 time points), whereas it is easier to obtain total system degradation or dissipation half lives (e.g. excluding M0, 1 rate parameter is fit for in single first order kinetics).

In this work we propose to use the sediment water sorption relation (Kd) to reduce the number of fitting parameters and thus increase the likelihood of statistically robust fits. Case studies will be presented to show the difference in fitting for 4 rate parameters versus 3 rate parameters. Since the number of time points in water sediment studies is typically around 8 to 12 (i.e. not very large), there is a large gain in certainty from only fitting 3 rate parameters rather than 4. However, whilst fitting for 3 parameters improves the robustness of results, robust fits are not always guaranteed. Therefore, the uncertainty of fitted parameters across theoretical parameter space was also investigated. It was found that robustness of back transfer (α_s) is high except for when both sorption and α_s are high, and certainty of degradation in water (k_w) is highest when k_w is large, particularly when sorption and α_s are low. Conversely, degradation in sediment (k_s) is most accurate when k_s and sorption are high. To improve the procesure further it is possible to use results from other experimental data (e.g. a concomitant OECD 309 test).

In summary, current regulatory methods often only yield total system degradation rates and dissipation rates of the specific compartments. This may lead to an overly conservative risk assessment, especially if behaviours over long time frames are considered (e.g. FOCUS SW repair). Conversely the simplified approach proposed here allows the decoupling of degradation and sorption and hence more accurate parameterisation of surface water models.

3.15.B.T-02 Comparison of simulated and observed downwind deposits of spray drift in arable crops across Europe: a test case using the IDEFICS model

Henk Jan Holterman[1]*, Mechteld ter Horst*[2] *and Pauline Iris Adriaanse*[3]*, (1)Agrosystems Research, Wageningen University & Research (WUR), Netherlands, (2)Wageningen University & Research (WUR), Netherlands, (3)Environmental Risk Assessment, Wageningen University & Research (WUR), Netherlands*

EU Regulation 1107/2009 requires the assessment of pesticide exposure risk for several groups of non-target organisms, such as Non Target Arthropods. Spray drift deposition is a major exposure route, that has not yet been estimated reliably at an European level, while accounting for the wide variety of factors and conditions across Europe. Typically, this variety is caused by differences in crops, crop height, agronomic practices and agro-environmental conditions.

Mechanistic spray drift models can be helpful to deal with this variety by appropriately parameterizing the above-mentioned factors and conditions. By demonstrating that mechanistic models can predict spray deposits for a range of conditions sufficiently well, modelled depositions may improve the current exposure assessment within the regulatory risk assessment at EU and Member State level. A few mechanistic spray drift models exist in Europe that take account of such factors and conditions. In principle, these models can be tested to see how they perform in a relatively wide range of situations compared to experimental field trials. In this study the Dutch IDEFICS model (Holterman et al, 1997) was selected to carry out this comparative test. IDEFICS computes downwind deposits of spray drift for arable crops with conventional boom sprayers. Computed spray drift deposits are a function of crop type and height, sprayer settings and meteorological conditions. However, this model has only been tested and validated for Dutch situations. A set of experiments was selected from the EU-wide database of SETAC-DRAW and a few other sources, complying to predetermined criteria, to test the wider validity of

IDEFICS estimates of spray drift deposition. In total, five datasets were selected covering short and tall crops in the three different EU regulatory zones (North, Central, South), kindly provided by various research groups in Europe. Field trials generally consist of several replicates, each experiencing slightly different e.g. meteorological conditions, such as wind velocities, therefore each replicate needs to be simulated separately. The comparison shows that mechanistic spray drift models can be useful to account for environmental and conditional differences across Europe. However, experimental variability still remains an important issue that has to be dealt with adequately.

3.15.B.T-03 Estimating high resolution exposure at landscape-level – on the development, evaluation, and application of the droplet and atmospheric dispersion (DAD) drift model

Mike Fuchs[1,2]*, Sebastian Gebler*[1] *and Andreas Lorke*[2]*, (1)BASF SE, Germany, (2)University of Kaiserslautern-Landau (RPTU), Germany*

Information on the fate and transport of pesticides is of great interest for pesticide registration, product stewardship, authorities, and other stakeholders. Major transport pathways include surface and subsurface runoff, leaching, subsurface drainage, and spray drift. Modeling of pesticide fate and transport within watersheds, where pesticide transport is controlled by the dominant hydrological processes, has been increasingly applied at the plot scale and the landscape scale. However, due to its complexity, the process of spray drift is largely neglected or oversimplified in landscape-level modeling approaches.

With the Droplet and Atmospheric Dispersion (DAD) drift model, we have developed a computationally efficient modeling approach, capable of accounting for the physical basis of spray drift, the relative location of application areas to non-target areas, and local weather conditions at the landscape scale. The DAD drift model is a combination of a mechanistic droplet model, a micrometeorological model, and a three-dimensional Gaussian puff model and was developed for ground application.

The model was successfully evaluated against two field-scale spray drift studies for ground application covering a wide range of drift potentials. In a sensitivity analysis, DAD drift showed coherent and comprehensible behavior for variations of important input parameters (e.g., different nozzle types, wind speed). In a virtual experiment, the model was compared with different drift prediction approaches using simplistic algorithms based on drift curves. Results indicate that predictions of DAD drift are within the range of other landscape-level approaches. However, for individual elements in complex landscapes, significant differences in drift predictions up to several orders of magnitude can be found. Furthermore, DAD drift was applied in a meta-modeling approach using generalized linear models (GLM). The nozzle type in terms of the drop size distribution, closely followed by the distance between application and non-target area, were found to be the two most influential drivers of spray drift at the landscape scale.

To further improve the understanding of pesticide transport pathways at the landscape scale, work on a high-resolution SWAT+ model of an agriculturally dominated catchment in Germany in combination with the DAD drift model is ongoing.

3.15.B.T-04 Model-Based analysis of pesticide transport pathways in a drained agricultural farm, northern Germany

Anne-Kathrin Wendell[1]*, Björn Guse*[2]*, Katrin Bieger*[3]*, Jens Kiesel*[4]*, Uta Ulrich*[5]*, Paul Wagner*[2] *and Nicola Fohrer*[5]*, (1)Hydrology, Kiel University, Germany, (2)Kiel University, Germany, (3)Aarhus University, Denmark, (4)Stone Environmental, Inc., (5)Christian-Albrechts University Kiel, Germany*

Pesticides are currently detectable in all types of water bodies and pose a serious threat to the environment. Waters in the northern German lowlands are particularly at risk, as subsurface drainage of cropland quickly transports pesticides, including persistent transformation products (TPs), to surface waters. The eco-hydrological model SWAT+ is a useful tool that links hydrological processes with agricultural practices and the degradation and transport of pesticides. In this study, the focus is on the simulation of three herbicides (pendimethalin, diflufenican, and flufenacet) with different environmental behaviours, as well as the simulation of two TPs of flufenacet, flufenacet-oxalic acid (FOA) and flufenacet-sulfonic acid (FESA). SWAT+ is applied on a 100-hectare farm with an extensive drainage network of 6.3 kilometres. The farm is managed using conventional agricultural methods.

SWAT+ models the discharge of the area with very good agreement during calibration and validation. For pesticides, the model performance for the highly mobile TPs and the moderately mobile flufenacet is better than for the non-mobile diflufenican and pendimethalin. The tile drain transport of moderately to very mobile substances plays a significant role in the total losses. The contribution of tile drain transport increases with increasing time after the application and can dominate in phases of peak losses. No transport via tile drains can be modelled for the non-mobile pendimethalin, as particle-bound pesticide transport via tile drains is not simulated in the model.

We conclude that SWAT+ is capable of modelling the transport and degradation of moderately mobile pesticides and very mobile TPs and can be used for the evaluation of transport pathways. However, the model has limitations when considering the underground transport of non-mobile substances, which can lead to an underestimation of the total losses.

3.15.B.T-05 Moving towards field specific risk assessment: A drainflow risk assessment case study in the UK.

Gregory Hughes[1]*, Robin Sur*[2]*, Adrian Simon Terry*[3] *and Abdul Abu*[3]*, (1)GeoSpatial Analytics Ltd, United Kingdom, (2)Environmental Safety, Bayer AG - Crop Science Division, Germany, (3)Cambridge Environmental Assessments (CEA),*

United Kingdom
The registration of plant protection products in Great Britain includes an assessment of risk to surface water via agricultural drains using the MACRO preferential flow model. The drainflow risk assessment considers the number of years in which the regulatory acceptable concentration (RAC) is exceeded for 20 pedo-climatic scenarios. Depending on the species driving the RAC up to 3 (aquatic invertebrates and fish) or 18 (aquatic plants and algae) out of the 30 years simulated may exceed the RAC in any given pedo-climatic combination. As such, even if a small number of pedo-climatic combinations fail the risk assessment no product registration is possible even though the simulations indicate that there are many pedo-climatic combinations which demonstrate safe usage along with all undrained soils.

This poster outlines a spatially distributed drainflow modelling (SDDM) approach that allows (a) vulnerability maps that identify areas that may pose a risk to edge of field waterbodies to be established and (b) decision support tools to be developed that facilitate farmer compliance with spatially varying label restrictions that preclude application to specific drained soil series. The Macro model based SDDM defines a broader suite of drained soils classes as well as simulating exposure for all MARS weather grid squares in GB thereby capturing a wider range of pedo-climatic combinations associated with arable land than the standard scenario-based approach. By aligning the risk assessment of these SDDM combinations with the current regulatory approach 3 broad classes of vulnerability are defined: (1) areas where no drained soil classes are predicted to exceed the RAC; (2) areas where all drained soils exceed the RAC and (3) those where some intermediate risk is identified requiring further investigation. Such an approach is closely aligned with the existing regulatory modelling and decision-making processes to facilitate regulatory adoption. It is also aligned with the increasing prevalence of precision agriculture, digital pesticide labels and field specific mitigations to achieve required product label mitigation levels. Moving to a field specific risk assessment approach would allow GB growers access to a more diverse suite of plant protection products whilst maintaining protection of the environment.

3.15.C Measuring and Modelling the Environmental Fate and Exposure of Pesticides

3.15.C.T-01 Occurrence and Bioaccessibility of Pesticides in Agricultural Plastics

Gabriela Castro[1], Victoria Fernandez-Fernandez[2], Miguel Cobo Golpe[2], María Ramil[1] and ***Isaac Rodriguez Pereiro**[3]*, *(1)University of Santiago de Compostela, Spain, (2)Analytical Chemistry. Institute for Research on Chemical and Biological Analysis, Universidade de Santiago de Compostela, Spain, (3)Analytical Chemistry. Institute for Research on Chemical and Biological Analysis, University of Santiago de Compostela, Spain*
Intensive agriculture employs large amounts of plastics (i.e., greenhouse and mulching films, anti-grass covers, plant protection tubes, irrigation pipes and tying systems) to increase the productivity of crops. The above materials are exposed to pesticides sprayed on crops. Depending on the features of the employed compounds, the type of polymer and its weathering grade, these compounds might be sorbed and/or accumulated in plastics. Physical degradation of agricultural plastics leads to smaller size pieces, difficult to recover from fields, and susceptible to migrate to other environmental compartments.

Recycling of agricultural plastics has become a common practice to reduce the environmental impact of end-of-life materials, limiting the generation of microplastics in the terrestrial environment. Considering sell figures, low density polyethylene, employed in greenhouse and mulching, is one the most important of the recycled agricultural plastics. Pesticides sorbed in the aged material might be transfer to pellets produced in the recycling process. Thereafter, they might even reach the second-hand items prepared using this recycled raw material.

Meso- and microplastics generated from agriculture use materials are practically impossible to collected from crop soils. Moreover, they are susceptible of ingestion by wild animals and life-stock feeding on non-commercial rest of crops. On one hand, a fraction of pesticides associated to ingested plastics might be accessible in the digestive tract of animals. On the other hand, plastics and associated pesticides are transported and excreted at significant distances from the generation site.

The aims of this presentation were (1) to characterize the composition of plastic debris collected from agricultural plots, (2) to assess the presence of pesticide residues in these materials as well as in new plastic items, suspected to be prepared from recycled plastics, and (3) to evaluate the bioaccessibility of pesticides sorbed in agricultural plastics during simulated digestion experiments. The characterization of plastic debris was made by infrared spectroscopy. Determination of pesticide residues was carried out by liquid chromatography tandem mass spectrometry (LC-MS/MS), after solid-liquid extraction. Finally, the stability of sorbed compounds and their bioaccessibility during simulated digestion of aged materials were investigated under standardized conditions, using aged polymers from agricultural fields.

3.15.C.T-02 Testing the PEC-CKB Model with Data from a Monitoring Study in Small Freshwater Streams in Germany

***Paula Scharlach**[1] and Andreas Focks[2], (1)Osnabrück University, Systems Science Group, Institute of Mathematics, Germany, (2)Institute of Mathematics, Osnabrück University, Germany*
Predicted environmental concentrations (PEC) result from mathematical fate models and are used as a quantitative indicator for the expected occurence of chemicals in the environment. Recently, the PEC-CKB model (Boström et al., 2019) was suggested as an additional possible tool for prospective exposure assessment, and stands out for its simplicity. The regression

model equation includes factors such as application dose (D), transport loss (M) and substance-specific sorption behaviour (F_w) as well as a dilution factor, and results in a simplified equation $PEC=0.5*D*F_w$. With that, good results have been obtained by comparing model-generated PEC with Swedish monitoring data.

This study, which is part of the PARC (*European Partnership for the Assessment of Risks from Chemicals*) project, aims to test the PEC-CKB model with German monitoring data obtained from the Kleingewässermonitoring (KgM) (Liess et al., 2021). The monitoring data comprised of 124 sites and 108 substances were measured between 2018 and 2019. Model results using original parameters significantly overestimated measured environmental concentrations (MEC) in Germany, in contrast to prior research in Sweden. This has prompted an investigation into regional and seasonal variations in environmental conditions. By using the average application doses given for Germany, already more accurate model results could be obtained. Additionally, we are examining the land use in various catchments by using geographical information systems (GIS). From the expected results we aim to derive site-specific parameter values to enhance the model's performance in Germany by including country-specific factors in the model equation. Finally, the PEC-CKB model, although conservative, seems suitable for lower-tier analyses. It appears advisable to match the intended objectives, taking into account any variances in accuracy and protection levels when choosing models.

3.15.C.T-03 > Sixty-Year Historical Records- Fate and Persistence of Plant Protection Products in Aquatic Systems

***Aurea C. Hernández**, Emmanuel Schaad, NIchole Fahrni, Olivia Wagner, Ann-Kathrin Stalder and Martin Grosjean, University of Bern, Switzerland*

Plant protection products (PPPs), applied to agricultural fields in the range of hundreds of thousands of tons per year in Europe, pose rapidly growing risks to soils, atmospheric and aquatic environments, ecosystems in general, and human health. The pathways of PPPs through the environment are highly complex and need to be better understood. Although many studies have analyzed the losses of diffuse PPPs from agricultural fields to surface water (e.g., rivers and creeks), few attempts have been made to comprehensively understand the transport and deposition of current-use PPPs in freshwater lake systems. In addition, the ability to assess PPP loads in the dissolved and particulate phase is a key issue that has not yet been adequately addressed by models due to limited or non-existent data to evaluate deposition and re-emission processes in sediments.

Our work uses a novel multiproxy workflow to assess > 60 PPPs in sediment samples from different Swiss lakes under heavy agricultural pressure. The results show the appearance of PPPs for the first time in the early 1960s, with an overall detection of more than 30 PPPs per lake. Paleolimnological data (e.g., chronology, hyperspectral imaging of sedimentary green pigments, and semi-quantitative elemental composition (µXRF scans)) combined with chemical analysis (LC-MS/MS and HRMS) shows that once PPPs are embedded in sediments, they are often quite stable and PPP trends over time (since the 1960s) are not related to land surface processes such as soil erosion or lake biogeochemistry, but are mainly attributed to PPP application (inferred from sales) or regulatory measures (bans). In addition, our work shows that PPPs are not equally distributed in sediments across space, but they can be readily scavenged and removed from the water body. In addition, our work shows that physicochemical properties to predict the accumulation of pesticides in sediment show limitations and often fail to predict their behaviour.

Lake systems like those abundant in Europe are often used as freshwater supplies. Therefore, our findings likely represent many agriculturally influenced lakes in Europe.

3.15.C.T-04 Contaminated Landscapes – Current Use Pesticides Residues in Soil and Vegetation along Altitudinal Gradients in a European Alpine Valley

***Carsten A. Brühl**[1], Nina Engelhard[2], Nikita Bakaonv[2], Jakob Wolfram[1], Koen Hertoge[3] and Johann Zaller[4], (1)Rhineland-Palatinate Technical University Kaiserslautern-Landau (RPTU), Germany, (2)RPTU Kaiserslautern-Landau, Germany, (3)PAN Europe, (4)BOKU - University of Natural Resources and Life Sciences, Austria*

Pesticides applied in crops are transferred to non-target areas, exposing biota. We examined current used pesticide (CUP) distribution in terrestrial habitats by sampling soil and vegetation as important exposure matrices for insects in an Alpine valley. Sampling was conducted along eleven transects extending from the valley floor at 517 m a.s.l. to mountain peaks at 2.318 m a.s.l. in the Vinschgau valley (South Tyrol, Italy), Europe's largest apple growing area. We used a recently developed extraction method followed by a high-performance liquid chromatography coupled with an electrospray ionization tandem mass spectrometry system (HPLC-ESI-MS/MS) for 97 target CUPs. A total of 27 CUPs (10 insecticides, 11 fungicides, and 6 herbicides) were detected, originating mostly from apple orchards in the valley. Only one of the 53 vegetation samples was free of CUP residues. CUP numbers and concentrations decreased with altitude and distance to orchards. Valley areas without apple cultivation showed more homogenous contamination along altitudinal gradients, suggesting a valley-wide transport, also into nature conservation areas in high alpine habitats. The insecticide methoxyfenozide was detected in almost half of the vegetation samples, potentially exposing insects orally. Subsequent regression analysis and mapping based on detected residues suggest that CUPs occur everywhere, from the valley floor to mountain tops. This first terrestrial landscape-scale investigation of CUP residues in the European Alps demonstrates widespread multiple residue contamination creating chemical landscapes. Current risk assessment does not consider mixtures of CUPs and measurements in vegetation and soils are scarce. Based on our results, we recommend that the European soil monitoring law must include CUPs and analyse several substances at the same time, as there is currently no data available on realistic exposure of terrestrial ecosystems and the biota inhabiting them.

3.15.P Measuring and Modelling the Environmental Fate and Exposure of Pesticides

3.15.P-Mo229 Particulate and Mineral Associated Organic Matter Contribution to Pesticide Sorption in Agricultural Soil

Marija Gadzimuradova[1], *Valentina Sechi*[2], *Peter van der Maas*[3] *and Nora B Sutton*[4], *(1)Environmental Technology, Wageningen University & Research (WUR), Wageningen, Netherlands, (2)Wetsus European centre of excellence for sustainable water technology, Netherlands, (3)Van Hall Larenstein university of applied sciences, Netherlands, (4)Environmental Technology, Wageningen University & Research (WUR), Netherlands*

Intensive agricultural practices heavily rely on land exploitation and high inputs of pesticides to produce crop monocultures. Some applied compounds persist in soil, whereas the more mobile pesticides run off or leach through the soil profile and enter surface and groundwater sources. Soil organic matter content is recognized as one of the main factors determining the mobility and transformation fate of agrochemicals. However, to the authors' knowledge, the role of particulate (POM) and mineral-associated (MAOM) organic matter pools in determining pesticide fate and the implications for soil management practice choice is yet to be elucidated. This research aims to understand how the distribution of organic matter into the physical pools of POM and MAOM influences the sorption of pesticides in soil.

Using wet sieving, we fractionate the soil into the two physical fractions POM (> 53 µm) and MAOM (< 53 µm). After removing organic matter from POM and MAOM fractions, we obtain the rPOM and rMAOM, which serve as control treatments. We perform batch sorption tests to determine the efficiency of 9 pesticide removal from soil solution using separated and treated soil fractions. Our hypotheses are: 1) separated soil fractions with intact organic matter (POM, MAOM) will perform better in pesticide sorption than rPOM and rMAOM; 2) the nature of organic matter determines the extent of pesticide sorption efficiency, and MAOM will be more efficient than POM. The findings of this research can provide new insight into the effect of soil properties in reducing pesticide runoff, leaching, and subsequent environmental contamination and thus have important implications for choosing agricultural land-management practices (tillage, animal manure application, etc.).

3.15.P-Mo230 On the search for alternative herbicides to treat Swiss railway tracks.

Valérian Zeender[1], *Roy Kasteel*[2], *Thomas Poiger*[2] *and Ignaz Buerge*[2], *(1)Agroscope, Switzerland, (2)Plant Protection Products – Impact and Assessment, Agroscope, Switzerland*

Weeds can have detrimental effects on the railway infrastructure. This mainly through the accumulation of humus, which can increase water retention and may damage both sleepers and rails, as well as the overall stability of the ground. Ultimately, these factors can result in track deformation, which directly influences the speed at which trains are able to travel.

In Switzerland, herbicides are predominantly utilized for weed control, although alternative methods such as mechanical and thermal techniques are also employed. Currently, glyphosate is the only herbicide used to remove weeds from railway tracks, which has proven to be relatively effective. However, uncertainties concerning the renewal of authorisations of the substance in Europe have prompted railway companies to explore alternative herbicides that may replace glyphosate. Due to the inherent permeability of railway tracks and therefore increased net infiltration, it is important to choose herbicides with a low risk of leaching to groundwater. The characteristics of a suitable herbicide include thus a high sorption in the soil and/or rapid degradation (also for metabolites), as well as low application rates.

In order to help decision-makers to make informed decisions, we constructed ten lysimeters with railway materials from three locations, allowing us to study the leaching behaviour of herbicides in close-to-real conditions. Using liquid chromatography–mass spectrometry, we investigate the leaching potential of 12 alternative herbicides and their main metabolites. The selected group of alternative herbicides includes six auxin-mimics, three acetolactate synthase inhibitors, as well as three pigment-synthesis inhibitors.

Half a year after the first application of the substances in May 2023, we observe that leaching is influenced by both the lysimeter soil properties and the herbicides used. While some of the herbicides have already reached their maximum concentrations under all soil conditions, some have not been detected yet. These undetected herbicides may have degraded completely or may still elute later. The project will continue for at least 2 years (from the time of the first application) and will allow us to conclude on the leaching potential of the applied substances and their metabolites under realistic conditions. Moreover, the project will allow a direct comparison of all applied substances under identical weather conditions in 3 different soil types.

3.15.P-Mo231 Concentration dependence of the persistence of the fungicide tebuconazole in fresh water - results of a one-year mesocosm study

Valeska Contardo Jara[1], *Silvia Mohr, PhD*[1], *Björn Kusebauch*[1], *Stefan Bader*[1], *Johannes Ranke*[2] *and Stefan Meinecke*[1], *(1)IV 2.5, Umweltbundesamt (UBA), Germany, (2)Agroscope, Switzerland*

Understanding the consequences of the increasing use of pesticides in agriculture and the associated entry into terrestrial and aquatic ecosystems is essential to efficiently protect the biosphere from collateral damage. Especially the risk assessment of pesticides considering their persistence, which is usually derived from standard degradation tests, may not be safe, since the half-life of substances can be driven by site-specific conditions, as well as e. g. inhibition of microbial degradation capabilities. Tebuconazole (TBZ), classified as persistent, is a water-insoluble triazole fungicide with inhibitory effects on fungal growth. The use of water-soluble formulations containing TBZ and co-formulants during agricultural activities, led to detectable concentrations in the low µg/L range in freshwater ecosystems.

In order to investigate the degradation kinetics of TBZ in an aquatic environment, freshwater mesocosms simulating a stream lake, were dosed once with the formulation Folicur® in concentrations of 5, 50, 100, 500, 1000 and 5000 µg/L TBZ. The mesocosms were stocked with plankton, periphyton, aquatic fungi, macrozoobenthos and planted with three macrophyte species. TBZ concentrations were measured at regular intervals over an entire year (365 days) in the water and the upper sediment layer (0-5 cm) using GC-MSMS technique. The residue data were normalized to 20°C using time-step normalisation and analyzed with the R package mkin applying the five most common degradation kinetic models to the whole data set, with additional consideration of covariates like concentration or pH. For the evaluation without covariates, the combination of the single first order reversible binding degradation model (SFORB) with a two-component error model was identified to be most suitable for the degradation of TBZ.

DT_{50} values derived from the slower phase of the biphasic SFORB degradation curve of TBZ in water showed a clear concentration dependence, varying between approximately 70 days for the lowest initial concentration of 5 µg/L, and approximately 600 days for the highest initial concentration of 5000 µg/L. Concluding, in comparison to laboratory derived DT_{50} values TBZ can be surprisingly persistent under near-natural conditions highlighting the importance of higher tier studies in regulatory science and the need for more complex decomposition models.

3.15.P-Mo232 Investigating the Impact of Test Conditions on Aerobic Degradation Kinetics of Aniline and Sodium Benzoate in Surface Water

***Suresh Gundoju**, Nabanita Sam and Sateesha S, Environmental Fate, Metabolism and Residue, Eurofins Advinus Agrosciences Services India Private Limited, India*

The study evaluated the performance of aniline and sodium benzoate as reference substances for the OECD Test No. 309 (Aerobic Mineralization in Surface Water) under different test conditions. While the OECD guideline (OECD Test No. 309) recommends conducting the test at 20°C, REACH guidance for persistence assessment of PBT/vPvB substances suggest a lower temperature of 12°C. The expected time interval for degradation for these reference substances is less than 2 weeks which may correspond to 20°C. But no data is available on whether this is the case even at 12°C. Three test systems were prepared using natural surface water, which are, surface water (as such), surface water fortified with 10 mg/L suspended solids and surface water fortified with 1000 mg/L suspended solids. Each system (after spiking with the reference substance) was incubated at 20°C and 12°C each in duplicate. Samples were analyzed until complete degradation of reference substance. The natural surface water was fully characterized, including the analysis for bacterial biomass, which was measured to be 1×10^4 colony forming units (CFU) per mL prior to treatment. In case of aniline, no significant differences were observed in degradation half-lives, which are ranging between 4.7 and 6.3 days, in all the test conditions applied. On the other hand, sodium benzoate exhibited significant differences across the test conditions. The degradation of sodium benzoate increased with higher temperatures and the presence of suspended solids. The half-lives in the surface water (as such), surface water with 10 mg/L suspended solids and surface water with 1000 mg/L suspended solids, were observed to be 3.9, 3.2, and 0.8 days at 20°C, respectively. However, the degradation rate decreased with lower temperatures (at 12°C), and the corresponding half-lives were 5.4, 4.1, and 3.0 days.

The results showed that both reference substances degraded to below detection levels within two weeks even at 12°C, indicating that both perform well in assessing the validity of the test.

The degradation of sodium benzoate was found to be influenced by temperature and the presence of suspended solids. The half-lives of sodium benzoate were shorter at higher temperatures and in the presence of suspended solids. These findings suggest that the OECD Test No. 309 can be reliably performed at 12°C and that the presence of suspended solids should be considered when interpreting the results of the test.

3.15.P-Mo233 High Resolution Experimental Data to Study the Remobilization and Leaching of Pesticide Residues in Vegetative Filter Strips from a Mesoscale Experimental System

***John Adam Howe**[1], Rafael Muñoz-Carpena[2] and Robin Sur[3], (1)University of Florida, Gainesville, United States, (2)University of Florida, (3)Environmental Safety, Bayer AG - Crop Science Division, Germany*

VFSMOD, the storm-based vegetative filter strip (VFS) design model calculates runoff, sediment, and pesticide mitigation through the filters under long-term ecotoxicological regulatory exposure assessments. After each storm, the model calculates degradation of surface trapped pesticides and currently adopts a risk-conservative assumption of full remobilization for all remaining residues in the VFS surface during subsequent rainfall-runoff events. Although risk conservative, for highly-sorbed chemicals this assumption is unrealistic. As a result, an updated partial remobilization scheme was introduced in VFSMOD. We employ a mesoscale laboratory experiment as a model VFS system to validate this scheme and better understand the remobilization and leaching of surface trapped pesticide residues during a continuous sequence of rainfall runoff events. The experimental system consists of 3 vegetated soil monoliths (1.2Lx0.5Wx0.5D m) in a rain simulator. Each experiment consists of a series of 3 rainfall events with 1 week dry period between. The series is repeated for combinations of 2 soil types and 2 seasons. Representative rainfall and field edge lateral inflow (water, sediment, tracer, and 3 pesticides of distinct sorption, K_{oc} and half-life, $t_{1/2}$) inputs are controlled with >90% accuracy. Each monolith contains 12 soil probes that measure water content, electrical conductivity, and temperature at 1-min steps in a 4x3 grid along the length of the monolith. As outputs, hydrographs and breakthrough curves are collected from a surface runoff flume and 3 drainage outlets below the soil profile. Samples from each outlet are collected at 1.25-min intervals, passed through a spectral analyzer, and stored by a fraction collector. In addition, thin column soil cores are collected and divided into a vegetation and 4 soil depth samples. The water samples are analyzed for tracer and pesticide concentrations and the soil and vegetation samples are measured for pesticide concentration. From a preliminary run, the system exhibited closely the mass balance on water and tracer. Preliminary results of chemical analysis also show that there is a range of Koc for which chemicals are more susceptible to remobilization, also predicted by the new remobilization algorithm in VFSMOD. These finding illustrate the need for high spatiotemporal resolution measurements to recreate the fate and transport dynamics of a soil-plant VFS system. Plant uptake will be considered in future studies.

3.15.P-Mo234 The exposome and glyphosate, room for discussion

Norbert Fraeyman[1]*, Luc Hens*[2] *and Eric Mortier*[3]*, (1)Ghent University (UGent), Belgium, (2)Em. Prof. Free University Brussels, (3)Ghent University, Medical School, University Hospital, Belgium*

Humans are simultaneouse exposed to many chemicals known as the exposome. Although its composition is unknown, glyphosate (GLY) is likely to be one of the components in view of its ubiquitous presence in nearly all segments of the environment and in many human consumption goods.

The use of GLY is fiercly discussed since 2015 when IARC concluded in monograph 112 that GLY is "possibly carcinogenic to humans" (carcinogenicity class 2B). In contrast, certifying international bodies such as EPA, EFSA, ECHA... allow its further use. How should we deal with this dillema?

Glyphosate is linked to negative effects on biodiversity, honeybees and on the microbiome in animals, including humans. Whether or not GLY is a carcinogen is still debated.The carcinogenicity of GLY is clearly demonstrated in vitro but carcinogenicity in real life conditions is questionable. Based on offd ratios of the risk of getting cancer after exposure to GLY, the carcinogenicity of GLY is less than the carcinogenicity of known carcinogens such as asbestos or smoking cigarettes (HGR, 2020).

After exposure to realistic doses of GLY, honeybees lose orientation during foraging and when returning to the hive while clear effects on social behavior are seen. Of note is that the acute toxic effect of GLY-preparations (e.g. roundup) is due to the adjuvant and not to GLY (Straw et al., 2023).

Killing herbs using chemicals is by definition devastating for biodiversity. However, the main reason for declining biodiversity is not (agro)chemicals but climate change and the introduction of alien species.

The effect on the microbiome is undeniable since the target of GLY in plants (the enzyme EPSPS) is also present in lower-developed organisms such as gut bacteria. Since there is a link between the microbiome and the central nervous system, disturbing the delicate balance within the enteric bacterial population is likely to affect the brain functioning.

In conclusion, GLY as part of the exposome might affect human health although the information is not complete. Application of the precautionary principle dictates the gradual and well-controlled replacement of the herbicide.

3.15.P-Mo235 Novel Triple Quad Approaches for Robust and Reliable Pesticide Analysis with Ultimate Sensitivity

Javier Lopez[1]*, Miguel Angel Perez*[1]*, Arnd Ingendoh*[2]*,* ***Carsten Baessmann***[3] *and Noud van der Borg*[4]*, (1)Bruker, Spain, (2)Bruker Daltonics GmbH & Co. KG, Bremen, Germany, (3)Bruker Daltonics GmbH, Germany, (4)Bruker Nederland B.V., Netherlands*

Pesticides are by far the largest number of hazardous compounds analyzed in food and feed worldwide. The Rapid Alert System for Food and Feed (RASFF) network alone has reported nearly 1000 notifications of the presence of pesticides in fruits and vegetables during border control and on the marker. The challenge for current technology is the number of pesticide analytes per single run. Screening techniques are becoming more popular especially for organic and pesticide-free products, while maintaining the ability to quantify the positive samples.

We propose a methodology for the analysis of pesticides in food using a novel triple quadrupole mass spectrometer. The first calibration level for most of the compounds in the study was 0.2 ng/mL in plant matrix (QuEChERS extract) with a total run time of 10 minutes (2 uL injection). The scan time used for each compound was less than 5 ms, resulting in a method that can accommodate more than 1000 pesticides (positive and negative with fast polarity switching) with at least 2 transitions each in a single run.

Under these conditions, the calibration curve showed an R2 value greater than 0.99 for 95% of the compounds included in the study. Typical ion ratios for most compounds are less than 10% of deviation. The % RSD for 10 consecutive injections is less than 10% for most pesticides in a real matrix spiked with 2 ppb of all of them. All of these parameters indicate a robust and reliable method for testing up to 1000 pesticides in a single run.

3.15.P-Mo236 Study on environmental behaviour of Thiamethoxam in Stringy stonecrop

Seung-Hyun Yang Ph.D, ***Hoe-Gun Kwon B.S.****, Hyeon-Woo Shin M.S., Kyung-Min Na B.S., Chang-Ho Lee M.S. and Pyoung-Yeol Kim M.S., Korea Testing & Research Institute, Korea, Republic of (South)*

This study explores the behavior, dissipation, and leaching (OECD TG 312) of Thiamethoxam in three typical Stringy stonecrop (Sedum sarmentosum) planting soils. Dissipation patterns of pesticide residues in agricultural products were investigated during cultivation, and pre-harvest residue limits (PHRLs) were suggested based on dissipation patterns and biological half-lives. Thiamethoxam was applied to agricultural products in three different regions at the recommended dose. Samples for the dissipation pattern study were harvested at 0, 1, 3, 5, 7, 10, and 14 days after treatment, and analyzed by HPLC-MS/MS. The result indicated that Thiamethoxam dissipation followed the first-order kinetic equation in the three Stringy stonecrop samples, with similar degradation rates. The degradation half-lives in Field 1, Field 2, and Field 3 were 3.4, 3.5, and 4.0 days, respectively. For soil leaching (OECD TG 312), a PVC tube with an inner diameter of 5 cm and a length of 40 cm was used as a packed column. Dry soil (600–689.9 g) was weighed for filling, and the column was fully wetted with 0.01 M $CaCl_2$ *to prepare a* 30 ± 0.2 *cm high leaching soil column. Thiamethoxam leaching behavior in the soil exhibited a result of 3.0 (V mobile) in the three soils. For method validation, experiments on the limit of quantitation, standard calibration curve, linearity, repeatability, reproducibility, sensitivity, and specificity were conducted. Recovery experiments validated the analytical method, satisfying criteria for pesticide residue analysis, including a recovery range of 70~110%, less than 10% relative standard derivations, and sensitivity greater than 0.01 mg/kg for the limit of quantitation or half of the maximum residue limits. The biological half-lives of pesticides in three different field studies were calculated, and PHRLs were recommended for 10 days before harvest, respectively.*

3.15.P-Mo237 QuEChERS Extraction and Chromatographic Determination of Selected Carbamate Pesticides in Soil Samples

Luleka Luzi-Thafeni[1] and ***Vernon Somerset[2]****, (1)Department for Environment Food & Rural Affairs (DEFRA), South Africa, (2)Cape Peninsula University of Technology, South Africa*

Pesticides are generally applied to agricultural crops for protection but their residues present a potential risk to non-target organisms, affecting aquatic ecosystems and posing risks to human health. Organophosphates and carbamates impair nerve transmission in insects and poses even higher human health risks if left undetected. Recent advances have shown that these pesticides can be extracted and pre-concentrated from aqueous samples by liquid-phase micro-extraction (LPME), solid phase extraction (SPE) and headspace solid phase micro extraction (HS-SPME), while supercritical fluid extraction (SFE) and pressurised fluid extraction (PFE) can be employed for sediments. This study has shown that improved extraction allows for sensitive detection of carbamates in soil and fruit samples.

The study involves the testing of a rapid, reliable and low-solvent extraction procedure for selected carbamate pesticides of carbaryl, carbofuran, and methomyl from soil and fruit samples. It involves an investigation to determine which solvents to use, extraction optimisation, and how much of the applied carbamates are found in the fruit, compared to the soil in the same geographical location.

Preliminary results have shown that the concentrations are accumulated in the soil samples and have seasonal trends.

3.15.P-Mo238 Exposure Assessment for Biopesticides and Inorganics – Challenges and Improvement Needs

Andreas Häusler*, Kari Moshenberg and Christopher Bradatsch, GAB Consulting GmbH, Germany*

For biopesticides and inorganics, there can be significant challenges meeting the exposure assessment requirements of Reg (EU) No 283/2013 and No 284/2013. These challenges are common to several biopesticides and inorganic pesticides, and can cause uncertainties in defining appropriate risk mitigation measures and inconsistencies in product authorisations. Recommendations for improvements, such as adapted approaches for substance mixtures are presented. This should facilitate the authorisation and integration of these pesticides into sustainable agriculture.

The data requirements for Reg (EC) No 1107/2009 are targeted primarily at discrete, single-compound, chemical pesticides. Biopesticides consist of active substances of natural origin including plant extracts (often complex mixtures), micro-organisms and semiochemicals. The environmental exposure of microorganisms and inorganic compounds is assessed generally using non-standard approaches that vary significantly from the approaches used for chemical pesticides.

Exposure evaluations of biopesticides and inorganic pesticides are often conducted by comparing expected environmental concentration with background concentrations. This requires spatially dense data which is commonly not available or too costly to acquire. To quantify exposure of micro-organisms as well as inorganics, standard approaches are simplified limiting the possibilities for risk mitigation measures. For single components of plant extracts, standard (FOCUS) approaches are generally suitable whereas problems arise for multi-component substances (often UVCBs). For latter substances, non-availability of modelling endpoints for all relevant components raises concerns. Particularly for compounds with heterogenous compositions, defining a single representative component can be difficult and limits the identification of appropriate concepts for risk assessment. Different approaches will be presented to address these challenges, such as proposals for improving the definition of representative/lead components of substance mixtures and alternative methods to derive modelling endpoints. Also improved concepts for exposure assessment are discussed based on current experience.

There is an urgent need for adapting current methodology for exposure assessment of biopesticides and inorganics to support their role in sustainable agriculture. These advances would also help to avoid inconsistencies in decisions on authorisation of pesticides in the EU.

3.15.P-Mo239 Demonstrating the complexity of determining pH dependence of pesticide active substances and their metabolites in GB pesticide risk assessment

*Emily Cumming[1], Chloe Blackham[1], James A. Hingston Dr.[2], **Katherine Lees**[3], Michelle Morris Dr.[1], Amy Proctor[4] and George P. T. Roddy[2], (1)Chemicals Regulation Division, Health & Safety Executive, United Kingdom, (2)Health and Safety Executive (HSE) - Chemical Regulation Division, United Kingdom, (3)Health and Safety Executive, United Kingdom, (4)Chemicals Regulation Division, Health and Safety Executive*

The dependence of degradation and/or sorption parameters with soil pH occurs when the properties - and therefore behaviour - of a substance are directly influenced by changing pH. In environmental exposure assessments, pH dependence is considered in the groundwater and surface water compartments only. Currently GB soil exposure assessments utilise the longest available DT50 (and do not consider leaching) and therefore additional consideration of pH dependence is not required for this compartment.

The two most likely reasons that the properties of a substance are directly influenced by pH are either that the substance is ionisable, or that it is prone to hydrolytic breakdown. It is important to follow the following 3 steps to determine whether pH dependence is relevant:

1. Establish if there are good scientific or **mechanistic** reasons to suspect that a relationship exists
2. Investigate the significance of the correlation using adequate **statistical** tests
3. If steps 1 and 2 indicate pH dependence, the exposure assessment should be performed accounting for any significant correlation.

Where contradictory information exists, a weight of evidence approach should be observed to determine the inclusion of pH effects in the exposure assessment. This is because if there is a plausible mechanistic basis for pH effects, supported by at least one of the statistical analyses, possible pH effects should not be discounted from the exposure assessment based on the results from the statistical tests. Determining statistically robust relationships between substance and soil properties can be difficult when dealing with small data sizes.

The subsequent exposure assessment accounts for pH dependence by undertaking modelling calculations using substance parameters derived from different agriculturally relevant acidic and alkali soil pHs. By modelling the active substance behaviour across a variety of pH dependent soil parameters (such as DT50 and Koc), the worst case PECs can be calculated based on this combination of factors.

This poster aims to demonstrate the decision making process when using mechanistic and statistical methods for concluding pH dependence in pesticide active substance exposure assessments.

3.15.P-Mo240 Proposed revision of the aged-sorption guidance document in combination with field degradation studies in regulatory assessments

*Ian Hardy[1], Wendy van Beinum[2], **Bernhard Jene**[3], Sevil Payvandi[4] and Klaus Hammel[5], (1)Battelle, United States, (2)Enviresearch Ltd., United Kingdom, (3)BASF SE, Germany, (4)Syngenta Ltd, United Kingdom, (5)Bayer AG*

In the EU Aged Sorption Guidance the use of field DegT50 values in combination with aged sorption parameters is only possible to a very limited extent. If the leaching assessment for a plant protection product (PPP) is based on field DegT50 values only, it is not recommended by the current guidance to derive a $DegT50_{equilibrium}$ (rescaling of DegT50) for input in exposure models in combination with aged sorption parameters (f_{NE}, k_{des}) as described for laboratory DegT50 values. This virtually prevents the mitigating effect of aged sorption on leaching and limits the applicability of the aged sorption guidance in combination with field DegT50 to very few cases.

However, the guidance mentions that "Industry is preparing evidence for aged sorption in field studies and this option should replace the current recommendations as soon as appropriate guidance has been developed and tested".

Therefore, additional field studies were evaluated to show the relevance of aged sorption in the field. The evaluation was mainly based on the comparison of observed concentration depth profiles versus FOCUS-PEARL simulations with and without consideration of aged sorption. Where possible, site-specific aged sorption parameters from laboratory studies with the respective field soils were used. The depth to which 95% of the residues are found was defined as metric [P5 metric] for comparison.

Proposed revisions to the current EU Aged Sorption Guidance fully allowing for the combination of field degradation and aged-sorption data are presented.

3.15.P-Mo241 Can Drainage Losses be Reduced by Optimizing Pesticide Application Dates?

Prakash Srinivasan[1]*, Carolin Kley*[2] *and Dieter Schaefer*[2]*, (1)Bayer AG, (2)Bayer AG - Crop Science Division, Germany*

Presently, in the EU risk assessment for plant protection products, there are no mitigation or refinement options available for drainage exposure apart from reducing the intended application rate and generic application time restrictions. One more flexible mitigation option could be to look in more detail at the application timing to omit the application at dates which lead to highest potential exposure via drainage. Recently published monitoring data (Tournebize et al., 2023) from the La Jaillière experimental site in France has revealed that drainage losses remarkably increased when soil moisture exceeded a certain threshold at the time of pesticide application, thereby increasing the pesticide concentrations in the receiving water bodies.

This study examines the role of soil moisture on the application day as a potential trigger in influencing exposure via drainage. Existing FOCUS and UK drainage scenarios were used to calculate a soil moisture trigger value in terms of the soil wetness index (SWI). Limiting the pesticide application to periods when the SWI is below this trigger value could reduce environmental safety concerns and enable safe uses with respect to drainage entries into water bodies. Three herbicides were chosen for this assessment. Step 3 MACRO runs were simulated with no interception and with additional hydrological outputs being switched on needed for calculating SWI on the day of application. Predicted environmental concentrations (PEC) in ditch and stream were calculated using TOXSWA model with no drift entry. The resulting maximum PEC/RAC ratio for a 1-year period after application was plotted against the SWI on the day of application.

The results show that for herbicide C for scenario D2 Brimstone a potential trigger could be set at 60% SWI. Herbicide B for scenario D6 Thiva has a potential trigger of 85% SWI. For D5 La Jaillière, for herbicide A, B and C, no clear threshold trigger was observed with 10% of the data points not following the pattern observed in the monitoring study; excluding these values, a potential SWI trigger of 85% could be observed.

It can be concluded that the threshold triggers and the magnitude of their effect on drainage losses varied between scenarios and substances depending on their properties. Thus, the decision about the applicability of this approach as a potential drainage mitigation must be done on a case-by-case basis.

3.15.P-Mo242 A Workshop Discussion on Options for Mitigation of Drain Flow and Groundwater Contamination by Pesticides

James Garratt, Adam Doxford and ***Charles Hazlerigg****, Enviresearch Ltd., United Kingdom*

There are relatively few options available for mitigating the risk for drain flow or groundwater in the UK. The usual approach is to reduce the application rate or change the timing. The UK Health and Safety Executive (HSE) funded a project to explore additional options for mitigation. The focus of this project was an online workshop to gather the views of various stakeholders from product development through to land management.

There were 38 external participants in the workshop, plus 10 participants from the project team and from the UK authority (HSE). The workshop was structured into three parallel sessions that covered 'Land Management', 'Precision Agriculture' and 'Formulation Development'. The conversations were moderated to encourage engagement but not to direct the responses. The goal was free-flowing discussion that enabled all ideas to be aired. Following a review of the workshop output, we suggest the following measures as promising new solutions, evolutions of existing solutions or furthering those currently in development.

- *New label phrases* with restrictions based on identifiable features of the field (e.g. the presence of field drains, particular soil types), coupled with Geographical Information Systems to ensure compliance.
- Inclusion of the *Scale of Use* in the regulatory regime could take a more proportional approach to risk mitigation of groundwater, and to some extent drain flow, for minor crops.
- *Better quantification of Precision Application* could give a more accurate representation of pesticide applied to a proportion of the field.
- In a *2-staged Application Process*, 'test cases' could be considered by HSE before the main evaluation, reducing the perceived risk by applicants in taking new approaches to a full evaluation. Linked to this, better guidance to support *Non-standard Assessment* methodologies.

- The integration of *Water Monitoring* into the authorisation process would allow quantitative assessment of the impact of any new measures or changes to the risk assessment.
- A consideration of *Adjuvant Risk Assessment* could permit authorisation of a formulation when applied with an adjuvant that reduces the exposure/risk.
- A measure of *Rainfastness* has the potential to refine the assessment to give a more accurate representation of what has adhered to the crop, thus reducing overall exposure.
- *Decision Support Systems* used by land managers could be considered for possible integration into risk management tools.

3.15.P-Mo243 Landscape level modelling for derivation of worst-case surface water dilution factors at drinking water abstraction locations

***Mohammad Hatamjafari**, Sebastian Gebler and Tom Schröder, BASF SE, Germany*

EFSA issued a guidance document on the impact of water treatment processes on residues of active substances or their metabolites in water abstracted for the production of drinking water. The guidance contains recommendations for the step 1 screening process, the exposure assessment of plant protection products at drinking water (DW) abstraction locations, originating either from ground water or surface water (SW). For drinking water abstracted from surface water, the guidance proposes calculating predicted environmental concentrations (PEC) at drinking water abstraction locations (PECdw) by applying a dilution factors (DF) to edge-of-field PEC_{sw} calculated according to FOCUS (FOrum for the Co-ordination of pesticide fate models and their USe). Worst-case DF are to be used as first tier; DF derived from GIS-based landscape-level assessments can be used as higher tier options. This study is an extension and continuation of a previous geospatial analysis that builds upon the Dutch DROPLET model and investigated generic dilution factors starting from edge-of-field PECsw and extending to a potential drinking water abstraction location downstream at the catchment outlet. This innovative approach incorporates agricultural land use and hydrology considerations and utilizes a stepwise GIS-based approach at EU level to include the impact of further environmental parameters that determine the environmental fate of chemical substances. The present study explores the significance of upstream agricultural land use, catchment hydrology, and connectivity of treated fields in relation to the proposed datasets and parameters outlined in the guidance, as well as beyond. This includes the use of higher resolution state-of-the-art land use data together with a more granular catchment and stream network for all EU regulatory zones. Results show a significant difference with the proposed worst-case dilution factors in the guidance. The methodology and used datasets contribute to a more realistic step 1 screening process.

3.15.P-Mo244 Drinking Water Treatment – Impact Assessment on a Newly Guided Process for Crop Protection Products in the European Union

***Kristina Ziegler** and Lydia Pape, knoell Germany GmbH, Germany*

After years of uncertainty how to address the data requirements for drinking water treatment processes under the Regulation (EC) No 1107/2009 the European Food Safety Authority (EFSA) published in August 2023 the final ‘Guidance document on the impact of water treatment processes on residues of active substances and their metabolites in water abstracted for the production of drinking water’.

The new assessment framework introduces an interdisciplinary tiered approach which should reflect the real situation regarding drinking water treatment in the EU and should allow for a conclusion on concerns for public health from exposure to harmful by-products in drinking water. Starting with an environmental fate perspective, novel compounds potentially evolving from known residues in groundwater and surface water (active substances and their environmental metabolites) during the water treatment processes shall be identified and assessed further.

For understanding the outline and potential consequences of the guidance document from an environmental fate and modelling perspective, an impact assessment was initiated. Publicly available data on active substance approval level will be searched and evaluated on the success of current attempts to address the data requirement on drinking water treatment in the area of crop protection. Further, gathered information will be consolidated to allow for conclusion on common approaches, *e.g.* for structurally similar compounds.

Many previously submitted assessments focused mainly on chlorination and ozonation. This will not be sufficient anymore as the new guidance document additionally considers the processes of UV disinfection and sand filtration. In this context, the possibility to make use of already existing approaches and options for data cross-reading will be evaluated to avoid extensive experimental laboratory testing, where applicable.

Conclusively, the presentation will highlight the challenges related to the EFSA guidance document on the impact of drinking water treatment processes from a crop protection perspective and will provide conceptual strategies for solutions.

Keywords: crop protection, active substance approval, drinking water treatment, chlorination, ozonation, UV disinfection, sand filtration, water treatment transformation products

3.15.P-Mo245 Groundwater Dilution Factor Evaluation in the EU using the Spatial LUCAS PEARL Modelling Framework

Chunming Sui[1]*, Trung-Hieu Mai*[2] *and Tom Schröder*[2]*, (1)BASF Services Europe GmbH, United States, (2)BASF SE, Germany*

EFSA and ECHA have published a new Guidance on the impact of water treatment on residues of active substance or their metabolites in water abstracted from surface water or groundwater for drinking water production. In this guidance, the exposure assessment of Plant Protection Products (PPPs) at drinking water abstraction locations from surface water considers an attenuation effect during the fluvial transport process. This is achieved by introducing a dilution factor (DF) which varies for different regulatory zones in the EU. However, the guidance does not propose a DF for the exposure at drinking water abstraction locations from groundwater. Instead, it assumes that the simulated Predicted Environmental Concentrations in groundwater at a soil depth of 1 meter ($PEC_{gw,1m}$) will serve as the final exposure indicator for drinking water abstraction evaluation. The attenuation of PPP concentrations along the flow path from the regulatory $PEC_{gw,1m}$ to raw groundwater abstraction location has been scientifically discussed on a catchment scale. However, peer-reviewed literature does not provide a systematic study on the groundwater DFs estimation on the EU level. Comprehensively quantifying groundwater DFs, by considering both vertical and horizontal aquifer attenuation processes, poses a challenge due to the limited availability of geohydrological data at the EU level.

The new Guidance on drinking water treatment suggests that a depth of 1–2m below the shallow groundwater table (i.e. GWT < 10 m) can be used as a conservatively representative depth for aquifer quality evaluation. In this work, we investigate the EU-level groundwater DFs from $PEC_{gw,1m}$ to PEC_{gw} at this suggested groundwater depth (i.e. $PEC_{gw, GWT+1\text{-}2m}$ for GWT < 10m) by considering vertical attenuation processes only. For this the LUCAS spatial soil data was coupled with the 1D leaching model FOCUS-PEARL 5.5.5. Dummy compound experiments in the LUCAS PEARL modelling framework will be used for quantification of groundwater DFs from the 1m soil depth towards the 1-2m below GWT depth (GWT < 10m) for the whole EU. Additionally, the impact of compound properties on groundwater DFs will be explored through varying the values of half-life degradation (DT_{50}) and adsorption distribution (K_{oc}) parameter in the dummy compound experiments. The work will contribute to fill the knowledge gap of groundwater DF estimation for the regulatory groundwater exposure assessment for drinking water production on EU level.

3.15.P-Mo246 Sensitivity of Water and Sediment Concentrations Simulated by the TOXSWA Model

Héloïse Thouément, Wim Beltman and ***Pauline Iris Adriaanse****, Environmental Risk Assessment, Wageningen University & Research (WUR), Netherlands*

The TOXSWA model simulates exposure concentrations for the aquatic risk assessment as part of the Dutch and EU pesticide registration procedures. We present initial results of a sensitivity analysis of TOXSWA for surface water systems with dynamic flows such as the EU FOCUS ponds, ditches or streams.

The aim of the analysis is to assess which input parameters contribute most to the studied target output parameters, esp. the peak PEC_{wat} and PEC_{sed} (Predicted Exposure Concentrations in water and sediment). We first studied the effect of the pesticide properties input for the FOCUS R1 pond. The sampled pesticide properties originate from the Pesticide Properties DataBase.

We used the sampling method consisting of Saltelli's extension of the Sobol sequence to calculate the S_1, S_2 and S_T indices, i.e. the first-order, second-order and total-order Sobol indices. S_1 measures the contribution to the output parameter's variance by a single model input alone, S_2 the contribution by the interaction of two model inputs, for all possible combinations, while S_T measures the contribution by a model input, including both its first-order effects and all higher order interactions. We did around 50 000 model runs.

The S_1 indices for the R1 pond show that a single parameter accounts for 89% of the variation in the PEC_{wat}: the $K_{om,ss}$, the coefficient for Freundlich sorption to suspended solids. The next most sensitive input parameter is the K_{mp}, the coefficient for linear sorption to macrophytes, with a S_1 index of only 2%. This is significantly lower than expected based on field experiments. Very probably, this is related to the limited input range of the K_{mp}, compared to the one of the $K_{om,ss}$. Concerning the PEC_{sed} the three highest S_1 indices are 34% for the $K_{om,sed}$ (Freundlich coefficient for sorption to sediment) and 6% for the degradation half-lives in water and in sediment. Their S_T indices raise to 63%, 21% and 18%, indicating that significant interactions with other input parameters exist. The sum of the S_T indices for all studied input parameters is 147%, indicating that the TOXSWA model behaves non-linearly with respect to the PEC_{sed}.

A next step is to look into the variation of the PEC_{wat} and PEC_{sed} for the FOCUS R1 stream with its high flow velocities. The results of the sensitivity analysis allow for a better understanding of the TOXSWA model behaviour, which is useful for model validation and for definition of e.g. sediment scenarios for use in registration.

3.15.P-Mo247 Reduction of Complexity: Variance-based Sensitivity Analysis for FOCUS STEPS

Dimitrios Alexander Skodras *and Judith Klein, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany*

To standardize the role of models in the European Union (EU) plant protection product authorization process, Forum for the Co-ordination of pesticide fate models and their use (FOCUS) has established guidelines, including the FOCUS STEPS models for surface water risk assessment. Conservative scenarios representing EU member states are used, with a 4-tier approach for limit value exceedance. Higher-tier calculations, while requiring more information, provide more accurate results. When calculating the respective tiers, however, the accuracy of the model parameters does not have to be specified. This can mean that a parameter to which the model reacts very sensitively - i.e. the result depends relatively heavily on variations of it - can lead to a large inaccuracy.

The project employs sensitivity analysis using the Sobol' method. Model parameters are sampled using low-discrepancy sequences, and Sobol' indices are calculated to determine the sensitivity of the FOCUS STEPS models to parameter variances. The analysis focuses on the first order Sobol' indices representing the main effects, providing insights into parameter influence.

FOCUS STEPS 1 as the simplest example, is presented with a limited set of parameters. The analysis of scenario parameters, such as drift and runoff proportions, field-to-water ratio, and water depth, reveals sensitivity patterns. For low values of the sorption constant Koc, the model is sensitive to runoff parameters, while higher Koc values make it more sensitive to drift fraction. With low Koc leading to high concentrations, the variance of runoff parameters should, hence, be decreased to a minimum. Higher Tiers are handled to some extend afterwards.

Sensitivity analyses help identify influential processes and parameters. The variance-based analysis guides users on reducing uncertainties, especially when concentrations are near regulatory thresholds. Considerations for modifying model user interfaces to suggest variance sensitivity based on input configurations are proposed for enhanced user guidance.

3.15.P-Mo248 The Effect of Time-Varying Soil Properties Caused by Ploughing and Consolidation on Pesticide Fate in Soil and Groundwater

*Pavan Cornelissen[1], **Louise Wipfler**[1], Maarten Braakhekke[2] and Marius Heinen[3], (1)Environmental Risk Assessment, Wageningen University & Research (WUR), Netherlands, (2)Environmental Risk Assessment, Wageningen Environmental Research (WUR), Netherlands, (3)Soil, Water and Land Use, Wageningen Environmental Research (WUR), Netherlands*

Soil properties such as the dry bulk density and soil hydraulic parameters can significantly affect the environmental fate of pesticides. These properties are often assumed to remain constant in time in numerical models. However, these properties change over time during ploughing and consolidation in reality. In this study, we modeled the time-varying soil properties induced by ploughing and consolidation and assessed its effect on pesticide accumulation in the topsoil and leaching to the groundwater. For this purpose, time-dependent soil properties have been implemented in the pesticide fate model PEARL. Ploughing instantaneously decreases the bulk density, after which it gradually increases again to its original value through consolidation caused by rainfall. The time-dependent soil properties are modelled based on empirical relationships between the dry bulk density and the Mualem-Van Genuchten parameters found in the literature.

Ploughing leads to a short-term deviation of the soil water content and concentration compared to the reference case (i.e., the case with constant soil properties). We included mixing of pesticide over the ploughing layer due to ploughing in both cases. However, under Central European climate conditions, the effect of ploughing vanishes within several months in the entire soil profile. For assessing the impact on the leaching of pesticide to groundwater, we evaluated the pesticide concentration in pore water at 1 meter depth. The effect of time-varying soil properties due to ploughing and consolidation on the leaching concentration was found to be small for both a tracer and an adsorbing solute. Even for an extreme case with three ploughing events per year, the effect on the 90th-percentile of daily leaching concentration was smaller than 0.3%. For assessing the impact on the exposure of soil organisms to pesticides, we considered the pesticide concentration in pore water averaged over the upper 20 centimeters of the soil. For the tracer, ploughing resulted in a 1.2% decrease of the 90th-percentile of daily topsoil concentration data for the extreme case of three ploughing events per year. Interpretation of the results for adsorbing solutes in the topsoil is hampered by the fact that soil mass is not conserved in the current approach. More advanced models must be developed that allow for conservation of soil mass for assessing the impact of time-dependent soil properties on concentrations in the topsoil.

3.15.P-Mo249 C2D2 Novel Crop Development Data for Use in Pesticide Exposure Modelling and Risk Assessment

***Gregory Hughes**[1], Andrew Eatherall[2], Michael Bird[3], Gerald Reinken[4], Philip R Branford[5], Sebastian Gebler[6], Anthony Lozano[7], Paul Massey[8] and Liz Whitworth[9], (1)GeoSpatial Analytics Ltd, United Kingdom, (2)Corteva Agrisience, United Kingdom, (3)Syngenta, United Kingdom, (4)Bayer, Germany, (5)ADAMA Agricultural Solutions, United Kingdom, (6)BASF SE, Germany, (7)Sumitomo Chemical Agro Europe SAS, France, (8)FMC Agricultural Solutions, Afghanistan, (9)RSK ADAS, United Kingdom*

Determining appropriate pesticide application windows is an important part of pesticide exposure modelling. Increasingly, regulators are constraining application windows using the AppDate software. Given exposure assessments are a function of the application dates this software generates, it is important to understand how representative they are; however, an appropriate pan-European crop phenology dataset was previously unavailable for such an assessment. Efficacy trial datasets sourced from seven members have been harmonised to create the Crop Life Europe Crop Development Database (C2D2) that meets this need and has been made freely available under a Creative Commons licence (https://zenodo.org/records/8393135) to facilitate innovation in exposure science to allow for more accurate and realistic risk assessment leading to enhanced crop and environmental protection.

The C2D2 database holds data for a wide range of crops, including some crops that have a limited geographic distribution and extent, for example cotton. Another such crop is rice which has very specific production requirements and is only produced in a small number of locations within the EU. While rice is not covered by the FOCUSsw/gw scenarios, exposure scenarios to assess the fate of active substances applied to this crop are available and evolving. A comparison of the rice data held within C2D2 was made against the proposed scenario crop development dates for the four scenarios covering Greece, Italy, Spain and France/Portugal. The analysis indicates that there is sufficient C2D2 rice data in Spain and Italy that a comparison can be undertaken and indicates that the proposed crop development is plausible albeit there is room for refinement. This assessment illustrates how crop development stages for novel and/or minor crops that are not covered by the existing FOCUSsw/gw scenarios might be developed using C2D2. While previous C2D2 publications have focussed on the widespread combinable crops, this poster explores how C2D2 might be used for other novel and minor crops, for example nuts, citrus, cotton, tobacco and lavender.

3.15.P-Mo250 The role of the ratio of sorption to degradation in leaching

Siul Ruiz[1]*, Sevil Payvandi*[2]*, Paul Sweeney*[3] *and Tiina Roose*[1]*, (1)Bioengineering Sciences Research Group, Department of Mechanical Engineering, School of Engineering, Faculty of Engineering and Physical Sciences, University of Southampton, (2)Syngenta Ltd, United Kingdom, (3)Product Safety, Syngenta, United Kingdom*

Models are used extensively to predict the leaching of pesticides. For example in the EU, PEARL, PELMO, and MACRO are numerical models used in the regulatory risk assessment. These models are often complex in that they consider many processes (e.g. temperature and water distribution within the soil, crop growth, nonlinear compound sorption, and compound transport due to advection, diffusion, and dispersion). The purpose of regulatory models is to be a conservative indicator of the potential for leaching, and it is important that these models continue to incorporate advancements in mechanistic understanding.

Whilst scientific development of these models is necessary, it is also paramount to understand the relative importance of the processes considered. There is a risk that ever-increasing complexities associated with pesticide transport in soils causes models to be treated as black boxes and fundamental understanding is lost. In this work we will use mathematical methods to highlight the role of the ratio of sorption and degradation in compound transport.

To derive fundamental insight, we extend the work of Jury (1987) and analytically derive the steady state solution for pesticide transport as a function of depth considering nonlinear sorption using the mathematical technique of asymptotic expansions. We consider that degradation occurs in both the soil and liquid phases and that transport is driven by advection, diffusion, and dispersion. We include the influence of temperature on biodegradation, and the role of depth on sorption and biodegradation. We compare the steady state analytical solution with extended duration PEARL runs for all FOCUS scenarios and find that the ratio of sorption to degradation is generally the dominant factor in leaching. However as absolute values of degradation and sorption decrease, the influence of weather fluctuations increases.

In summary, we present an analytical solution of the steady state of pesticide leaching that considers nonlinear sorption and biodegradation in all soil phases. We show the importance of considering the ratio of sorption and degradation as a dominant determinant in pesticide leaching rather than independent properties. Lastly, whilst this method is applied here to PEARL and FOCUS scenario weather files, this method can be applied to any region where chromatographic flow is relevant, and this method allows either simple or complex parameterisation (i.e. from average conditions to weather files).

3.15.P-Mo251 MACRO 5 Multithreading for the CRD UK higher-tier drainflow tool

Denis Weber[1]*,* ***Michael Brauer***[1]*, Jonathan Evans*[2]*, James A. Hingston Dr.*[2] *and Tim Jarvis*[3]*, (1)Exponent International Ltd., Switzerland, (2)Health and Safety Executive (HSE) - Chemical Regulation Division, United Kingdom, (3)Exponent International Ltd., United Kingdom*

Introduction: A software tool was developed that allows the application of MACRO 5 multithreading to the official HSE CRD UK higher-tier drainflow tool. The current UK higher-tier drainflow tool allows sequential runs of MACRO 5, i.e. it is based on a "single run" MACRO 5 approach, resulting in high simulation times for all 12 scenarios.

The MACRO 5 multithreading tool is an add-on to the HSE CRD UK higher-tier drainflow tool v2.1. The add-on was developed in collaboration with the UK pesticide authority HSE. The purpose of the multithreading tool is to reduce the simulation time of the MACRO 5 runs by allowing multiple MACRO runs in parallel instead of running MACRO sequentially.

Technical details of the tool and benefits for the UK higher-tier drainflow assessment are presented and discussed.

Materials and methods**:** The multithreading software tool was developed in C# as a standalone GUI. The tool is able to run the 12 scenario/climate combinations in parallel. It is able to run all three types of MACRO runs (Parent, Driving files and Metabolite). Evaluations are still possible with the HSE CRD software tool. In addition, the multithreading add-on tool can be opened in multiple instances. Therefore, two or more separate substances with e.g. 12 scenarios each, could be run in parallel, only limited to the processor power in a computer. Test runs were performed with different setups and total number of MACRO runs.

Results and discussion: The calculation time decreased significantly for MACRO 5 by ~80 to 90% using multithreading. If metabolites are considered, the simulation time would increase for sequential runs because of additional intermediate and metabolite runs.

Conclusions: In conclusion, the multithreading software tool has the following properties:

- Standalone GUI
- Multithreading allows a reduction of MACRO 5 calculation time by around 90%
- No adaptation or manipulation of the existing MACRO model necessary, no changes in program code
- Offical add-on to the offical UK higher-tier drainflow tool, to be released via HSE CRD website

Future implementations

- A standalone MACRO multithreading GUI for the current FOCUS SW and GW software is already available
- Implementation into the current FOCUS software suite possible without any software adaptation or model changes
- GUI for FOCUS SW multi-year approach would be also available soon
- Discussion about implementation with FOCUS VC and EFSA necessary

3.15.P-Mo252 Acre Tool For Automated Surface Water Modelling
Alice Tagliati*, Wendy van Beinum and Scott Watson, Enviresearch Ltd., United Kingdom*
Acre is Enviresearch's automation software designed to aid the agrochemical industry in modelling the fate of pesticides in the environment. Using the same FOCUS models and scenarios as the official FOCUS tools, Acre offers a low effort solution for conducting surface water modelling to support preliminary aquatic risk assessments for new products, uses, and product renewals.

It streamlines the surface water assessments for pesticides by automating the FOCUS Step 3 and 4 surface water modelling process. With Acre, modelling a large set of scenarios that would typically require several days to run manually can be performed in a matter of hours.

- All inputs necessary for running the FOCUS Step 3 and Step 4 simulations within a single user-friendly spreadsheet. This eliminates the need to navigate various interfaces for setting up simulations and reducing the risk of human error from input of inaccurate information.
- Enables high-throughput running simulations, allowing multiple substances, crops, pesticide application rates and timings, and mitigation combinations to be managed within a single spreadsheet.
- Low effort solution for scoping new products with a large set of potential uses and mitigations across various countries in the EU.

Enviresearch is looking for regulatory acceptance of automated modelling tools such as Acre to be recognized and accepted alongside the official tools overseen by FOCUS version control. Acre replaces the FOCUS shells by controlling the input and execution of the models. It is therefore essential that Acre is taken through the same level of scrutiny and testing as the FOCUS tools. Whilst automation is becoming the norm, there is a general need within the regulatory community to address the process for regulatory acceptance of new tools, and how to manage testing and version control.

3.15.P-Mo253 Development of an Interim Modelling Methodology using the FOCUS Models for Simulating the Fate of Copper in Soil, Water and Sediment
Simon Charles Ford[1]*, Ian Hardy*[1] *and Stephen Lofts*[2]*, (1)Battelle, United States, (2)UK Centre for Ecology & Hydrology (UKCEH), United Kingdom*
The 2021 EFSA PPR Statement on environmental risk assessments for transition metals indicates that exposure models and scenarios would need to be adapted to address environmental processes and parameters relevant to the fate and behaviour of transition metals in water, sediment and soils.

This study on behalf of the EU Copper Task force seeks to identify shortfalls in the current suite of FOCUS pesticide fate models for simulating the fate of copper in soil and water and develop an interim modelling methodology with the FOCUS models to address those shortfalls until a full modelling framework for transmission metals is available.

Processes common to copper and organic plant protection products and present in the FOCUS MACRO, PEARL or TOXSWA models were identified e.g. equilibrium sorption to soil solids, non-equilibrium sorption to soil solids, equilibrium sorption to suspended sediments, diffusive exchange between water column and bottom sediments and equilibrium sorption to macrophyte surfaces.

Processes important for copper not present in MACRO, PEARL or TOXSWA were also identified e.g. fixation of copper into soil and sediment solids, soil erosion and transfer of copper to surface waters, deposition and resuspension of sediments in surface waters, dissolution of solid copper forms and formulations following deposition onto plant surfaces, soils and surface waters, complexation in surface water, influence of the presence of a natural background of copper and formation and dissolution of copper sulphide in anoxic sediment layers.

Methodologies were developed to implement important copper processes within the current FOCUS models through parameterisation of surrogate processes included in the models. Processes such as dissolution of particulate copper formulations were simulated as a parent (solid) to metabolite (dissolved) relationship in soil, water and sediment using dissolution study data while degradation in soil served to simulate ageing of copper in soil and sediment.

The modelling approaches developed retain the FOCUS modelling framework and scenarios we know to provide an acceptable description of agronomically relevant hydrological scenarios and simulate important processes for describing the fate of copper in soil, water and sediment, allowing for risk assessment of environmentally relevant and available dissolved copper as an interim modelling approach until such time as bespoke models and frameworks are available for transmission metals.

3.15.P-Mo254 Development and validation of a hybrid GIS catchment vulnerability ranking model for losses of pesticides to surface water

Liesa Brosens[1]*, Ingeborg Joris*[1]*, Piet Seuntjens*[1] *and Robin Sur*[2]*, (1)Flemish Institute for Technological Research (VITO), Belgium, (2)Environmental Safety, Bayer AG - Crop Science Division, Germany*

The intensive use of pesticides has led to their widespread presence in the environment. Although pesticides are primarily applied to crops or soil, various transport mechanisms contribute to elevated pesticide concentrations in surface waters. To comprehend the potential sources and pathways of pesticides to surface waters, detailed monitoring and modelling studies have been undertaken. To extrapolate the insights gained from these studies to other locations, it is crucial to contextualize these catchments and their vulnerability to pesticide presence in surface water. The development of a catchment vulnerability ranking index is essential in this regard, serving as a decision-making tool to prioritize catchments for future studies or to identify locations where mitigation measures would be most beneficial.

A catchment vulnerability ranking method was developed for the presence of pesticides in surface waters. This method has been applied to Flanders, Belgium, a region characterized by frequent exceedances of pesticide environmental limits in surface waters. The vulnerability of catchments is assessed based on a hybrid GIS approach, considering pesticide emissions through two primary transport routes: surface runoff and soil erosion. Pesticide emissions are calculated at the parcel-level considering environmental factors such as land use, crop rotations, soil characteristics, precipitation, and topography, as well as the chemical properties and usage patterns of the selected substances. Pesticide emissions are evaluated at the catchment level, thereby explicitly accounting for landscape connectivity.

Leveraging data on discharge and pesticide concentrations from a monitoring network in Flanders, pesticide loads were calculated at 15 locations. An automated point-detection algorithm was applied and only observations during the application period were considered for load calculations. These loads and their associated catchment vulnerabilities served as a validation dataset for the developed method. Initial findings indicate a good agreement between observed and modeled loads, particularly when considering inputs from erosion alone or a combination of erosion and runoff.

The application of this method to the entirety of Flanders will empower policymakers to readily identify catchments prone to pesticide presence in surface waters and to guide them in selecting priority locations for monitoring and implementing mitigation measures to safeguard water quality.

3.15.P-Mo255 Modeling the Exposure of Soil Organisms to Pesticides in Brazil: A Scenario for Tier-1

Jhon Kenedy Moura Chagas[1]*, Gabriel Sehnem Heck*[1]*,* ***Vicente Arcela***[1]*, Daniel Leão Bandeira de Melo*[1]*, Clara Wandenkolck Silva Aragão*[1]*, Rosana Quirino de Souza*[1]*, Stephany da Costa Soares*[1]*, Bruno Fernandes Falcão*[1]*, Michelle Caroline Santos Rocha*[1]*, Bianca Vidal Freire*[1] *and Romulo Scorza Junior*[2]*, (1)Brazilian Institute of Environment and Renewable Natural Resources (IBAMA), Brazil, (2)Embrapa, Brazil*

Pesticides, widely used in agriculture, can pose risks to soil organisms and ecosystem functions. Thus, it's crucial to conduct a tiered Environmental Risk Assessment (ERA) of pesticides in soil, starting with a conservative and simplified scenario (Tier-1) and progressing to more complex scenarios. However, the ERA for soil organisms in Brazil is yet to be implemented.

This study proposes a Tier-1 exposure scenario for soil organisms in Brazil, based on a geospatial analytical model. This model estimates the environmental concentrations of pesticides in soil using spatially explicit data on soil properties, temperature, and agricultural land use.

The model applies first-order kinetics with temperature adjustment and a Q10 factor to calculate the predicted environmental concentration (PEC) for each day of the year, over 10 years, assuming a constant application rate of 1 kg a.i. ha^{-1} on the first day of each year. Five half-life values (DT_{50} = 10, 31, 100, 316, and 1000 days) were tested to represent different levels of pesticide persistence in soil.

The model considers first-order kinetics, temperature adjustment, and conservative assumptions, such as no interception, retention, or removal processes of pesticides in soil. It estimates the PEC of pesticides in soil for each pixel of 1 km^2 and each half-life time, using geospatial data of soil density and daily mean temperature.

The 90th percentile (P_{90}) of the PEC distribution was used as the reference parameter for the exposure assessment. The location and characteristics that best matched the P_{90} value were identified and used as the Tier-1 exposure scenario for soil organisms in Brazil. This scenario is located in the south of São Paulo state, on a Latossolo Vermelho-Amarelo (Oxisol) of sandy clay texture with low organic carbon and CEC, and a mean daily temperature ranging from 15.6 to 24.3 °C.

The scenario method is easy to apply on ESCAPE 2.0, providing a conservative estimate of the PEC for Tier-1 ERA. It can also be adapted to other DT_{50} values and exposure patterns and can be refined in higher tiers using crop-specific dependent scenarios or numerical models. This method can help advance the implementation of the ERA for soil organisms in Brazil, supporting the decision-making process for pesticide registration and management.

3.15.P-Mo256 Promoting Defensible Science in Aquatic Exposure Estimation by Integrating Landscape-Level Data into US Endangered Species Assessments

***Christopher M Holmes**[1], Logan Insinga[1], Steve Kay[2], Matthew E Kern[3], James L. Cowles[4] and Kevin Henry[5], (1)Applied Analysis Solutions, LLC, (2)Pyxis Regulatory Consulting, Inc. / Generic Endangered Species Task Force (GESTF), (3)Balance EcoSolutions LLC, (4)Tessenderlo Kerley, Inc. / NovaSource, (5)Tessenderlo Kerley, Inc.*

Prospective aquatic exposure modeling is a key component of the assessment of potential jeopardy of endangered species during the preparation of a risk assessment related to federal US pesticide (re)registration. The “Biological Evaluation” prepared by the US Environmental Protection Agency (USEPA) provides the foundation of aquatic exposure estimates using well-established pesticide fate and transport models applied to a standardized set of crop/soil/weather scenarios. Exposure estimates are based on 30 years of model simulation representing labeled uses of the pesticide assuming maximum application rates, maximum number of applications, and minimum re-application intervals, as well as assuming treated crop is adjacent to the aquatic environment. This modeling forms the basis from which subsequent refinements incorporating spatial, temporal, and pesticide usage variability can be applied. Further refinement of the screening-level modeling is essential to more accurately inform the weight of evidence process used by the US Fish and Wildlife Service and National Marine Fisheries Service to determine species jeopardy in the next stage of the assessment, the “Biological Opinion”. To support this refinement, we present a highly efficient, quantitative approach that builds on the USEPA’s aquatic modeling by increasing the spatial/temporal context and resolution of exposure estimates to species of interest and producing well-defined and reproducible species-specific estimated aquatic concentrations. Utilizing data for each species, a set of high-resolution catchments, landscape-based crop proximity and density, and pesticide usage, inputs were processed to produce landscape-level exposure concentrations suitable for aggregation at multiple spatial scales appropriate for the species being examined. These refinements show that aquatic concentrations based on screening level assumptions of pesticide use and hypothetical water body scenarios may occur at some locations at limited times, but they are far less likely to occur within species range/habitat than is assumed in the screening-level risk assessments. The methodologies presented are a quantitative approach to refining aquatic exposure estimates that incorporate variations in landscape and agronomic practices near endangered species locations and provide essential information to help inform localized mitigations for individual species across specific use patterns.

3.15.P-Mo257 Patterns in agricultural practice related concentrations of currently-use pesticides in soils from the province Friesland, Netherlands

***Aagje Ingetje Saarloos**[1], Wouter Bakker[2], Paul van den Brink[1] and Nico van den Brink[1], (1)Wageningen University & Research (WUR), Netherlands, (2)Toxicology, Wageningen University & Research (WUR), Netherlands*

Farmland birds are often of sensitive conservation status. One of the stressors that may result in their population size decline, is that these birds depend on areas where often multiple pesticides are used. In 2020, 5 million killogram of pesticides were applied on Dutch agricultural fields and a total of 257 active substances are approved for usage in the Netherlands. Despite this wide variety of pesticides and their large-scale application, a potential direct correlation between pesticide usage and the decline in farmland birds remains poorly studied. As a first step to achieve a better understanding of the potential exposure of farmland birds to pesticides, our current study aims to quantify currently-used pesticides that are present in soils of famland birds’ habitats, and relate these observed pesticide concentrations to current and historic land-use. Soil samples were collected from 26 different agricultural fields in June and July 2020 in the province Friesland (Netherlands), which is an essential breeding area of the famland bird *Limosa limosa.* The sampled plots consisted of: i) 4 bulb fields, ii) 7 corn fields, iii) 8 grassland fields, and iv) 7 old-grassland fields. Old-grassland means that, as far as known, no other crop than grass has been cultivated on the field. 15 samples were randomly obtained (0-5 cm depth) from each plot and pooled into 3 composite samples per plot. All soil extracts were screened for 648 pesticides using LC-MS/MS, detected pesticides were quantified and the derived concentrations correlated to current land-use, historic land-use, and agricultural practice. Not all derived pesticide concentrations are in line with expected patterns about pesticide usage mentioned in literature. An explanation is that our current study does not cover different seasons or time points, while time is a decisive factor. Although work is still in progress, we can already conclude that: i) the general pattern is that bulb and corn fields contain the highest concentrations of pesticides, ii) the lowest concentrations and lowest number of pesticides were observed in old-grassland fields, iii) the number and pesticide concentrations in grassland are dependent on the land-use history of a plot, and iv) over time, pesticide concentration levels resulting from bulb cultivation, decrease. However, pesticides used for bulb cultivation may still be observed years after ending bulb cultivation.

3.15.P-Mo258 Accelerated Solvent Extraction with Liquid Chromatography Targeted Tandem Mass Spectrometry and Nontargeted High Resolution Mass Spectrometric Methods as a Tool for Targeted Pesticide Management

***Alina Sadchenko**[1], Ganna Fedorova[1], Helena Švecová[1], Ales Klement[2], Radka Kodesova[3] and Roman Grabic[4], (1)University of South Bohemia in České Budějovice, Faculty of Fisheries and Protection of Waters, Czech Republic, (2)Soil Science and Soil Protection, Czech University of Life Sciences, Czech Republic, (3)Soil Science and Soil Protection, Czech University of Life Sciences Prague, Czech Republic, (4)University of South Bohemia in Ceske Budejovice, Faculty of Fisheries and Protection of Waters, Czech Republic*

Using pesticides to ensure high crop yields is integral to modern agriculture. However, with increased productivity comes growing concern about the potential impact of pesticides and their metabolites on the environment and human health through food and groundwater.

Herbicides are the most used class of pesticides in the Czech Republic. However, they are usually applied to crops like rape, corn and sugar beets. This work focused on 14 agricultural fields in the Czech Republic in July 2023, mainly used for fast-growing and highly variable crops like vegetables. Out of 110 pesticides and their metabolites analyzed by the targeted LC/QqQ method, 73 were above the LOQ in at least one soil. Fields with the same crops showed highly variable contamination patterns. Only one field with carrots was polluted with bentazone (320 ng/g) and linuron (140 ng/g). In other samples, those compounds were not detected or were 2 orders of magnitude lower.

On the other hand, azoxystrobin, a fungicide widely used in agriculture, was detected in all tested fields (in carrot fields 22-1600 ng/g; potato fields 15-720 ng/g; onion, lettuce, and parsley fields- 220-340 ng/g). The targeted method used for analysis was rooted in the range of pesticides and their transformation product frequently found in surface and ground waters. Despite some overlaps, e.g., azoxystrobin, epoxiconazole and tebuconazole, we hypothesize that soil pesticide patterns should differ from surface water. We applied nontargeted LC – full scan HRMS with a data-independent MS2 (DIA) method for screening other present unknown pesticides or their transformation product. We have identified many compounds at Schymanski identification uncertainty 2 or 3.

Consequently, we have purchased reference standards for the most interesting ones and developed a targeted method. We aimed to investigate how valid the abundance of unknowns expressed like peak area is for ranking and prioritizing pesticide selection for targeted management on the local scale, i.e., if using peak area only can be applied for local pesticide management. The study was conducted within the project of the Ministry of Agriculture of the Czech Republic, National Agency for Agricultural Research (project no. QK23020018).

3.15.P-Mo259 Spatial Heterogeneity of Soil Properties Shapes Residual Pesticide Concentrations on the Meter-Scale

***Yiqing Zhang**[1], Marie Uksa[1], Qiuguo Fu[2], Anne Röhrig[2], Thorsten Reemtsma[3], Hauke Harms[1] and Lukas Wick[1], (1)Department of Environmental Microbiology, Helmholtz Centre for Environmental Research (UFZ), Germany, (2)Department of Analytical Chemistry, Helmholtz Centre for Environmental Research (UFZ), Germany, (3)Helmholtz Centre for Environmental Research (UFZ), Germany*

Conventional agricultural management often includes field-wide, mostly homogenous application of pesticides without considering the spatial heterogeneity of soil properties or the degradation potential of microbial degrader communities. The environmental fate and soil residual concentrations of pesticides, however, vastly depend on the soil properties and environmental conditions. In an agricultural field (0.5 km^2) we here determined the meter-scale spatial soil heterogeneity at 60 different locations at two soil depths and correlated the data to residual concentrations of pesticides (and their transformation products) that had been applied in the last ten years. While there were small differences between the two soil depths, we found a significant spatial soil heterogeneity of soil texture (loamy sand to clay soils; 2.0-87% sand content), pH (5.6-7.3), water holding capacity (25-67%), total nitrogen (TN; 8-24%), soil organic carbon (SOC; 0.8-2.5%), and 16S rRNA (3-13 * 10^9 copies g^{-1}_{dw}) and ITS (9-114 * 10^7 copies g^{-1}_{dw}) gene copy number as proxies for bacterial and fungal biomass. 34 herbicides, 11 fungicides, and 5 insecticides were detected in our samples with the herbicide chlortoluron being the most abundant compound at concentrations of up to 58.1 ng g^{-1} in clay loam soils. 21 of the pesticides were detected in all soil samples. Total pesticide concentrations exhibited positive correlation with TN, SOC, fungal biomass, and the ratio of ITS to 16S rRNA gene abundance as indicator of soil microbial community composition, while they negatively correlated with the sand content, the WHC. By contrast, lower concentrations of transformation products were detected in soil with lower ITS to 16S rRNA gene abundance ratios, lower sand content and higher water holding capacity, resp. Our data demonstrate high meter-scale spatial variability with concomitant effects on residual pesticide loads should be considered in future precision farming applications. Our ongoing work relates intra field-specific heterogeneity to microbial pesticide degradation and determines its potential effects on toxic endpoints by bio-analytical tools.

3.15.P-Mo260 Pesticides in Agricultural Soils: Major Findings From Various Monitoring Campaigns in Switzerland

Thomas D. Bucheli[1], *Nora Bartolomé*[2], *Elias Barmettler*[3], *Isabel Hilber*[2], *Karel Hornak*[2], *Reto G. Meuli*[4], *Vanessa Reininger*[4], *Judith Riedo*[5], *Andrea Rösch*[1], *Philipp Sutter*[1], *Marcel Van der Heijden*[3], *Florian Walder*[5] *and Daniel Wächter*[4], *(1)Environmental Analytics, Agroscope, Switzerland, (2)Environmental Analytics, Environmental Analytics, Agroscope, Switzerland, (3)Plant-Soil Interactions, Agroscope, Switzerland, (4)Swiss Soil Monitoring Network (NABO), Agroscope, Switzerland, (5)Agroscope, Switzerland*

Synthetic pesticides are widely applied in modern agriculture, where they are used against diseases, pests, and weeds to secure crop yield and quality. However, their intensive application has led to widespread contamination of the environment, including soils. Due to their inherent toxicity, they might pose a risk to soil health by causing harm to non-target organisms and disrupting ecosystem services in both agricultural and other exposed soils. Following the Swiss National Action Plan on the reduction of pesticide risks, Agroscope has conducted several soil monitoring studies that are briefly presented here. All of them resort to different multi-residue trace analytical approaches to simultaneously quantify up to about 150 modern pesticides by either accelerated solvent, or Quick, Easy, Cheap, Efficient, Rugged, Safe (QuEChERS) extraction, followed by separation and detection with liquid chromatography-triple quadrupole mass spectrometry. While partly still in progress, our investigations led to the following major findings this far: Multiple pesticides are commonly present in soils, with individual concentrations in agricultural soils often reaching up to a few tens of µg/kg. Pesticide occurrence and concentrations in agricultural soils primarily depend on land use, land use history and cultivated crops. Pesticides can prevail much longer than predicted by their half-lives, and were found in soils even decades after conversion from conventional to organic farming. Corresponding residual fractions can be in the order of a few percent of the originally applied amounts. We further found negative associations of pesticide residues with the abundance of beneficial soil life, underpinning their potential risk to the fertility of agricultural soils. Traces of pesticides are also detected in soils to which they were never applied, indicating contamination, e.g., via spray drift or atmospheric deposition. These results confirm the general notion of both scientists and legislators that prospective risk assessments (RA; as executed during registration and use authorization) should be confirmed and adjusted by retrospective RA (e.g., by environmental monitoring studies of currently used compounds) to jointly lead to an overall reduced environmental risk of pesticides.

3.15.P-Mo261 Current Use Pesticides in Spatial and Temporal Distribution in Soil and Vegetation of Agricultural Sites

Carolina Honert[1], *Ken M. Mauser*[2] *and Carsten A. Brühl*[2], *(1)Institute for Environmental Sciences Landau, Rhineland-Palatinate Technical University Kaiserslautern-Landau (RPTU), Germany, (2)Rhineland-Palatinate Technical University Kaiserslautern-Landau (RPTU), Germany*

In recent decades, awareness of the potential impact of pesticides on the environment has increased. Pesticides are widely used in agriculture to control pests and diseases and to increase crop yields. However, they can also have negative impacts on the environment and are also discussed in the context of insect decline. Insects developing in soil and feeding on vegetation are exposed to pesticides. To gain a better understanding of the presence and seasonal variations of pesticide residues in agricultural landscapes, a comprehensive study was conducted to better understand realistic exposure of insects.

The main objective of this study was to record current use pesticide residues in fields and meadows over a period of one year to cover the seasonal change of occurring pesticides. For this purpose, monthly soil and vegetation samples were taken from different agricultural fields (viticulture, vegetable fields, arable crops, three fields each) in the crop and at three points of increasing distance (1 m, 5 m, 20 m from the field) in adjacent meadows. The analyses for residues of 94 different pesticides were carried out with a high-performance liquid chromatograph coupled with an electrospray ionization tandem mass spectrometry (HPLC-ESI-MS/MS) to ensure accurate qualification and quantification of residues. To our knowledge this is the first temporal pesticide distribution dataset for soil and vegetation.

Our unique dataset shows that over the course of a year, different current use pesticides (CUP) were detected in sampled soil and vegetation from agricultural fields, but also from untreated meadows in their surroundings. We detected a variety of pesticides in different concentrations and mixtures with up to 28 pesticide residues in soil (Ø 10.3 CUPs per soil sample) and 25 in vegetation (Ø 7.24 CUPs per vegetation sample), with residues of some substances (fluopyram, boscalid) being recorded in almost all samples. Seasonal fluctuations were observed in vegetation samples, while almost no changes were observed in the topsoil samples over the course of the year.

The available data provide essential insights into the long-term fate of pesticides in the environment and provide realistic exposure data for insects in agricultural landscapes. Our results can help to develop targeted measures to reduce pesticide exposure and a protective environmental risk assessment.

3.15.P-Mo262 Contaminated Landscapes – Current Use Pesticides Residue Measurement in the Upper Rhine Valley

Ken M. Mauser, *Jakob Wolfram, Jürg Spaak and Carsten A. Brühl, Rhineland-Palatinate Technical University Kaiserslautern-Landau (RPTU), Germany*

Pesticides are applied on crops and would optimally be restricted to agricultural fields. Yet they have been detected in non-target areas including nature conservation areas, that serve as refuges for protected plant and animal species and are therefore of particular concern. This research aims to examine the landscape scale distribution of current-use pesticides in the Upper Rhine Valley in Germany, a region characterized by intensive agricultural practices in the valley and remote areas in the Palatinate Forest and Black Forest. In 2022, vegetation, soil, and water samples were collected at 78 non-target, off-crop sites

in 6 systematic 30 km long transects with west/east orientation during the pesticide application season and subjected to a comprehensive extraction and analysis that included 94 different pesticides. In total, 68 different pesticides (29 fungicides, 22 herbicides and 17 insecticides) were detected in the samples (n=186). Residues were detected in 97% of all vegetation (n=78), 97% of all soil samples (n=78) and 87% of all water samples (n=30). In total, 144 unique mixtures with ≥ 2 components were recorded. Samples in off-crop habitats in agricultural landscapes (valley) showed 90 unique mixtures, whereas 57 unique mixtures were detected in mountain regions. A higher mean number of CUP detections was recorded in the valley (mean = 10.1) than in the mountain region (mean = 3.2) across all sample types. Applying the pesticide detections and site-specific parameters in a linear model, a prediction map was generated to illustrate the extent of pesticide exposure across the entire landscape of the Upper Rhine Valley on 50 by 240 km. To our knowledge this is the largest scale exposure model available for a Central European landscape. Specific spatial weightings for land use types were identified. The results indicate a widespread presence of pesticides that extends beyond areas where pesticides are applied and reaches remote areas such as the Black Forest National Park. Of particular concern is the significant number of pesticides predicted in small nature conservation areas, surrounded by agricultural areas. This study indicates the need for a re-evaluation of the distribution potential of frequently detected pesticides and the development and implementation of a mixture risk assessment approach for terrestial organisms in current pesticide regulation schemes.

3.15.P-Mo263 Occurrence and Persistence of Pesticides in Agricultural Soils from Different Viticulture Areas

*Victoria Fernandez-Fernandez[1], **Isaac Rodriguez Pereiro**[2], María Ramil[1], María Dolores Loureiro Rodríguez[3], Emilia Díaz-Losada[3], Emiliano Trigo-Córdoba[3], Jesús Marín Benito[4], María Sonia Rodríguez-Cruz[4] and María Soledad Andrades[5], (1)Analytical Chemistry. Institute for Research on Chemical and Biological Analysis, Universidade de Santiago de Compostela, Spain, (2)Analytical Chemistry. Institute for Research on Chemical and Biological Analysis, University of Santiago de Compostela, Spain, (3)Evega, AGACAL, Spain, (4)IRNASA, CSIC, Spain, (5)Universidad de la Rioja, Spain*

Modern agriculture uses large amounts of pesticides (i.e., fungicides, insecticides and herbicides) in order to increase the productivity and profitability of crops. The Sustainable Development Goals require combine the access to cost-affordable and safe food commodities with the preservation of the agricultural soil fertility and its biodiversity, preventing accumulation of these compounds in soil and/or their migration to other environmental compartments, including wildlife animals, live-stock and aquatic media. Moreover, policies derived from the Green Deal aim a 50% reduction in the use of agricultural pesticides by year 2030.

Viticulture is one of the agricultural practices using the highest ratios of fungicide per unit of surface. As a permanent crop, vineyards have been sprayed with this group of compounds for decades, which might lead to accumulation of those compounds with degradation periods longer than the annual application and rest cycles of vines. In addition to fungicides, vineyards are also treated with insecticides to control different pests (i.e., *Lobesia botrana*) and herbicides. The latter ones are particularly used in those plots where mechanization results complex due to limited distances between the rows of vines, and/or the slope of vineyards in hilly areas.

Herein, a target liquid chromatography triple quadrupole mass spectrometry (LC-QqQ-MS) procedure was developed to assess the occurrence and persistence of 80 pesticides, including mainly fungicides, but also insecticides and herbicides, in composite samples of topsoils (0-15 cm layer) collected in the geographical areas of La Rioja and Galicia. Samples corresponded to different sub-zones, or Qualified Designation of Origin, aiming to obtain a plot of soil samples existing in areas affected by different kinds of pests. Persistence of pesticides in soils was assessed through three consecutive sampling seasons. A range of currently approved and already expired pesticides were identified in the analysed samples. Among them, several azolic fungicides, boscalid, fluopicolide and the herbicide diflufenican were identified as persistent compounds, with dissipation periods longer than the rest period of vines.

3.15.P-Mo264 Fungicides Residues in Surface and Groundwater Samples from High Pressure Viticulture Areas

*Victoria Fernandez-Fernandez[1], **Isaac Rodriguez Pereiro**[2], María Ramil[3], María Soledad Andrades[4], Jesús Marín Benito[5], María Sonia Rodríguez-Cruz[5], Emiliano Trigo-Córdoba[6], María Dolores Loureiro Rodríguez[6] and Emilia Díaz-Losada[6], (1)Analytical Chemistry. Institute for Research on Chemical and Biological Analysis, Universidade de Santiago de Compostela, Spain, (2)Analytical Chemistry. Institute for Research on Chemical and Biological Analysis, University of Santiago de Compostela, Spain, (3)University of Santiago de Compostela, Spain, (4)Universidad de la Rioja, Spain, (5)IRNASA, CSIC, Spain, (6)Evega, AGACAL, Spain*

Controlling the pollution of continental waters by anthropogenic compounds is a challenging issue in a context of sustainable development. In rural areas, agriculture activities use significant amounts of pesticides, with a variable persistence and/or mobility in the different environmental compartments. As example, neonicotinoids are known to be prone to fast photochemical degradation; however, they are stable in soil and highly soluble in water; thus, they might migrate into groundwater. Furthermore, relatively non-polar compounds might reach surface water environments associated to soil particles transported with run-off water during rainfall events.

Viticulture uses large amounts of fungicides and insecticides sprayed directly on the canopy of vines. A fraction of the applied compounds reaches the vineyard soil during application. Washing from vine leaves also contributes to their transport to the topsoil layer. Thereafter, these pesticides might migrate through the soil profile reaching groundwater, or being transported to surface water bodies, both dissolved and associated to soil particles. Erosion of topsoil in vineyards from hilly areas might be a relevant input source of pesticides in non-permanent streams and rivers. Another potential source of pesticides in ground- and surface water from vineyard areas is the misuse, aerial diffusion during application and/or disposal of sprayers´ washing waters.

The aim of this work was to develop a sensitive, automated methodology for the determination of pesticide residues in surface and groundwater samples, obtained from springs and wells, located at different vineyards in Galicia and La Rioja (Northern Spain). Samples were concentrated using solid-phase extraction on-line combined with liquid chromatography coupled to mass spectrometry detection. The final procedure achieved limits of quantification in the range of low ng/L with a linear response range up to 2000 ng/L. Analysis of surface and groundwater samples taken at the beginning, middle and end of the growing season of vines reflected relevant contamination problems mostly in groundwater.

Acknowledgement -Funds received from projects TED2021-129962-C42 (Next Generation Program) and ED431C2021/06 are acknowledged

3.15.P-Mo265 Widespread but Different – Synthetic Pesticides Show Strong Spatiotemporal Dynamics While Copper Pollution Is Generally High Across Swiss Vineyards

Elias Barmettler[1,2]*, Andrea Rösch*[3]*, Lina Egli-Künzler*[4]*, Pierre-Henri Dubuis*[5]*, Kathleen Mackie-Haas*[4]*, Stefanie Lutz*[1]*, Marcel Van der Heijden*[1,2] *and Thomas D. Bucheli*[3]*, (1)Plant-Soil Interactions, Agroscope, Switzerland, (2)Department of Plant and Microbial Biology, University of Zurich, Switzerland, (3)Environmental Analytics, Agroscope, Switzerland, (4)Viticulture in German-speaking Switzerland, Agroscope, Switzerland, (5)Mycology, Agroscope, Switzerland*

The intensive use of plant production products (PPP) has led to a widespread accumulation of those substances in agricultural soils, and we are only at the beginning of understanding their ecological consequences. Vineyard soils are especially exposed due to the large amounts, broad range, and repetitive use of PPP. A comprehensive study on exposure of vineyard soils to PPP should therefore cover a large number of synthetic pesticides and also consider copper-based fungicides that play an integral role in vine protection, especially in organic farming. Further, the strong within-field heterogeneity of vineyard soils should be taken into account that originates from differences in vine row and inter-row management and low turbation of the soil layers.

To represent Swiss viticulture, 62 conventional and organic vineyards in three major winegrowing regions were analyzed. Samples were taken separately in vine row and inter-row and split into top and bottom soil. Soil samples were analyzed with a newly developed method covering 146 synthetic pesticides and transformation products. Copper concentrations were measured with two methods to get a proxy for total copper and bioavailable copper.

For synthetic pesticides, up to 60 substances per vineyard were detected and strong differences between management systems were found. There was a clear decrease in synthetic pesticides with increasing years of organic farming, but after more than 20 years up to 32 pesticides could still be found. The clear regional differences found might be explained by climate and soil properties. As hypothesized, soils displayed a high within-field heterogeneity and the distinctness of those within-field differences depended on management type and region. In contrast, copper pollution was not affected by management type or region and was generally high. Organic vineyards did not display higher copper concentrations than conventional despite the limited availability of substitutes. We argue that copper pollution is mainly explained by historic applications.

Our study confirmed a generally high pollution of Swiss vineyard soils with PPP. Strong contrasts were found between copper with an even distribution and synthetic pesticides which responded strongly to management, regional, and within-field differences. Further, we stress that future studies on vineyard soil pollution should consider within-field heterogeneity in their sampling strategy.

3.15.P-Mo266 Point Source Contamination via Sprayer Cleaning Water Dispersal: A Northern Italian Vineyard Area Case Study to increase local farmers' awareness

Nicoleta Suciu[1]*, Ettore Capri*[2]*, Anastasia Lomadze*[3]*, Terenzio Bertuzzi*[4]*, Gian Maria Beone Prof*[4]*, Emanuela Delpero*[5]*, Maura Calliera*[6]*, Alessandro Varotto*[5] *and Stefano Bergaglio*[5]*, (1)Universita Cattolica del Sacro Cuore, Italy, (2)Universitá Catolica del Sacre Cuore, Italy, (3)Catholic University of the Sacred Heart (UNICATT), Italy, (4)Università Cattolica del Sacro Cuore, (5)Anadiag srl, (6)European Observatory on sustainable agriculture (OPERA), Università Cattolica del Sacro Cuore, Italy*

Point source contamination by pesticides is a problem of increasing concern and represents an important threat due to the potential adverse effects of these substances on the non-target organisms of soil and natural water resources. Point source contamination could occur as a result of spillages, leakages, and mismanagement of pesticide-contaminated water produced during in-farm and post-farm activities. In order to evaluate the relevance of the impact of wastewater resulting from the cleaning operations of the fitosanitray application equipment and understand the farmers' awareness level regarding the environmental impact of in farm point source contamination, a participatory monitoring campaign was conducted across five viticultural farms located in Tortona hills. the content of six organic plant protection products (PPPs) and of Cu were analyzed in 52 samples of external and internal washing water, collected in the period May-August 2022 and 2023 in five farms (3 conventional and 2 organic). Considering the quantity of water used for the cleaning operations, the concentrations found in the washing water, the quantity of the active ingredient used for each treatment, and the vineyard area treated, it was possible to quantify the percentage of the active ingredient dispersed with each washing. The estimated percentage of the active ingredient dispersed with washing water ranged from 0.001% to 53.90% for organic active ingredients, while from 0.01% to 0.4% for metalic Cu. The results have been shared with the participating farms with the aim to increase their awareness abourt the necessity of proper managemnt of the wastewater generated after cleaning spraying equipment.

3.15.P-Mo267 Challenges Conducting Higher Tier Groundwater Monitoring Studies in France

Dirk Liss[1]*, Nils Kehrein*[1]*, Jerome Pierrard*[2]*, Julie Maillet-Mezeray*[1]*, Francois-Xavier Moinet*[3]*, Laurent Monrozies*[4] *and Gregory Hughes*[5,6]*, (1)Bayer AG - Crop Science Division, Germany, (2)Bayer SAS, Crop Science, (3)SCE, Nantes, (4)SCE, Toulouse, (5)GeoSpatial Analytics, (6)RSK ADAS, United Kingdom*

Targeted groundwater monitoring studies represent a higher-tier approach in the regulatory evaluation of plant protection products. Recent scientific recommendations have outlined and evaluated their design and conduct. The key objective is to align with defined exposure assessment goals (ExAGs), focusing on measured environmental concentrations in shallow groundwater within aquifers susceptible to leaching in the designated product application area. However, ExAGs are seldom defined, as exemplified by the current situation in France.

While comprehensive national guidance is lacking, the French regulatory agency (ANSES) impose specific requirements. French studies have to focus on catchments linked to (1) active water supply wells, and/or (2) wells in the French Water Database (ADES) with prior analyte detection. Additionally, attention is given to (3) wells in vulnerable areas using the product, encompassing diverse terrains like karst landscapes, fractured rock formations, and alluvial aquifers. Specific considerations, including soil pH, are incorporated into this targeted methodology with the intention to derive proper risk mitigation measures based upon environmental descriptors of most vulnerable areas.

These requirements pose a number of challenges in finding suitable sites: (1) assuring well quality; (2) assessing shallow unconfined groundwater with limited seasonal fluctuation; (3) securing multi-year access with water suppliers; (4) having a manageable catchment size to enable characterisation of soils, hydrogeology, crops and pesticide usage history; (5) engaging farmers for data sharing; (6) selecting areas where the crop is frequently grown despite rotation; and (7) ensuring active substance usage across the catchment at the desired rate to limit false negatives and support the GAP being applied for. Additionally, the requirements support ExAGs that differ from those supported by edge-of-field sites. This results in a mixed European Union monitoring data package where French data may be considered only supportive in other Member States and vice-versa. This poster presentation aims to elucidate the complexities of this monitoring approach in France, providing examples and exploring potential implications for the results.

3.15.P-Mo268 From Field to Catchment: Comparing the Impact of Groundwater Exposure Assessment Goals for a Case Study in France

Nils Kehrein[1]*, Dirk Liss*[1]*, Gregory Hughes*[2]*, Francois-Xavier Moinet*[3] *and Laurent Monrozies*[4]*, (1)Bayer AG - Crop Science Division, Germany, (2)GeoSpatial Analytics Ltd, United Kingdom, (3)SCE, Nantes, (4)SCE, Toulouse*

The regulatory framework in the European Union describes a tiered approach to assess the environmental impact of plant protection products on groundwater. In lower tiers, mechanistic modeling approaches and pre-defined scenarios are used to predict groundwater exposure. Predictions are refined by a spatially distributed assessment in Tier 3b, which simulates combinations of soils and weather conditions occurring within the evaluated area of interest. Currently, there is no consensus at EU or member state level on how to design Tier 3b assessments which are universally accepted and regulatory binding.

Current scientific recommendations on Tier 3b are closely aligned with FOCUS guidance, such as (a) assuming a product will be used in the highest frequency and rate that is registered or being applied for, (b) disregarding dissipation processes below one metre soil depth, and (c) calculating the exposure assessment goal (ExAG) from leachate concentrations at one metre depth. Spatial exposure assessments akin to Tier 3b are recommended to support the site selection in Tier 4 groundwater monitoring studies. However, using Tier 3b results to characterise Tier 4 monitoring sites may require consideration of additional factors to increase realism if ExAGs are defined on a (sub)catchment basis.

A groundwater monitoring study was conducted in France in compliance with national regulations and scientific guidelines. Diverging from the conventional approach, the study focused on catchments of water supply wells rather than the edge-of-field design. Results of a Tier 3b assessment were used to derive national exposure estimates and were refined to account for realistic product use and cropping practices to reflect agronomic realities in France. In addition, the ExAG was adjusted in line with French requirements to represent the risk to groundwater wells more accurately. The exposure risk of groundwater sampled from a well is defined by additional fate processes below one metre depth and aggregated substance exposure in its catchment, which are influenced by temporal and spatial factors which are not necessarily reflected in current scientific recommendations. This refinement contributed to a more comprehensive understanding of observed Tier 4 groundwater exposure and enabled the estimation of an inherent safety factor, establishing a link between the tiers.

3.15.P-Mo269 Contrasting dissipations of legacy and current pesticides from agricultural soil to drainage water during potato cultivation challenge traditional risk assessment models

*Simon Mangold, **Karel Hornak**, Nora Bartolomé, Isabel Hilber and Thomas D. Bucheli, Environmental Analytics, Agroscope, Switzerland*

Pesticides are widely applied to agricultural crops to control weeds, plant diseases, outbreaks of insects and other pests. Although designed to target specific pests only, the intensive pesticide use also poses a risk to beneficial organisms and inevitably results in the distribution of pesticides into different environmental compartments. Several models using pesticide persistence (DT_{50}) and leaching potential (groundwater ubiquity score - GUS) are currently used to assess the environmental pesticide risk. In this study, we simultaneously quantified 18 pesticides in soil and drainage water during a conventionally grown potato culture at high temporal resolution. The measured pesticide concentrations were then fitted to the above models. Overall dissipations of all freshly applied compounds in soil were in line with published DT_{50} field values and their occurrences in drainage water were generally consistent with GUS model, documenting that the fractions of pesticides exported via drainage water were proportional to their leachability. In contrast, concentrations of the legacy pesticide atrazine (last application in 2009) and one of its transformation products (atrazine-2-hydroxy) were stable during the entire sampling campaign. Moreover, atrazine concentrations in drainage water were substantially diluted during peak discharge, whereas those of freshly applied pesticides were at maximum, concomitantly with the first drainage water discharge event after the respective spray application (first flush effect). In conclusion, the applied risk assessment models were capable of predicting environmental concentrations and dissipation of pesticides at the short and medium time scale of a few half-lives, but felt short of capturing long term trace residues.

3.15.P-Mo270 Assessing Plant Protection Product and Transformation Product Contamination in the Soils Surrounding Lentic Small Water Bodies: A High-Resolution Study in Northern Germany

***Lukas Paul Loose**, Nicola Fohrer and Uta Ulrich, Christian-Albrechts University Kiel, Germany*

Lentic small waterbodies (LSWB) are widespread worldwide and play a diverse ecohydrological role that is crucial for biodiversity in rural areas. Due to their unique size and location, LSWB exhibit complex interactions with their surroundings that are not present in other water bodies. Despite their importance, there is a limited database on the pollution of LSWB by plant protection products (PPP) and their transformation products (TP), with transport pathways and pollution sources poorly understood.

This study addresses the exposure of PPP and TP in soils in the vicinity of two LSWB in northern Germany and highlights the importance of long-term storage and as a potential source of contamination for LSWB. From September 2020 to April 2022, monthly composite samples were taken from the inflow and outflow areas of the LSWB at four depths each. The soil samples were extracted with $CaCl_2$ and MeOH solutions to analyze both bioavailable and potentially available compounds. The extracted samples were quantified for 26 PPP/TP by LCMS analysis. In addition, chemical and physical soil parameters were determined, and soil moisture was measured continuously at three depths at both LSWB.

The results show the presence of PPP/TP in all samples and demonstrate the degradation, transformation, and leaching of various applied PPP over several months, including herbicides such as flufenacet and metazachlor. The degradation rates of the applied PPP were determined. Non-applied substances such as the fungicide bixaphen were consistently found, reflecting the persistent long-term storage of PPP/TP in the soil. The MeOH extraction showed the contamination of the soil by PPP/TP with the highest results, while the aqueous extraction revealed the availability and easy solubility of the particularly mobile PPP/TP, whether applied or not, indicating their potential translocation to shallow groundwater. The high-resolution measurement campaign improves our understanding of the dynamics of PPP/TP in soils adjacent to LSWB. In the next steps, the findings will be compared with further results from groundwater and LSWB examinations to better comprehend the soil as a potential pollutant source for the LSWB.

3.15.P-Mo271 Glyphosate and Aminomethylphosphonic Acid (AMPA) in Surface Water from the Tagus River basin

***Adrián de la Torre**[1], Irene Navarro[2] and María Ángeles Martínez[2], (1)Center for Energy, Environmental and Technological Research (CIEMAT), Madrid, Spain, (2)Center for Energy, Environmental and Technological Research (CIEMAT), Spain*

The present study investigated the presence of glyphosate and its main metabolite aminomethylphophonic acid (AMPA) in surface water samples (n = 89) collected from the Tagus River watershed during 2020, 2021 and 2022. The analytical method included derivatization with 9-fluorenylmethoxycarbonyl chloride (FMOC-CL), solid-phase extraction, high performance liquid chromatography tandem mass spectrometry (HPLC-TqMS/MS) and isotope dilution for quantification. Limits of quantifications meeting SANTE/2020/12830 and SANTE/11312/2021 criteria were set at 5 ng/L for both analytes.

High quantification frequencies were obtained for both glyphosate (89%) and AMPA (96%). Currently, there is no environmental quality standard (EQS) for glyphosate or AMPA at the EU level. However, glyphosate concentrations ranging from N.D. to 641 ng/L offered annual average (AA) concentrations (120, 115 and 104 ng/L for 2020, 2021 and 2022) well below the threshold included in the proposal for amending the Water Framework Directive (86.7 µg/L AA-EQS and 398.6 µg/L maximum allowable concentration MAC-EQS) in inland surface waters. Nevertheless, glyphosate annual average concentrations are slightly higher than the limit of 0.1 µg/L (AA-EQS) proposed for freshwater used for the abstraction and preparation of drinking water. No seasonal or temporal (2020-2021-2022) tendencies ($p>0.05$: Kruskal-Wallis test) were found. However, samples collected near urban areas presented higher ($p<0.05$: Mann Whitney U Test) glyphosate and AMPA concentrations compared to those obtained from agricultural/ rural zones, suggesting that the presence of these pollutants in the Tagus River basin could be mainly related to nonagricultural uses. Besides, samples with high urban influence, revealed lower AMPA/Glyphosate ratios suggesting a fresh glyphosate input. Similar behavior was also observed for 2 agricultural areas where the use of glyphosate in irrigated crops was tentatively identified as the major source. Glyphosate risk assessment conducted for aquatic organisms revealed a negligible ($RQ < 0.01$) or low risk ($0.01 < RQ < 0.1$) at median (P50) and worst case (max) scenarios. However, AMPA levels may pose a medium risk ($0.1 < RQ < 0.1$) in 8 of the 13 sampling points even at P50.

The present study is part of the project PID2019-105990RB-I00 funded by MCIN/AEI/10.13039/501100011033.

3.15.P-Mo272 Glyphosate and Aminomethylphosphonic Acid (AMPA) in Spanish Indoor Dust

Adrián de la Torre[1]*, Irene Navarro*[2] *and María Ángeles Martínez*[2]*, (1)Center for Energy, Environmental and Technological Research (CIEMAT), Madrid, Spain, (2)Center for Energy, Environmental and Technological Research (CIEMAT), Spain*

Glyphosate is the most employed herbicide in Europe. However, it is also a source of controversy since the World Health Organization's cancer agency concluded in 2015 that it was probably carcinogenic to humans. Recently, the European Union Commission adopted the Implementing Regulation to renew, for 10 years, the approval of glyphosate. Nevertheless, the last EFSA's peer review report on glyphosate (July 2023) identified data gaps that should be addressed. For this reason, the purpose of this work was to investigate the occurrence of glyphosate and aminomethylphosphonic acid (AMPA), its main metabolite, in Spanish indoor environments (homes, offices and schools). The validated analytical method (SANTE 2020/12830 and SANTE 12682/2019) including derivatization with 9-fluorenylmethoxycarbonyl chloride (FMOC-CL) and UHPLC-MS/MS analysis, was applied to 50 settled (<0.5 m) and suspended (>0.5 m) dust samples. Both homes, offices and schools presented glyphosate and AMPA levels above limits of quantification (50 and 100 ng/g; LOQs for glyphosate and AMPA, respectively). Dust concentrations range between (0.05: Mann-Whitney test) were obtained between suspended and settled dust in terms of glyphosate and AMPA levels, nor between indoor environments ($p>0.05$: Kruskal-Wallis test). Besides, no correlation was found between both analytes, and AMPA/glyphosate ratios range from 6 to 35, reflecting high dispersion in the data obtained. Risk assessment conducted for dust ingestion revealed no risk since Estimated Daily Intakes (EDIs) for infants (<6 months; 0.27 ug/Kg bw/ per day) and adults (0.01 ug/Kg bw per day) at worst case scenario (glyphosate and AMPA maximum concentrations) were well below the acceptable daily intake (ADI) of 0.5 mg/kg bw per day proposed by EFSA.

The present study is part of the project PID2019-105990RB-I00 funded by MCIN/AEI/10.13039/501100011033.

3.15.P-Mo273 The Glyphosate Dilemma: The Tug-Of-War Between Food Security And Environmental Health

Lohan Bredenhann*, Rialet Pieters and Suranie Horn, North-West University, South Africa*

Agriculture is vital for South Africa's economy. Glyphosate-based herbicides (GBHs) are common, as crops are genetically modified for glyphosate (GLY) resistance. Despite widespread use, limited data exists on GLY and its metabolite, aminomethylphosphonic acid (AMPA), in South Africa’s environment. GBH applications for maize, soybeans, wheat, and sunflower represent 80% of total use (15 484 tonnes). By visualising these four crops with geographic information systems, one of the main maize-growing provinces, the Free State, had the highest applications, with 1 753 tonnes in 2017 and 1 065 tonnes in 2019 according to an international market research company. This was mostly located along the Vaal River, which is the hardest working river in the country. Maize dominated GBH use at 74% in 2017 and 61% in 2019, with soybean applications increasing from 19% to 28%. About 2–2.5% of GBH use has non-agricultural application. South Africa, sub-Saharan Africa's largest pesticide consumer, saw GBH use double from 3 721 tonnes in 2009 to 7 977 tonnes in 2017, slightly decreasing to 7 507 tonnes in 2019. Concerns about non-target biota risks and human health effects led to GBH bans in some countries, but not in South Africa, despite the local cancer association labelling glyphosate as a group 2A carcinogen. Using data from 2017 and 2019, we chose sampling locations in a rainfed area, an irrigation scheme, and some non-agricultural sites. Analysis by ultra high-pressure liquid chromatography coupled to mass spectrometry of samples collected after spraying resulted in no quantifiable concentrations of GLY or AMPA. The limit of detection (LOD) for GLY and AMPA in water samples was 300 and 200 ng/L, respectively. In sediment, the LOD for GLY and AMPA were both 500 ng/L (0.042 ng/g when back calculated for the soil extracted). These results sharply contrasted with the expectation. One possible explanation is that other than GBH herbicides were used. Confirmation of reportedly-used herbicides is absent due to unreliable communication of pesticide-use by the farming community. The outcomes of this study emphasizes the need for establishing regular environmental monitoring of GLY and AMPA covering a greater surface area of the country to realistically assess the use of GBH and therefor realistic risk assessment.

3.15.P-Mo274 The impact of rice cultivation systems in a Mediterranean wetland: Evaluation of the occurrence, behaviour and fate of pesticides and their transformation products

Yolanda Soriano Juan[1]*, Nicola Montemurro*[2]*, Marcello Messi*[3]*, Andreu Rico*[4]*, Yolanda Pico*[5]*, Luis Blanch*[6] *and Maria Luisa Astolfi*[7]*, (1)University of Valencia, Spain, (2)Department of Environmental Chemistry, Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain, (3)Department of Chemistry, Department of Chemistry, Sapienza University of Rome, Italy, (4)Cavanilles Institute of Biodiversity and Evolutionary Biology, University of Valencia, Spain, (5)Centro de Investigaciones sobre Desertificación, Universidad de Valencia, Spain, (6)Polytechnic Universitat Politècnica de València, Spain, (7)Department of Chemistry, Sapienza University of Rome, Italy*

L'Albufera Natural Park, in Valencia (Spain), is a Mediterranean wetland mainly devoted to rice cultivation. Therefore, it is

crucial to assess the impact of pesticides on the environmental compartments (water, sediments and biota) affected by agricultural activities. Moreover, the accumulation of organic pollutants has considerably degraded these areas, which may adversely affect human health.

The objective of the study was to evaluate pesticides accumulating in rice growing areas including identification of major metabolites. The study included the identification of the main transformation products of pesticides. The sampling campaign was performed from May to September 2021 during the rice harvest period. Samples were collected every week to compare the emissions of pesticides. Four sampling cases were considered: a local spring (called Ullal), one organic production system and two other sampling points with traditional crop production systems (Sollana and Alfafar) to obtain information regarding the accumulation, transport, and degradation of pesticides in water and sediments. Pesticide application history in this field has been recorded.

Pesticides were extracted from water samples by solid phase extraction and sediments by the citrated buffered QuEChERS. Pesticides were determined by LC-HRMS in an Orbitrap Exploris 120 mass spectrometer. Pesticides and their transformation products were determined using wide target screening against a positive list of compounds and non-target screening by applying ddMS2 of the four more intense ions in each cycle. The target analysis was focused on 10 pesticides used during rice cultivation (azoxystrobin, cyhalofop-butyl, 2-methyl-4-chlorophenoxyacetic acid, penoxulam, propanil, difenoconazole, bentazone, cyhalofop acid, imazamox and acetamiprid) as well as their transformation products.

The results revealed the presence of pesticides in varying amounts in water and sediments, even within organic parcels employing eco-friendly planting strategies. The occurrence of these pesticides is directly associated with irrigation water that, in many cases, goes from one field to another and the proximity to crops from conventional production systems. However, Ullal showed very low pesticide levels in comparison to conventional systems.

3.15.P-Mo275 Pesticides Screening on Surface Water and Soil along the Mekong River in Cambodia
Putheary Ngin, *Chemistry, Umea University, Sweden*
The widespread use of pesticides has raised serious concerns about environmental contamination, particularly with regard to aquatic and soil ecosystems [(1)] and the screening of pesticides in those environmental matrices in Cambodia has never been studied, published studies have focused on vegetables or rice [(2&3)]. The study assessed pesticide residues in surface water and soil across four Mekong River provinces in Cambodia during dry and rainy seasons, analyzing 276 samples for 64 pesticides. A semi-structured interview was conducted to identify pesticide use by local farmers and an ecological risk assessment of the detected pesticide residues in surface water was evaluated using risk quotients (RQs). A total of 56 pesticides were found in surface water, and 43 in soil, reaching maximum concentrations of 2,600 ng/L and 1,100 ng/g dry weight, respectively. Tebufenozide and bromophos-ethyl showed the highest concentrations in surface-water and soil samples, present in nearly all samples. The semi-structured interview showed that the farmers tended to apply more insecticides, especially when they observed certain pests in their fields. Inappropriate pesticide use, including the timing, frequency, concentration, and type of products used, is widespread. Risk assessment indicated high ecological risk, especially for bromophos-ethyl, dichlorvos, and iprobenfos. Overall, this work highlights the occurrence of pesticide residues in surface water and soil along the Mekong River in Cambodia and emphasizes the urgent need for enhanced monitoring and regulation of pesticide use in the region.

3.15.P-Mo276 Exposure and Combined Risk of Pesticide Mixtures in Wetlands of the Great Barrier Reef Catchment Area, Australia
Carly Beggs[1], *Cath Neelamraju*[2], *Sarit Kaserzon*[2] *and Maria VanderGragt*[3], *(1)QAEHS - The University of Queensland, Australia, (2)University of Queensland, Australia, (3)Department of Environment and Science, Australia*
Wetlands of the Great Barrier Reef Catchment Area (GBRCA) provide a range of ecosystem services supporting the health and resilience of the GBR ecosystem, many of which serve to protect the GBR from land-based effects including acting as pollutant traps for pesticide runoff from local agriculture. However, knowledge of the occurrence of pesticides in GBCRA wetlands is limited, leaving them vulnerable to excessive loading of pesticides resulting species decline, loss of value, reduced function of ecosystem services.

The aim of this work was to investigate the combined risk from the occurrence of pesticides in wetlands of the GBRCA. Located within the GBRCA, the Herbert River Floodplain is designated as an area of Nationally Important Wetlands, though surrounding agricultural land use puts the health and function of these wetlands at risk. Five freshwater wetlands of the Herbert River Floodplain were monitored using a combination of grab (collected monthly) and passive sampling (approx. 1-month deployments) techniques between February 2021 and March 2023. Samples were analysed for 55 pesticides by high performance liquid chromatography tandem mass spectrometry (HPLC-MS/MS).

Thirty-six pesticides were detected across five wetlands, 8 of which exceeded regulatory guidelines at least once. The combined risk of 19 commonly detected pesticides was assessed using a novel Pesticide Risk Metric (PRM) model, calculated as the acute (grab samples) and chronic (passive samples) percentage of species affected. Wetlands are afforded either a 95% or 99% species protection goal based on the surrounding land use and conservation status. Forrest Beach wetland – located within a conservation zone, was the only monitored wetland to continuously meet its species protection goal of 99% throughout the study period. The greatest number of PRM values exceeding the site-specific species protection goal was at Legges Road wetland – afforded 95% species protection, where 9 daily and 12 monthly PRM values were >5% species affected. Seasonal rainfall is known to be a driver of pesticide occurrence and risk in surface waters of the GBRCA, so wet/dry season was investigated as a driver of risk in wetlands. The monthly average (chronic) risk was found to be increased in two wetlands during the wet season, though no increase in daily (acute) risk was detected in the season at any site. These finding indicate that wetlands behave differently to rivers and creeks in the GBRCA.

3.15.P-Mo277 Estimation of glyphosate and AMPA mass loads from twenty-two Wastewater Treatment Plants across Australia

***Garth Campbell**, University of Queensland, Australia*

Glyphosate is the most frequently used herbicide globally yet data on its prevalence in Australia is scarce. This study aimed to investigate glyphosate concentrations and release in Australian wastewaters and wastewater treatment plants (WWTPs). Glyphosate and its main biodegradation product, aminomethylphosphonic acid (AMPA) highly polar nature has historically made detection and investigation challenging. After concentrations are determined, mass loads were then calculated for effluent WWTPs. Sub-aims included assessing the spatial and temporal trends of glyphosate and AMPA in WWTPs from 2009-2021, determining the removal efficiency of WWTPs, and assessing the stability of glyphosate in WW samples over a year. The study found that glyphosate was present in the influent of all sampled WWTPs at concentrations of 22 ± 76 µg/L. Glyphosate was detected in 18 WWTP sites sampled in both pools 1 and 2, with concentrations in effluent ranging from <LOD - 11 µg/L, the highest concentration being at site 6, with an average of 2 ± 3 µg/L. Glyphosate removal efficiency varied depending on the treatment process used, but were generally effective except in primary WWTPs, which showed a negative removal efficiency. The mass loads of glyphosate in effluent were calculated at 572.3mg per day per 1000 people. Temporal trends for glyphosate show an increase in use from 2009-2021. This study is the first-time characterisation of glyphosate and AMPA in Australian WWTPs. Given the toxicity claims to humans and species of glyphosate in the environment, determining its presence in WWTPs and estimating its mass loads can help inform regulatory bodies on managing exposure to glyphosate.

3.15.P-Mo278 Down-The-Drain Pathways for Fipronil and Imidacloprid Applied as Spot-on Parasiticides to Dogs - Estimating Aquatic Pollution

***Rosemary Perkins**[1], Leon Barron Dr[2], Gaetan Glauser[3], Guy Woodward[4] and Dave Goulson[5], (1)University of Sussex, United Kingdom, (2)Environmental Research Group, Imperial College London, United Kingdom, (3)University of Neuchatel, Switzerland, (4)Imperial College London, United Kingdom, (5)School of Life Sciences, University of Sussex, United Kingdom*

Fipronil and imidacloprid have been widely detected in UK surface waters in recent years, often at concentrations that ecotoxicological studies have shown can harm aquatic life. Down-the-drain (DTD) passage of pet flea and tick treatments are being implicated as an important source, with many of the UK's 22 million cats and dogs receiving routine, year-round preventative doses containing these parasiticides. The UK Water Industry's 3rd Chemical Investigation Programme (UKWIR CIP3) has confirmed wastewater as a major entry pathway for these chemicals into surface waters, but the routes by which they enter the wastewater system remain unclear. We addressed this knowledge gap by conducting the first quantification of DTD emissions from 98 dogs treated with spot-on ectoparasiticides containing fipronil or imidacloprid, through bathing, bed washing and washing of owners' hands. Both chemicals were detected in 100% of washoff samples, with bathing accounting for the largest emissions per event (up to 16.8% of applied imidacloprid and 24.5% of applied fipronil). Modelled to account for the frequency of emitting activities, owner handwashing was identified as the largest source of DTD emissions from the population overall, with handwash emissions occurring for at least 28 days following product application and an estimated 4.9% of imidacloprid and 3.1% of fipronil applied in dog spot-ons passing down-the-drain via this route. The normalised daily per capita emissions for all routes combined were 8.7 µg/person/day for imidacloprid and 2.1 µg/person/day for fipronil, equivalent to 20-40% of the daily per capita load in wastewater, as estimated from UKWIR CIP3 data. Within the current international regulatory framework adhered to by the UK, the environmental exposure of veterinary medicines intended for use in small companion animals is assumed to be low, and DTD pathways are not considered. We recommend a systematic review of regulations and practices to address this overlooked pollution pathway.

3.15.P-Mo279 Occurrence of pesticides in fish: a comprehensive monitoring study across Europe

***Isabel Campos**[1], Ana Ré[2], Joana Luisa Pereira[3], Carlos Alexandre[4], Hans Mol[5], Abdallah Alaoui[6], Florian Christ[6], Vera Silva[7], Paula Harkes[8], Trine Norgaard[9], Igor Paskovic[10], Marija Polić Pasković[11], Glavan Matjaz[12], Jakub Hofman[13], Violette Geissen[7] and Nelson Abrantes[14], (1)CESAM - Centre for Environmental and Marine Studies and Department of Biology, University of Aveiro, Portugal, (2)Department of Environment and Planning, Department of Environment and Planning &*

Centre for Environmental and Marine Studies (CESAM), University of Aveiro, Portugal, (3)University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Portugal, (4)MARE, (5)Wageningen Food Safety Research, Wageningen University & Research, Netherlands, (6)University of Bern, Switzerland, (7)Soil Physics & Land Management Group, Wageningen University & Research (WUR), Netherlands, (8)Wageningen University & Research (WUR), Netherlands, (9)Aarhus University, Denmark, (10)Institute of Agriculture and Tourism, Department of Agriculture and Nutrition, Croatia, (11)Institute of Agriculture and Tourism, (12)University of Ljubljana, Slovenia, (13)RECETOX, Masaryk University, Czech Republic, (14)Department of Biology, Department of Biology & Centre for Environmental and Marine Studies (CESAM), University of Aveiro, Portugal
It is widely known that the intensive and widespread use of pesticides can pose risk to environmental and human health. Pesticides applied in agricultural farms to safeguard crops can reach the nearby water bodies raising serious concerns on water quality and toxic effects on aquatic organisms. In the framework of the H2020 SPRINT project, the present study investigated the occurrence of pesticides, comprising 156 active substances and 34 metabolites, in the muscle and liver of 30 fish samples. Fish were collected during the 2021 growing season from water bodies of distinct typology (reservoirs, rivers, ditches, channels, lakes, streams, creeks and ponds) located in the vicinity of conventional/integrated and organic farms across 7 case studies in Europe (Croatia, Czech Republic, Denmark, the Netherlands, Portugal, Slovenia and Switzerland). Multiple pesticides residues were detected in fish (31 analytes: 13 in muscle and 24 in liver), of which 17 analytes were quantified (11 and 12 in muscle and liver, respectively). The insecticide folpet PHI exhibit the highest median concentration, quantified in all the muscle samples and in 12 liver samples). In the muscle, fluopicolide and terbuthylazine followed folpet PHI, while for the liver, the sequence included DDE, p,p’, the fluopicolide, the diflufenican, and prosulfocarb. It is worth mentioning that the DDE, p,p’ was the pesticide found in more samples of fish liver (19), and only in 1 sample for the fish muscle. Furthermore, the presence of the metabolite, DDE, p,p’ , derived from the banned DDT compound, remains a significant component of the environmental mixture of pesticides and therefore should be taken into consideration in further environmental risk assessments. Our results raise awareness of the potential risks posed by pesticides mixtures to aquatic ecosystems, which can ultimately be translated into human health impacts through the consumption of fish.

3.15.PC Measuring and Modelling the Environmental Fate and Exposure of Pesticides

3.15.P-Mo229 Particulate and Mineral Associated Organic Matter Contribution to Pesticide Sorption in Agricultural Soil

Marija Gadzimuradova[1]*, Valentina Sechi*[2]*, Peter van der Maas*[3] *and Nora B Sutton*[4]*, (1)Environmental Technology, Wageningen University & Research (WUR), Wageningen, Netherlands, (2)Wetsus European centre of excellence for sustainable water technology, Netherlands, (3)Van Hall Larenstein university of applied sciences, Netherlands, (4)Environmental Technology, Wageningen University & Research (WUR), Netherlands*
Intensive agricultural practices heavily rely on land exploitation and high inputs of pesticides to produce crop monocultures. Some applied compounds persist in soil, whereas the more mobile pesticides run off or leach through the soil profile and enter surface and groundwater sources. Soil organic matter content is recognized as one of the main factors determining the mobility and transformation fate of agrochemicals. However, to the authors' knowledge, the role of particulate (POM) and mineral-associated (MAOM) organic matter pools in determining pesticide fate and the implications for soil management practice choice is yet to be elucidated. This research aims to understand how the distribution of organic matter into the physical pools of POM and MAOM influences the sorption of pesticides in soil.

Using wet sieving, we fractionate the soil into the two physical fractions POM (> 53 µm) and MAOM (< 53 µm). After removing organic matter from POM and MAOM fractions, we obtain the rPOM and rMAOM, which serve as control treatments. We perform batch sorption tests to determine the efficiency of 9 pesticide removal from soil solution using separated and treated soil fractions. Our hypotheses are: 1) separated soil fractions with intact organic matter (POM, MAOM) will perform better in pesticide sorption than rPOM and rMAOM; 2) the nature of organic matter determines the extent of pesticide sorption efficiency, and MAOM will be more efficient than POM. The findings of this research can provide new insight into the effect of soil properties in reducing pesticide runoff, leaching, and subsequent environmental contamination and thus have important implications for choosing agricultural land-management practices (tillage, animal manure application, etc.).

3.15.P-Mo230 On the search for alternative herbicides to treat Swiss railway tracks.

Valérian Zeender[1]*, Roy Kasteel*[2]*, Thomas Poiger*[2] *and Ignaz Buerge*[2]*, (1)Agroscope, Switzerland, (2)Plant Protection Products – Impact and Assessment, Agroscope, Switzerland*
Weeds can have detrimental effects on the railway infrastructure. This mainly through the accumulation of humus, which can increase water retention and may damage both sleepers and rails, as well as the overall stability of the ground. Ultimately, these factors can result in track deformation, which directly influences the speed at which trains are able to travel.

In Switzerland, herbicides are predominantly utilized for weed control, although alternative methods such as mechanical and thermal techniques are also employed. Currently, glyphosate is the only herbicide used to remove weeds from railway tracks, which has proven to be relatively effective. However, uncertainties concerning the renewal of authorisations of the substance in Europe have prompted railway companies to explore alternative herbicides that may replace glyphosate. Due to the inherent permeability of railway tracks and therefore increased net infiltration, it is important to choose herbicides with a low risk of leaching to groundwater. The characteristics of a suitable herbicide include thus a high sorption in the soil and/or rapid degradation (also for metabolites), as well as low application rates.

In order to help decision-makers to make informed decisions, we constructed ten lysimeters with railway materials from three locations, allowing us to study the leaching behaviour of herbicides in close-to-real conditions. Using liquid chromatography–mass spectrometry, we investigate the leaching potential of 12 alternative herbicides and their main metabolites. The selected group of alternative herbicides includes six auxin-mimics, three acetolactate synthase inhibitors, as well as three pigment-synthesis inhibitors.

Half a year after the first application of the substances in May 2023, we observe that leaching is influenced by both the lysimeter soil properties and the herbicides used. While some of the herbicides have already reached their maximum concentrations under all soil conditions, some have not been detected yet. These undetected herbicides may have degraded completely or may still elute later. The project will continue for at least 2 years (from the time of the first application) and will allow us to conclude on the leaching potential of the applied substances and their metabolites under realistic conditions. Moreover, the project will allow a direct comparison of all applied substances under identical weather conditions in 3 different soil types.

3.15.P-Mo240 Proposed revision of the aged-sorption guidance document in combination with field degradation studies in regulatory assessments

*Ian Hardy[1], Wendy van Beinum[2], **Bernhard Jene**[3], Sevil Payvandi[4] and Klaus Hammel[5], (1)Battelle, United States, (2)Enviresearch Ltd., United Kingdom, (3)BASF SE, Germany, (4)Syngenta Ltd, United Kingdom, (5)Bayer AG*

In the EU Aged Sorption Guidance the use of field DegT50 values in combination with aged sorption parameters is only possible to a very limited extent. If the leaching assessment for a plant protection product (PPP) is based on field DegT50 values only, it is not recommended by the current guidance to derive a $DegT50_{equilibrium}$ (rescaling of DegT50) for input in exposure models in combination with aged sorption parameters (f_{NE}, k_{des}) as described for laboratory DegT50 values. This virtually prevents the mitigating effect of aged sorption on leaching and limits the applicability of the aged sorption guidance in combination with field DegT50 to very few cases.

However, the guidance mentions that “Industry is preparing evidence for aged sorption in field studies and this option should replace the current recommendations as soon as appropriate guidance has been developed and tested”.

Therefore, additional field studies were evaluated to show the relevance of aged sorption in the field. The evaluation was mainly based on the comparison of observed concentration depth profiles versus FOCUS-PEARL simulations with and without consideration of aged sorption. Where possible, site-specific aged sorption parameters from laboratory studies with the respective field soils were used. The depth to which 95% of the residues are found was defined as metric [P5 metric] for comparison.

Proposed revisions to the current EU Aged Sorption Guidance fully allowing for the combination of field degradation and aged-sorption data are presented.

3.15.P-Mo241 Can Drainage Losses be Reduced by Optimizing Pesticide Application Dates?

***Prakash Srinivasan**[1], Carolin Kley[2] and Dieter Schaefer[2], (1)Bayer AG, (2)Bayer AG - Crop Science Division, Germany*

Presently, in the EU risk assessment for plant protection products, there are no mitigation or refinement options available for drainage exposure apart from reducing the intended application rate and generic application time restrictions. One more flexible mitigation option could be to look in more detail at the application timing to omit the application at dates which lead to highest potential exposure via drainage. Recently published monitoring data (Tournebize et al., 2023) from the La Jaillière experimental site in France has revealed that drainage losses remarkably increased when soil moisture exceeded a certain threshold at the time of pesticide application, thereby increasing the pesticide concentrations in the receiving water bodies.

This study examines the role of soil moisture on the application day as a potential trigger in influencing exposure via drainage. Existing FOCUS and UK drainage scenarios were used to calculate a soil moisture trigger value in terms of the soil wetness index (SWI). Limiting the pesticide application to periods when the SWI is below this trigger value could reduce environmental safety concerns and enable safe uses with respect to drainage entries into water bodies. Three herbicides were chosen for this assessment. Step 3 MACRO runs were simulated with no interception and with additional hydrological outputs being switched on needed for calculating SWI on the day of application. Predicted environmental concentrations (PEC) in ditch and stream were calculated using TOXSWA model with no drift entry. The resulting maximum PEC/RAC ratio for a 1-year period after application was plotted against the SWI on the day of application.

The results show that for herbicide C for scenario D2 Brimstone a potential trigger could be set at 60% SWI. Herbicide B for scenario D6 Thiva has a potential trigger of 85% SWI. For D5 La Jaillière, for herbicide A, B and C, no clear threshold trigger was observed with 10% of the data points not following the pattern observed in the monitoring study; excluding these values, a potential SWI trigger of 85% could be observed.

It can be concluded that the threshold triggers and the magnitude of their effect on drainage losses varied between scenarios and substances depending on their properties. Thus, the decision about the applicability of this approach as a potential drainage mitigation must be done on a case-by-case basis.

3.15.P-Mo247 Reduction of Complexity: Variance-based Sensitivity Analysis for FOCUS STEPS

Dimitrios Alexander Skodras *and Judith Klein, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany*

To standardize the role of models in the European Union (EU) plant protection product authorization process, Forum for the Co-ordination of pesticide fate models and their use (FOCUS) has established guidelines, including the FOCUS STEPS models for surface water risk assessment. Conservative scenarios representing EU member states are used, with a 4-tier approach for limit value exceedance. Higher-tier calculations, while requiring more information, provide more accurate results. When calculating the respective tiers, however, the accuracy of the model parameters does not have to be specified. This can mean that a parameter to which the model reacts very sensitively - i.e. the result depends relatively heavily on variations of it - can lead to a large inaccuracy.

The project employs sensitivity analysis using the Sobol' method. Model parameters are sampled using low-discrepancy sequences, and Sobol' indices are calculated to determine the sensitivity of the FOCUS STEPS models to parameter variances. The analysis focuses on the first order Sobol' indices representing the main effects, providing insights into parameter influence.

FOCUS STEPS 1 as the simplest example, is presented with a limited set of parameters. The analysis of scenario parameters, such as drift and runoff proportions, field-to-water ratio, and water depth, reveals sensitivity patterns. For low values of the sorption constant Koc, the model is sensitive to runoff parameters, while higher Koc values make it more sensitive to drift fraction. With low Koc leading to high concentrations, the variance of runoff parameters should, hence, be decreased to a minimum. Higher Tiers are handled to some extend afterwards.

Sensitivity analyses help identify influential processes and parameters. The variance-based analysis guides users on reducing uncertainties, especially when concentrations are near regulatory thresholds. Considerations for modifying model user interfaces to suggest variance sensitivity based on input configurations are proposed for enhanced user guidance.

3.15.P-Mo248 The Effect of Time-Varying Soil Properties Caused by Ploughing and Consolidation on Pesticide Fate in Soil and Groundwater

Pavan Cornelissen[1], ***Louise Wipfler[1]****, Maarten Braakhekke[2] and Marius Heinen[3], (1)Environmental Risk Assessment, Wageningen University & Research (WUR), Netherlands, (2)Environmental Risk Assessment, Wageningen Environmental Research (WUR), Netherlands, (3)Soil, Water and Land Use, Wageningen Environmental Research (WUR), Netherlands*

Soil properties such as the dry bulk density and soil hydraulic parameters can significantly affect the environmental fate of pesticides. These properties are often assumed to remain constant in time in numerical models. However, these properties change over time during ploughing and consolidation in reality. In this study, we modeled the time-varying soil properties induced by ploughing and consolidation and assessed its effect on pesticide accumulation in the topsoil and leaching to the groundwater. For this purpose, time-dependent soil properties have been implemented in the pesticide fate model PEARL. Ploughing instantaneously decreases the bulk density, after which it gradually increases again to its original value through consolidation caused by rainfall. The time-dependent soil properties are modelled based on empirical relationships between the dry bulk density and the Mualem-Van Genuchten parameters found in the literature.

Ploughing leads to a short-term deviation of the soil water content and concentration compared to the reference case (i.e., the case with constant soil properties). We included mixing of pesticide over the ploughing layer due to ploughing in both cases. However, under Central European climate conditions, the effect of ploughing vanishes within several months in the entire soil profile. For assessing the impact on the leaching of pesticide to groundwater, we evaluated the pesticide concentration in pore water at 1 meter depth. The effect of time-varying soil properties due to ploughing and consolidation on the leaching concentration was found to be small for both a tracer and an adsorbing solute. Even for an extreme case with three ploughing events per year, the effect on the 90^{th}-percentile of daily leaching concentration was smaller than 0.3%. For assessing the impact on the exposure of soil organisms to pesticides, we considered the pesticide concentration in pore water averaged over the upper 20 centimeters of the soil. For the tracer, ploughing resulted in a 1.2% decrease of the 90^{th}-percentile of daily topsoil concentration data for the extreme case of three ploughing events per year. Interpretation of the results for adsorbing solutes in the topsoil is hampered by the fact that soil mass is not conserved in the current approach. More advanced models must be developed that allow for conservation of soil mass for assessing the impact of time-dependent soil properties on concentrations in the topsoil.

3.16 Measuring Chemicals in the Environment – Maximising the Utility of Monitoring Data for Environmental Assessment

3.16.T-01 An Approach for Evaluating the Reliability of Measured Environmental Concentrations in Environmental Risk Assessment

***Iain Wilson**[1], Michelle L. Hladik[2], Arjen Markus[3], Dennis Helsel[4], Lisa Nowell[2], Stefano Polesello[5], Heinz Ruedel[6] and Drew Szabo[7], (1)wca environment Ltd., United Kingdom, (2)U.S. Geological Survey (USGS), (3)Deltares, Netherlands, (4)Practical Stats LLC, (5)Water Research Institute - Italian National Research Council (IRSA-CNR), Italy, (6)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (7)Stockholm University, Sweden*
The Criteria for the Reporting and Evaluation of Exposure Data (CREED), developed through a SETAC Technical Workshop, are designed to account for all aspects of data reliability, as well as the relevance of the data for the purpose of the assessment; the end result is an overall score for the dataset to be used for that purpose. Through a workshop and meetings held by a group of experts detailed criteria for data reliability were developed, alpha- and beta testing was then conducted to refine the set of criteria. The focus of this presentation is the reliability evaluation contained in CREED.

Prior to completing the CREED reliability (or relevance) assessment, a dataset must meet a minimum set of criteria (called the Gateway Criteria). If the dataset to be evaluated meets the gateway criteria it can be further assessed. If the dataset does not meet the gateway criteria the assessment should be stopped, or the missing information should be obtained (if possible).

The overall reliability assessment consists of up to 19 criteria covering six different aspects: Media, Spatial, Temporal, Analytical, Data Handling and Statistics and Supporting Parameters. The number of criteria requiring completion is dependent on the dataset being assessed. All criteria are answered using the rating system of Fully met, Partly met, Not met/inappropriate, Not reported or Not applicable. It is important that Not met/inappropriate should only be used where the information reported is determined by the assessor to be Not appropriate; if the data are missing then Not reported should be utilised.

Once the criteria have been rated, the dataset is scored into a final reliability category (Reliable Without Restrictions, Reliable With Restrictions, Not Reliable or Not Assignable) at each of two scoring levels, Silver and Gold. The Silver level is less rigorous, as the reliability score is based on only 8 criteria (those designated as required for most assessment purposes). At the Gold level, all criteria (required plus recommended) are included in the scoring, representing an ideal dataset.

The criteria have been designed to allow for consistent and accurate assessment of environmental concentration datasets in risk assessments and when used with the CREED relevance criteria to provide a standardised reporting format for data. CREED may also be used by data generators to identify the information assessors require to ensure that the maximum amount of data generated can be used.

3.16.T-02 Assessing the Reliability and Relevance of a Dataset for Evaluating the Occurrence of Hexa(methoxymethyl)melamine in Surface Waters

***Jeanne Vuaille**[1], Adam Peters[2] and Leonard Oste[3], (1)Biodiversity, Health and Resources, European Environment Agency (EEA), Denmark, (2)wca environment Ltd., United Kingdom, (3)Aveco de Bondt, Business line Water and Climate, Netherlands*
The CREED (Criteria for Reporting Environmental Exposure Datasets) assessment approach provides a framework for evaluating in a systematic and transparent manner both the reliability and relevance of environmental exposure datasets. This assessment approach is applied here to evaluate the reliability and relevance of a combined dataset on the occurrence of hexa(methoxymethyl)melamine (HMMM) in surface waters. More specifically, the dataset was assessed for the purpose of understanding to what extent the substance HMMM occurs in Dutch surface waters and whether temporal trends and regional patterns exist. For the given purpose, the dataset was scored as ‘usable without restrictions’ at the Silver level i.e., at the level required for data usability. Information on analytical tools was initially not available, making the dataset unusable. Enquiring the monitoring organisation allowed accessing the missing information to reach the silver level for the reliability assessment. With respect to relevance, all the criteria were found fully met. Thus, all data suppliers in the dataset could reach the silver level.

This presentation highlights how applying the CREED approach promotes a more thorough and transparent assessment of exposure data: by establishing clear criteria of usability for a given purpose it encourages data users to ask for and assess additional information missing in the dataset, while encouraging data suppliers to provide the relevant information needed for using the data.

3.16.T-03 Trend Analysis of Environmental Concentrations of Bisphenol A in European waters

***Chesney Swansborough**[1], Emma Pemberton[2], Javier Soto[2], Imogen Shapland[2], Margaret E. McArdle[3], Ellen M. Mihaich[4], Evelyn Majoris[5], Michael Bunge[6] and Christopher Hughes[2], (1)Ricardo Energy & Environment, United Kingdom, (2)Ricardo, United Kingdom, (3)Exponent Inc., (4)ER2, (5)Covestro, LLC, (6)Covestro AG, Germany*
Bisphenol A (BPA) is a high production volume chemical that has been in commercial production for over fifty years. Increasing regulatory scrutiny over the potential endocrine disrupting properties of BPA and other bisphenols has led to proposals for regulatory measures. There are numerous reports of the presence of BPA in environmental media, with the aquatic environment being the compartment of most focus.

We present a robust analysis of measured environmental concentrations of BPA from 2010 to 2022. Monitoring data for BPA in European fresh and saline surface waters and sediments published in peer reviewed scientific literature and publicly accessible monitoring databases such as the NORMAN network's EMPODAT database were collated. Data were systematically evaluated for relevance and reliability using the Criteria for Reporting and Evaluating Exposure Datasets (CREED) approach, developed by a SETAC Technical Workshop with the aim of fostering consistent and transparent evaluation of chemical exposure data. All relevant and reliable data were compiled into a database. Data are available for 21 countries. Limits of detection (LOD) varied between studies and a significant proportion of the data were reported as less than LOD.

The dataset underwent statistical processing to address censored data and the variability in reported detection limits. Data presented as summary statistics were imputed for the known sample size and observations were weighted to accommodate variations in sampling locations.

Summary statistics (mean, standard deviation) were determined for each environmental compartment and compared to analyses from earlier time periods. Concentrations of BPA varied spatially and temporally between countries. Reported concentrations of BPA ranged over several orders of magnitude in all relevant compartments.

Examination of the data suggested an overall decrease in median concentrations over time in freshwater and freshwater sediment. A noticeable decrease in median BPA concentration in European freshwaters was evident after 2015. Trends in BPA concentrations in individual countries with a substantial dataset were also observed.

3.16.T-04 Concentrations of copper in the environment across the EU: an analysis of national copper monitoring data and the influence of land use

Gareth Le Page[1]*, Gregory Hughes*[2]*, Francesco Agostini*[1]*, Elenaor Long*[1] *and Matthias Weidenauer*[3]*, (1)Battelle UK, United Kingdom, (2)GeoSpatial Analytics Ltd, United Kingdom, (3)European Union Copper Task Force, Switzerland*

Copper provides a vital role across a broad range of industries including agriculture, as a fertilizer, growth promotor and fungicide. In recognition of the shortcomings of standard regulatory frameworks to handle transition metals such as copper, the European Food Safety Authority PPR panel published 'a framework for the environmental exposure and risk assessment for transition metals when used as active substances in plant protection products'. This framework expands the role and importance of public environmental monitoring data in support of the environmental risk assessment.

To satisfy these requirements and to support the renewal of copper as a fungicide according to regulation (EC) 1107/2009, all available EU relevant national and transnational copper monitoring data in surface waters, groundwaters, sediments and soils were sourced from regional and national environment agencies/institutes. They were then harmonised and collated into a database suitable for regulatory assessments, which included supplied or assigned landcover attributes using the CORINE landcover dataset. An analysis of these data was undertaken to determine natural and land use specific background copper concentrations for different environmental compartments for use in environmental risk assessment. This included landcovers of particular relevance to fungicidal copper use (e.g. vineyards, orchards and arable cropland). These background values determined were compared to the estimates from other European monitoring programmes such as LUCAS, GEMAS and FOREGS

Key findings include: 1) there is considerable variability in the data quantity, quality and distribution, showing that chemical monitoring data in the EU is not always easily obtained nor sufficiently characterised that it can be integrated into an EU dataset; 2) The data that is reliable for inclusion and use in regulatory assessments can be spatially and temporally variable resulting in small sample numbers for specific countries and/or landcovers; 3) the results from these analyses yield concentrations that are comparable to other estimates such as those derived by the LUCAS topsoil survey.

3.16.T-05 Persistence, seasonality and sporadic releases of micropollutants within the urban water cycle - the benefit of four-year monitoring program

Maricor Arlos[1]*, Victoria Irene Arnold*[2]*, Jorge Seth Bumagat*[3]*, Jiangboyuan Zhou*[3]*, Katrina Cereno*[3]*, Alison Deas*[3]*, Kaiping Dai*[4]*, Norma Ruecker*[5] *and Kelly R. Munkittrick*[6]*, (1)Department of Civil and Environmental Engineering, Canada, (2)City of Calgary, Canada, (3)University of Alberta, Canada, (4)Water Services, City of Calgary, Canada, (5)Water Quality and Regulatory Assurance, The City of Calgary, Canada, (6)University of Calgary, Canada*

Regulatory changes reflect the growing understanding of micropollutant impacts in the aquatic environment. By understanding the public health (drinking water) and ecosystem (wastewater) impacts of micropollutants via extensive monitoring, water utilities can actively foster environmental stewardship and positive relationships with community members, business partners, and regulatory agencies. This study spanned 48 months of monitoring along the 95 river km of the Bow River watershed in Calgary, Alberta, Canada. We aim to **(1)** establish baseline data for water utility operations, **(2)** enhance our understanding of micropollutant behavior in the urban water cycle, **(3)** assess the contributions of three wastewater treatment plants (WWTPs) to downstream receiving waters, and **(4)** prioritize a subset of substances for continuous monitoring. Our results indicate the extensive persistence of metformin (antidiabetic), seasonality of N,N-diethyl-*m*-toluamide (DEET, insect repellant), O-desmethylvenlafaxine (antidepressant metabolite), and sulfamethoxazole (antibiotic) in source waters, and sporadic detections of a well-known perfluoroalkyl substance (PFOA). The seasonality of pharmaceuticals at the sentinel downstream monitoring site appeared to coincide with river dilution while that of DEET was likely attributable to peak usage during the warmer months. Steroidal estrogens were rarely detected in wastewater effluents although total estrogenicity was evident, suggesting the presence of less potent but more abundant non-steroidal estrogens (e.g., flame retardants, bisphenols, and phthalates). Finally, hierarchical clustering revealed a close association between *E. coli* and caffeine, supporting the use of caffeine as an indicator of short-term, untreated anthropogenic inputs. Overall, this study provides insights on the sources and behaviour of organic micropollutants and identifies indicators useful for prioritizing future monitoring campaigns in Calgary and elsewhere.

3.16.P Measuring Chemicals in the Environment – Maximising the Utility of Monitoring Data for Environmental Assessment

3.16.P-Th321 Regression on Order Statistics – An Improved and Straightforward Approach to Dealing with Non-Detects?

Iain Wilson *and Mike Gardner, wca environment Ltd., United Kingdom*

Treatment of data reported as below the limit of detection (LoD) represents a challenge when performing a chemical risk assessment. Numerous methods of dealing with this have been applied, ranging from simple (non-statistical) approaches, for example ignoring censored values or using the half LoD method (also known as substitution), to complex statistical methods such as Maximum Likelihood Estimation and Kaplan-Meier analysis. What appears to be required is a proven statistical method that can be readily applied. The method of Regression on Order Statistics (ROS) is such an approach that addresses the potential defects of either questionable simplicity or off-putting complexity.

To apply the ROS method, the distribution of the dataset to be analysed is required to be determined, typically for environmental datasets they are found to be lognormally distributed. Once the distribution has been identified, the natural logarithm of data is calculated, the transposed data is sorted in ascending order, with blanks for the censored values, and rank orders are created. Q-Q plots are produced and the y-intercept of the straight line and the slope provide the population mean value and standard deviation, respectively. These values can be re-transformed to real world values based on defined equations, and used as the basis of the (estimated) uncensored data distribution in a cumulative frequency distribution (CFD). In the CFD the data distribution of the non-detect observations can be plotted using the inverse lognormal data distribution versus the median rank values corresponding the non-detect values. This "invented" section of the CDF is not strictly part of the ROS output and is shown merely as an aid to the visualisation of the distribution of lower percentiles. This method has been shown that it reduces both systematic and random errors of the mean compared to the substitution method.

As complex as this sounds, this poster will show that it can be applied relatively easily using basic tools. Additionally, using real-world data the affect the use of ROS can have on the estimation of the mean when a dataset includes censored data compared to the substitution method on datasets of differing degrees of censorship and how this can potentially impact the risk conclusion to European surface waters will be demonstrated. This approach is designed to show that ROS can be applied by non-statistical experts and provide greater confidence in results from censored datasets.

3.16.P-Th322 AQUA-GAPS/MONET-derived concentrations and trends of PAHs and polycyclic musks across global waters

Rainer Lohmann[1]*, Branislav Vrana*[2]*, Derek C.G. Muir*[3] *and Foppe Smedes*[2]*, (1)Graduate School of Oceanography, University of Rhode Island, (2)Recetox, Masaryk University, Czech Republic, (3)Air Quality Processes Research Section, Environment and Climate Change Canada, Canada*

The AQUA-GAPS/MONET network was established to provide global trends of organic contaminants in the waters of the world while relying on the same passive sampling material analyzed by a central laboratory to ensure quality control. Prior work reported on concentrations, global distributions and trends of organochlorine compounds (PCBs and OCPs). In here, we discuss the presence of polycyclic aromatic hydrocarbons (PAHs) and polycyclic musks (PCMs) derived from the same set of passive samplers. The detection frequency of the targeted PAHs ranged from 35% (cyclopenta[cd]pyrene) to 98% (triphenylene). Seven PAHs were present in > 90% of all sampling events: triphenylene, chrysene, retene, benzo[*g,h,i*]fluoranthene benzo[*b*]fluoranthene, fluoranthene, and benzo(*e*)pyrene. There was a general trend of decreasing aqueous concentrations with an increasing molecular mass. The sum of 28 PAHs (S_{28} PAHs) concentrations ranged from 61 – 45,000 pg/L, with mean (median) concentrations of 7,200 pg/L (3,200 pg/L). Greatest concentrations of phenanthrene, fluoranthene and pyrene were typically from the same sites, mostly in Europe and North-America. While the exact ranking varies by compound, similar trends applied to several more PAHs, including anthracene, pyrene, fluoranthene and benz(a)anthracene. These PAHs are typically associated with the incomplete combustion of (fossil) fuels. Different geographical abundances were present for retene, which ranged from ND – 490 pg/L, with greatest concentrations present in water bodies from Chile, Brazil, Norway and remote lakes in Slovakia. The presence of retene is typically interpreted as an indication of wildfires/the burning of coniferous biomass. Of the 6 PCMs, only galaxolide (HHCB, detected in 72% f samples) and tonalide (AHTN, 61%) were regularly detected. Maximum concentrations reached up to 20,000 pg/L for galaxolide and 1,900 pg/L for tonalide. Concentrations of 11 of 28 PAHs, galaxolide and tonalide were positively correlated ($P<0.05$) with population density within a radius of 5 km of the sampling site. There were no significant correlations between any of these PAHs or PCMs and temperature, latitude or longitude – implying the lack of global fractionation or physicochemical properties on the distribution of PAHs or PCMs. This was not surprising, given the known reactivity of these compounds, and their multiple active sources with different emission rates and patterns around the globe.

3.16.P-Th323 Effectiveness and Interpretation of Surface Water Chemical Quality Indicators: A Case Study in England.

***Neve Hughes**, University of Birmingham, United Kingdom*

The evaluation of the Water Framework Directive (WFD), in relation to the surface water environment, in 2019 revealed that all England's surface waters have failed to meet a good standard for chemical quality. The 25-year environment plan (25YEP) seeks to improve the environmental health of the UK over the next 25 years and includes new indicators to monitor progress. This study analysed different indicators used to monitor chemical quality of surface waters, including the H4 pesticides in surface water indicator of the 25YEP.

The case study focuses on assessing the chemical quality of England's surface water bodies using data gathered from the Environment Agency (EA) water quality monitoring (WIMS) database, specifically their semi-quantitative gas chromatography-mass spectrometry (GCMS)/ liquid chromatography-mass spectrometry (LCMS) dataset. The chemical water quality indicators were developed using this data for the period 2007 - 2021. The indicators were assessed on how factors including spatial, temporal and substance specific factors impact the indicator in order to draw conclusions as to their effectiveness and potential issues to be aware of during interpretation.

The indicators are impacted by number of samples; number of substances analysed; changes in substance availability and use; seasonal and annual variations and changes in chemical pressure. It is important to have reliable indicators of chemical water quality to track progress of policies given the increasing pressure on water resources due to overuse and deterioration of quality and this study provides insights into indicators that are currently used and makes recommendations for their improvement and interpretation.

3.16.P-Th324 LUCI - A GIS-tool to select monitoring sites in river networks based on catchment properties allowing for hypothesis testing and statistical independence

***Tom Galle**, Christian Braun and Philippe Pinheiro, Erin, Luxembourg Institute of Science and Technology (LIST), Luxembourg*

Regulatory monitoring of surface waters is often unfit to derive diffuse pollution inputs from the landscape because the sites of measurement are located at confluences of rivers with limited land use property variability. Statistical analysis of land use vs exposure/load of pollutants is therefore often very weak or nonexistent. In order to investigate land use impacts on surface water pollution we developed a web-based GIS tool that allows for the filtering of monitoring points in river networks that represent specific land use properties and consequently pressures on surface waters. The tool allows to build gradients of pressures by choosing different levels of land use or activities in a catchment while being able to exclude others. This approach strengthens statistical power of the analysis by building gradients of expected impact (moving to extreme land use) and sampling independent sites (avoiding longitudinal profiles which are auto-correlated). Hence plausibility of results can also be investigated through the array of independent monitoring sites. The contribution will illustrate the use of the powerful tool with examples of sealed surfaces in metal and PAH pollution of low-flow suspended sediments, the pharmaceutical/biocide footprint of waste water treatment plants in catchments of different sanitary pressure and the link between maize cultures and herbicide impacts on macrophytes in agricultural headwaters.

3.16.P-Th325 The challenges of creating a pan-European database and open-access dashboard of readily available public chemical monitoring data

***Gregory Hughes**, GeoSpatial Analytics Ltd, United Kingdom*

Access to public environmental monitoring data has improved in the last two decades, largely owing to open data initiatives linked to the public access to environmental information regulation (2003/4/EC). These data are collected by public bodies, like environment agencies, or organisations working in the public interest, like water/utility companies, to meet regulatory obligations and research objectives according to regional/national guidelines for sample collection, storage and analysis. In short, the data is collected by different organisations, for different purposes in different ways which makes creating a harmonised database at a pan-EU scale challenging. However, this is increasingly required for regulatory purposes, for example the assessment of chemical quality data for a range of environmental compartments under the Water Framework Directive and Plant Protection Products regulation (1107/2009/EC).

In some cases, the chemical quality data is readily available online but takes many different forms ranging from pdf documents/Excel spreadsheets and zipped data archives through to elaborate web-portals that not only provide access to the data but allow the user to interrogate the data and display data summaries. In many cases, the data need to be requested and in some cases a data extraction fee paid. Much of the data is available under an open-data type of license but in some cases, where third party data is involved, use is restricted through a specific use agreement. The geolocation of monitoring sites is provided in different projections and at different spatial accuracies depending on location security policies, especially for drinking water supply abstractions. The format of the data is highly variable requiring significant effort to harmonise the data into a coherent curated database suitable for regulatory use.

This poster outlines the collection and transformation of readily available public chemical quality data into information with the creation of a curated, harmonised, SQLite based public environmental monitoring database using a range of techniques, including the use of python based web-scrapers. It also documents the leverage of this information into knowledge through an open access R-Shiny dashboard that allows pan-EU summaries of chemical water quality data to be interrogated. The utility of easy access to pan-EU environmental information and its role in promoting sustainable practices whilst protecting the environment is outlined.

3.16.P-Th326 Comparison of the relevance of a dataset for different assessment purposes

*Adam Peters[1] and **Jeanne Vuaille**[2], (1)wca environment Ltd., United Kingdom, (2)European Environment Agency (EEA), Denmark*

The CREED (Criteria for Reporting Environmental Exposure Datasets) assessment approach provides a framework for evaluating both the reliability and relevance of environmental exposure datasets. Whilst the reliability of any individual dataset is independent of its purpose, the relevance of a dataset is always purpose-dependent and different criteria are therefore required for different assessment purposes. This presentation compares the relevance of a single dataset for three different, but related purposes and aims to highlight the important differences in the data requirements for the different purposes. The different assessment purposes are (1) the prioritisation of a substance for Environmental Quality Standard (EQS) development, (2) deriving a bioavailability based environmental quality standard, and (3) evaluating whether a substance still poses a sufficiently widespread problem for a statutory environmental quality standard to still be required. The prioritisation is focused on exposure data, but given that this occurs before the derivation of an EQS the requirements for the limits of quantification and spatial representation of data may be less stringent than for other purposes. The derivation of a bioavailability based EQS is focused on the sensitivity of the surface waters to identify sensitive water types, and not on the exposures themselves. An assessment to evaluate the continuing need for a statutory standard has specific requirements in relation to the timescales, the representativeness of the sampling, and the spatial coverage, as well as the limits of quantification. These differing requirements result in differing levels of relevance of a given dataset for the different purposes. The assessment is performed using a single dataset from the UK to illustrate these issues.

3.16.P-Th327 Assessing the Reliability and Relevance of a Dataset for Evaluating the Effects of Metal Mixtures on Benthic Macroinvertebrates in the Field

*Adam Peters[1], Iain Wilson[1], Graham Merrington[1], **Jeanne Vuaille**[2] and Yamini Gopalapillai[3], (1)wca environment Ltd., United Kingdom, (2)European Environment Agency (EEA), Denmark, (3)International Copper Association, Ltd.*

The CREED (Criteria for Reporting Environmental Exposure Datasets) assessment approach provides a framework for evaluating both the reliability and relevance of environmental exposure datasets. This assessment approach is applied here to evaluate the reliability and relevance of a combined dataset of chemical and ecological data that is used for assessing the effects of metals and metal mixtures on benthic macroinvertebrates and their communities in the field. Although the CREED assessment approach was developed specifically for data on chemical exposures it is extended here to also include information on the freshwater habitat at sampling sites and the abundance of benthic macroinvertebrates, although in a more limited manner. This application of the CREED assessment approach demonstrates that clear, transparent, and auditable assessments of reliability and relevance can be applied to other kinds of environmental data beyond purely chemical measurements. This presentation highlights some of the limitations of the CREED approach, particularly as applied to these kinds of data that it was not originally generated for, and draws conclusions about the suitability of the dataset evaluated for evaluating the effects of metal mixtures on freshwater invertebrate communities.

3.16.P-Th328 Temporal Trends of Atmospheric PBDEs in Spain: An Analysis over a Decade (2008-2019)

*Juan Munoz-Arnanz, Pere Colomer Vidal, Maria Ros, Alba Vicente, Cielo Salcedo, Estela Nogales and **Begoña Jiménez**, Institute of Organic Chemistry, Spanish National Research Council (IQOG-CSIC), Spain*

Polybrominated diphenyl ethers (PBDEs) are among the dominant flame retardants used for decades. This class of Persistent organic pollutants (POPs) are regulated under the Stockholm Convention (SC). This study, within the framework of the Spanish Monitoring Program on POPs since 2008, focuses on assessing PBDE concentrations in the air in urban and background areas in Spain to evaluate the effectiveness of the measures taken under the SC. PBDEs were analyzed by GC-HRMS in more than 500 air samples, obtained with passive sampling devices during a decade.

Despite fluctuations in measured concentrations, a consistent pattern of relative abundance in the air emerged: PBDE-209 predominantly contributed to ΣPBDEs, followed by PBDE-47 and PBDE-99 in both urban and background sites. Urban areas exhibited notably higher median concentrations than background locations, with significant differences observed between various urban and background locations.

Within the study period, a positive correlation between time and global PBDE concentrations was detected, indicating an overall increase in PBDE levels. Interestingly, the correlation of only PBDE-209 with time was just marginally ($p=0.055$) significant, while the sum of the remaining PBDEs did not exhibit a significant positive correlation with time. Moreover, minor contributors (BDE-17, 28, 66, 85, 100, 153, 154, 183, 191, 196 and 197) showed a significant negative correlation, suggesting a decrease over time.

Location-specific trend analysis revealed time-concentration relationships with ΣPBDEs in various cities. Significant positive correlations were observed in several urban and background areas, while a negative correlation was found at one background area. Similar correlations were found for PBDE-209 in almost all locations, underscoring the high influence of this congener on the general trends.

Our chemical monitoring dataset underscores how PBDE temporal trends are highly location-dependent, emphasizing the importance of long-term monitoring and location-specific influence in assessing atmospheric PBDE pollution. The divergence in the PBDE congener abundance and the significant variations among locations highlight the necessity to better understand pollution patterns in the environment to support chemical regulation and their implications for human and environmental health.

3.16.P-Th329 Contextualisation of RAC exceedances reported for small surface water bodies in Germany
***Oliver Körner**[1], Carola Schriever[2], Herbert Resseler[3], Andreas Solga[4], Stefan Kimmel[5], Judith Neuwöhner[6], Stephan Partsch[7], Sophia Müllner[8] and Mark Winter[8], (1)ADAMA Deutschland GmbH, Germany, (2)BASF SE Agricultural Solutions, Germany, (3)Syngenta Agro GmbH, Germany, (4)Bayer AG - Crop Science Division, Germany, (5)Corteva Agriscience, Germany, (6)Nufarm Europe GmbH, Germany, (7)FMC Agricultural Solutions, Germany, (8)Industrieverband Agrar e.V., Germany*
A surface water monitoring campaign (2018-2019) was commissioned by the German Federal Environment Agency (UBA) to assess the chemical and biological condition of small agricultural watercourses and verify the effectiveness of risk assessment and management in the pesticide approval process. The final campaign report concluded that regulatory acceptable concentrations (RAC) of pesticide active substances were exceeded in more than 73% of the investigated watercourse sections, indicating a general underestimation of the actual risk in pesticide approval.

The German Plant Care Industries Association (IVA) evaluated the publicly available raw data from the campaign to understand the causes for the reported RAC exceedances. The IVA found that for approximately 75% of active substances with RAC exceedances listed in the final report, the considered RACs (UBA-RACs) differed from the legally binding RACs valid at the time of approval (BVL-RACs; BVL = Federal Office of Consumer Protection and Food Safety). Considering the BVL-RACs, the total number of exceedances is approximately 50% lower compared to the final report of the campaign. UBA-RACs were lower due to various reasons: additional safety factor of 3 was applied, supportive (higher-tier) studies (e.g., metamitron or 2,4-D) or data from EU documents (e.g., acetamiprid) were not considered.

Reviewing the concentrations from the campaign report, the IVA observed that for the majority of analysed active substances, more than 95% of the water samples contained concentrations below the BVL-RACs. Only three active substances exceeded BVL-RACs in more than 5% of the samples with two of them being also used in the non-agricultural sector and being detected alongside waste water markers. In conclusion, the campaign results suggest that surface water exposure under real world conditions is below levels of concern for the vast majority of analysed active substances and sites, indicating a functioning pesticide approval process.

3.16.P-Th330 Monitoring chemical emissions from offshore wind farms: assessing impacts, gaps and opportunities
***Bavo De Witte**[1], Lieven Bervoets[2], Simone Hasenbein[3], Daniel Pröfrock[4], Ali Sarhadi[5], Javier Castro-Jiménez, PhD[6], Karien De Cauwer[7], Johan van der Molen[8], Tom Baur[9], Andy Booth, PhD[10] and Niklas Czerner[11], (1)Marine Research, Institute for Agriculture and Fisheries Research (ILVO), Belgium, (2)University of Antwerp, Belgium, (3)German Federal Maritime and Hydrographic Agency (BSH), Germany, (4)Inorganic Environmental Chemistry, Helmholtz-Zentrum Hereon, Germany, (5)DTU, Denmark, (6)Chemical Contamination of Marine Ecosystems, IFREMER, France, (7)RBINS, Belgium, (8)NIOZ Royal Netherlands Institute for Sea Research, Netherlands, (9)POM West-Vlaanderen, Belgium, (10)SINTEF Ocean, Norway, (11)TU-Braunschweig, Germany*
Offshore wind energy offers many advantages to society as well as the marine ecosystem. Next to the primary aim of producing renewable energy, offshore wind farms (OWFs) also offer opportunities to combine energy production with other activities such as nature conservation or aquaculture. The vast increase in offshore energy production urged different European countries to monitor the potential effects of OWFs on the marine ecosystem, including the effects of underwater noise and the introduction of novel habitats, but also the exclusion of fisheries. However, the potential risk of chemical emissions by OWFs remains largely unknown.

Chemical emissions from OWFs may be divided into three groups: metals, organics and particles. OWF turbines and substations contain corrosion protection systems which can leach metals such as aluminium or zinc into the ocean. Organic chemical emissions are expected from different sources such as leaching from paints, leakages of transformer and lubricating oils, and the unintended release of fire extinguishing agents. Particulate emissions result from the release of paint flakes and the abrasion of small composite and plastic parts from the rotor blades. To the best of our knowledge, no significant risks from OWF chemical emissions into the marine ecosystem have currently been identified.

Within the Interreg North Sea Region project Anemoi, the aim is to assess impacts, knowledge gaps and opportunities related to chemical emissions of OWFs. In this poster presentation, an overview of potential emission sources will be provided and the potential challenges to monitoring and forecasting will be addressed. These challenges include measuring low concentrations of a diverse set of pollutants in marine compartments, estimating the relative share of emissions originating from OWFs compared to other marine sources and predicting the behaviour of particles in a dynamic marine environment.

First data of contaminants measured in sediment samples taken in/near OWFs will be presented and future steps toward emission reduction outlined.

Acknowledgement: we acknowledge the project Anemoi (Project number 41-2-13-22), an Interreg North Sea project co-funded by the European Union.

3.16.P-Th331 Using biota monitoring data to identify priority substances and improve chemical risk assessment and management under REACH

Oliver Machate[1], *Gabriele Treu*[1], *Romana Hornek-Gausterer*[2], *Maria Uhl*[2], *Paola Movalli*[3], *Koos Biesmeijer*[3], *Peter Fantke*[4], *Susan Oginah*[5], *Martina G. Vijver*[6], *Laura Scherer*[6], *S. Henrik Barmentlo*[6], *Nikolaos S. Thomaidis*[7], *Maria-Christina Nika*[7], *Georgios Gkotsis*[7], *Marissa B Kosnik*[8], *Guy Duke*[9], *Nikiforos Alygizakis*[9], *Natalia Glowacka*[9] *and Jaroslav Slobodnik*[9], *(1)German Environment Agency (UBA), Germany, (2)Environment Agency Austria (EAA), Austria, (3)Naturalis Biodiversity Center, Netherlands, (4)Quantitative Sustainability Assessment, Department of Environmental and Resource Engineering, Technical University of Denmark, Denmark, (5)Technical University of Denmark (DTU), Denmark, (6)Institute of Environmental Sciences (CML), Leiden University, Netherlands, (7)National and Kapodistrian University of Athens, Greece, (8)Department of Environmental Toxicology, Eawag: Swiss Federal Institute of Aquatic Science and Technology, Switzerland, (9)Environmental Institute, Slovakia*

Most chemicals are registered under REACH. There the traditional environmental risk assessment is based on predicted environmental concentrations (PECs), usually in water, to be compared with predicted no-effect-concentrations (PNECs), usually derived from algae, daphnia and fish. Only for high tonnage industrial chemicals, also sediment and terrestrial toxicity data are available. Therefore, exposure and effects in higher trophic level species and on terrestrial organisms are often not assessed, as seldom data are available - at least under the European REACH regulation. Biomonitoring data offer a direct insight into which substances organisms are exposed to and, additionally, can be used to perform the bioaccumulation assessment within REACH and CLP. Therefore, environmental biomonitoring data can give a more realistic estimate of the actual exposure level of organisms than traditional exposure assessments, especially when more species are analysed at the same location and time. However, interpreting internal chemical concentrations in the context of toxicity assessments within regulatory risk assessment - at organism or even at ecosystem level - remains challenging. Particularly, since systematic approaches on how to make use of biota monitoring data on this vital aspect are scarce. To address this knowledge gap, the German Environment Agency (UBA) is actively engaged in several projects aiming at constructing a robust database and bridging the gap from internal concentrations to adverse effects on organisms and ecosystems. Most prominent these are the HORIZON TerraChem and the UBA funded Beyond Life Apex project. Results will be used (1) to identify and prioritize chemicals that are driving biomagnification, toxicity and ecological risks, and (2) to enhance current risk assessment methods and management practices. This poster will outline UBA's efforts in leveraging biomonitoring data, display the first results from Europe wide biota monitoring and open the door for discussions on how to shape a more effective regulation and biodiversity protection.

3.16.P-Th332 Copper does not appear to drive adverse effects on German aquatic biodiversity: A spatial analysis of copper concentrations in German surface waters and sediments and biomonitoring data

Gareth Le Page[1], *Ines Hotopp*[2], *Anja Russ*[3], *Elenaor Long*[1] *and Matthias Weidenauer*[4], *(1)Battelle UK, United Kingdom, (2)Tier3 Solutions GmbH, Germany, (3)tier3 solutions GmbH, Leverkusen, Germany, (4)European Union Copper Task Force, Switzerland*

Copper and copper compounds have been a vital fungicidal tool in agriculture for over a century and continues to be of key importance, especially for organic farming where a more limited range of fungicides are available to support crops. In addition to fungicidal use, copper is a key component of fertilizers, biocides and has many other industrial applications leading to a continuous input into the environment. Additionally, copper, a transition metal, is nutritionally essential, but toxic in high doses and non-degradable. Recognizing this, the European Food Safety Authority (EFSA) published a statement on the environmental risk assessment for transition metals that expands the role and importance of monitoring data.

In order to examine the impact of copper on aquatic wildlife, we performed a spatial analysis combining publicly available copper monitoring data (extracted from a database of all national monitoring and catchment based monitoring programs) and biomonitoring data in German surface waters and sediments. The analysis aimed to assess if there were any adverse effects on the biodiversity in German freshwater ecosystems due to the presence of copper. Specifically, Generalized Linear Mixed Models were used to identify any correlations between the number of species of fish, macrophytes and phytobenthos, phytoplankton or macrozoobenthos and localised copper concentrations.

Our key findings are: 1) median measured copper concentrations in surface waters were 2.4 µg/l and 2.1 µg/l, for total and dissolved copper respectively; 2) median measured copper concentration in German sediments was 49.0 mg/kg; 3) no correlations were found between copper concentration and macrophytes, phytobenthos, phytoplankton or macrozoobenthos species; 4) a minor increase in the number of fish species was associated with increasing copper concentrations although this is most probably an indirect effect due to other environmental influences; and 5) monitoring and biomonitoring data are not always easily accessible nor are they consistent between programmes causing complications with spatial and temporal representativity. Consideration must be put into a more unified approach to make use of what is otherwise a large and highly valuable dataset. Overall, this analysis shows that copper in German surface waters and sediments does not appear to be a key driving force number of aquatic taxa.

3.16.P-Th333 Determination of Biogenic Sterols in Surface Sediments of Admiralty Bay, Antarctic, and their Relationship with Recent Environmental Changes

Gabrielle Vieira Lube[1]*, Rafael Andre Lourenço*[1]*, César Martins*[2]*, Satie Taniguchi*[1] *and Rosalinda Carmela Montone*[3]*, (1)Oceanographic Institute, University of São Paulo (USP), Brazil, (2)Universidade Federal do Paraná, Brazil, (3)Oceanography, University of São Paulo (USP), Brazil*

The Antarctic Continent is considered one of the most untouched areas on the planet due to its geographical location and distance from populated regions. In recent decades, the Antarctic Peninsula has experienced a sharp rise in temperature, being higher than the global average. The main consequence of this change is linked to the loss of area and volume of the glaciers, generating a greater discharge of continental material to the glaciomarine environment, thus bringing changes in the dynamics of carbon in the area. Sterols are important biogeochemical tools applied to understand the sources, transport, and fate of organic compounds in the marine environment. In addition, they act as fingerprints of primary production at different time scales. Thus, the present work seeks to investigate the spatio-temporal distribution of geochemical markers (sterols) as indicators of origin, variations in input, preservation, and degradation of sedimentary organic matter in samples of surface sediments. Sampling was carried out along the three major inlets of the bay, namely: Martel, where the Brazilian station Comandante Ferraz (EACF) is located, Mackelar, where the Peruvian station Machu Picchu is located, and Ezcurra, where the Polish station Henryk Arctowski is located, during 2002 - 2018. The sterols were analyzed by gas chromatography with a flame ionization detector after Soxhlet extraction, purification in the liquid adsorption column, and derivation reaction. The results obtained suggest that in this environment there is a multiplicity of marine sources and the variability of the concentration over time may indicate a predominance or decline of producing species in the face of environmental changes. Cholesterol was the dominant sterol (2.85 ± 1.63 µg.g-1), and the contributions of penguins and seals feces as well as inputs associated with phyto and zooplankton explained this trend. Sitosterol showed an average concentration of 1.42 ± 0.53 µg.g-1. Brassicasterol and stigmasterol were detected in practically all samples along the time series, with averages equal to 0.84 ± 0.23 and 0.47 ± 0.19 µg.g-1 respectively, evidencing the contribution of diatoms, cyanobacteria, and dinoflagellates to the buried organic matter in marine sediments. In addition, the concentration differences between inlets may also reflect the variation in the abundance of organisms in different locations, indicating that their distribution in the environment is not always homogeneous.

3.16.P-Th334 Estimation of Gas-particle partitioning Coefficients (Kp) of POPs in different Antarctic region.

Victoria A Gómez[1]*, Thais Luarte*[2]*, Andrea Hirmas*[2]*, Rosario Vargas*[1]*, Karla Pozo*[3]*, Jakub Martiník*[4]*, Petra Pribylova*[5]*, Eduardo Castro-Nallar*[6]*, Nicolás Hunneus*[7]*, Gustavo Chiang*[2]*, Eduardo Chamorro*[2] *and Cristobal Galban-Malagon*[1]*, (1)Universidad Mayor, Chile, (2)Universidad Andrés Bello, Chile, (3)Universidad San Sebastián, Chile, (4)Recetox, RECETOX, Masaryk University, Czech Republic, (5)Recetox, Masaryk University, Czech Republic, (6)Universidad de Talca, Chile, (7)Departamento de Geofísica, Universidad de Chile, Chile*

Gas/particle (G/P) partition, describing the distribution between the gas and particle phase in atmosphere, is an important influencing factor for the deposition, chemical reaction, and the long-range transport of semi-volatile organic compounds (SVOCs). Another hand, some of the persistent organic pollutants (POPs) reach Antarctic atmosphere through long-range atmospheric transport. In this study, the concentration of organochlorine pesticides (OCPs), polychlorinated biphenyls (PCBs) and polycyclic aromatic hydrocarbons (PAHs) in air samples (gaseous and particulate phase) was determined at four sampling points in Antarctica during the Austral summer from 2019 to 2022. The samples were collected using a high-volume air sampler (MCV: CAV-A/HF, Collbató, Spain) and quantified using Gas Chromatography-Mass Spectrometry (GC-MS). The concentration ranges of OCPs in the gaseous and particulate phases were 8.26-64.15 pg/m^3 and 0.30-1.32 pg/m^3, respectively. For PCBs, the ranges were 0.12-9.62 pg/m^3 and 0.08-0.26 pg/m^3, while for PAHs, they were 0.32-5.93 ng/m^3 and 0.04-0.60 ng/m^3, respectively. The gas/particle partition coefficients (KP) for each sampled compound were calculated as the concentration in the particle phase divided by the product of the concentration in the gas phase and the total suspended particle (TSP) concentration. The results obtained demonstrated that the analysis of atmospheric samples of persistent organic pollutants reveals that these substances tend to predominate in the gaseous phase rather than the particulate phase. The preference for the gaseous phase has significant implications for the dispersion and transportation of these pollutants in the atmosphere, which can influence their effects on human health and the environment and facilitating their long-distance transport. The atmosphere is the dominant transport pathway for these chemical substances at these latitudes. These findings underscore the importance of understanding the distribution of pollutants in different atmospheric phases for a more comprehensive assessment of their impact and to inform effective strategies for pollution management and control.

3.16.P-Th335 Differences in the concentrations of organic pollutants in suspended particulate matter in Admiralty Bay, Antarctic Peninsula, during the summer of 2022/23

Amanda Câmara Souza[1]*, Josilene Da Silva*[1]*, Satie Taniguchi*[1]*, Tatiane Combi*[2]*, César Martins*[1] *and Rafael Andre Lourenço*[1]*, (1)Oceanographic Institute, University of São Paulo (USP), Brazil, (2)Center for Marine Studies, Federal University of Paraná, Brazil*

Organic pollutants, such as Polychlorinated Biphenyls (PCBs) and Polycyclic Aromatic Hydrocarbons (PAHs), are introduced into Antarctica through local tourism, fishing, and research activities or transported over long distances. Along the coastal regions of Antarctica, organic compounds in snowmelt can be transferred to seawater during the austral summer melting. Thus, this study aimed to determine the variations of PCBs and PAHs in the water column of Admiralty Bay, located on King George Island, Antarctic Peninsula, within a short-time scale perspective (from late spring to late summer). Sampling was conducted in five campaigns during the 2022/2023 summer at 16 sites. Approximately 20 liters of surface water were vacuum filtered through GF/F Whatman® (0.7 μm) filters to obtain the suspended particulate matter (SPM). Identification and quantification of 51 PCBs and 16 priority PAHs were performed using an Agilent gas chromatograph model 7890B coupled with an Agilent triple quadrupole TQMS model 7010B operating in multiple reaction monitoring. PCBs contents in SPM varied from 2.64 to 78.15 ng g^{-1}. The November and December 2022 campaigns were statistically different from the campaigns of January to March 2023 (Kruskal-Wallis non-parametric test and Mann-Whitney post hoc test; $p < 0.01$). PCBs concentrations were higher in the latter campaigns, coinciding with the increase in snowmelt in late summer. PAHs values varied from 486.3 to 4323.0 ng g^{-1}. The February 2023 campaign was the only one that had a significant increase in PAHs concentrations (Kruskal-Wallis non-parametric test and Mann-Whitney post hoc test; $p < 0.05$). After decades of emissions, PCBs have accumulated in soils and snow/ice. Therefore, when the ice melts, the input of PCBs into the water column increases. In contrast, this increase is masked for PAHs since they are currently introduced into the environment through research station operations and ship traffic present in Admiralty Bay. Spatially, PCBs and PAHs showed no significant statistical variations (Kruskal-Wallis non-parametric test; $p > 0.05$) among the three inlets of the bay (Ezcurra, Mackellar, and Martel). The spatial distribution of these pollutants in the SPM of Admiralty Bay is homogeneous, probably due to the strong influence of wind speed on the movement and mixing of the water in this area. This study contributes to the scientific basis for understanding the cycles of PCBs and PAHs in marine environments.

3.16.P-Th336 Detection of Particulate and Metal(loid) Emissions from Offshore Wind Farms

Alexa McCormick Zonderman[1,2]*, Michelle Ferdinand*[3,4]*, Lars Michael Hildebrandt*[4] *and Daniel Pröfrock*[2]*, (1)Universität Hamburg, Germany, (2)Inorganic Environmental Chemistry, Helmholtz-Zentrum Hereon, Germany, (3)Department of Applied Natural Sciences, Technische Hochschule Lübeck, Germany, (4)Department of Inorganic Environmental Chemistry, Helmholtz-Zentrum Hereon, Germany*

Current global threats, in particular climate change and geopolitical events, have increased demand for a rapid transition to renewable energy sources. In response, many nations have set ambitious goals concerning the development and installation of energy-generating technologies, including offshore wind farms (OWFs). However, information is still lacking in terms of the long term chemical impacts of these structures and their operation on the marine environment. The goal of this study is to investigate the levels of chemical contaminants within OWF and nearby sites, and to evaluate their traceability to OWF-based sources such as passive and active corrosion protection strategies.

The analyzed sample set originates from a 2023 campaign in the North Sea. Locations within the boundaries of multiple OWFs were sampled in addition to nearby and reference locations with varying levels of anthropogenic impact. Particulate samples were taken from seawater using a filtration cascade down to a filter size of 10 μm. In the laboratory, samples are reduced to a single filter and subjected to two-step digestion and density separation prior to analysis via laser direct infrared (LDIR) imaging. Inorganic seawater and sediment samples to be analyzed with inductively coupled plasma tandem mass spectrometry (ICP-MS/MS) were taken at all particulate sample sites and additional locations.

The abundance and distribution of particulate pollutants including microplastics within OWFs is at the current time virtually unknown and data concerning metal(loid) distributions in OWF areas are still scarce. This study aims to provide initial data on the presence of both OWF-related particles and to implement proposed methods of tracing OWF impacts. The data may be combined with further sampling campaigns, laboratory studies, and toxicological data to obtain an initial perspective on the relevance and magnitude of the chemical emissions and therefore unwanted side effects from renewable offshore wind energy production. Due to planned increases in global offshore capacity, this study is of relevance to regulatory and industry organizations in understanding and mitigating chemical impacts on the marine ecosystem in upcoming decades.

3.16.P-Th337 Footprints of Biohazards (VOCs, Volatile Organic Compounds): Monitoring of wastewater

Parth Gupta Dr.[1]*, Dnyaneshwar Rameshrao Shinde*[1]*, Raghu Tadala Mr.*[1]*, Bhaskar Karubothula Mr.*[1]*, Wael Elamin*[2]*, Samara Bin Salem*[3] *and Grzegorz Brudecki Dr.*[4]*, (1)Organic Chemistry, G42 Healthcare, United Arab Emirates, (2)Environment Sciences, G42 Healthcare, United Arab Emirates, (3)Adqcc, ADQCC Abu Dhabi UAE, United Arab Emirates, (4)Environmental Sciences, G42 Healthcare, United Arab Emirates*

The presence of volatile contaminants needs to be monitored at regular intervals to understand the implications on human health and diverse ecosystems. These purgeable incorporate a huge class of chemical compounds, some of which are benzene, toluene, ethylbenzene, and xylenes (BTEX), and other carcinogenic compounds like trichloroethene (TCE), perchloroethylene (PCE), and vinyl chloride. These volatiles enter the groundwater via varied natural as well as anthropogenic (industries, oil spillages, and automobile exhaust) sources which in turn causes contamination. Therefore, an uncontrolled discharge of these VOCs may lead to long-lasting effects on the water bodies which imbalances the biodiversity. To provide sufficient evidence of the presence of these VOCs, this work concentrates on one such case study that particularly focuses on monitoring TCE and PCE in wastewater. Continuous surveillance of TCE and PCE was achieved using a Headspace-trap (HS-trap) technique coupled with the Gas Chromatography-Mass Spectrometry (GC-MS). This sophisticated instrument is proven to have the ability to analyse and precisely report accurate levels of these known carcinogens at sub-below ppb levels. The findings revealed that the levels of these biohazards in varied locations are more than 50% higher than the globally accepted levels for these VOCs, as per WHO regulations for drinking water. Hence, continuous monitoring of these discharged chemicals needs to be continued over longer periods considering their moderate volatility as well as their consistently higher levels. Further, single source-oriented sampling can help in strengthening their presence as well as provide scientific signatures towards understanding their trend of release into the wastewater systems. Nevertheless, the obtained levels for these volatiles will support the local environmental agencies to curb their release as well as provide control measures to minimize their hazardous impact on ecosystems.

3.16.P-Th338 Toxicity of Wastewater with Elevated Bromide concentration

***Nabiazam Fuzail Ahmed Sayed**, Dibin Bhasi, Abdul Raheem Chevidenkand, Shanid Thayyil and Grzegorz Brudecki, G42 Healthcare, United Arab Emirates*

Wastewater management is a critical concern for safeguarding our environment and public health. In recent years, the scientific community has been increasingly focused on understanding and mitigating the impact of various contaminants present in wastewater. One such contaminant that has gained attention is Bromide. Bromide is a naturally occurring element that can be found in various water sources, including freshwater and seawater. It is also a common constituent of wastewater, often originating from coal-fired power plants, industrial processes, agricultural runoff, and domestic sources. The presence of bromide in wastewater is of particular concern due to its potential to form disinfection byproducts (DBPs) when it comes into contact with disinfectants like chlorine during the water treatment process. These DBPs can have adverse effects on public health and the environment. Our investigation examines the concentration of bromide in wastewater samples over time, with a focus on identifying spikes or unusual patterns. By doing so, we aim to better understand the sources, effects and associated exposure and health risks.

3.16.P-Th339 Presence of anthropogenic contaminants in urban groundwater wells

***Sergio Santana-Viera**[1], Erik Mestanza-Castelltort[1] and Sandra Perez Solsona[2], (1)Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain, (2)Onhealth, Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain*

Warranting that drinking water resources are secure from unwanted and toxic chemicals is a central goal of human health protection and human rights, and it is one of the Sustainable Development Goals of the United Nations. One of the water sources considered is groundwater, since its operating costs are lower than those of seawater. However, numerous chemical compounds are used in our daily lives and many of them are not efficiently eliminated in wastewater treatment plants, giving rise to the presence of anthropogenic contaminants in large bodies of water such as rivers, putting the viability of groundwater at risk. In this work, more than 80 anthropogenic contaminants of environmental interest belonging to various groups were selected: drugs, agrochemical compounds, industrial compounds and transformation products. These compounds were analyzed in the Besos River (Barcelona, Spain) and in 16 nearby wells. Approximately, 85% of target analytes were detected in concentrations ranging from 1 to 338 $ng \cdot L^{-1}$, depending on the well and the compound. Furthermore, 60% of the compounds were detected in more than 75% of the samples, showing a constant pollution.

3.16.P-Th340 Introduction to Automated Analysis of Multiclass Biohazardous Chemicals (BCs) and Persistent Organic Pollutants (POPs) in Water by APGC-MSMS with RTC PAL SPME Arrow

***Dnyaneshwar Rameshrao Shinde**[1], Vijayakumar Murugan Mr.[2], Parth Gupta Dr.[2], Urvikkumar Dhagat Mr.[2], Raghu Tadala Mr.[2], Bhaskar Karubothula Mr.[2], Samara Bin Salem[3], Wael Elamin[4] and Grzegorz Brudecki Dr.[5], (1)G42 Healthcare, United Arab Emirates, (2)Wwml, G42 Healthcare, United Arab Emirates, (3)Adqcc, ADQCC Abu Dhabi UAE, United Arab Emirates, (4)Environment Sciences, G42 Healthcare, United Arab Emirates, (5)Environmental Sciences, G42 Healthcare, United Arab Emirates*

Industrial development and widespread usage of chemicals lead to an anthropogenic environmental pollution. Deliberate or unintentional disposal of these Biohazardous Chemicals (BCs) and Persistent Organic Pollutant (POPs) into biosphere has increased in the last half century. Because of the highly carcinogenic and bio-accumulative nature of these chemicals, they pose a serious threat to the environment and humanity. These compounds are further classified as Volatile Organic Compounds (VOCs), Poly-Aromatic Hydrocarbons (PAHs), Organo-Chlorine Pesticides (OCPs), Poly-Chlorinated Benzenes (PCBs), Phenols, Phthalates, Dioxins, and other chemicals. All these chemicals are analysed using traditional EI-GC-MS/MS, with Liquid-Liquid Extraction (LLE) or Solid Phase Extraction (SPE). However, both the instrumental and sample preparation with these techniques comes with limitations with respect to selectivity for molecular ions, time taking sample preparation, use of larger volume of samples, solvents, and CRMs. The objective of this study is to introduce solvent free automated analysis of BCs and POPs. Solid Phase Micro-Extraction (SPME) is a green i.e., solvent free sample preparation technique, which involves automated extraction and pre-concentration of the analytes by ad/absorption on SPME arrow phase and injection of the analytes by desorption in GC inlet. This technique is evaluated for the Ion Ratio, Coefficient of Determination (r^2), Precision (%RSD), % Recovery for SPME performance check standard and 20 selected multi-class BCs and POPs using RTC-PAL with SPME Arrow (DVB/PDMS) by APGC-MS/MS. The results of intra-day precision for compounds in mix i.e., 2 Nitrotoluene and Nitrobenzene is ranging from 3.91 to 8.98 and inter-day precision is 10.54 and 12.45 which is within acceptable criteria of 20% RSD. Further, the results for selected 20 multi-class (VOCs, Phenols, Phthalates, PAHs, OCPs and Dioxin) are acceptable. Results for % recovery at 1 ppb spike level (2,3,7,8 TCDD @ 0.05ppb) in water (ASTM Type I) is ranging 85.58 to 111.38 and precision is ranging from 2.30 to 14.28. Therefore, it is evident from the results that with the pragmatic and systematic approach for method development and use of the Internal Standards (IS), automated SPME arrow-based extraction can be considered as tool for qualitative and quantitative analysis of Multiclass BCs and POPs.

3.16.P-Th341 Analysis of Difficult Test Chemicals in Support of Aquatic Toxicity Studies (Organization for Economic Cooperation and Development Guidance Document 23)

***Marc Baremans**, Charles River Laboratories, United Kingdom*

The Organisation for Economic Co-operation and Development (OECD) is an international organisation that works to build better policies for better lives. One of their Guidance Document on Aqueous-Phase Aquatic Toxicity Testing of Difficult Test Chemicals (GD 23) provides additional guidance and approaches for aquatic toxicity studies for difficult test chemicals.

Typical difficult test chemicals are poorly water-soluble or unstable test chemicals in aqueous phase. Multi-component test chemicals or Unknown/Variable composition, complex reaction products and biological materials (UVCBs) are also considered as challenging test chemicals. Such difficulties require a specific approach for aquatic toxicity testing as well as analytical support to test the aquatic media for presence of correct test chemical and correct concentration levels.

To challenge difficult test chemicals in a more structured manner, historical studies have been evaluated to consider logical and successful decisions in study approach. In combination with the OECD guidance document, this evaluation resulted in standardized procedures for both the aquatic toxicity testing as well as the analytical method development and validation at CRL. The standardization is based on critical defined questions and corresponding pre-defined decisions to divert the study towards the correct study set-up. It includes pre-defined moments, where both aquatic toxicity and analytical chemistry experts discuss the challenges from both perspectives including the opportunities from both fields.

Typical examples of difficult test chemicals will be presented regarding the challenges with respect to poor water solubility, stability, or multi-component composition of the test chemical. The structured and standardized approach resulted in a robust and correct study set-up of difficult test chemicals and will be used for future assessments.

3.16.P-Th342 The development of salinisation in German waterways from 2000 to 2022

***Theresa Piana**[1] and Elisabeth Berger[2], (1)Department of Social-Ecological Systems, Rhineland-Palatinate Technical University Kaiserslautern-Landau (RPTU), Germany, (2)Social-Ecological Systems, University of Kaiserslautern-Landau (RPTU), Germany*

In Germany and across most parts of Europe, especially in the non-Mediterranean area, little is known about the extent of freshwater salinisation. Driven by natural processes such as geological weathering, atmospheric salt deposition and saltwater intrusion, as well as anthropogenic activities like mining, irrigating, farming, excessive land use, road de-icing and waste water discharging, overall salinity in German waterways is expected to increase with global warming. Higher temperatures and prolonged and fortified droughts with periods of high evaporation are predicted, leading to higher salt loads, lower water levels and a reduction of the dilution capacity in rivers, especially in the warm summer months. This is problematic as higher ion concentrations cause osmotic stress for freshwater organisms, loss in species richness and reductions in ecosystem functioning inducing high environmental, recreational and economic costs.

To prevent catastrophes like the mass fish die-off in the river Oder in 2022 and a reduction in biodiversity, a better understanding on the state of freshwater salinisation, its development and sources is crucial. So, and to identify and assess the contribution of different salinisation drivers, and to extrapolate to future implications, we compiled an extensive data set from routine state monitoring programs across Germany, covering the years 2000 to 2022. Using this dataset, we plan on using time series analysis to explore the spatial distribution and temporal development of salinity parameters, such as electrical conductivity and salt ion concentrations, and to correlate these to potential freshwater salinization drivers.

Using this data, we already generated the first view on the current state of freshwater salinisation in Germany and its development since 2000, which indicates an increasing trend, accounting for seasonal fluctuations. With a better understanding on the contribution of different salinisation drivers, effective regulations and thresholds could then be established.

3.16.P-Th343 Monitoring of seven N-nitrosamines in raw and cooked Korean food by UPLC-APCI-MS/MS

***In-Kyu Lee**[1], Na-Youn Park[2], Hyeri Jeon[2], Ye EUN Seo[3], Younglim Kho[2] and Jung-Hoan Kim[3], (1)Department of Food Technology & Service, Eulji University, Korea, Republic of (South), (2)Department of Health, Environment & Safety, Eulji University, Korea, Republic of (South), (3)Eulji University, Korea, Republic of (South)*

N-nitrosamines (NAs), potential carcinogens, can be formed through environmental pollution, additives, and the use of pesticides and fertilizers. NAs, compounds in which nitrogen (N) and oxygen (O) are bonded to an amine group (-NH2), can be generated through interactions with contaminants in soil, water, and air, as well as during the cooking process. Therefore, this study aims to explore the differences of NAs levels between raw and cooked Korean foods.

The target NAs for analysis include NDMA, NDEA, NMEA, NDBA, NPIP, NMOR, and NPYR. The total number of samples is 1000, selected from agricultural, livestock, fishery, and processed products based on their intake frequency, consumption, and fat content. This selection included 307 raw foods and 693 cooked foods by 18 representative cooking methods according to the Korean National Health and Nutrition Examination Survey. Sample preparation for the analysis of the seven NAs in food was performed using the QuEChERS (Quick, Easy, Cheap, Effective, Rugged and Safe) method, followed by instrumental analysis using UPLC-APCI-MS/MS.

Total NAs in food were detected at a rate of 58%, with NPYR showing a detection rate of 27% and a maximum concentration of 113 ng/g. Among food categories, agricultural products exhibited the highest detection rate at 61%. In cooked food, the detection rate of total NAs was 54%. Among them, NMOR showed the highest detection rate at 27%, and NDMA exhibited the highest concentration at 150 ng/g. Depending on the cooking method, dry heat cooking led to an increase in NAs levels, with the highest increase observed during direct flame roasting. Conversely, there was a tendency to decrease during moist heat cooking.

This study confirms the diverse detection of NAs in food and observes a wide range of concentrations depending on the cooking method. Therefore, continuous monitoring studies are necessary.

3.17 New Perspectives and Developments in Chemical (Bio)Degradation and Persistence Assessment

3.17.T-01 Impacts of Sample Storage and Reference Compounds in the OECD 309 Surface Water Mineralisation Test
Sigrid Hakvåg[1]*, Katharina Giray*[2]*, Christopher Hughes*[3]*, Deni Ribicic*[1,4]*, Odd Gunnar Brakstad*[1,4]*, David M Brown*[3]*, Kate Schofield*[5]*, Christian Maeß*[2]*, Dirk Scheerbaum*[2] *and Silke Fiebig*[2]*, (1)SINTEF Ocean, Norway, (2)Noack Laboratorien GmbH, Germany, (3)Ricardo Energy & Environment, United Kingdom, (4)SINTEF, Norway, (5)Ricardo-AEA Ltd, United Kingdom*
Biodegradation is an important process for the removal of several environmental organic contaminants and is a major determinant of both chemical- persistence and -exposure, and standardised laboratory tests have been developed for assessing persistence. The OECD 309 method is a simulation test for aerobic biodegradation of chemicals in surface waters and is the preferred method for generating data for persistence assessment under EU REACH. Although the guideline defines several parameters, there are some challenges and uncertainties related to the recommended test requirements which are likely to lead to variation in observed degradation.

In this ongoing work, the OECD 309 Surface Water Mineralisation Test has been investigated by providing an in-depth assessment of inoculum quality and viability; identifying and validating more relevant reference substances that better reflect the vital status and composition of the inoculum; and providing a data-based evaluation of the test robustness and applicability at the 12°C test temperature. By using a suite of quantitative and qualitative tests (as MPN/CFU, respirometric analysis, 16S rDNA microbiome analyses), the data obtained has provided a basis for suggesting improved guidance on surface water sample collection, storage, and treatment. Further, it has been suggested that the currently recommended reference compounds (sodium benzoate and aniline) do not provide good indicators of inoculum performance due to their high biodegradability, and this ongoing Cefic-LRI ECO55 project has therefor aimed at identifying potential new reference substances with a slower/less easily degradation. Based on an initial screening program, three compounds have been selected for further analyses, namely aniline, Caffeine and 2,4-dichlorophenoxyacetic acid. A pre-test to check varying envionmental and laboratory conditions have been performed.

The data obtained forms a basis for providing improved guidance on surface water sample collection, storage, and treatment. An interlaboratory ring trial is initiated by the end of 2023 to validate the proposed candidates for use as reference substances under OECD 309. Together the work is intended to support an update to the OECD 309 Test Guideline, to improve its robustness and support reaching reliable persistence conclusions in regulatory processes.

3.17.T-02 Comprehensive and Non-target Persistence Testing of Chemicals Discharged from Offshore Oil Platforms
Mette Moller[1]*, Heidi Birch*[2]*, Karina K. Sjøholm*[2]*, May Britt Rian*[3]*, Stefano Papazian*[3,4]*, Aina Charlotte Charlotte Wennberg, MSc*[5]*, Jonathan W. Martin*[3,4] *and Philipp Mayer*[2]*, (1)Department of Environmental and Resource Engineering, Technical University of Denmark (DTU), Kongens Lyngby, Denmark, (2)Department of Environmental and Resource Engineering, Technical University of Denmark (DTU), Denmark, (3)Department of Environmental Science, Stockholm University, Sweden, (4)Department of Environmental Science, Stockholm University / Science for Life Laboratory (SciLifeLab), Sweden, (5)Ecotoxicology and environmental risk assessment, Norwegian Institute for Water Research (NIVA), Norway*
In 2018 more than 300 million m^3 of produced water were discharged from offshore oil and gas production to the North Sea. Produced water contains a complex mixture of petroleum hydrocarbons and other chemicals added during production. It is important to avoid discharges that contain persistent chemicals, as concentrations in the environment can otherwise increase over time and have irreversible consequences. It is urgently needed to improve the environmental relevance of biodegradation testing as well as the efficiency in data generation for persistence assessment of chemicals. This study aims to combine environmentally relevant biodegradation tests with advanced analytical methods to reveal persistent chemicals in complex oil platform discharges. Two experiments were conducted, where produced water and seawater were sampled at offshore oil platforms, transported to shore by helicopter and experiments were started within 48h. Test systems were prepared by diluting produced water in seawater (biotic test systems) or in artificial seawater (abiotic test systems). Dilution ratios tested ranged from 1:20 to 1:500. The test systems were set up in closed 20 mL headspace vials. For one experiment, additional test systems were prepared for studying the inhibition of the inoculum by the produced water through measurements of bacteria cell count. The test systems were incubated for 60 days at 9-10°C. Test systems were analyzed by SPME GC-MS and SPE LC-HRMS, and each analysis included triplicate biotic and abiotic test systems. Persistence/biodegradation were evaluated based on peak

area ratios (biotic/abiotic). The GC-MS analysis of experiment 1 (1:200 dilution) showed that 96% of 163 chemicals were more than 50% biodegraded on day 60, including all major peaks. Only 7 chemicals were found to be persistent, and a tentative structual annotation was made for 2 of these. SPE LC-HRMS analysis was applied to a limited number of test systems within the same experiment, and allowed the determination of biodegradability/persistence for additionally 733 features. However, these tests were run at 1:60 dilution, where we observed moderate inhibition of the inoculum. Experiment 2 included tests on produced water from two oil platforms, higher dilutions and a more elaborate non-targeted SPE LC-HRMS analysis. The approach can be used for revealing persistent chemicals in complex discharges, in order to improve treatment or substitute production chemicals.

3.17.T-03 Applicability of screening and simulation studies in polymer biodegradation assessments

***Kathleen McDonough**[1], Jennifer Menzies[2], Ashley Wilcox[1] and Nigel Yates[1], (1)Procter & Gamble, (2)Procter & Gamble, Mason, United States*

As interest continues in assessing existing and developing biodegradable polymers, there is a need to understand the ability of screening and simulation studies to be used for biodegradation assessments. The standard test methods were developed for and have been largely applied to single constituent, small molecuar weight (MW) molecules and their applicability to assess complex multi-constituent polymeric mixtures needs to be evaluated. This research evaluated the biodegradation rate and extent of different polymers in standardized and modified screening studies with activated sludge and river water used as inocula and in wastewater treatment plant simulation studies. Polymers evaluated covered different monomeric starting materials, different functionalization levels, and different molecular weights which are all components known to impact biodegradation. OECD 301B Ready Biodegradation Studies and OECD 302B Zahn-Wellens Studies were conducted using activated sludge as inocula, biodegradation tests using river water as inocula were conducted in a respirometric system following CO_2 evolution as the analytical endpoint, and OECD 303A Simulation Test for Aerobic Sewage Treatment studies were conducted following DOC as the main analytical endpoint for evaluation. Mineralization extent was similar between OECD 301B and 302B studies but time to reach complete mineralization was faster in OECD 302B studies. Mineralization extent in respirometry screening studies with activated sludge inocula was predictive of extent in river water studies but rates were slower in river water studies likely due to lower microbial counts in the test system. The high mineralization quantified in screening studies using activated sludge as inocula was predictive of high removal via biodegradation in wastewater treatment plant simulation studies.

3.17.T-04 Persistence assessment in the regulatory assessment and management of chemicals

*Romanas Cesnaitis, Lale Carstensen, Anna-Maija Nyman, Doris Hirmann, Anne-Mari Karjalainen, Kostas Andreou, **Marta Sobanska** and Anu Kapanen, European Chemicals Agency (ECHA), Finland*

Introduction: Chemical’s persistence is a key property heavily influencing or even driving its hazard, exposure or risks. Cousins *et al.* proposed to consider high persistence alone as a major cause of concern [1]. Persistence of chemicals is assessed using degradation rates and degradation half-lives derived usually from laboratory-based simulation degradation tests. Ready biodegradability methods are stringent screening tests and a positive result in such test can be considered indicative of rapid and ultimate degradation in most environments. Simulation tests are relatively expensive and sometimes challenging to conduct. Therefore, use of alternative approaches (e.g. models and/or read-across/grouping approaches etc.) is of high importance.

In ECHA Guidance [2] it is noted that models for predicting ready biodegradation are normally not yet sufficiently accurate to predict rapid degradation. ECHA is aiming to analyse if currently available models (e.g. BIOWIN and Vega) are able to accurately predict the outcome of newly generated reliable experimental data on ready biodegradability.

To speed up the identification of chemicals that need regulatory action, ECHA addresses groups of structurally related substances together. This is done via the assessment of regulatory needs (ARN) which is an iterative and informal screening process, linking the REACH and CLP regulatory processes to enable faster regulatory risk management.

Discussion and conclusions: ECHA is aiming to share results of an analysis conducted to compare results of predictions for ready biodegradability with results of standard experimental ready biodegradability studies requested under dossier evaluation process of REACH Regulation. Furthermore, work on groups of substances with achievements so far in respect of identification of PBT and PMT candidates will be presented. This will include an overview of groups with inconclusive or potential PBT/vPvB/PMT/vPvM hazard identified during ARN screening with a focus on groups containing UVCB substances and how use of grouping and screening information, including QSAR predictions, may support the ARN process.

3.17.P New Perspectives and Developments in Chemical (Bio)Degradation and Persistence Assessment

3.17.P-Tu280 Accelerating the Invisible: Unveiling the Impact of Suspended Sediment Concentrations on Biodegradation of Organic Chemicals in Water-Sediment Suspension Systems

Yijing Li[1], *Run Tian*[1], *Joeselle Serrana*[2], *Malte Posselt*[3] *and Michael McLachlan*[3], *(1)Stockholm University, Sweden, (2)Stockholm University Center for Circular and Sustainable Systems, Sweden, (3)Department of Environmental Science, Stockholm University, Sweden*

Determining biodegradation is the core of regulatory assessment of chemical persistence. The OECD 309 test is widely used in regulation as a higher tier test for measuring biodegradation in surface water. However, the lack of a clearly defined sediment concentration in the OECD 309 suspension test may cause variability in biodegradation studies. To address this question, the influence of sediment concentrations on biodegradation was investigated using a modified OECD 309 suspension test. The biodegradation kinetics of 129 chemicals were studied at six sediment concentrations, spanning from 0 to 125 g L^{-1}, over a 13-day incubation period. A positive linear correlation between the biodegradation rate constant, *k*, and sediment concentration was observed for many chemicals. The strong influence of sediment concentration on *k* indicates that much of the degrading capacity in the suspension test is associated with the sediment. The results indicate that it may be necessary to specify a fixed sediment concentration in the OECD 309 suspension test or find a way to normalize the test results for the effect of sediment concentration. Additionally, the linear relationship demonstrated in our study may be useful for extrapolating biodegradation rate constants obtained from laboratory studies to field conditions.

3.17.P-Tu281 Extending the applicability domain of persistence testing of organic chemicals in soil to dissimilar bioavailability scenarios

Rosa Posada[1], *Carmen Fernandez-Lopez*[2] *and Jose Julio Ortega-Calvo*[1], *(1)Instituto de Recursos Naturales y Agrobiologia, Spain, (2)Universidad Politécnica de Cartagena, Centro Universitario de la Defensa, Spain*

Microbial degradation is often the main dissipation route in persistence tests and it operates preferentially on the most bioavailable chemicals, from there the necessity of connect bioavailability to persistence endpoints. Although bioavailability is still unexisting in persistence standardized tests, it is possible to incorporate it into the current OECD persistence simulation tests, thefore providing more realism than that provided by total concentrations of the parent chemical only. With this aim, bioavailability measurements were integrated in persistence testing of organic compounds in situations of partial biodegradation, i.e., not leading to mineralization, and *a-priori* dissimilar bioavailability. In this integration, two methods were used, the OECD 307 guideline for degradation in soil and the ISO method 16751:2020 for bioavailability assessments through Tenax extraction during 20 h. This approach was applied to two ^{14}C-labelled organic compounds (pyrene and carbamazepine, with Log K_{ow} of, respectively, 4.8 and 2.7), and soil and compost-amended soil as dissimilar bioavailability scenarios. With the objective of increasing the sorption of organic pollutants and reducing their bioavailability, traditional compost and co-composted biochar were used as soil amendments. For the two compounds, it was possible to determine the percentage distribution of the parent compound and the metabolites in each phase of Tenax extraction (i.e., soil, water and Tenax) before and after the OECD 307 incubation test. In this way, major bioavailability changes were observed during persistence tests that gave similar dissipation losses of the total parent chemical. With pyrene, the transformation led to lowering the risk due to ageing and the formation of nondesorbable metabolites, whereas with carbamazepine, the remaining parent chemical desorbed more slowly (thus allowing Tenax to act as a perfect sink), but the metabolites showed a high mobility in water, therefore contributing to risk. Polar carbamazepine metabolites remained in the water phase, whereas Tenax adsorbed preferentially the more hydrophobic transformation products and the parent molecule. For both compounds, the bioavailability decreased in amended soils and for carbamazepine the strongest bioavailability reduction was measured with a co-composted biochar amended soil (70 % compost with 30 % biochar).

3.17.P-Tu282 Prioritisation of known contaminants in drinking water resources for a biodegradation simulation test according to OECD Test No. 309: Aerobic mineralisation in surface water

Michael Neumann[1] *and Karsten Nödler*[2], *(1)IV 2.3 Chemicals, German Environment Agency (UBA), Germany, (2)TZW: DVGW Water Technology Center, Germany*

In 2023, the German Environment Agency (UBA) published a broad literature search (55 studies between 2000 and 2019) listing 1289 chemicals that have been detected to date in the six water matrices wastewater treatment plant effluent, surface water, bank filtration water, groundwater, raw water and drinking water (FKZ 3719654080, UBA TEXTE 20/2023). However, for 47% of the 509 REACH-registered substances detected, no conclusive assessment of persistence in the aquatic environment is available. The need for radioactive labelling of the test substance is generally used as main reason why an OECD simulation test is difficult and expensive. However, under specific conditions, a valid and reliable OECD TG 309 test results can be carried out by any water laboratory without an isotope laboratory. In Germany and Europe for example the large to medium size drinking water suppliers and the water monitoring authorities have such laboratories.

Non-radiolabelled test substances which dissipate from the test vessel are not suitable for a "cold" OECD TG 309 as this would lead to an invalid and unreliable result. We assessed a total of 1271 chemical structures known to contaminate different water matrices. As a result, we de-prioritised 222 chemicals structures based on a high potential for adsorption and/or a high potential for volatilisation and we de-prioritised further 158 based on consistent information on an available potential for degradation.

We prioritised the remaining 891 known contaminants as they are “easy to test chemicals” with a high risk of lack of biodegradation potential and consequently they are suitable for a “cold” OECD TG 309 tests system. If such a test result is without uncertainty, also the "cold" OECD TG 309 fulfils the high quality and reliability requirements of e.g. the ECHA PBT EG and the MSC and can then be used to derive a half-life for the conclusive persistence assessment.

The German Environment Agency (UBA) expects an increasing demand from drinking water suppliers and water monitoring authorities to carry out a "cold" OECD TG 309 in their own analytical laboratories for contaminants in their local watershed. Our work will support this demand and also provides recommendations how to reduce the variability between test vessels, minimising uncertainty and thus strengthening the overall validity of a “cold” OECD TG 309 test result.

3.17.P-Tu283 Application of (enhanced) ready biodegradability tests in persistency evaluation

Stefan Gartiser and ***Christoph Hafner****, Hydrotox GmbH, Germany*

(Enhanced) ready biodegradability tests (eRBTs) are used to show that a substance is non-persistent, when the pass level of 60% is reached within 60 days. However, negative results in these tests are inconclusive and require the application of complex OECD simulation tests. The applicability of inherent tests in persistence evaluation seems being limited, because of the pass level must be reached within 14 days. Recently, the Microplastic Regulation (EC) No 1907/2006 established a similar testing scheme, ready tests, eRBTs and inherent tests (OECD 302 C), but also included several tests specifically designed for polymers for different compartments while allowing test durations up to 6 months.

In a practical testing programme 5 compounds (non- polymers) with controversial degradation data have been tested in 4 ready test series including prolongation to 60 days and use of different inocula (activated sludge, final effluent from a STP), flask sizes, and endpoints (CO_2, O_2, DOC). Two of them, the drug ibuprofen and the intermediate 4-fluorophenol were readily biodegradable. The pesticide synergist piperonylbutoxide and the antioxidant octadecyl 3-(3,5-di-tert-butyl-4-hydroxyphenyl)propionate achieved 20%–50% (=“potentially P”) while the cosmetic ingredient cis-13-docosenonamide (Erucamide) showed degradation extents between 21%–64% after 60 days.

Surprisingly, diethylene glycol reached the pass level of 60%mineralization within 28 days in all test series and thus proved to be a suitable reference substance for eRBTs next to inherent tests. In this context also the role of eRBTs in relation to inherent biodegradation screening tests in the context of persistence evaluation needs to be clarified.

3.17.P-Tu284 Accumulating Knowledge of Biodegradability Weight-of-Evidence Approach for Persistent Assessment of Difficult Substances

Yuto Amano[1]*, Shintaro Enoki*[1]*, Tohru Nishioka*[2]*, Takahiro Suzuki*[3] *and Masayuki Yamane*[1]*, (1)Safety Science Research, Kao Corporation, Japan, (2)Safety Science Research, Safety Science Research, Kao Corporation, Japan, (3)Kao Corporation, Japan*

Appropriate management of persistent substances is one of the crucial issues for achieving a sustainable circular economy. However, evaluating the degradation half-life of substances through simulation tests to examine the persistence criteria is cumbersome, and it is important to assess non-persistence based on other test information for efficient evaluation. Although the European Chemicals Agency (ECHA) has published guidance for persistence, bioaccumulation, and toxicity (PBT) assessment (Guidance on Information Requirements and Chemical Safety Assessment Chapter R.11: PBT/vPvB assessment. (version 3.0)), it does not indicate which test results, except for the (enhanced) ready biodegradability test and inherent biodegradability test, would satisfy the weight-of-evidence approach. However, substances with specific properties such as being poorly water soluble, volatile, adsorptive, unstable, or toxic to inoculum, often called difficult substances, present difficulties in evaluation of their intrinsic biodegradability by these studies, so accumulating knowledge through non-guideline tests is desirable.

In this study, we conducted several biodegradability studies for poorly water soluble and cationic toxic substances. To evaluate the intrinsic biodegradability, we performed testing at low concentrations, with additives, and in river water.

For poorly water soluble substances, the degree of degradation varied depending on the length of the alkyl chain and several substances showed greater than 50% degradation at 40 days in low-concentration tests conducted at 5 mg ThOD/L with activated sludge. Also, degradation progressed quickly with aeration in the degradation test using river water. On the other hand, no significant improvement in degradation rate was observed with the dispersants. For cationic toxic substances, the addition of linear alkylbenzene sulfonate (LAS) as an additive accelerated degradation in the test with activated sludge, and degradation tests using river water also confirmed that degradation progressed quickly.

Based on these studies, both substances were considered to be non-persistent as a result of the weight-of-evidence approach. In this presentation, we will explain the non-guideline tests that we conducted and discuss which non-guideline study results are appropriate for a weight-of-evidence decision for difficult substances.

3.17.P-Tu285 Preserving the Biotransformation Potential of Activated Sludge in Time: Towards Reproducible Incubation Experiments for Persistence Assessment

Martina Anna Kalt *and Kathrin Fenner, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland*

Due to their widespread presence, (pseudo-)persistence, and potential ecotoxicological effects, micropollutants pose a growing environmental concern. Environmental persistence, as one potential key hazard, is typically assessed for environmental compartments such as water, soil and sediments. Biotransformation assays conducted in activated sludge from wastewater treatment plants offer various benefits over soil and sediments, as activated sludge is easily manageable and readily available. Additionally, the high microbial density enables a short experimental duration of 72 hours, and rate constants determined in activated sludge experiments have been shown to be reasonably predictive of soil half-lives. These points imply that conducting biotransformation experiments with activated sludge could serve as a valuable foundation for developing high-throughput persistence tests used for screening purposes, e.g., in a benign-by-design framework. Despite standardized procedures under the REACH regulation, screening tests in activated sludge though face challenges due to low reproducibility linked to inocula diversity.

In this study, we developed protocols for the preservation of activated sludge microbial communities using lyophilization or cryopreservation. Their performance in preserving the biotransformation potential was evaluated on forty representative micropollutants in lab-scale batch assays lasting 72 hours, with fresh activated sludge as reference. Lyophilization was the least representative preservation method, with over 85 % of micropollutants showing significantly slower or faster biotransformation compared to fresh activated sludge. Cryopreservation using either DMSO or glycerol was more effective with approximately 40 % of micropollutants exhibiting significantly different biotransformation kinetics than in the fresh matrix. We also explored the impact of the storage time (two weeks vs. four month) as well as the effect of using artificial supernatant instead of preserved native supernatant. We examined shifts in community composition based on amplicon sequencing data. Our results indicate that cryopreservation can effectively preserve the biotransformation potential of activated sludge, improving long-term reproducibility in persistence assessments. This enhances reliability for regulatory hazard assessments and biotransformation screening in the design of novel chemicals.

3.17.P-Tu286 Microbial community analyses of a ring test for a new marine biodegradation test for persistence screening (MaP test)

*Amelie Ott[1], **Russell Davenport Prof**[2] and Timothy J Martin Dr[3], (1)International Collaboration on Cosmetics Safety (ICCS), New York, United States, (2)Newcastle University, United Kingdom, (3)Department of Environment Food and Rural Affairs, United Kingdom*

A newly developed screening test for substances in the marine environment, the Marine Persistence (MaP) test, has recently been accepted as a method under the Convention for the Protection of the Marine Environment of the North-East Atlantic (OSPAR). The MaP test incorporates increased prokaryotic cell numbers with the aim to better represent the microbial (prokaryotic) diversity inherent in the sampled environments and runs beyond 60 days, which is the half-life threshold for persistence in the marine environment. The MaP test underwent a ring test comprising 13 laboratories and was found to provide a more reliable and less variable characterization of the biodegradation behavior of five reference chemicals (sodium benzoate, triethanolamine (TEA), 4-nitrophenol (4-NP), anionic polyacrylamide, pentachlorophenol), than the current marine biodegradation screening test, OECD 306, with respect to REACH and OSPAR persistence thresholds.

Microbial analyses demonstrated that prokaryotic communities in replicate samples from the same location were significantly more similar than those between different locations. An average dissimilarity of 91% between the prokaryotic communities sampled from the different locations used in the study suggests that prokaryotic communities in the marine environment are very diverse. There was a positive relationship between total cell counts and biodegradation potential. Half the samples in which the prokaryotic cells were concentrated were also associated with an increase in the observed number of prokaryotic taxa ("species"). However, there was no statistically significant relationship between total cell counts and prokaryotic diversity indices: the greatest rates and extents of degradation were not necessarily observed for samples of prokaryotic communities with the highest cell concentrations or diversity indices. The probability of biodegradation of TEA and 4-NP was significantly negatively correlated with salinity, which was significantly correlated with the depth and distance from shore that the samples were sourced (Pearson's correlation, $P<0.01$). Those sources which resulted in the biodegradation of TEA and 4-NP were associated with genera that were either differentially over- or under-represented in the prokaryotic communities studied compared to those that showed no biodegradation. These findings suggest that prokaryotic community composition rather than prokaryotic diversity *per se* is important in driving biodegradation.

3.17.P-Tu287 New Approaches to Persistence Testing With Increased Cell Number Using Tangential Flow Filtration.

***Katie Endersby**, Dave Gore and Chris Finnegan, Safety and Environmental Assurance Centre (SEAC), Unilever, United Kingdom*

Assessment of a chemical's persistence is fundamental to understanding its environmental fate, exposure and ultimately for determining environmental risk. It is one of the key criteria used for the regulation of organic chemicals. Evidence for determining a chemical's potential persistence is primarily obtained from the understanding of its biodegradability in relevant test compartments, derived from biodegradation screening and simulation tests. Current testing frameworks, including OECD Testing Guidelines, are recognised as having limitations with difficult to assess chemicals such as large, polar, or poorly soluble materials. Testing is often not reflective of real, variable environmental conditions, with little consideration for the microbial inoculum captured within tests or its influence on test outcomes. To support better understanding of the potential persistence of chemicals, new methods have been proposed to facilitate more consistent testing for hard to assess chemicals, including increasing the concentration of microbial inoculum in tests.

Tangential flow filtration (TFF) techniques can be adopted for use with aqueous environmental samples. The approach can negate inconsistencies in biodegradation often seen in testing using environmental samples with low microbial biomass, such as freshwater, by increasing the probability that the chemical tested will encounter a potential microbial degrader within the test media. In addition to allowing a larger, more representative proportion of a microbial community to be captured within the test, predictions of persistence can be carried out within shorter testing timeframes than traditional tests, with increased bacterial number often facilitating a shorter lag period in detectable chemical degradation.

Here we present how new TFF approaches can be integrated with current screening methods, i.e., OECD Test Guideline 301F, by using samples of increased microbial number, and including measurements of bacterial enumeration in testing protocols, to better ascertain a chemical's degradation kinetics. Microbial -omics techniques can subsequently be utilized to investigate the lack of knowledge on the influence and dynamics of microbial communities in test systems, to characterize the catabolic potential of real environments used in testing, and to generate data that can be used to support new in-silico approaches to predicting persistence of chemicals; ultimately improving assessments of environmental risk.

3.17.P-Tu288 Chemical Biodegradability and Persistence Assessment

***Kirit Wadhia**, Environmental, NOV Inc, United Kingdom*

In consideration of ecotoxicological perspective regarding the impact of chemicals in the environment, indubitably it is important to ascertain the chemicals' persistence. Thus, a significant criterion is the rate of degradation in the environment and of particular value tests that can expeditiously screen out chemicals which are prone to degradation in diverse environments.

Biodegradation determination of chemicals is critical as it provides valuable insight of exposure and subsequently the long-term adverse effects on biota and implications for mankind (OECD, 2006).

Biodegradation screening tests (BSTs) have been developed and approved by the Organisation for Economic Co-operation and Development (OECD). BSTs are often a vital integral component of regulatory frameworks; OSPAR Agreement (2012-05) dealing with Harmonised Chemical Notification Format (HOCNF) is a casing point. Its remit is the management of offshore exploration and production activities in the OSPAR maritime area. Their prominence in this context has been due to the associated relative low cost and presumed ease of implementation and interpretation.

However, biodegradation evaluation intrinsically is complex and unpredictable. Whereas the intended initial purpose of the BSTs was to screen out chemicals which easily degrade, they have not evolved at the same rate as regulatory concerns, which now place an increased emphasis on environmental persistence.

Since the suitability of BSTs, for example OECD 306, is not deemed to be robust to identify persistent chemicals, projects to modify protocol have been instigated and proposal submitted to OECD for a new test guideline for a marine biodegradation screening test for chemical persistence assessment (MaP test).

The MaP test incorporates increased bacterial cell numbers and uses manometric respirometers to run for 60 days or more. It has undergone ring-testing with the participation of 13 laboratories in 7 countries.

Does it have application in marine regulatory frameworks and conventions

3.17.P-Tu289 "Characterization of Industrial Wastewater Samples: Application of a Degradation Assay and Bioassays"

***Xenia Klaus**[1], Katharina Lühmann[1], Aline de Courten[1] and Miriam Langer[1,2], (1)University of Applied Sciences and Arts Northwestern Switzerland (FHNW), Switzerland, (2)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland*

Industrial and commercial wastewaters often contain unknown components and mixtures of substances. Some of them can be of concern, but they can only be identified to a limited extent and sometimes great expense by chemical analysis. Thus, it is of great interest to develop practical alternative approaches to characterize industrial wastewater streams without affecting trade secrets. Flagging problematic streams can foster the establishment of suitable disposal routes or wastewater pretreatment steps in the future to reduce the input of non-degradable problematic substances in wastewater treatment plants (WWTP) and latter surface water systems.

Bioassays do provide an interesting possibility for the characterization of industrial wastewater, but to date the potential has rarely been exploited in Switzerland, as there is no legal basis for the use of biological test methods and there is a lack of experience among companies and authorities. The ABIScreen ("Abbautest Biotest Industrieabwasser Screening") screening approach developed at University of Applied Sciences and Arts Northwestern Switzerland (FHNW) combines a newly established time-efficient degradation test, simulating the WWTP degradation, and a bioassay battery to characterize industrial wastewater to close this gap.

The alternative inherent degradation test ("Alternativer Inhärenter Abbautest AIA") determines the rate of biodegradation and the refractory organic load of an (industrial) wastewater sample four times faster than the commonly used Zahn-Wellens test and also provides information on nitrifier inhibition. The ecotoxicological bioassay battery is used to estimate the toxic potential of the non-biodegradable substances in the sample. The test organisms used are daphnia, algae and luminescent bacteria as well as a mutagenicity test to visualize the effects of all components contained in a sample, regardless of their chemical identification status.

ABIScreen can be applied to identify problematic industrial wastewater with non-biodegradable substances and increased toxic potential. The first large-scale ABIScreen campaign is currently underway in Switzerland to test industrial wastewater from various sectors with ABIScreen and to compile a broad collection of data. The data basis will be used to develop threshold values for the classification of toxicity values on the one hand and industry-specific adaptations of the screening tool on the other.

3.17.P-Tu290 Ultimately Biodegradable, or Not Ultimately Biodegradable - That is the Question!

Karen Jenner[1]*, Tina Haupt*[2]*, Arturo Mendoza*[2]*, Andreas Natsch*[2] *and Yumiko Weiner-Sekiya*[2]*, (1)Givaudan UK Ltd, United Kingdom, (2)Givaudan Suisse SA, Switzerland*

Ultimate biodegradation signifies the ability of bacteria to mineralize organic chemicals by converting the carbon skeleton into CO_2. To be considered ultimately biodegradable, a substance typically needs to reach the pass level of ≥ 60% within a specified timeframe according to international test guidelines such as OECD 301. These tests are stringent and a negative result does not necessarily mean a chemical will not degrade in the environment.

Whether a substance is ultimately biodegradable or not can be studied with more targeted studies, e.g. over a more prolonged time window or using an inoculum after an enrichment culture or using specific isolated bacteria. Such tests do not indicate biodegradability under OECD accepted conditions, but they indicate whether the initial sewage sludge contains bacteria able to express the relevant enzymes to ultimately degrade a particular substrate. Such data may add to a weight-of-evidence assessment on persistency.

Here, we present our work on 2-cyclohexylidene-2-phenylacetonitrile (Peonile). This chemical was selected because it is composed of biodegradable substructures (mainly a phenyl and a cyclohexane-ring) yet only partial mineralisation is observed in OECD 301F tests. Further, the molecule lacks typical non-biodegradable features, such as extensive alkyl-branching or quaternary carbon atoms.

We tested Peonile for mineralisation by an adapted inoculum after three 28-days cycles of enrichment. This inoculum was able to mineralise Peonile with a biphasic curve. Isolation of bacteria from this inoculum first led to isolates able to degrade the phenyl ring of Peonile generating the stable metabolite, 2-cyano-2-cyclohexylideneacetic acid. However, isolation of further bacteria at the end of a mineralisation experiment conducted with this adapted inoculum led to a bacterial strain able to degrade the metabolite. A mixture of the two bacteria types was then tested under OECD 301D and 301F incubation conditions and shown to mineralise Peonile.

The need for two separate bacteria for mineralisation explains the biphasic curve observed in the mineralisation by the adapted sludge, yet it indicates that Peonile is ultimately biodegradable by bacteria originally present in sewage sludge. It appears, that under the dilute conditions of the standard OECD tests, the bacteria performing the second step do not get sufficiently enriched to allow for this mineralisation to occur within the time window of OECD screening tests.

3.17.P-Tu291 Biodegradable or not? Developing a standardized international approach to assessing the biodegradability of cosmetic formulations

Silke Fiebig[1]*, Juliet Hodges*[2]*, Amelie Ott*[3]*, Ryan Heisler*[4]*, Karina J Reynolds*[5]*, Andrea Carrao*[6]*, Guillaume Cottin*[7]*, Jennifer Dorts*[8]*, Judith Kaumanns*[9]*, Monica Lam*[10]*, Fanny Minetto*[11]*, Beta Montemayor*[12]*, Jennifer K. Saxe*[13]*, Harald Streicher*[14]*, Cyril Sweetlove*[7] *and Nadin Wedler*[15]*, (1)Vitis Regulatory, Pean Hill, United Kingdom, (2)Safety & Environmental Assurance Centre, Unilever, United Kingdom, (3)International Collaboration on Cosmetics Safety (ICCS), New York, United States, (4)International Collaboration on Cosmetics Safety (ICCS), (5)WSP E&I, United Kingdom, (6)Kao USA, (7)L'Oréal, France, (8)IFRA, (9)Product Safety & Regulatory Affairs, Wella Company, Germany, (10)Procter & Gamble, (11)Chanel, (12)Science, Regulation and Market Access, Cosmetics Alliance Canada, Mississauga, Canada, (13)Kenvue, (14)Beiersdorf, Germany, (15)Kao Germany GmbH, Germany*

Consumer expectations and demands for environmentally benign, biodegradable product formulations are increasing rapidly. Although biodegradability assessment of cosmetic formulations is included in various certification and labelling programs and environmental/sustainability scoring tools, so far, no clear guidance is available to address how to consistently assess the biodegradability of cosmetic formulations. Therefore, the global non-for-profit science organization International Collaboration on Cosmetics Safety (ICCS) is undertaking development of an internationally validated process setting out standardized approaches for evaluating the biodegradability of cosmetic ingredients including how to calculate the biodegradability of product formulations. To support the development of a standardized approach, a critical review of regulatory positions, existing criteria, and standards specifically for assessing the biodegradability of ingredients, formulations and chemical mixtures is being performed and will be presented in this poster. The review includes cosmetics, personal care, and homecare products. Based on the results of the review, suggestions regarding international standard development will be mapped and a roadmap for gaining acceptance of a possible international standard will be highlighted.

3.17.P-Tu292 Assessment on the Degradability of Emerging Contaminants in Freshwater and Marine Sediments
*MLuz Tovar[1], Marina G. Pintado Herrera[2] and **Pablo Antonio Lara Martín**[2], (1)University of Cadiz, Spain, (2)Universidad de Cadiz*
Contamination of aquatic systems by newly detected chemicals, such as many pharmaceuticals and personal care products, represents a rising concern. Many organic contaminants are not persistent *per se* but their occurrence is owing to their continuous release into the aquatic systems. This encourage the need to assess the environmental behavior and to investigate the microbial degradation processes involved which could remove or reduce their concentration in the environment. Among the different environmental compartments involved are sediments, which, due to the hydrophobic nature of many organic contaminants, tend to accumulate significant fractions of these chemicals, acting as natural sinks.

In this study, we have conducted a 100-day incubation experiment to determine the partitioning and microbial degradation of 5 selected pollutants in two systems: a fresh water- river sediment microcosm and a seawater- marine sediment microcosm, where microbial communities are expected to be significantly different. The five chosen contaminants were: the insect repellent N,N-diethyl-meta-toluamide, the organophosphorus flame retardant tris(2-chloroethyl) phosphate, the fragrance OTNE (Iso E Super) and two UV filters, octocrylene and benzophenone-3 (BP-3). Samples were taken at regular intervals and contaminants extracted by pressurized liquid extraction with in-cell clean-up (in-cell PLE) for the particulate fraction and by stir-bar-sorptive-extraction (SBSE) for the aqueuos fraction. Separation and quantification of target analytes were performed on a GC-APGC-Q-ToF-MS instrument (Bruker Impact II) and the processing was performed using TASQ software 2022b.

Sorption coefficients and degradation kinetics have been determined for the aforementioned target pollutants. The fraction of chemicals accumulated in sediments varied accordingly with the octanol-water partition coefficient of the chemicals, from lowest (e.g., DEET) to highest (e.g., OC). The bioavaliability of each contaminant had a siginificant impact on the degradation and speed, with BP-3 showing the highest removal (>90%). Differences between fresh and marine microcosms were also observed, indicating that variabliity in microbial communities can heavily impact the degradation process from one depositional environmetn to another.

Köchling, T., et al(2011). Microbial community composition of anoxic marine sediments in the Bay of Cádiz (Spain). *International Microbiology*, *14*(3), 143-154.

3.17.P-Tu293 Variability of Biodegradation Rates in Rivers from Different Regions of Europe
***Run Tian**[1], Malte Posselt[2], Kathrin Fenner[3] and Michael McLachlan[2], (1)Stockholm University, Sweden, (2)Department of Environmental Science, Stockholm University, Sweden, (3)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland*
Contaminant attenuation varies considerably between rivers, and this has been attributed in part to spatial differences in biodegradation. However, the variability of biodegradation rates between aquatic systems has not been studied for a large number of chemicals. To study systems with broad climatic and geographic variability, we collected samples from 19 different river segments in the Mediterranean (Spain and Greece), alpine (Switzerland), central plain (Germany), and boreal (Sweden) regions of Europe during summer and early autumn (20.5 ± 3.5 °C). In each country, we sampled pristine river segments as well as segments strongly impacted by urban wastewater effluent. We performed a modified OECD 309 test with water and sediment from each river segment. An aqueous mixture of 129 compounds was spiked to a concentration of 1 $\mu g\ L^{-1}$ each and their dissipation was followed over a 10-day incubation. Significant differences in biodegradation rates (ANOVA, $P < 0.05$) between the 19 river segments were observed for 98% of 97 quantified compounds. We found that the spatial variation in biodegradation rates between pristine river segments across countries was smaller than the variation observed between contaminated river segments. Additionally, we identified regional specificity in the biodegradation rates of certain compounds that share specific functional groups.

3.17.P-Tu294 Field-to-lab Microbial Profile of Batch Incubation Experiments for Biodegradation Testing
***Joeselle Serrana**[1], Arild Gustafsson[2], Yijing Li[2], Run Tian[2], Michael McLachlan[3], Elias Broman[4], Benoît Dessirier[5] and Malte Posselt[3], (1)Stockholm University Center for Circular and Sustainable Systems, Sweden, (2)Stockholm University, Sweden, (3)Department of Environmental Science, Stockholm University, Sweden, (4)Department of Ecology, Environment, and Plant Sciences, Stockholm University, Sweden, (5)Baltic Sea Centre, Stockholm University, Sweden*
Biodegradation tests are essential for assessing organic chemical persistence in the environment. The OECD 309 test is a highly recognized method for measuring biodegradation rates of organic test substances in aerobic natural surface water

through pelagic or suspended sediment batch incubations. Although it is a highly recommended biodegradation test, inconsistencies and variable results are still some of the significant issues that need further assessment. These may result from the guideline's lack of consideration of both the biological and ecological complexities in the environmental sample. Microbial communities are the key drivers of environmental degradation and are naturally subjected to temporal and spatial variation. However, we still lack a fundamental understanding of the microbial dynamics of environmental samples in simulated tests. This raises concerns about whether the OECD 309 test provides environmentally relevant estimates of biodegradation compared to in situ assessments. Knowing how each step, from field collection to laboratory processing and batch incubation experiments, influences microbial diversity and community composition could provide important insights for the further standardization of simulated biodegradation testing. Here, we profiled the diversity and composition of the sediment microbiome from field collection and sediment processing in the laboratory to the batch incubation experiments. We followed the OECD 309 test guidelines for sediment-water collection and preparation, and sampled a river segment with homogenous environmental conditions. Five sediment cores were collected along a 20-meter transect, and a subsample of these sediments was pooled to represent one homogenized sample. We profiled the microbiome of all six sediment samples from the field, processing in the laboratory after 18 hours, and during the 1st, 5th, and 10th-day batch incubation in a setup spiked with 129 organic compounds. In this study, we present a better understanding of the microbial dynamics of sediment samples and their influence on the OECD 309 test. Our observations will be useful in improving our knowledge of the microbial community response to field and laboratory conditions before and after starting biodegradation tests. This will also provide insights into the environmental relevance of sediment microbiome samples used for standard simulation tests.

3.17.P-Tu295 Building Knowledge from Available Degradation Simulation Studies to Improve their Usability

Louise Camenzuli[1]*, Michael Earl*[2]*, Katie Endersby*[3,4]*, Kathrin Fenner*[5]*, Richard Gibson*[6]*, Patricia Anna Golombek*[7]*, Jasmin Hafner*[8]*, Damian Helbling*[9]*, Christopher Hughes*[10]*, Aurelia Lapczynski*[11]*, Sven Peter*[12]*, David MV Saunders*[13]*, Chiara Maria Vitale*[14]*, Neil Wang*[15]*, Miriam Leon Paumen*[16]*, lemaire philippe*[17]*, Johannes Tolls Dir*[18] *and Marie Collard*[19]*, (1)ExxonMobil, Belgium, (2)Syngenta Ltd, United Kingdom, (3)School of Life Sciences, University of Warwick, United Kingdom, (4)Safety and Environmental Assurance Centre (SEAC), Unilever, United Kingdom, (5)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (6)UK Environment Agency, United Kingdom, (7)RG/TC, BASF SE, Germany, (8)Environmental Chemistry, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (9)Cornell University, (10)Ricardo, United Kingdom, (11)Research Institute for Fragrance Materials, (12)GBP/RA, BASF SE, Germany, (13)Shell Global Solutions, Netherlands, (14)Procter & Gamble, (15)Solvay, France, (16)ExxonMobil Biomedical Sciences, Inc., Belgium, (17)Total, (18)Corporate Scientific Services, Henkel AG & Co. KGaA, Germany, (19)DSM-Firmenich, Belgium*

Persistence assessments are an increasingly important component in regulatory evaluation and management of industrial chemicals. In recent years there has been a significant increase in requests from the European Chemicals Agency for degradation simulation studies (OECD TG 307, 308, 309) - 50% increase from 2020 to 2021. Additionally, these requests are foreseen to increase even further with the newly added Persistent, Mobile and Toxic and very Persistent and very Mobile hazard classes in the CLP regulation. However, degradation simulation studies are complex, costly and can be technically challenging for a broad range of chemicals. In this context, it is important to ensure that the test produces adequate and relevant results to be used in the Persistence assessment for these regulations. We aim to collect and curate information available from OECD 309 degradation simulation studies from various sources and use necessary meta data to understand which are the most influential factors that may be affecting the results of these tests. The factors considered include substance properties and test system set-up. The ultimate goal is to identify several critical factors which could enable stakeholders to design better studies and guide the Persistence assessments with scientifically robust approaches.

3.17.P-Tu296 How do River Channel Geometry and Sediment Calibre Affect the Degradation of Wastewater Pollutants? Insights from a Laboratory Experiment

Robert Newbould[1]*, Mark Powell*[1]*, Alexandre Teixeira*[2]*, Juliet Hodges*[2] *and Mick Whelan*[1]*, (1)School of Geography, Geology and the Environment, University of Leicester, United Kingdom, (2)Safety & Environmental Assurance Centre, Unilever, United Kingdom*

Microbially mediated transformations (e.g. biodegradation and nitrification) are often the most important mechanisms for the removal of wastewater pollutants in rivers. These transformations predominantly take place in fixed biofilms attached to sediment on the channel bed and banks. This means that in-stream transformation rates are likely to be affected by channel geometry which determines the extent of chemical contact with the biofilms. It is hypothesized that microbially mediated transformation rates will be inversely proportional to hydraulic radius (the ratio of channel cross-sectional area to wetted perimeter) – i.e. transformations will be more rapid in wide, shallow channels than in narrow, deep ones. Microbial degradation is also expected to be more rapid in channels with fine bed sediment, compared to coarse sediment because the sediment surface area available for biofilm colonisation per unit bed area is greater. We tested these hypotheses in controlled laboratory experiments by monitoring the nitrification of ammonium and biodegradation of linear alkylbenzene sulphonate over two-week periods in mesocosms with different channel geometries and sediment sizes. Models of chemical transformation which account for lags in microbial development were also developed to describe the observed phenomena. Microbial degradation was inversely proportional to hydraulic radius. The sediment size experiment revealed a more complex set of controls which, in addition to sediment calibre, are likely to include bed permeability which affects exchanges of nutrients for biofilm development and contaminants for processing. This study highlights the need to consider geomorphology in chemical exposure modelling and environmental risk assessments.

3.17.P-Tu297 Electron Donor Availability and Biodegradability Dictates Co-metabolic Organic Micropollutant Biodegradation

***Nora B Sutton*[1]**, *Rita Branco[1], Roel Meulepas[2], Pieter van Veelen[2] and Huub H.M. Rijnaarts[1], (1)Environmental Technology, Wageningen University & Research (WUR), Netherlands, (2)Wetsus*

Biodegradation of organic micropollutants is a key process determining fate and supporting attenuation of these compounds in the environment. Typical micropollutant concentrations in the ng/L- µg/L range are too low to support microbial activity as the sole carbon substrate. Instead, biodegradation commonly occurs co-metabolically, thus requiring an additional primary substrate to support metabolic activity. The availability and biodegradability of this primary electron donor therefore dictates microbial activity and consequently micropollutant biodegradation. This study investigated how different electron donors with varying biodegradability affect micropollutant biodegradation in oligotrophic groundwater. We monitored biodegradation of 15 micropollutants in simulated nitrate reducing groundwater systems in upflow columns. We tested both the effect of electron acceptor (oxygen) addition to create (micro)aerobic conditions as well as different electron donor biodegradability (humics, dextran, acetate, and ammonium). Under nitrate reducing conditions, no micropollutant biodegradation was observed regardless of the electron donor added. However, when oxygen was added, 2,4-D and MCPP were biodegraded. Biodegradation rates were highest under fully aerobic conditions when acetate was added. Micropollutant biodegradation was lower under microaerobic conditions, most likely due to oxygen limitation resulting from competition with the supplemented electron donor for oxygen. We observed that with time, microbial communities grew and adapted, yielding higher biomass densities and higher biodegradation rates. We also examined the development of the microbial community by sequencing a fragment of the 16S rRNA gene. We found that the microbial community composition was overall dictated by electron acceptor and electron donor availability, not micropollutants, supporting our hypothesis that supplementing alternative electron donors is crucial for supporting overall microbial activity and thus micropollutant biodegradation. Our results indicate that the overall richness and diversity of the community was low, which probably limited biodegradation of other micropollutants tested. Overall, this study provides insight on the role of primary electron donors in selecting for biodegradation of micropollutants as secondary substrates, which can be used for assessing micropollutant environmental fate as stimulating biodegradation.

3.17.P-Tu298 Challenges with biodegradation simulation testing of difficult substances: a look at volatile hydrophobic substances in OECD 309

***Christopher Hughes*[1]**, *Louise Camenzuli[2], Prasit Shrestha[3], Dieter Hennecke[3] and Marco Kraas[4], (1)Ricardo, United Kingdom, (2)ExxonMobil, Belgium, (3)Ecological Chemistry, Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany, (4)Evonik, Germany*

Higher tier biodegradation simulation tests are used to assess the degradation kinetics and transformation products of substances under realistic environmental conditions. Data from such tests are utilised in persistence assessments, and are information requirements under several chemical regulations in the EU, such as REACH and PPPR. Simulation tests include the OECD test guideline (TG) for testing of chemicals in surface water – the OECD TG 309.

Certain physicochemical properties of substances can have important implications for their behaviour in standardised tests, and the ability to reliably measure the property under investigation. These substances are termed ‘difficult to test’. In the area of biodegradation testing, substances that are both hydrophobic and volatile can be particularly challenging. Test systems may need to be modified in order to account for these challenging substance properties. These modifications may have implications for the reliability and relevance of the data generated. The OECD TG 309 specifies a maximum Henry’s law constant of test substances as part of its applicability (<100 Pa.m^3/mol). However, testing of substances of greater volatility has previously been requested under REACH.

In this presentation, the assessment of volatile hydrophobic substances under OECD TG 309 will be explored. The concept of OECD TG 309 will be presented, including experimental conditions and boundaries as specified in the guideline, and the data generated. The implications of volatile hydrophobic test substances will be described, in the context of both behaviour of the test substance in the system, as well as guideline validity criteria. Potential adapted and alternative test systems for assessing degradation rates in surface water will be presented and discussed. These will include known examples using passive dosing and solvent carriers. The advantages and disadvantages of these systems will be discussed, as well as recommendations for future research to further develop suitable test systems for assessing the degradation of volatile hydrophobic substances in surface waters.

3.17.P-Tu299 Non-Extractable Residues in Persistence Assessment: Effect on the Degradation Half-Life of Chemicals

Cindy Michala Jespersen *and Stefan Trapp, Technical University of Denmark (DTU), Denmark*
Cindy Jespersen and Stefan Trapp

Technical University of Denmark, Kongens Lyngby, Denmark

In the European Union, persistence assessment of pesticides and other substances is done in simulation tests in soil, sediment, or surface water (OECD TG 307, 308 and 309), using ^{14}C-labeled substances. Non-extractable residues (NER) are formed in every degradation test with labeled parent substance. The guidelines for handling these non-extractable residues (NER) in persistence assessment have recently been changed from more or less disregarding NER to consider all NER as non-degraded unless demonstrated otherwise. In this project our aim was to investigate how calibrated degradation half-lives change with different approaches towards NER. Moreover, we also tested whether the amount of (harmless) biological residues (bioNER) is relevant, and whether it can be estimated by the Microbial Turnover to Biomass (MTB) method. We collected data from 48 degradation tests of 24 compounds and compared the following scenarios: i) parent compound only (former approach used in ECHA and EFSA), ii) parent + total NER (new default approach in ECHA), iii) parent + total NER-MTBbioNER, and iv) parent+NER I (experimental). The degradation half-life (DegT50) was found for all four scenarios using the software tool CAKE (Computer Assisted Kinetic Evaluation). We found that there is a trend in half-lives from shortest to longest: i) parent only, iv) parent+NER I, iii) parent+total NER-MTBbioNER, ii) parent + total NER. As scenario i) is no longer acceptable, the shortest possible half-life following the new guideline can be obtained by quantifying the amount of NER I experimentally (scenario iv). In 2 cases the quantification and subtraction of bioNER using the MTB method changed the outcome of the persistence assessment from persistent in scenario ii) parent+total NER (current mandatory method) to not persistent in scenario iii) parent+total NER-MTBbioNER. In this study we found that the approach towards NER can have large impact on the outcome of the persistence assessment and that experimental characterisation of NER can lower the DegT50 values significantly. As determination of MTBbioNER is a calculation method, it doesn't require any new laboratory tests and can be implemented in the persistence assessment as a cheap method for refining the DegT50.

3.17.P-Tu300 The Use of Tritium Labelled Compounds in Environmental Fate Studies: Considerations and Experience
Katerina Hamnett, *Fera Science Ltd., United Kingdom*
Where possible Carbon-14 is the isotope of choice in for environmental fate studies. The positioning of the radiolabel allows investigation of the fate of the test item in environmental matrices. However, in some instances radiolabelling may not be compatible with the synthesis route of the compound. it may therefore not be possible to synthesise the compound of interest in sufficient quantities or at all. In addition, the synthesis of Carbon-14 radiolabelled compounds can be costly and time consuming. As a result of these issues, it is becoming more common for experimental studies to move to non-labelled test items or tritiated test items. A non-labelled test item does not enable the identification of transformation products or the quantification of mass balance within study samples. Hydrogen-3 (tritium) may therefore be a better alternative for use.

The benefits of using tritium include identification of transformation products, quantification of mass balance in samples and due to the positions of the label accurate measurements can be made with much smaller quantities of test item. In addition, there will be more tritium labelled transformation products when compared to compounds containing the Carbon-14 label as tritium compounds are labelled throughout the structure.

However, there are limitations to working with tritium mainly due to the transfer of the of energy to light water. As a result, radiochemical detection alone may not be suitable for quantifying the test item remaining in environmental samples.

This poster will look at how a study can be designed to incorporate both radiochemical and non-radiolabelled (LC-MS/MS) analysis to quantify test item transformation in environmental fate studies. It will incorporate the investigation of tritium labelled test items where carbon labelling is not possible and include confirmatory LC-MS/MS analysis to support findings. In addition, where transfer of the tritium label to water or other products present in environmental samples occurs, a route to provide usable data from these studies using non-radiolabelled confirmatory analysis will be presented.

3.17.P-Tu301 Time-dependent overall persistence as a tool in a weight-of evidence for persistence assessment
Stefan Hahn[1], *Judith Klein*[2] *and Michael Klein*[2], *(1)Fraunhofer ITEM - Institute for Toxicology and Experimental Medicine, Germany, (2)Fraunhofer Institute for Molecular Biology and Applied Ecology (IME), Germany*
Chemical persistence plays a key role in the determination of environmental exposure making it an important endpoint in risk assessment and regulation. For persistence assessment information is required on the degradation rates in different compartments (soil, water, sediment, air). However, many substances are difficult to test or fall outside the applicability domain of existing guidelines due to their specific characteristics. In addition, degradation rates are prone to wide variability depending on environmental conditions. Finally, evaluating degradation half-lives using a compartment-by-compartment approach is overly simplistic, and neglects dynamic multimedia exchanges and degradation processes that may have an important bearing on the overall persistence of a substance in the environment. Results from multi-media modelling could be used case-by-case in order to evaluate the environmental exposure and compartment(s) of specific concern in a qualitative or semi-quantitative approach. Furthermore, overall persistence (Pov) has been proposed to be a suitable replacement metric for the compartment-specific half-lives in persistence assessment.

The multimedia model MUST (level III and IV) is applied on case studies taking into account different properties (degradation half-lives, volatility, solubility, adsorption), and different mode of entries. In addition, emission scenarios such as emission stop are used to evaluate the impact on the overall persistence and the relevant compartment. Overall persistence is given usually for the steady-state concentration. However, concentration in the different compartments will change over time due to distribution and different degradation rates. For this reason, overall persistence will change over time (Pov(t)) as well. For this reason, overall persistence is calculated for each time point of environmental exposure to illustrate the alteration over time. Such simulations may give additional evidence on the persistence of a substance, improve the robustness of current persistence assessment methodologies, and the option to use multimedia modelling (overall persistency) in a weight-of-evidence approach for persistence assessment.

3.17.P-Tu302 Assessing Chemical Persistence: The Imperative of Looking Within Our Homes

Li Li*[1] *and Paola Miramontes Gonzalez*[2]*, (1)School of Public Health, University of Nevada, Reno, (2)Department of Natural Resources & Environmental Science, University of Nevada, Reno

"Persistence" describes a chemical's resistance to physical, chemical and biological elimination from the environment. It is a crucial indicator for characterizing the long-term, irreversible exposure risks to humans and wildlife. To date, the frameworks for assessing environmental persistence have exclusively focused on *outdoor settings*, such as freshwater, soil, and sediment. However, chemical usage is not limited to outdoor settings. *Indoor spaces*, such as homes and offices, are also significant sources of chemical release, including substances like flame retardants, plasticizers, indoor pesticides, and liquid crystal monomers (LCMs). Indoor "near-field" comtamination has been identified as a major pathway for human exposure to these substances. Notably, these substances can accumulate significantly in the human body without needing to persist in outdoor environmental media or accumulating in food and water sources. However, less attention has been paid to *defining* and *quantifying* the persistence of chemicals in indoor environments. In this presentation, we use 93 LCMs as an example of chemicals originating indoors to compare and contrast their "indoor persistence" and the commonly studied "outdoor persistence". We use an established and validated model named "PROduction-To-EXposure (PROTEX)", which is distinguished from other models by its unique ability to integrate the fate of chemicals in nested indoor, urban, and rural environments. Our findings reveal that when outdoor persistence is selected as the point of assessment, <10% of the investigated LCMs are more persistent than known persistent organic pollutants based on the "overall persistence" indicator, and 1/3 to 2/3 of the investigated LCMs meet the criteria for persistence set by the Stockholm Convention based on medium-specific half-life thresholds. However, our analysis demonstrates that most LCMs tend to persist for much longer periods indoors compared to outdoors, mainly due to their low volatility and strong partitioning into indoor surface compartments. Notably, the indoor environment may serve as a reservoir to sustain the long-term regional contamination with LCMs after the cessation of indoor release. This presentation reveals and highlights the importance of including indoor factors in assessments of a chemical's persistence in an entire region, for both LCMs and a wider range of lowly-volatile, indoors-released chemicals.

3.17.P-Tu303 Microbial Synergy: Exploring Bioremediation and Microplastic Dynamics in Environmental Resilience

***Serena Cabigliera*[1]*, Tania Martellini*[2]*, David Chelazzi*[1]*, Alessandra Cincinelli*[2]*, Andrew Jenkins*[3] *and Daniele Cantagalli*[4]*, (1)University of Florence, Italy, (2)Department of Chemistry "Ugo Schiff", University of Florence, Italy, (3)University of South-Eastern Norway, Norway, (4)ÈCOSÌ s.r.l.*

Solutions to address plastic pollution may exist at the microscopic scale. We employ an interdisciplinary approach to understand how microorganisms utilize organic materials as sources for energy. Many organic compounds are susceptible to partial or complete carbon chain breakdown through enzyme activity by naturally occurring microorganisms [1,3]. While multiple factors influence the extent and speed of this degradation, evidence suggests bioremediation, a method employing biological processes to remove pollutants and detoxify contaminated environments, may be a promising approach to address plastic and microplastic (MP) polluted environments [2]. Strains of bacteria capable of degrading Low Density Polyethylene (LDPE) may also have the potential to degrade mineral oil (MO) due to their shared linear hydrocarbon nature and the potential bioavailability of oil. This evidence emerged from the bacterial cultures in Petri dishes carried out at regular intervals to constantly monitor growth or any variations. Of the 40 strains of bacteria we identified as capable of degrading LDPE, we focused our study on the four most promising. We recorded the regular degradative activity of the chosen bacterial strains through specific ATP tests. Our study's findings provide valuable insight for selecting bacterial species with high degradation capacity. However, further research is necessary to better comprehend their mechanisms and potential for environmental remediation.

3.17.P-Tu304 Effect of Internal Hydrophilic Groups of Surfactants on Biodegradability and Ecotoxicity: An Example of a Newly Developed Surfactant, Bio IOS

***Takahiro Suzuki*[1]*, Tohru Nishioka*[2] *and Masayuki Yamane*[3]*, (1)Kao Corporation, Japan, (2)Safety Science Research, Safety Science Research, Kao Corporation, Japan, (3)Safety Science Research, Kao Corporation, Japan*

Recently, a new sustainable anionic surfactant called Bio-based Internal Olefin Sulfonate (Bio IOS) has been developed. It has a unique structure of long hydrophobic alkyl chains (C16 to C18) with two types of hydrophilic groups in its midsection, which distinguish it from other conventional anionic surfactants. However, the effects of the specific structural features of the surfactants, especially the internal hydrophilic groups on its environmental properties and the consequent effects on the environment remain unclear. In this study, we investigated the environmental fate and ecotoxicity of Bio IOS, and elucidated whether different types and positions of hydrophilic groups will affect biodegradability and ecotoxicity. Biodegradation studies demonstrated that Bio IOS is readily biodegradable with >99.5% removal in wastewater treatment activated sludge and a fast half-life of 5.8 h in river water; the excellent biodegradability is likely due to the high water solubility attributed to the internal hydrophilic groups. Meanwhile, moderate ecotoxicity was observed, whereby the 50% lethal and effect concentrations of the three freshwater species were above 1 mg/L. Ecotoxicity studies with different types and positions of hydrophilic groups revealed that hydroxyalkane sulfonate was less toxic and that toxicity was reduced in the presence of more internally located hydrophilic groups. These findings suggest that the hydroxyl group and the internal position of hydrophilic groups that constitute the molecular configuration resembling two separate shorter alkyl chains may reduce the adverse effects on organisms despite the long alkyl chains. Our study suggests that it is the internal hydrophilic group that may impart environmental properties. In this presentation, the importance and positive aspects of the internal hydrophilic group in surfactants on biodegradability and ecotoxicity will be discussed.

3.17.P-Tu305 Biodegradation and biotransformation products of oxygen-containing Liquid Organic Hydrogen Carrieris (oxo-LOHCs)

Yohan Seol[1], *Marta Markiewicz*[2], *Stephan Beil*[1], *Viktor Schmalz*[1] *and Stefan Stolte*[1], *(1)Institute of Water Chemistry, Dresden University of Technology, Germany, (2)Institute of Water Chemistry, Technical University Dresden, Dresden, Germany*

Liquid Organic Hydrogen Carriers (LOHCs) are very promising vectors for hydrogen storage and transportation as they have high gravimetric hydrogen storage capacity. The LOHC systems consist of a pair of H_2-lean, typically (poly)cyclic aromatic compounds, and H_2-rich form, (poly)cyclic aliphatic compounds. Pilot projects of energy storage and transport operate at the scale of hundreds of tons of LOHC per year and could increase considerably in the future. The search for LOHC systems with excellent technological performance and acceptable hazard profiles is of paramount interest. Recently novel oxo-LOHC systems that have demonstrated favorable technological properties yet their environmental impacts are unknown. This study presents the ultimate biodegradation, primary biodegradation, and biotransformation products of a series of oxo-LOHCs. Our results show that monocyclic oxo-LOHCs are readily biodegradable (mineralization > 60%) while bicyclic oxo-LOHCs are not. Some of the bicyclic oxo-LOHCs are inherently biodegradable while others show minimal mineralization, especially H_2-rich forms (<20%). In the benzophenone-based LOHC system, four compounds showed 100% primary biodegradation, whereas the other two oxo-LOHCs lacking a phenyl ring showed lower degradation. Methylbenzophenones showed a relatively lower biodegradation rate, suggesting that methyl substitution decreases the biodegradability with some compounds showing neither ultimate nor primary degradability. Additionally, high-resolution mass spectrometry identified three types of hydroxylated benzophenones following benzophenone biodegradation that could exhibit endocrine activity. The primary degradation half-life of most oxo-LOHCs is shorter than 35 days. These findings offer valuable guidance for LOHC developers in selecting or designing the least harmful substances with outstanding performance as hydrogen carriers.

3.17.P-Tu306 Degradation of Metribuzin in a Tropical Soil Amended with Sugarcane Straw Biochar

Kassio Ferreira Mendes[1], *Kamila Mielke*[1] *and Rodrigo Sousa*[2], *(1)Federal University of Viçosa, Brazil, (2)Soil Science, ESALQ/USP, Piracicaba, Brazil*

Biochar-amended soils influence the degradation of herbicides depending on the pyrolysis temperature, application rate, and feedstock used. Metribuzin is a pre- and post-emergent herbicide, a selective residual of the triazinone group, with the ability to effectively control a wide spectrum of eudicot weeds. The objective of this study was to evaluate the influence of sugarcane straw biochar (BC) produced at different pyrolysis temperatures (350 ◦C, 550 ◦C, and 750 ◦C) and application rates in soil (0, 0.1, 0.5, 1, 1.5, 5, and 10% *w*/*w*) on metribuzin degradation. Detection analysis of metribuzin in the soil to find time for 50% and 90% metribuzin degradation (DT_{50} and DT_{90}) was performed using high-performance liquid chromatography (HPLC). BC350 ◦C-amended soil at 10% increased the DT50 of metribuzin from 7.35 days to 17.32 days compared to the unamended soil. Lower application rates (0.1% to 1.5%) of BC550 ◦C and BC750 ◦C decreased the DT50 of metribuzin to ~4.05 and ~5.41 days, respectively. The addition of low application rates (0.1% to 1.5%) of sugarcane straw biochar produced at high temperatures (BC550 ◦C and BC750 ◦C) resulted in increased metribuzin degradation and may influence the residual effect of the herbicide and weed control efficiency.

Keywords: application rate; carbonaceous material; degradation time; herbicide residual; pyrolysis temperature.

Funding: This research was funded by the National Council for Scientific and Technological Development (CNPq—404240/2021-6) and the Foundation for Research Support of the State of Minas Gerais (FAPEMIG—2070.01.0004768/2021-84).

3.17.P-Tu307 Degradation of glyphosate in drinking water with 60Co gamma radiation using LC-MS/MS

Kassio Ferreira Mendes[1], *João Victor Araújo Freitas*[2], *Mariana Beatriz Teixeira Diniz*[3] *and Rodrigo Sousa*[4], *(1)Federal University of Viçosa, Brazil, (2)Chemistry, University of the Fraser Valley (UFV), Brazil, (3)Agronomy, University of the Fraser Valley (UFV), Brazil, (4)Soil Science, ESALQ/USP, Piracicaba, Brazil*

Glyphosate (N-(phosphonomethyl)glycine) is a systemic, post-emergence, non-selective herbicide. Due to the control of a wide range of weeds and transgenic events (crops resistant to this herbicide), glyphosate has become the most important and widely used herbicide in the world. However, due to its toxicity, especially to aquatic beings, it is necessary to study the control and degradation of glyphosate in water bodies, since it is more persistent than in soil. The aim of this study was to evaluate the degradation of glyphosate in drinking water using gamma radiation. This study was carried out using a sample of tap water from Viçosa, MG, Brazil. Initially, it was verified that the sample did not contain the herbicide, and then a dose of glyphosate of 0.5 mg L^{-1} was added. Subsequently, the samples were subjected to different doses of gamma radiation (0, 0.5, 1.0, 2.5, 5.0, and 10 kGy) in an irradiator of the type Gammacell 220 Excel, MDS, Nordion (Atomic Energy of Canada Limited - AECL, Ottawa, Ontario, Canada). The procedure was performed at room temperature with a dose rate of 0.08 kGy/h (source power: 215.95 Ci). This equipment has a high capacity to emit gamma rays through a Cobalt 60 (^{60}Co) source, located in Piracicaba, SP, Brazil. Glyphosate was quantified using liquid chromatography coupled with mass spectrometry (LC-MS/MS). The dose constant (k) was determined from the slope of ln (C_D/C_0) versus absorbed dose (D) by considering the pseudo-first order degradation kinetics; $-\ln(C_D/C_0)= k D$. The value of k was used to find out the amount of irradiation doses required for 50 ($D_{0.5}$) and 90% ($D_{0.9}$) degradation of each compound by using equations: $D_{0.5} = \ln(2)/k$ and $D_{0.9} = \ln(10)/k$, respectively. The pseudo-first order model of the glyphosate degradation kinetics study was very well adjusted. The D0.5 was 8.97 kGy and the D0.9 of glyphosate was 29.82 kGy. The highest dose of irradiation applied (10 kGy) was able to degrade ~63% of glyphosate, but the presence of 20% of its metabolite aminomethylphosphonic acid (AMPA) was detected. Thus, this study concluded that the use of gamma radiation is a possibility for the degradation of glyphosate in water from treatment plants, but it is necessary to use higher doses.

Keywords: decontamination, organic pollutant, metabolite, herbicide.

Funding: This research was funded CNPq.

3.17.P-Tu308 Oxygen-containing Liquid Organic Hydrogen Carriers (oxo-LOHCs) as materials for storage of green hydrogen – environmentally acceptable, circular, and free of critical raw materials?

Yohan Seol[1]*, Marta Markiewicz*[2]*, Stephan Beil*[1]*, Viktor Schmalz*[1] *and Stefan Stolte*[1]*, (1)Institute of Water Chemistry, Dresden University of Technology, Germany, (2)Institute of Water Chemistry, Technical University Dresden, Dresden, Germany*

Liquid Organic Hydrogen Carriers (LOHCs) are very promising vectors for hydrogen storage and transportation as they have high gravimetric hydrogen storage capacity. The LOHC systems consist of a pair of H_2-lean, typically (poly)cyclic aromatic compounds, and H_2-rich form, (poly)cyclic aliphatic compounds. Pilot projects of energy storage and transport operate at the scale of hundreds of tons of LOHC per year and could increase considerably in the future. The search for LOHC systems with excellent technological performance and acceptable hazard profiles is of paramount interest. Recently novel oxo-LOHC systems that have demonstrated favorable technological properties yet their environmental impacts are unknown. This study presents the biodegradation, ecotoxicity, mobility, and the *in vitro* bioconcentration potential of a series of oxo-LOHCs. Our results show that monocyclic oxo-LOHCs are readily biodegradable (mineralization > 60%) while bicyclic oxo-LOHCs are mostly inherently biodegradable. In the benzophenone-based LOHC system, four compounds showed 100% primary biodegradation, whereas the other two oxo-LOHCs lacking a phenyl ring showed lower degradation. Methylbenzophenones showed a relatively lower biodegradation rate, suggesting that methyl substitution decreases the biodegradability with some compounds showing neither ultimate nor primary degradability. Additionally, high-resolution mass spectrometry identified three types of hydroxylated benzophenones following benzophenone biodegradation that could exhibit endocrine activity. Ecotoxicity tests conducted with *Daphnia magna* (water flea) and *Raphidocelis subcapitata* (green algae) showed that the toxicity of oxo-LOHCs is generally moderate belonging to the acute 2 and acute 3 categories according to the Globally Harmonized System classification. Notably, some methylbenzophenones exhibited high toxicity to green algae (Acute 1: EC_{50}<1mg/L). oxo-LOHCs are expected to be generally mobile in the soil environment based on their log Koc values (mainly below 3.0). Lastly, oxo-LOHCs show a low bioconcentration potential due to their low measured membrane-water partition coefficients (log Kmw). These findings offer valuable guidance for LOHC developers in selecting or designing the least harmful substances with outstanding performance as hydrogen carriers.

3.18.A Next-Generation Urban Water Management: Improved Understanding of the Fate of Micropollutants, Transformation Products, Pathogens, and Antimicrobial Resistance

3.18.A.T-01 Occurrence of pollutants of emerging concern in urban runoff samples

Sergio Santana-Viera[1]*, Francesc Labad Roig*[2]*, Marc Teixidó*[3]*, Nicola Montemurro*[4]*, Marina G. Pintado Herrera*[5]*, Pablo Antonio Lara Martín*[5] *and Sandra Perez Solsona*[2]*, (1)Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain, (2)Onhealth, Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain, (3)Geosciences, Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain, (4)Department of Environmental Chemistry, Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain, (5)Universidad de Cadiz*

Emerging pollutants are contaminants of anthropogenic origin that have been studied with great interest over the last 20 years, mainly in wastewater. Among them, persistent and mobile compounds (PMs) are contaminants of new emerging concern due to their lack of information. As happened in the last century with persistent, bioaccumulative and toxic compounds (PBTs), PM compounds pose a great threat to the water cycle. One of the main sources of this pollution are the effluents of wastewater treatment plants, but there is more like runoff after rain events in cities. Runoff water in cities is considered one of the main pollution vectors, causing considerable deterioration of the receiving water masses. However, the analysis of pollutants with such a wide range of polarities is very challenging. Therefore, in this work, we have created a methodology able to preconcentrate and measured, detecting 75 compounds in urban runoff samples. The total contamination of the samples ranges from 5 - 76 µg/L, so contamination in runoff water in cities must be taken into account. Among analysed pollutants, 9 analytes were detected with average concentrations above 1000 $ng \cdot L^{-1}$: mono-methyl phthalate, 2,3-dimethylbenzenesulfonic acid, naphthalene-1-sulfonic acid, e-caprolactam, tris(2-butoxyethyl) phosphate, glufosinate, docusate, 1,3-diphenylguanidine and tolyltriazole; all of them used as industrial compounds or in the manufacture of objects except the herbicide glufosinate and the laxative docusate. Overall, this research aims to contribute to a better understanding of the pollutants present in stormwater runoff and provide insights into effective strategies for their identification and mitigation.

3.18.A.T-02 Lysimeter Experiments to Investigate the Retention and Degradation of the Urban Biocides Terbutryn, Diuron and Octylisothiazolinone in Typical Urban Surface-Soil Interfaces

Tobias Junginger[1]*, Sylvain Payraudeau*[2]*, Felicia Linke*[3]*, Jens Lange*[3] *and Gwenaël Imfeld*[2]*, (1)VEGAS Research Facility for Subsurface Remediation, Institute for Modelling Hydraulic and Environmental Systems, University of Stuttgart,70569 Stuttgart, Germany, University of Stuttgart, Germany, (2)Institut Terre et Environnement de Strasbourg (ITEST), University of Strasbourg, France, (3)Chair of Hydrology, Faculty of Environment and Natural Resources, University of Freiburg, Germany*

Urban biocides, such as terbutryn, diuron, and octylisothiazolinone, are emitted from facade paints and plasters, reaching groundwater through infiltration through permeable surfaces. While the presence of urban biocides in groundwater is established, their pathways and reactive behavior across surface-soil interfaces remain poorly understood. This study employs field lysimeter experiments and reactive transport modelling to examine urban biocide reactive transport in soil. The results indicate that pavement and drainage gravel had insufficient capacity to retain biocide fluxes, releasing 10-50% of the initial mass to deeper soil layers. In contrast, mass transfer through vegetated soil systems was limited, with less than 0.5% released. After 207 days, up to 9% of the initially applied terbutryn mass was extractable in all lysimeters, with a substantial amount (7-18%) still available for further leaching to groundwater. Compound-specific isotope analysis enabled to evaluate the degradation contribution to total dissipation, revealing a higher degradation extent in the pavement than in the gravel lysimeter. Given the time limitations of outdoor experiments, reactive transport models helped predicting the primary entry paths and mass fluxes of urban biocides through urban surfaces to evaluate associated risks over years. Thus, continuous biocide release after rain events from a 10 m^2 facade, was employed to assess the reactive transport through various surface-soil interfaces to groundwater over an 8-year period. Terbutryn, along with transformation products, reached deeper soil layers (>30 cm) through pavement and gravel, accounting for 22% and 36%, respectively, over the 8-year period. Only 0.2% of terbutryn leached through vegetated soils. In summary, this study represents a fundamental step towards integrating biocide leaching into the design of sustainable stormwater management approaches to evaluate risks of groundwater contamination.

3.18.A.T-03 Sources of Persistent and Mobile Chemicals in Municipal Wastewater: A Sewer Perspective

Alina H. Seelig[1]*, Daniel Zahn*[1] *and Thorsten Reemtsma*[2,3]*, (1)Department of Analytical Chemistry, Helmholtz Centre for Environmental Research (UFZ), Germany, (2)Helmholtz Centre for Environmental Research (UFZ), Germany, (3)University of Leipzig, Germany*

By definition, persistent and mobile (PM) chemicals are poorly degraded by microbial processes and hardly sorb to natural surfaces. This is why PM chemicals can spread in the water cycle and may be found throughout the aquatic environment. Monitoring studies demonstrated the occurrence of PM chemicals in various environmental compartments. All these studies indicate the widespread presence of some PM chemicals like acesulfame or 1-cyanoguanidine which appear in almost every sample while others were detected more sporadically but then partially in high concentrations. Since many of these chemicals are only partially removed by wastewater treatment knowledge of their sources becomes essential to devise appropriate mitigation options like the implementation of an on-site pretreatment of the wastewater or a more focused search for replacement chemicals for specific applications if their release is found to be problematic. Furthermore, a better understanding of sources may inform future monitoring and screening campaigns by aiding in a tailored sample selection.

In this study 67 PM chemicals were investigated to explore the potential of sewer sampling for identifying sources in municipal wastewater. In total, 37 analytes (54%) were detected in at least one of the wastewater sample. The sewer samples analyzed were highly variable in both, composition and concentration: 22 of the 37 detected compounds analyzed (49%) were detected in less than 50% of the samples, while 15 compounds (41%) spanned up to three orders of magnitude in concentration. For source identification the samples were categorized in clinical, domestic, and industrial wastewater. The generated data showed that PM chemicals analyzed (a) originated from diffuse (e.g. vincubine) or point sources (e.g. 1-cyanoguanidine) and (b) what kind of point source a chemical originated from. While many chemicals categorized as industrial were also diffusely emitted by households, high concentration emissions could be linked to specific applications and industries for some PM chemicals like 1-cyanoguanidine.

3.18.A.T-04 Modeling the fate of CEC during wastewater treatment processes by using fluorescence

Paolo Roccaro[1]*, Luigi Marino*[1]*, Ruggero Todesco*[1]*, Erica Gagliano*[2] *and Domenico Santoro*[3]*, (1)University of Catania, Italy, (2)University of Genoa, (3)Aquasoil, Fasano BR, Italy*

In this study fluorescence measurements suitable for real-time monitoring of CEC removal from wastewater during conventional and advanced oxidation processes (AOPs) has been investigated. The study focused on tracking and modelling the fate of CEC during the treatment processes by using fluorescence measurements and Artificial neural network (ANN).

Several samples were collected at two different municipal WWTPs and at a AOP pilot plant operated downstream of a water reuse facility (WRF) for agricultural purposes. In particular, some samples were collected before and at different stages of AOP pilot plant operated at different flowrates and treatment train.

The organic micropollutants were detected by means of an Orbitrap mass spectrometer coupled with high resolution liquid chromatography with a non-target suspect-screening metedology. Fluorescence data were collected using a Shimadzu RF-5301PC fluorescence spectrophotometer (Kyoto, Japan) with the scanning range from excitation wavelength 220 nm–450 nm and emission wavelength from 250 nm to 580 nm. Five fluorescence peaks were selected and used for CEC modeling. These are referred as I1 (ex 225, em 290), I2 (ex 230, em 355), I3 (ex 245, em 440), I4 (ex 275, em 345), I5 (ex 345, em 440).

ANN model has been developed using Matlab software with ANN toolbox to match the measured and the predicted concentrations of CEC. The input parameters selected for the model included the abovementioned five fluorescence peaks of EEM. A feed-forward three-layer trained with Levenberg-Marquardt with a log-sigmoid transfer function for the hidden layer and a pure-linear transfer function for the output layer has been used. The network has been fed with three subsets of data, with 50% being used for training, 25% for testing the performance and 25% for validation to avoid the overfitting.

Obtained results show that selected fluorescence indexes can be used to monitor and model the fate of CEC during wastewater treatmetn processes. For instance, a strong inear correlation between the sum of CEC (normalized concentration) and a selected fluorescence index (normalized values) obtained at varying treatment process (AOPs based) and operational day.

The CEC concentrations were also well predicted by the ANN-based model that incorporated as input parameters the values of I3, I4, and I5. Indeed, the ANN-based model can predict the CEC concentrations with a high determination coefficient (R^2>0.9).

3.18.A.T-05 Phase Separation of Anaerobic Digestion to Elucidate the Transformation Products of Organic Micropollutants during Acidogenesis and Methanogenesis

Rodrigo Braz Carneiro[1], *Ruben Gil-Solsona*[2], *Esteban Restrepo-Montes*[2], *Marcelo Zaiat*[3], *Álvaro J. Santos-Neto*[4] *and Pablo Gago Ferrero*[2], *(1)São Carlos Institute of Chemistry, University of São Paulo (USP), Butantã, Brazil, (2)Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain, (3)São Carlos School of Engineering, University of São Paulo (USP), Brazil, (4)São Carlos Institute of Chemistry, University of São Paulo (USP), Brazil*

The presence of organic micropollutants (OMPs) in wastewater treatment plants (WWTPs) has been frequently reported and the risks inherent to their environmental exposure by animals and humans is being increasingly elucidated. These OMPs can be completely mineralized or undergo various processes of cometabolic transformation mediated by different microbial communities in WWTPs. This study aimed to elucidate the biotransformation products (BTPs) from OMPs during anaerobic digestion, emphasizing the specific contribution of acidogenesis and methanogenesis in the transformation products of each compound. The experimental apparatus was composed of two anaerobic fixed-film bioreactors: a single-phase (SP) methanogenic and a two-phase (TP) sequential acidogenic-methanogenic reactor. The bioreactors were fed with wastewater spiked with 10 $\mu g\ L^{-1}$ of ten selected OMPs: carbamazepine, naproxen (NPX), diclofenac (DCF), ibuprofen, acetaminophen, metoprolol, sulfamethoxazole, ciprofloxacin, methylparaben and propylparaben. Influent and effluent liquid samples from each bioreactor were processed by solid phase extraction and analyzed by LC-HRMS (Q-Exactive QOrbitrap). By applying a suspect screening analysis, for the potential BTPs the experimental MS2 spectra obtained were compared with fragmentation patterns found in databases (e.g., Massbank) to confirm the chemical structure of each compound. In summary, fourteen BTPs were confidently identified and it was possible to establish some possible transformation pathways, emphasizing the main chemical reactions involved, e.g., demetylation of NPX and hydroxylation of DCF to generate demethyl-NPX and hydroxy-DCF, respectively. Apart from the transformation pathways, we compared the BTPs found in the SP and TP reactor. We observed that certain BTPs are generated during the acidogenic phase and further utilized during methanogenesis (e.g., demethyl-NPX). On the contrary, another subset of BTPs is generated under acidogenesis but exhibits an increase in concentration in the TP-reactor effluent (e.g., hydroxy-DCF). As a conclusion, it was found that the OMPs transformation was closely linked to the fermentative cometabolism of organic acid production, since all BTPs were found in acidogenic condition. The TP anaerobic bioreactor enhanced the biodegradation of OMPs in wastewater, but greater attention should be given to the potential risks of the generated BTPs in the effluent stream from these reactors to the environment.

3.18.B Next-Generation Urban Water Management: Improved Understanding of the Fate of Micropollutants, Transformation Products, Pathogens, and Antimicrobial Resistance

3.18.B.T-01 Development of an automated workflow for conducting degradation experiments and elucidating transformation products

Ingrida Bagdonaite[1,2,3,4], *Rick Helmus*[3], *Pim de Voogt*[3], *Maarten van Bommel*[4,5,6], *Emma Schymanski*[7], *Annemarie van Wezel*[3] *and Thomas L. ter Laak*[3,8], *(1)VU University Amsterdam (VU), Amsterdam, Netherlands, (2)Chemistry for Environment and Health, Vrije Universiteit Amsterdam, Amsterdam Institute for Life and Environment (A-LIFE), Netherlands, (3)University of Amsterdam, Institute for Biodiversity and Ecosystem Dynamics (IBED), Netherlands, (4)Centre for Analytical Sciences Amsterdam (CASA), (5)University of Amsterdam, van 't Hoff Institute for Molecular Sciences, Netherlands, (6)University of Amsterdam, Amsterdam School for Heritage, Memory and Material Culture, Conservation and Restoration of Cultural Heritage, Netherlands, (7)Luxembourg Centre for Systems Biomedicine (LCSB), University of Luxembourg, Luxembourg, (8)KWR Water Research Institute, Netherlands*

Organic micropollutants (OMPs), including pharmaceuticals and their transformation products (TPs), are prevalent in aquatic environments, and challenge conventional water treatment processes. Advanced oxidation processes such as UV photolysis serve as an effective strategy to remove OMPs by direct and indirect photolysis mechanisms. However, the non-selectivity of OH radicals raises concerns about the unpredictable formation of various TPs with unknown toxicity, requiring a comprehensive understanding of degradation pathways. Liquid chromatography coupled to high-resolution mass spectrometry (LC-HRMS) paired with non-target analysis (NTA) is typically used for comprehensive screening of OMPs and their TPs. While powerful, NTA faces challenges such as complex data interpretation, low concentrations of compounds of interest, lack of reference standards, and the need for sophisticated data analysis workflows. This study aimed to establish comprehensive workflows for degradation experiments and TP elucidation, combining an automated photodegradation setup ('TooCOLD') with software NTA workflows ('patRoon 2.0'). The TooCOLD setup integrates UV light and LC-HRMS, eliminating manual labor and expediting experimental processes. The TP screening was based on patRoon, an open source software platform to perform comprehensive NTA. These workflows were then applied to a case study on the photodegradation of the pharmaceuticals flecainide, metoprolol, sulfamethoxazole and phenazone. The study examined UV photodegradation in the presence and absence of H_2O_2 and natural organic matter (NOM), assessing parent chemical dissipation and employing NTA to identify TPs. The integration of these methodologies provided insights into transformation processes and TP formation during water treatment, under controlled conditions. The studied pharmaceuticals exhibited diverse degradation patterns under the investigated treatment conditions. Preliminary NTA results revealed a total of 256,784 features, which were reduced to 38 features through various prioritization steps, and tentatively identified using various suspect and unknown screening approaches. This work demonstrated how comprehensive workflows to systematically perform degradation experiments with complementary screening approaches can be used to effectively elucidate a significant number of structurally diverse TPs for different parent compounds.

3.18.B.T-02 Assessing the Fate and Behaviour of Micropollutants During Advanced Wastewater Treatment for Potential Water Reuse Applications

Jan Christof Specker[1]*, Harrie Besselink*[2]*, Abraham Brouwer*[2]*, Peter Alexander Behnisch*[2]*, Emiel Felzel*[2]*, Antonia Praetorius*[3]*, Nora B Sutton*[4] *and Annemarie van Wezel*[5]*, (1)University of Amsterdam (UVA), Netherlands, (2)BioDetection Systems BV (BDS), Netherlands, (3)Institute for Biodiversity and Ecosystem Dynamics, University of Amsterdam, Netherlands, (4)Environmental Technology, Wageningen University & Research (WUR), Netherlands, (5)University of Amsterdam, Institute for Biodiversity and Ecosystem Dynamics (IBED), Netherlands*

The ever-increasing freshwater stress across the globe requires innovative solutions to ensure a high-quality and constant water supply for the public, industry, agriculture, and nature. Reusing treated wastewater offers in this instance great potential to support existing water supply systems during periods of increased freshwater pressure either due to an increase in demand or decrease in water availability.

The focus of wastewater reuse related health concerns has so far been on potential adverse effects caused by microorganisms. Contrary, the numerous chemical contaminants that are present in wastewater treatment plants effluent, remain poorly understood during water reuse. Therefore, to address and limit potential risks caused by these chemical pollutants, their fate and behaviour during reuse needs to be comprehensively assessed.

To study the potential reuse of treated municipal wastewater effluent after advanced treatment, a pilot plant was installed on the wastewater treatment plant (WWTP) in Wervershoof, the Netherlands. The pilot plant receives WWTP effluent as intake water and treats it by a combination of ozonation, ceramic membrane filtration, and activated carbon. Over the summer of 2022, 90 samples were taken at this pilot plant before and after each individual treatment step. Samples were enriched by solid-phase extraction and were subjected to several *in vitro* bioassays covering multiple toxic endpoints. Furthermore, chemical target analysis of 98 micropollutants by liquid chromatography trapped ion mobility spectrometry coupled to a time of flight mass spectrometer is currently still ongoing. This analysis will help to assess removal efficiency of target compounds and will be supplemented by suspect as well as non-target screening.

This talk will emphasize the advantage of coupling chemical analysis and effect-based analysis for the analysis of complex mixtures. Their integration allows to address known pollutants to ensure compliance with existing regulations, while simultaneously accounting for unknown chemicals and the entire mixture. Therefore, extending the covered chemical regulatory space, which ultimately improves the overall risk assessment. The findings will especially be interesting for water authorities that aim to initiate water reuse applications as appropriate treatments options along with monitoring options are presented that will help to understand and minimise potential risks.

3.18.B.T-03 Qualitative and quantitative spatiotemporal analysis of new psychoactive substances in Slovenia through the analysis of influent wastewater

Maria Laimou-Geraniou[1,2]*, Dhayaalini Nadarajan*[3]*, Richard Bade*[3] *and Ester Heath*[2,4]*, (1)Jozef Stefan Institute, Slovenia, (2)Jozef Stefan International Postgraduate School, Slovenia, (3)Queensland Alliance for Environmental Health Sciences (QAEHS), University of Queensland, Australia, (4)Jozef Stefan Institute, Department of Environmental Sciences, Slovenia*

New psychoactive substances (NPS) are a constantly evolving class of psychoactive substances which were originally sold as legal alternatives to conventional illicit drugs such as ecstasy and cannabis while bypassing legal restrictions and are thus of international public health concern. The continuous appearance of new NPS derivatives on the market is making the monitoring and surveillance of NPS challenging using convenional socio-epidemiological methods. A complementary approach that could deliver additional information on the spatiotemporal consumption patterns of NPS is wastewater-based epidemiology (WBE). WBE measures trace concentrations of biomarkers in influent wastewater and converts these to per capita mass load estimates (mg/day/1000 inhabitants) of drugs using pharmacokinetics, daily flow rates of wastewater and population in the catchment area. In this study, influent wastewater samples from seven wastewater treatment plants in Slovenia (Ljubljana, Maribor, Velenje, Domžale-Kamnik, Koper and Novo Mesto) were analysed during six different sampling periods: summer 2019, winter/spring 2020, winter/spring 2021 and spring 2022. Following solid-phase extraction, two liquid chromatography-mass spectrometry (LC-MS) methods were utilised: targeted LC-MS/MS method of more than 70 NPS as well as an LC-quadrupole time-of-flight (LC-QTOF) suspect screening method using a HighResNPS database of more than 2000 NPS and illicit drugs. Our analysis allowed a spatiotemporal analysis to determine the extent of NPS use in Slovenia. Five NPS were semi-quantified across all sites: 3-methylmethcathinone (3-MMC), 4-fluoroamphetamine (4-FA), eutylone, mephedrone, and mitragynine. The highest number of residues (n=5) was measured in Koper, followed by Domžale-Kamnik and Ljubljana. Following the suspect screenign method, at least 10 additional compounds were detected. This wastewater-based study provides an insight into the NPS market in Slovenia, including before, during and after the COVID-19 pandemic, while combining qualitative and quantitative methods gives a more comprehensive overview of their use.

3.18.B.T-04 Wastewater Surveillance for Real-Time Micropollutant Monitoring and Advanced Treatment Assessment
***George Ruck**[1], Alexandre Decamps[2], Didier Neuzeret[2], Jean-Baptiste Aubin[3], Arnaud Chaumot[4], Olivier Geffard Pr[5], Laura Garnero[6] and Hervé Quéau[7], (1)UR RiverLy - Ecotox, National Research Institute for Agriculture, Food and Environment (INRAE), France, (2)ViewPoint, France, (3)INSA de Lyon, France, (4)INRAE (Institut National de la Recherche Agronomique), France, (5)UR RiverLy, Institut national de recherche pour l'agriculture, l'alimentation et l'environnement (INRAE), France, (6)UR RiverLy - ECOTOX, Laboratoire d'écotoxicologie INRAE, France, (7)INRAE, France*
Recent adoption of advanced treatment sees the use of efficient techniques for CEC elimination at WWTP outlets, such as granulated activated carbon (GAC) filters and ozonation. Most evaluation of such treatment relies on grab sampling measurements for only a select group of chemicals. Given the temporal variability associated with CEC discharge, treatment now requires real-time monitoring strategies to characterise micropollutant fate at times of micropollutant surge. ToxMate online biomonitoring, using multispecies (Erpobdella,Gammarus,Radix) organism avoidance behaviour as a biomarker, offers effluent characterisation using an effect-based non-targeted approach. The objective of the communication is to present results and variability in advanced treatment performance over a continuous 18-month surveillance period, as well as current laboratory work on fingerprinting for the identification of CECs.

ToxMate biomonitoring was used at an advanced treatment site (120,000-population equivalent WWTP) where biological treatment was followed by ozone treatment and then GAC tanks, one ToxMate after each respective treatment for comparative monitoring (3 total). Parallel sampling of model micropollutants showed moderate elimination after ozonation and good overall elimination (post GAC). However, there was both temporal and molecule dependent variability in the elimination. Our results from the long term monitoring highlight this variability, where residence times are used to estimate correlation in micropollutant surge, in some cases showing persistence of the outgoing pollution or even the appearance of avoidance reactions, perhaps related to treatment byproducts (ie.metabolites).

Lab studies for repeated spikes tested for over 40 micropollutants were modelled with a functional approach, grouping responses into clusters known as behavioural fingerprints. Our current research looks to reveal structural similarities within fingerprints, that could improve identification of CEC nature at sites such as the described WWTP. Coupling this method and the rare insight into the characterisation of pollutant fate in advanced treatment provides an opportunity for real-time alerting in WWTPs in the case of more persistent micropollutant surge, perhaps indicating temporary periods where applications such as re-use should be avoided. It also suggests the need for a review of current chemical analysis used to evaluate overall micropollutant elimination in advanced treatment.

3.18.B.T-05 Is the conventional treatment process sufficient to decrease the ecotoxicological effect of wastewater?
***Maria Catalina Trejos Delgado**[1], Andrea Dombrowski[1] and Jörg Oehlmann[1,2], (1)Aquatic Ecotoxicology, Goethe University Frankfurt, Germany, (2)Kompetenzzentrum Wasser Hessen, Germany*
Aquatic bodies face increasing levels of pollution worldwide, particularly from specific contaminants called micro-pollutants that can generate adverse effects for ecosystems and human health. Considering this fact, it is well known that just 40% of surface water bodies in Europe meet the requirements for good ecological and chemical status and in Germany the situation is even worse with just 10% of surface waters. Many studies confirm that one of the main entry path of these micro-pollutants into the aquatic environment is through treated and untreated wastewater.

It is therefore important to analyze the effectiveness of the WWTPs in eliminating micropollutants and other chemical stressors to mitigate the negative impacts of the treated wastewater (WW) in the aquatic ecosystems. For that reason, in the present study, we assessed, through effect based methods, two conventional wastewater treatment plants located in the Hessian Ried in Germany. The tests performed in this study were baseline toxicity with *Aliivibrio fischeri*, mutagenicity assay with *Salmonella typhimurium* and endocrine-disruption activity with *Saccharomyces cerevisiae*. These activities were measured at four different points in each WWTP: upstream, after mechanical treatment, after biological treatment, and downstream during spring and fall. In general, the results showed that the untreated WW had a very high baseline toxicity and also high endocrine and mutagenic activities; however the conventional wastewater treatment (consisting of mechanical and biological treatment with nitrification, denitrification and phosphate precipitation) reduces in more than 90% the baseline activity and in 80% the endocrine activities. Despite these high elimination rates, the remaining baseline toxicity, the endocrine, dioxin-like and mutagenic activities of the conventionally treated WW was so high that negative effects on the two receiving waters were to be expected. These results imply that a further advanced wastewater treatment is urgently needed to guarantee a safe effluent in both streams because the conventional treatment process is not sufficient to decrease the ecotoxicological effect of the wastewater.

3.18.C Next-Generation Urban Water Management: Improved Understanding of the Fate of Micropollutants, Transformation Products, Pathogens, and Antimicrobial Resistance

3.18.C.T-01 Evaluating membrane bioreactor treatment for the elimination of emerging contaminants using different analytical methods

Naroa Lopez[1,2], *Mireia Irazola-Duñabeitia*[1,3], *Iker Alvarez-Mora*[3,4,5], *Leire Mijangos*[3,6], *Dennis Bilbao*[1,3], *Nestor Etxebarria*[7,8], *Olatz Zuloaga*[3,9], *Maitane Olivares*[10,11] *and Ailette Prieto*[2,9], *(1)University of the Basque Country (UPV/EHU), Spain, (2)Research Centre for Experimental Marine Biology and Biotechnology (PiE-UPV/EHU), Spain, (3)Plentzia Marine Station of Basque Country University (EHU/UPV), Spain, (4)Department of Effect-Directed Analysis, Helmholtz Centre for Environmental Research (UFZ), Germany, (5)Helmholtz Centre for Environmental Research (UFZ), Germany, (6)Analytical Chemestry, University of the Basque Country (UPV/EHU), Spain, (7)Department of Analytical Chemistry, University of the Basque Country (UPV/EHU), Spain, (8)Research Centre for Experimental Marine Biology and Biotechnology (Plentzia Marine Station; PiE-UPV/EHU), University of the Basque Country (UPV/EHU), Spain, (9)Analytical Chemistry, University of the Basque Country (UPV/EHU), Spain, (10)Analtytical Chemistry, Research Center for Experimental Marine Biology Biotechnology "Plentziako Itsas Estazioa", University of the Basque Country (PiE-UPV/EHU), Spain, (11)Analytical Chemistry, Research Centre for Experimental Marine Biology and Biotechnology (PiE-UPV/EHU), Spain*

Wastewater treatment plants (WWTPs), originally not designed for the elimination of contaminants of emerging concern (CECs), are grappling with alternative strategies such as membrane bioreactor (MBR) technology to efficiently eliminate CECs and mitigate their potential environmental impact. This study evaluated the efficiency of two secondary treatments, conventional activated sludge (CAS) and MBR treatments, implemented at the largest WWTP in the Basque Country (Galindo, Biscay). Employing a suspect screening approach through liquid chromatography tandem high-resolution mass spectrometry (LC-HRMS) and multitarget analysis via both, LC-HRMS and gas chromatography-mass spectrometry (GC-MS), nearly 200 compounds were detected in both WWTP effluents. Removal efficiency (RE) evaluation revealed that merely 16 micropollutants exhibited enhanced removal by MBR (RE > 70 % or 40 – 60 %). The environmental risk, based on model calculation, posed by non-eliminated compounds post-treatment remained similar in both cases. Notably, anthracene, clarithromycin, bis(2-ethylhexyl) phthalate (DEHP), and dilantin were pointed out as the most potentially toxic compounds, exceeding the threshold of RQ > 1. The Microtox® bioassay experimentally confirmed the efficiency of MBR in baseline toxicity removal, while suggesting a similar performance of CAS treatment. These minimal treatment differences prompt reconsideration of the worthiness of MBR treatment, highlighting the essential quest and development of more efficient alternative treatment methods.

3.18.C.T-02 Bioaccumulation Of Emerging Contaminants: A Fishy Story

Ganna Fedorova[1], *Petra Galicova*[1], *Jitka Kolarova*[1], *Tomáš Randák*[1] *and Bryan W. Brooks*[2], *(1)University of South Bohemia in České Budějovice, Faculty of Fisheries and Protection of Waters, Czech Republic, (2)Environmental Science, Environmental Science & Public Health, Baylor University*

The ubiquitous occurrence of contaminants of emerging concern, as well as their environmental and health impacts, is an issue of high concern. Therefore, aquatic organisms living in water bodies affected by the effluent of wastewater treatment plants (WWTPs) are exposed throughout their lives to mixtures of various compounds. Effluent-dominated ecosystems represent worst-case scenarios for the exposure and potential adverse effects. The uptake of contaminants from polluted water or via food can lead to bioconcentration/bioaccumulation of these compounds in aquatic organisms.

Measurement of pharmaceuticals in fish has been proposed as a way of assessing potential hazards by comparing observed levels in fish blood plasma to human therapeutic plasma doses. The apparent volume of distribution (V_D) is a theoretical value representing how extensively a drug distributes throughout the body. V_D values can be used to estimate body burden by analyzing contaminants in fish plasma. In the current study, we employed an ecosystem-based treatment system, specifically employing a treated wastewater pond, which receives 100% treated WWTP effluent as a tertiary treatment component. The objective of this study was to calculate V_D for a broad range of contaminants for two fish species and estimate the time needed for their elimination from the fish body, aiming to provide recommendations for the safe consumption of fish produced in wastewater.

We detected a few of the studied contaminants in fish from wastewater pond. Only trace levels were observed for most of them, which were comparable with those found in wild fish. Moreover, some compounds were eliminated after a few days spent in the clean water. The results indicate that reusing wastewater for fish production is not only sustainable but also a relatively safe option with respect to the contaminants of emerging concern. Calculated V_D values will allow us to estimate the body burden using the analysis of fish blood plasma only, avoiding killing the fish.

3.18.C.T-03 On the Trail of Persistent Mobile and Toxic Compounds in Urban Stormwaters: Case Study of Barcelona Municipality

Filippo Chierchini[1]*, Sergio Santana-Viera*[2]*, Francesc Labad Roig*[1]*, Marc Teixidó*[3] *and Sandra Perez Solsona*[1]*, (1)Onhealth, Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain, (2)Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain, (3)Geosciences, Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain*

Persistent, mobile, and toxic (PMT) chemicals are contaminants of recent interest for urban water quality, increasingly at risk due to the rise in urbanization and extreme events. Despite many polar and persistent compounds have already been detected in various water sources, scarce monitoring data has hindered their comprehensive resolution. Conventional water treatments frequently prove ineffective in their removal, given the persistence and their high mobility, they can end up in both ground and surface waters. In 2019, German environmental authority UBA issued a list of PMT substances registered under the REACH, offering a relative prioritization grounded in a preliminary emission assessment.

Stormwater harvesting represents a promising resource, particularly in densely populated arid regions marked by water scarcity. Simultaneously, it is acknowledged as a significant driver of contamination. This holds true case for "sponge cities", where urban planning and design strategies are crucial for the sustainable management and utilization of rainwater. Among these, installation of stormwater blue-green infrastructures (BGI) is a promising practice in order to mitigate contamination, while recharging receiving urban aquifer and containing combined sewer overflow (CSO).

Herein, urban stormwater "first flushes" from various sites over 3 districts across the municipality of Barcelona, were collected during the period March to April 2022. Sampling design included conventional and pedestrian streets runoff through an evaporative enrichment methodology employed for targeted screening using a LC-MS/MS method. 34 PMTs of urban interest were selected, 14 of them being reported also in the UBA list of 2019. In this preliminary analysis, we observed that all targets were detected in at least one sample, among them 5 chemicals as benzenesulfonamide, 1,3 diphenylalanine, di-n-butyl phosphate, tolytriazole and TCPP, resulted to be the more abundant with median concentrations higher than 100 ng L^{-1}. Moreover, BGI effluent resulted in a diminished contamination load.

Results will eventually undergo thorough analysis to evaluate the extent in spatiotemporal domain of contingent related contamination. PMTs substances impacting urban stormwaters must be monitored in order to prevent spread in surface and ground waters and enable their safe use for water supply.

3.18.C.T-04 The Journey of Organic Micropollutants from Water towards Soil and Crops in a Reclaimed Water Irrigation System

Gianluigi Buttiglieri[1]*, Sara Rodriguez-Mozaz*[1]*,* ***Lucas Leonel Alonso***[1]*, Marc Castaño Trias*[1]*, Lúcia Santos*[1]*, Sofia Semitsoglou*[1]*, Evangelios Statiris*[2]*, Costas Noutsopoulos*[2] *and Simos Malamis*[2]*, (1)Catalan Institute for Water Research (ICRA), Spain, (2)National Technical University of Athens, Greece*

In the last decades, water scarcity has become a challenging issue, especially in arid and semi-arid regions, such as the Mediterranean basin. Agriculture is among the sectors threatened by water scarcity and reclaimed water for irrigation could be a promising alternative but organic micropollutants must be evaluated because they can make their way into the food chain and pose a challenge regarding food safety and human health. This work assessed the uptake of a variety of organic micropollutants, including pharmaceuticals, antibiotics, and endocrine disrupting compounds in three different matrices (water, soil, crops). Briefly, the wastewater treatment system consists of an upflow anaerobic sludge blanket reactor, a constructed-wetland system, and finally a tertiary treatment. The reclaimed water is collected in storage tanks and applied for irrigation on adjacent horticultural fields. First, the demonstration scale wastewater treatment plant in a water scarce area was sampled, in two different seasons and the removal efficiencies of the treatment steps were calculated. Afterwards, the organic micropollutant content was evaluated also in the soil and in three crops (lettuce, lavender, oregano) irrigated with the treated effluent of the wastewater treatment plant. The organic micropollutants were detected in the soils before and after the growth periods as well as in the corresponding control soils. As to the crops, reclaimed water irrigation resulted in slightly higher concentrations of the same contaminants in the leaves, whereas root composition was largely different. Finally, both environmental and human health risk assessments of the wastewater-derived organic contaminants detected in irrigation water were performed based on the obtained results. This study can provide an overall assessment as regards organic micropollutants from regenerated wastewater including in water scarce areas irrigation water, soil, and crops data.

3.18.C.T-05 Assessing the Impact of Municipal Effluent Discharge on a Small Watercourse in Aartselaar, Belgium: A Multi-Level Evidence Approach.

***Birte Raes**[1] and Maarten De Jonge[2], (1)Aquafin , Netherlands, (2)Flanders Environment Agency, Belgium*

Urban wastewater treatment plants (UWWTP's) in Flanders (Belgium) are compliant with the European Urban Wastewater Treatment Directive (UWWTD). However, recent evaluation of the directive identified residual pollution from urban sources as one of the three remaining challenges leading to a proposal for a revised UWWTD (91/271/EEC). Part of the remaining pollution is due to micropollutants, that impose risks for health and environment at low concentrations. The Flemish wastewater treatment utility (Aquafin) and the Flanders Environmental Agency (VMM) are monitoring micropollutants and ecotoxicity since May 2022 at the UWWTP of Aartselaar (BE) to gain insight in the contribution of UWWTP's to the aquatic ecotoxicity and the biotic communities present. The selected UWWTP treats domestic wastewater of about 60.000 population equivalents and discharges into the Grote Struisbeek, a small water body with a downstream flow rate of 0.2 to 1.3 m^3/s. In dry periods, the discharge makes up 60% of the total flow in the water body, therefore contributing significantly to its water quality, its ecotoxicological status and its biotic communities. More than 150 chemical substances, as well as 10 toxic end points (both *in vivo* and *in vitro*) were monitored in effluent of the UWWTP and in both upstream and downstream surface water, following the recommendations concerning monitoring methodology of the Dutch government. Proper flow rate data is collected to calculate load contributions from the UWWTP through a mass balance. Due to inconsistency of analytical limits of quantification (LOQ) on the one hand and predicted no-effect concentrations (PNEC) on the other hand, analysis of chemical substances on its own was insufficient to make a proper judgement. Meanwhile, monitoring toxic end points and biological communities appears to provide useful insights concerning the impact of effluent discharge. For certain chemicals and effects, toxicity of municipal effluent is clearly affecting downstream water quality in the Grote Struisbeek, often exceeding an environmental trigger value, as is for example the case for estrogenic toxicity. Currently, a quaternary treatment step, including ozone and granular activated carbon, to remove micropollutants, is taken in operation at the UWWTP in Aartselaar. Continued monitoring will help to understand water quality improvements that can be achieved by a post-treatment in cases with a similar context as the UWWTP of Aartselaar.

3.18.P Next-Generation Urban Water Management: Improved Understanding of the Fate of Micropollutants, Transformation Products, Pathogens, and Antimicrobial Resistance

3.18.P-Mo280 Bioretention Cell Design for Trace Organic Contaminant Removal

***Tim Frederick Mainguy Rodgers, PhD**[1], Sylvie Spraakman[2], Yanru Wang[1], Cassandra Johannessen[3], Rachel C Scholes[1] and Amanda Giang[4], (1)Department of Civil Engineering, University of British Columbia, Canada, (2)Engineering Department, City of Vancouver, Canada, (3)Chemistry and Biochemistry, Concordia University, Canada, (4)University of British Columbia, Canada*

Stormwater rapidly moves an "urban cocktail" of chemicals from the built to the aquatic environment, including many trace organic compounds (TrOCs). The risks posed by TrOCs to people and the environment depend on their toxicity and on their physicochemical properties, which influence how people and ecosystems are exposed. Bioretention cells, a green infrastructure technology, are traditionally designed primarily to provide hydrological benefits, but can also reduce loadings of some TrOCs to receiving bodies.

Herein, we used the Bioretention Blues model to simulate the fate and behavior of seven environmentally relevant TrOCs with representative log K_{OC} values between -1.5 to 6.74 in a bioretention cell for 28 design storms. Next, we tested combinations of eight design and management interventions and assessed the design potential and tradeoffs involved in optimizing bioretention systems for chemicals found in three illustrative use-cases. These use-cases represented a major highway next to a salmon-bearing stream receiving 6PPD-quinone ((N-(1,3-Dimethylbutyl)-N'-phenyl-p-phenylenediamine-quinone) and 6PPD; a residential area receiving TCEP (tris(2-chloroethyl) phosphate), PHE (phenanthrene), and B[a]P (benzo[a]pyrene); and an airport receiving PFOA (perfluorooctanoic acid) and (1H-) benzotriazole. We found that the optimal designs for the highway, residential, and airport scenarios reduced effluent loadings of all but the most polar compounds to <5% of influent mass, showing that substantial improvements in TrOC removal could be achieved through bioretention design. Further, our results suggest that the most important intervention for hydrophobic compounds was to increase the system area, while for hydrophilic compounds adding an amendment like biochar was by far the most effective. Our results show that the design of bioretention systems can allow them to effectively capture chemicals like 6PPD-quinone or PFOA (perfluorooctanoic acid), protecting important aquatic species like salmon and human health from chemical impacts.

3.18.P-Mo281 Identification of priority contaminants in groundwater for their protection and pollution prevention

***Natalia Sáez Rosique**[1], Teresa Garrido[2], Marta Expósito[2], Josep Fraile[2], Yolanda Soriano Juan[3], Yolanda Pico[4], Josep Mas-Pla[1], Mira Petrovic[1] and Meritxell Gros[1], (1)Catalan Institute for Water Research (ICRA), Spain, (2)Catalan Water Agency (ACA), Spain, (3)University of Valencia, Spain, (4)Centro de Investigaciones sobre Desertificación, Universidad de Valencia, Spain*

The increasing prevalence of global drought is a current challenge requiring urgent exploration of solutions to ensure water supply. In areas with limited restricted water availability and poor quality, groundwater bodies are an essential resource and require protection against chemical pollution. Indeed, Directive 2018/80/EU, which modifies Annex II of Directive 2006/118/EC, related with groundwater pollution and deterioration, emphasizes the need to define a comprehensive list of priority contaminants that may represent a potential risk to groundwater bodies. Thus, groundwater quality assessment grows into an evident need and monitoring studies are needed to identify such substances for inclusion in surveillance lists. In this context, the Catalan Water Agency (ACA) has established a monitoring network to identify and quantify selected emerging pollutants at control sites, with the aim of assessing the risk they pose to groundwater bodies and evaluate their suitability to be included in a watch list for further monitoring.

A total of 231 sampling locations will be analysed, comprising 137 points in agricultural areas and 94 in sites with urban and/or industrial influence distributed throughout Catalonia during the 2022 – 2024 timeframe. In these samples, 11 indicator pharmaceuticals (PhACs) and 12 perfluoroalkyl substances (PFAS) in the urban and industrial sites, along with 12 veterinary antibiotics in the agricultural areas, were measured using Ultra High Performance Liquid Chromatography coupled to tandem mass spectrometry (UHPLC-MS/MS).

Preliminary results have shown the detection of a wide range of PhACs, including primidone, sulfadiazine, sulfamethoxazole, and significant concentrations were observed, particularly for amidotrizoic acid, from 16 to 1374 ng/L and carbamazepine, from 1.30 to 168 ng/L. For PFAS, 7 analytes were identified, with perfluorooctanesulfonic acid (PFOS) notably standing out at a concentration of 1147 ng/L in a specific location. Finally, the presence of antibiotics is limited to a smaller number of sites, being sulfamethoxazole and sulfamethazine, the most ubiquitous compounds found at relatively low concentrations.

3.18.P-Mo282 How should we implement quaternary treatments in Wastewater Treatment Plants? A techno-economic analysis

Jessica Ianes[1], *Fabio Polesel*[2], *Beatrice Cantoni*[3], *Enrico Elisse Remigi*[2] *and Manuela Antonelli*[4], *(1)Politecnico Milan, Milano, Italy, (2)Dhi Group, (3)DICA, Politecnico di Milano, Italy, (4)Politecnico di Milano, Italy*

Micropollutants are a class of compunds found at trace level in the environment. They are released by several sources, but wastewater treatment plants (WWTPs) represent one of the biggest, since they are not designed to remove micropollutants. Currently, the revision of the Urban Wastewater Treatment Directive (UWWTD) addresses the problem of micropollutants (MPs) released by WWTP: a specific set of pharmaceuticals and cosmetics are required to be removed with a minimun efficiency of 80%. Among the best available technologies suggested and largely studied there are adsorption and ozonation. These technologies are widely applied for drinking water production, but they are scarcely applied in WWTPs. Moreover, these processes can be implemented with different configurations, but there are no indications on the design and type of implementation in the revision of the UWWTD. Furthermore, in the future the directive could be modified to include more MPs in the set of the targeted MPs, such as PFAS.

With this study we propose an approach to evaluate the costs associated with quaternary treatments, depending on several factors. A model was developed in WEST (DHI A/S) to (i) predict the removal of MPs by ozonation and by adsorption on activated carbon, and (ii) evaluate the best configuration for the selected wastewater treatment plant, depending on the specific target removal to be approached. In detail, not only the 80% removal, as stated in the UWWTD, will be used as target, but also we will refer to the removal that allows to guarantee a negligible environmnetal risk in the effluent. For each configuration, CAPEX and OPEX will be estimated and the results will be compared in order to identify the best solution.

In particular, as for adsorption, two configurations will be considered based on the activated carbon size: Powdered Activated Carbon (PAC) with recirculation, and Granular Activated Carbon (GAC) in fixed-bed columns. Pore diffusion and surface diffusion are included in the model and competition with the organic matter is also considered, using the simplified Ideal Adsorbed Solution Theory (IAST) model. Different combinations of filtration, GAC/PAC, ozonation and clariflocculation are compared.

This study provides a useful approach to allow water utilities identifying best quaternary solutions for their own WWTP, based on influent characteristics, WWTP layout, target removal, and costs.

3.18.P-Mo283 Development of a holistic (bio)analytical platform to assess the hazard of transformation products formed during water treatment

Ingrida Bagdonaite[1], *Marja Lamoree*[2] *and Frederic Béen*[2,3], *(1)Chemistry for Environment and Health, Vrije Universiteit Amsterdam, Amsterdam Institute for Life and Environment (A-LIFE), Netherlands, (2)Vrije University Amsterdam, Netherlands, (3)KWR Water Research Institute, Netherlands*

Organic micropollutants (OMPs) are widely distributed throughout the aquatic environment and pose significant difficulties for (waste)water treatment. In (waste)water treatment facilities advanced oxidation processes (AOPs), such as UV photolysis, are implemented for the removal of OMPs with the use of ultraviolet (UV) light and hydrogen peroxide (H_2O_2). When undergoing AOP treatment, contaminants tend to react and form unknown and potentially toxic transformation products (TPs). The main challenge in the characterization of unknown TPs consists of the development of a scalable and comprehensive method to detect and identify TPs, asses their potential (in-vitro) toxicity and link their formation to AOP and water characteristics. The development of such a method would allow us to obtain a better understanding of the conditions under which potentially hazardous TPs are being formed. Liquid chromatography coupled to high-resolution mass spectrometry (LC-HRMS) combined with non-target screening (NTS) is typically employed for chemical analysis of complex environmental samples. While NTS is a powerful tool for environmental analysis, it faces challenges related to data complexity, potential for false results, limited availability of reference standards, matrix effects and the need for significant computational resources. Addressing these issues is crucial for reliable identification and quantification of environmental contaminants. In this work, we present a (bio)analytical platform that relies on LC-HRMS, (in-silico) hazard assessment, high-throughput fractionation and effect-directed analysis (EDA), to detect and where possible characterize hazardous TPs formed during the (waste)water treatment. Our aim is to link the chemical and hazard space of TPs by understanding under which conditions they are formed and their potential (in-vitro) toxicity. For this purpose, we will implement in-silico approaches to predict the formation of TPs based on (predicted) molecular structures and enhance the discovery and identification rates of TPs. The first part of this study is focused on (i) defining the chemical space and hazard space in which we will operate the (bio)analytical platform, and (ii) testing available in-silico tools on our test data set to obtain a preliminary overview of expected TPs as well as their toxicity.

3.18.P-Mo284 AI Assistance for Chemical Analysis of PPCPs in Water and Wastewater: Highlights and Potentials

Babak Kavianpour[1]*, Farzad Piadeh*[2]*, Mohammad Gheibi*[3]*, Atiyeh Ardakanian*[2] *and Kourosh Behzadian*[2]*, (1)University of West London, London, United Kingdom, (2)University of West London, United Kingdom, (3)Association of Talent Under Liberty in Technology (TULTECH), Estonia*

A critical step in suspect or non-targeted analysis is to tentatively ascertain the existence of compounds using HRMS data compared with spectral libraries and then confirm them by reference standard substances. The challenges arise when many compounds are deemed to be detected or when the reference materials are not readily available, especially in the case of transformation or degradation products in complex environmental or wastewater matrices. To address this and to enhance confidence, artificial intelligence (AI) methods have facilitated the prediction of the retention time (RT) and collision cross section (CCS). However, the models validated versus real water and wastewater samples have not been surveyed sufficiently.

This presentation reviews selected features of AI-assisted chemical analysis of pharmaceuticals and personal care products (PPCPs) applicable in water and wastewater real matrices and highlights the potential for further research into this domain. The results show the importance of external validation, preferably by environmental samples, since the best-selected AI method during training and internal blind testing over the dataset for model development can differ from the most suitable one for new compounds. We envisage that AI-assisted models for predicting CCS considered as a matrix- or case-independent factor, either as single output or combined with RT, will be applied for future studies more frequently, especially for unknown detection of PPCPs and their metabolites, as well as their transformation and biodegradation products in the effluent of wastewater treatment plants and surface waters.

3.18.P-Mo285 Monitoring of Contaminants of Emerging Concern in Alternative Sources for Indirect Potable Water Reuse in Barcelona

Miren Lopez De Alda Villaizan[1]*, Dana Orlando Véliz*[2]*, Rocío Inés Bonansea*[3]*, Josep Sanchís*[4]*, Josep Fraile*[4]*, Carolina Sola*[4] *and Antoni Munne*[4]*, (1)Environmental Chemistry, Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain, (2)Enviromental Chemistry, Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain, (3)Environmental Chemistry, National University of Cordoba, Argentina, (4)Catalan Water Agency (ACA), Spain*

In the last decades, Catalonia and in particular the area of Barcelona has suffered several climate extreme events. Since the beginning of 2021, it has been immersed in a sustained situation of meteorological drought that has put significant pressure on its water resources. In an effort to find solutions to this situation, the Catalan Water Agency (ACA) has started to search for alternative water sources with the aim to increase the availability of pre-potable water in the Catalan River Basin District. As a first step in this process, water samples collected from several potential sources were subjected to a suspect screening study that allowed to identify and prioritise the presence according to risk of 57 contaminants of emerging concern (CECs) in them. As a follow up, the occurrence of these CECs in the potential water sources is currently being investigated in a more comprehensive way using target analytical methods. The results of the analysis of 16 of them, which include pesticides, pharmaceuticals, drugs of abuse, personal care products and industrial chemicals, is reported in the present work. Their analysis in waters from 3 investigated scenarios was performed by means of on on-line solid phase extraction-liquid chromatography-tandem mass spectrometry (SPE-LC-MS/MS) using different methods. All compounds were detected in at least one sample with the exception of Atrazine-desethyl (values below LOD: 0.03 ng/L). The most frequently detected compounds, present in all samples, were Carbendazim, O-Desmethyl-venlafaxine, N,N'-Diphenylguanidine, 4+5-Methylbenzotriazole, and Galaxolidone. In terms of concentration, the most abundant compounds were Sitagliptin (concentrations up to 60 µg/L), Galaxolidone (up to 11 µg/L), 4+5-Methylbenzotriazole (up to 4.1 µg/L), and O-desmethyl venlafaxine (up to 4.1 µg/L). Contaminants loads decreased from wastewater to surface water and ground water. Principal Component Analysis of the data allowed to differentiate the samples according to location and type of water matrix. Preliminary assessment of the risk using human health-based thresholds suggest potential risk in the case of Galaxolidone, Sitagliptin, and Benzoilecgonina in some samples. The results of this study and those conducted in parallel for other contaminants will be used to ensure the functionality of the investigated scenarios as pre-potable water resources and to define the optimal treatment trains to implement in upcoming purification plants.

3.18.P-Mo286 Methods for Identifying Priority Chemicals in Wastewater and Estimating Their Relative Environmental Risks: A Critical Review

Sagar Thakali[1] *and Jennifer K. Saxe*[2]*, (1)Kenvue, (2)KENVUE*

Researchers have proposed various approaches to identify and prioritise chemicals in wastewater and assess their relative environmental risks, which are critical to understand for judicious attribution of sources and subsequent allocation of resources to mitigate exposure. This study will review the literature on existing prioritisation approaches for chemicals in wastewater and estimation of their relative environmental risks, with particular focus on their original study purpose, the underlying technical basis, and their strengths and limitations. Most existing approaches rely on a measure of risk for chemicals prioritisation, as typically represented by the ratio of the environmental concentration (exposure) to the ecotoxicity benchmark (effect). However, the identification/establishment of an appropriate ecotoxicity benchmark depends on number of factors, including quality and quantity of available data for a specific chemical and an accounting of associated uncertainty. The uncertainty in ecotoxicity benchmarks is well known to factor critically in the reliability of risk-based prioritisation of chemicals in wastewater. Hence, this review will identify key considerations when attempting to attribute chemical-related environmental risks, focusing particularly on the use of discrepant ecotoxicity benchmarks and associated implications on prioritisation and relative estimates of risk, as well as potentially critical data gaps in ecotoxicity benchmarks for chemicals in wastewater. We use the proposed Urban Wastewater Treatment Directive Extended Producer Responsibility program as a case study to address the potential practical implications arising from scientific methodological choices.

3.18.P-Mo287 Impact of Drinking Water Treatment processes on Biocides in the EU
Sara Carreira[1] *and Lydia Pape*[2]*, (1)knoell Iberia S.L., Spain, (2)knoell Germany GmbH, Germany*
The Biocidal Product Regulation (BPR) (EU) 528/2012 regulates the placing on the market and use of biocidal products and ensures a high level of protection for human health and the environment. During the evaluation of active substances (AS) in biocidal products (BP) under BPR, a conclusion on the impact of water treatment processes on residues of AS and their metabolites in water abstracted for the production of drinking water could not be drawn so far. To fill in this information gap, ECHA and EFSA jointly developed a new guidance document "Impact of water treatment processes on residues of active substances or their metabolites in drinking water", published in August 2023. It aims to provide a clear framework for risk assessors and facilitate risk managers decisions concerning the approval of AS and products authorisation.

The guidance enables the identification of public health concerns from exposure to harmful by-products in drinking water and focuses on water treatment methods commonly used in the EU.

To ensure a proportionate approach and avoid unnecessary testing, a tiered framework is proposed in order to provide information on:

- Water residues that require further assessment;
- New potentially harmful transformation products that may be formed during drinking water treatment; and
- How to conduct a risk assessment that considers consumption of drinking water.

For the biocides sector, this guidance document means that, before they can market new products, manufacturers will be required to demonstrate that the products do not pose a danger to drinking water production.

ECHA proposed that the applicability of this guidance would be only for future applications outside of the review program (RP) or at the renewal of the approval (RNL) (excluding ongoing renewal evaluations). Therefore, the guidance would not apply to the RP substances under evaluation or those currently under RNL procedure. For product authorisations, the guidance is proposed to be applied, only once it has been used in the evaluation of the active substance(s) the product contains.

The presentation will provide details on the implementation of the new drinking water treatment guidance on the assessments for biocidal AS approvals/BP authorisations and discuss consequences and challenges for applicants.

Keywords**:** Biocides, active substance approval, biocidal product, drinking water treatment, chlorination, ozonation, UV disinfection, sand filtration.

3.18.P-Mo288 IDEN2REMOVE: Identification and Removal of Site-Specific Organic Pollutants to Preserve the Quality of Water Resources
Cristina Postigo[1]*, Jorge Ignacio Pérez-Pérez Prof*[2]*, Begoña Moreno-Escobar Dr.*[3]*, Luz Marina Ruiz-Hernández Dr.*[4]*, Ove Jonsson*[5]*, Susan D. Richardson Prof*[6] *and Miguel Angel Gómez-Nieto Prof*[1]*, (1)Civil Engineering / Institute of Water Research (IdA), University of Granada (UGR), Spain, (2)Building Engineering and Engineering Projects, University of Granada (UGR), Spain, (3)Building Engineering and Engineering Projects, Universidad de Granada, Spain, (4)Civil Engineering, Universidad de Granada, Spain, (5)Department of Aquatic Sciences and Assessment, Swedish University of Agricultural Sciences (SLU), Sweden, (6)Chemistry and Biochemistry, University of South Carolina*
The project IDEN2REMOVE aims at tackling organic pollution in water, which is one of the major causes of water quality impairment. It will deliver tools to uncover site-specific priority pollutants (SSPPs) in the different stages of the urban water cycle, so that preventive and corrective measures can be adopted to reduce or even avoid exposition to these chemicals. The proposed research i) will deliver a low-tech and low-cost active sampler to collect and simultaneously concentrate by solid-phase extraction time-integrated water samples, and ii) will advance current state-of-the-art methodologies for wide-scope screening of organic micropollutant mixtures with high-resolution mass spectrometry, in the sense that will cover the most

polar (and unknown) fraction of these mixtures. Information-rich data will be handled with advanced computing software and chemometric tools to characterize organic micropollutants present in each mixture. Moreover, the work conducted in the framework of this project iii) will provide a prioritization index based on the occurrence and hazard properties of the organic micropollutants detected in the water to identify SSPPs, and iv) will explore advanced treatment technologies currently used in water potabilization and regeneration treatment trains (i.e., ozonation, UV irradiation, membrane filtration, and granular active carbon filtration) to remove SSPPs from water. An additional outcome of the project will be v) the information to end-users (citizens) and stakeholders in the water sector on the research topic addressed by IDEN2REMOVE. The project is built on multi- and inter-disciplinary research, based on the collaboration of experts in environmental analytical chemistry and water treatment technologies. Besides reviewing the main objectives and expected impacts of IDEN2REMOVE, the work presented will introduce the three water circular economy labs where the project will be implemented and will present the first results obtained in its first steps regarding the low-tech and low-cost active water sampling device, and the methodolgy to be applied for wide-scope characterization of organic micropollutants mixtures in water.

3.18.P-Mo289 An integrated modelling framework for predicting wet-weather discharges pollution

Jessica Ianes[1]*, Fabio Polesel*[2]*, Beatrice Cantoni*[3]*, Luca Vezzaro*[4]*, Enrico Elisse Remigi*[2] *and Manuela Antonelli*[5]*, (1)Politecnico Milan, Milano, Italy, (2)Dhi Group, (3)DICA, Politecnico di Milano, Italy, (4)Department of Environmental and Resource Engineering, Technical University of Denmark (DTU), Denmark, (5)Politecnico di Milano, Italy*

Wet-weather discharges from urban areas by combined wastewater systems represent a threat for surface waters: when the system capacity is reached during medium/big rain events, an untreated mixture of stormwater and wastewater is discharged through combined sewer overflows (CSOs) or bypass (BP) of wastewater treatment plants (WWTPs) to a receiving water body. There is currently a lack of knowledge on the actual activation of CSOs and the actual volume and pollution discharged by each system, due to lack of proper monitoring and modelling tools. However, the proposal for the revision of the Urban Wastewater Treatment Directive (UWWTD) proposes to assess the pollution and volumes discharged during wet-weather events and limits the laods discharged to a small percentage of the collected wastewater during dry-weather (1% to 3%). It is clear that to be able to perfom this assessment, proper modelling tools are needed.

An integrated modelling framework was applied to a specific case study. The system considers not only the sewer sytem with all CSOs, but also the WWTP with the bypass. Data available on hydraulics of the sewer system were limited to few flowmeters and info on activation and deactivation of CSOs in time. Many information were present on the WWTP and on the bypass, including flowrate. Monitoring campaigns were then performed at the WWTP, both in wet-weather and in dry-weather. Moreover, samples were collected of the WWTP bypass at different timeframes for 7 events in 2023.

A conceptual model of the system was developed and implemented in WEST (DHI A/S). Both the hydraulic model and the quality model were calibrated in dry-weather and in wet-weather. It was possible to predict the activations of different CSOs structures, the volumes and the pollution discharged. Moreover, a comparison between the loads contribution of CSOs, WWTP bypass, and effluent of the WWTP was performed, together wth a comprehensive risk assessment.

This study will allow for a comprehensive understanding of the loads discharged by an entire catchment, including combined sewer system, CSOs, WWTP bypass, and WWTP effluent in dry- and wet-weather conditions. Based on this findings, proper interventions on the system can be planned and the efficacy of the implementation can be evaluated in advance.

3.18.P-Mo290 Evaluating the Occurrence of Chemicals of Emerging Concern in Tomato Plants: A Field Study on Agricultural Wastewater Reuse

Eirini Andreasidou[1,2]*, Ana Kovačič, Dr*[2,3]*, David Heath*[3]*, Marina Pintar*[4]*, Špela Železnikar*[4]*, Nina Kacjan Maršič*[4] *and Ester Heath*[2,3]*, (1)Jozef Stefan Institute, Slovenia, (2)Jozef Stefan International Postgraduate School, Slovenia, (3)Jozef Stefan Institute, Department of Environmental Sciences, Slovenia, (4)Department of Agronomy, Biotechnical Faculty, University of Ljubljana, Slovenia*

With increasing global concerns over water scarcity, there is growing emphasis on employing sustainable agricultural practices, such as wastewater reuse. However, the utilisation of treated wastewater can potentially introduce chemicals of emerging concern (CEC) into the environment. These chemicals can then be taken up into the edible parts of plants, entering the food chain and posing a potential risk to human health. This study investigates the safety of employing treated wastewater in tomato cultivation, focusing on the uptake of 27 CEC from different categories, through three specific aims: (1) to evaluate the uptake of CEC in tomatoes grown in soil and soilless media; (2) to study the translocation of CEC in plants; and (3) to assess dietary exposure to CEC from consumption of wastewater irrigated tomatoes. Our experiments involve hydroponic and lysimeter experiments, each consisting of four distinct growing regimes: potable water, potable water with the addition of CEC (1 mg/L), treated wastewater, and treated wastewater with the addition of CEC (1 mg/L). Aqueous and plant samples were extracted with validated methods based on solid phase extraction (Prime HLB 96 well plate 30 mg: aqueous samples) and ultrasound extraction (3 cycles, 20 minutes) followed by centrifugation (9000 rcf, 20 minutes) and solid phase extraction

(Prime HLB 500 mg: tomato samples) and extracts were analysed using liquid chromatography-tandem mass spectrometry. In hydroponically grown tomatoes irrigated with spiked media, 11 compounds were identified above the limit of quantification when using spiked potable water and 12 compounds in tomatoes irrigated with spiked treated wastewater. There was lower uptake in soil experiments, with only 4 compounds above the limit of quantificationin tomatoes irrigated with spiked potable water and 8 in tomatoes irrigated with spiked treated wastewater. The results will be used for risk assessment and understanding the translocation of potentially toxic organic compounds when applying wastewater reuse in agriculture. Finally, this study will add to the broader conversation about the safety of consuming crops grown using treated wastewater. With water resources becoming increasingly scarce, these findings underscore the critical significance of responsible wastewater management in safeguarding our food supply and advancing sustainable agricultural practices.

3.18.P-Mo291 Biocide Contamination of Domestic Greywater: an Indicator of Uses by Inhabitants
Pierre Louis Martinache[1], *Amandine Naprix*[2], *Lila Boudahmane*[2], *Emilie Caupos*[3], *Régis Moilleron*[2] *and Adèle Bressy*[2], *(1)ParisTech School of Bridges, France, (2)Leesu, Ecole des Ponts, Univ Paris Est Creteil, France, (3)Univ Paris Est Creteil, CNRS, OSU-EFLUVE, France*
Biocidal substances are used in several areas of the domestic environment (pharmaceuticals and personal care products, pesticides, cleaning products, etc.) but they can be a threat to environmental and human health. It is therefore essential to characterize contamination by biocidal substances in domestic greywater, which is too poorly documented. This will enable us to estimate the contribution of domestic activities to the biocidal substance discharges into the receiving environment. The aim of this research is (i) to conduct a survey on inhabitant habits in terms of product used and practices; (ii) to characterize domestic greywater contamination by analysing 29 prioritized biocidal substances; and (iii) to compare both approaches in order to assess the effect of inhabitant habits on greywater contamination. To carry out this study, greywater samples were taken from seven dwellings in the Paris conurbation (four washing machine samples, six manual dishwashing samples, five floor cleaning samples, four shower samples and one sink sample). 29 biocidal substances were quantified by liquid chromatography and tandem mass spectrometry. Information about the formulation of products used by participants was collected in order to establish a link between uses and contamination. 3 investigations were conducted in supermarkets to complete information about formulation and improve knowledge on marketed products. 26 molecules were quantified in at least one of the 20 samples. Four substances have a quantification frequency higher than 75%: 3 quaternary ammonium compounds (QACs) and 1 isothiazolinone. The substances quantified vary from one dwelling to another, but much more so according to the type of greywater used. Floor greywaters are the most concentrated when manual dishwashing and shower are the less concentrated. The highest concentrations were measured for QACs(benzalkonium chloride C16 > 20,000 ng/L) in floor greywater. Isothiazolinone and QAC concentrations are highest in greywater in line with the results of the market and inhabitant's surveys, which highlights the predominance of these molecules. The maximum concentration of cypermethrin measured exceeds 6,000 ng/L and can be explained by the presence of carpeting in corridors outside the dwelling. This new database gives us an idea of biocidal contamination in dwellings. The final aim is to estimate the daily tonnages of biocidal substances emitted from domestic environments via greywater.

3.18.P-Mo292 Advancing Technologies to Minimize Micro- and Nano-plastics (MNPs) in Industrial Laundry Wastewater from Bisperbjerg Hospital (Copenhagen, Denmark).
Olga Novillo Sanjuan, *Sophia Helena Andersen, Rosa Maria Falk Nørgaard, Dan Zhao, Angela Wenjing Zhang and Nanna B. Hartmann, Encvironmental and Resource Engineering, Technical University of Denmark (DTU), Denmark*
Washing textiles can release millions of microfibers into the water. Of these, more than half are estimated to be synthetic and eventually transform into MNPs (-micro, -nanoplastics) in the aquatic environment. Once in WWTPs, wastewater undergoes different filtration processes that capture MPs, among other hazardous materials. The efficiency of these processes is remarkably high, however, the volume of water filtered by these facilities daily and worldwide is so high that, still, massive amounts of MNPs are released altogether into the environment. Additionally, current technologies do not target sub-micron sized particles, hence, nanoplastics are expected to cross these membranes.

Targeting hotspots can be useful for testing new technologies that would allow for better water depuration. Previous studies have demonstrated that washing of textiles generate large amounts of microplastic fibres (Cai et al. 2020; Luogo et al. 2022), thereby constituting a potential hotspot for release. In this study, we use the Bisperbjerg Hospital (Copenhagen, Denmark) laundry facilities as a case study to identify and measure the amount of MNPs that are emitted with the laundry effluent. This industrial-scale laundry is used for the disinfection and washing of all the textiles used in the hospital, hence, amounts of MNPs released daily are expected to be high. In a subsequent phase of the SusBrane project (susbrane.dtu.dk), this laundry will be used as a pilot test for development of new ceramic membrane technologies that will specifically target MNPs, with the aim of achieving sufficient water quality so this water could be reused by the hospital laundry, saving energy and water resources.

For this purpose, laundry wastewater will be analyzed before and after the newly developed membranes. Water samples will be collected in every step of the laundry process and filtered under vacuum to extract present MNPs. The obtained MNPs will be later analyzed by laser-direct infrared (LDIR), a semi-automatic technology that will re-count the present particles and identify the polymers.

The findings of the Susbrane project should ultimately allow the implementation of more efficient filtration membranes in full scale, reducing an important source of MNPs to the wastewater in the Copenhagen area. Additionally, the increased volume of reusable water in the hospital laundry facilities will contribute to save energy and enable more efficient water resource consumption.

3.18.P-Mo293 Membrane Distillation as Technology to Remove Microplastics in Drinking Water Production by Desalination: Lab-scale System Performance, Microplastics Behavior and Removal, and Future Research

Mariana Nogueira Miranda[1,2,3]*, Ana Rita T. Fernandes*[2,4]*, M. Fernando R. Pereira*[2,4] *and Adrián M. T. Silva*[2,4]*, (1)Flanders Marine Institute (VLIZ), Belgium, (2)ALiCE - Associate Laboratory in Chemical Engineering, University of Porto, Portugal, (3)Ocean & human health, Flanders Marine Institute (VLIZ), Belgium, (4)LSRE-LCM - Laboratory of Separation and Reaction Engineering - Laboratory of Catalysis and Materials, Faculty of Engineering, University of Porto, Portugal*

The study of the occurrence and fate of microplastics (MPs) through the water supply chain has been identified by the World Health Organization as a priority research need since MPs are classified as contaminants of emerging concern with potential adverse effects on human health. There is also a need to ensure drinking water safety and affordability, and to minimize the effects of the increasing frequency of extreme events, such as droughts and heat waves, on freshwater availability. Membrane Distillation (MD) is a thermally driven separation process employed to obtain water from wastewater or seawater, with a high rejection efficiency for undesired non-volatile substances and particulate matter. Thus, it can be used as a viable technology to achieve vital progress to counter the growing drinking water crisis. The main goals of this work comprised the i) assessment of MPs behavior and removal during a lab-scale treatment of seawater with MD, and ii) the potential impact of the presence of MPs in the MD process regarding the amount of water produced and its quality. For that, i) filtered seawater with known spiked amounts of MPs of unplasticized poly(vinyl chloride) (UPVC) was fed into the MD system, ii) the MD parameters (vapor pressure gradient, membrane permeability for water, and the interval permeate flux) were monitored during the experiments, iii) the quality of the treated water was assessed in terms of its conductivity, salinity and presence of MPs (> 1.2 µm by Raman microscopy), iv) the MPs were recovered and characterized to assess their potential aging during the treatment, v) the membrane used in each experiment was characterized. The data collected revealed that a high load of MPs (> 0.1 g L^{-1} of UPVC) can decrease the amount of treated water produced. However, under the expected loads found in the environment, the presence of MPs that are relatively resistant to temperature is expected to have minimal interference with the normal operation of a desalination unit based on MD. The treated water quality was good concerning conductivity (maximum 10.6 µS cm^{-1}) and salinity (0.0 ppt), with no signs of the spiked MPs being found in it. At the end of the experiments, MPs were recovered from the system, suggesting a very high removal efficiency with MD (≥ 99%). This constitutes one of the first assessments of this technology to remove MPs during desalination, with favorable results, and raises new research questions to be tackled in the future.

3.18.P-Mo294 Do the Treatment Units Fragmentate or Remove Microplastics? A Case Study of an Urban Wastewater Treatment Plant (Southeast of Spain)

Erika Amparo Torres Reyes[1]*, Estefania Castro*[2]*, Nora Exposito Lorenzo*[1]*, Carlos Lafita López*[2]*, Joaquim Rovira*[3]*, Tatiana Montoya*[2]*, Jordi Sierra*[4] *and Sandra Contreras*[1]*, (1)Chemical Engeeniering, Universitat Rovira i Virgili, Spain, (2)Global Omnium Medioambiente S.L., Spain, (3)Institut d'Investigació Sanitaria Pere Virgili (IISPV), Spain, (4)Faculty of Pharmacy and Food Sciences, Universitat de Barcelona, Spain*

Plastic enters the environment in different ways, such as through wastewater treatment plants (WWTPs), which play an important role in releasing microplastics (MPs) into the environment. MPs are highly persistent and bioaccumulated in living organisms, suffering multiple adverse effects from their interaction with the MPs and their associated additives and contaminants.

This research aims to study the performance of various technologies in municipal wastewater treatment for microplastics removal and to understand the fate of microplastics through a wastewater surveillance study.

Four sampling campaigns were carried out during the four seasons of the year 2023 (from January to November), in an urban WWTP in south-eastern Spain with a daily water discharge of 7,500 m^3/day. The sampling points were selected according to the different treatment stages. All the samples were separated by size using a set of sieves ranging from 25 to 1000 µm. Depending on the characteristics of the samples, they were treated with Fenton/peroxide oxidation, enzymatic digestion, and/or density separation to remove organic matter and isolate the microplastics. Visual sorting with a stereoscopic microscope (10-80x) was for MP identification and quantification. MP identity was confirmed using µFTIR.

The wastewater analyzed during the first sampling campaign showed a concentration of 435 MPs/L in the influent and 23 MPs/L in the effluent, reaching a 95% MP removal efficiency. The treatment units in the water line showed different behaviors: 1) during the pre-treatment, after the grit and grease removal unit, a concentration of 431 MPs/L was found; 2) after the biological treatment, the presence of MPs increased to 1,323 MPs/L; 3) after the secondary clarifier, the removal efficiency was 95% (24 MPs/L). 246,595 MPs/kg wet weight were found in the dewatered sludge (83% moisture). In all the treatment units, the MPs with sizes between 100-500 µm were predominant (41-65%), and fibers were the most prevalent type of MPs (65-80%). The MPs analyzed are made of polyurethane, polyethylene, polypropylene, polyester, polyacrylonitrile, synthetic cellulose, etc. Polyurethane fragmentation was observed during pretreatment, and secondary treatment.

The MPs emission through the water effluent is approximately 1.72×10^8 MPs per day. An improvement of the pretreatment, primary treatment, and biological reactor operative conditions can lead to a higher MP removal efficiency.

3.18.P-Mo295 Development of an analytical method for the simultaneous determination of 50 semi-volatile organic contaminants in wastewaters

Naroa Lopez[1,2]*, Dennis Bilbao*[2,3]*, Leire Mijangos*[3,4]*, Natalia Ortueta*[2]*, Maitane Olivares*[5,6]*, Olatz Zuloaga*[1,7]*, Nestor Etxebarria*[8,9] *and Ailette Prieto*[1,7]*, (1)Research Centre for Experimental Marine Biology and Biotechnology (PiE-UPV/EHU), Spain, (2)University of the Basque Country (UPV/EHU), Spain, (3)Plentzia Marine Station of Basque Country University (EHU/UPV), Spain, (4)Analytical Chemestry, University of the Basque Country (UPV/EHU), Spain, (5)Analtytical Chemistry, Research Center for Experimental Marine Biology Biotechnology "Plentziako Itsas Estazioa", University of the Basque Country (PiE-UPV/EHU), Spain, (6)Analytical Chemistry, Research Centre for Experimental Marine Biology and Biotechnology (PiE-UPV/EHU), Spain, (7)Analytical Chemistry, University of the Basque Country (UPV/EHU), Spain, (8)Department of Analytical Chemistry, University of the Basque Country (UPV/EHU), Spain, (9)Research Centre for Experimental Marine Biology and Biotechnology (Plentzia Marine Station; PiE-UPV/EHU), University of the Basque Country (UPV/EHU), Spain*

The amount of chemicals released into the environment have been a matter of study, particularly since the explosive growth of the chemical industry. Recent decades have witnessed a shift in focus towards studying the so-called contaminants of emerging concern (CECs) due to their potential ecotoxicological impacts, including habitat loss, reduction of biodiversity or accumulation within various trophic levels. CECs constitute a heterogeneous group of compounds with varying physicochemical properties, including semi-volatile organic compounds (SVOCs) such as polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), phthalate esters, organochlorine pesticides, and other environmental endocrine disruptors. While the analysis of polar compounds in aqueous samples is widespread, the trend of SVOCs accumulating in biological tissues and different environmental compartments underscores the importance of their comprehensive monitoring. This work aimed to study the feasibility of extending a previously validated methodology for the analysis of polar compounds in aqueous samples to include non-polar compounds within a harmonised analytical procedure using gas chromatography coupled to mass spectrometry (GC-MS) for the chemical analysis. A rigorous evaluation of the factors influencing compounds' preconcentration during solid-phase extraction (SPE) was performed, covering the elution and evaporation steps, to improve the extraction yield. For the extraction step, the hexane:toluene mixture (4:1, v/v) was selected as the optimal elution solvent, showing recoveries ranging from 27 % to 92 %. Significantly, the addition of 5 % of MeOH before extraction was crucial for the enhancement of the recoveries. Concerning to the evaporation step, the addition of isooctane (approximately 0.5 mL) before, during and when around 0.5 mL of the extracts remained in the test tubes, seemed to be beneficial resulting in recovery values within the range of 40 % to 130 % for most of the compounds. Overall, the developed methodology exhibited robust performance for the simultaneous determination of 50 SVOCs and was successfully applied for the analysis of real wastewater treatment plant (WWTP) effluent samples. The multitargeted GC-MS analysis revealed the presence of 15 compounds, with lindane and its analogue beta-hexachlorocyclohexane, bis(2-ethylhexyl) phthalate and phenanthrene the most prominently detected at elevated concentration levels (41 – 18000 ng/L).

3.18.P-Mo296 In vitro toxicity of road runoff from different road types using reporter-gene assays

Jennifer Schmidt[1]*, Markus Schmitz*[1]*, Sarah Cüpper*[1]*, Martin Krauss*[2]*, Simone Lechthaler*[3,4]*, Volker Linnemann*[3]*, Henner Hollert*[5] *and Sabrina Schiwy*[5]*, (1)Evolutionary Ecology & Environmental Toxicology, Goethe University Frankfurt, Germany, (2)Department of Effect-Directed Analysis, Helmholtz Centre for Environmental Research (UFZ), Germany, (3)Institute of Environmental Engineering, RWTH Aachen University, Germany, (4)Hunziker Betatech AG, Switzerland, (5)Evolutionary ecology and environmental toxicology, Goethe University Frankfurt, Germany*

Rapid urbanization and the rising number of motor vehicles over the past few decades have resulted in dramatic environmental changes. In particular, tire and road wear particles (TRWPs) in road runoff are of increasing concern. Nonetheless, the environmental fate and ecotoxicological effects of road runoff are yet to be understood. Furthermore, the possibilities of interactions between TRWPs and other road runoff pollutants are rarely known. The presented study will be carried out as part of the interdisciplinary RoadTox project, which aims to conduct an ecotoxicological risk assessment of road runoff and further prioritize measures for input mitigation.

Runoff samples were taken throughout the years 2022 to 2023 at three different model road sites (highway, sub-urban and urban road) in Aachen, Germany, covering seasonal and meteorological variability (e.g., dry periods, freezing conditions, heavy rain events). Subsequently, the water samples were filtered and extracted via Solid Phase Extraction (SPE). In addition, organic extracts were prepared from suspended particulate matter (SPM), which were isolated from corresponding runoff samples and freeze dried prior to Ultrasound-Assisted Extraction (UAE). For use in *in vitro* assays, aliquots of the extracts were transferred to DMSO. An *in vitro* biotest battery with several reporter gene assays (dioxin-like activity, (anti-)estrogenic, and anti-androgenic activity) was applied to assess the mechanism-specific toxicity. Prior to the measurement of the mechanism-specific endpoints, the neutral red assay was performed for each used cell line to determine the cytotoxicity.

In previous *in vitro* studies, endocrine disruption and dioxin-like activities were already detected in selected samples. For the samples used in the current study, extensive *in vivo* data obtained from fish embryo toxicity assays and chemical data are available. Hence, the aim of the presented study is to provide corresponding mechanism-specific *in vitro* data focusing on the

comparison of different road types. The study is still in process, and the data obtained will be available for the presentation. The results will contribute to a better understanding of road runoff ecotoxicity and to identify possible toxicity drivers.

The project is funded by the Ministry for Environment, Agriculture, Conservation and Consumer Protection of the State of North Rhine-Westphalia (MULNV) and the RobustNature network, Germany.

3.18.P-Mo297 Elucidating the Inhibitory Effects of Phenolic Moieties in Natural Organic Matter on the Photodegradation of Organic Micropollutant

Anam Asghar[1]*, Klaus Kerpen Dr*[2] *and Torsten C. Schmidt*[2]*, (1)University of Duisburg-Essen (Uni DUE), Germany, (2)Instrumental Analytical Chemistry, University of Duisburg-Essen (Uni DUE), Germany*

UV-induced photochemical transformation efficiently degrades organic micropollutants (OMPs) without requiring a catalyst. This process involves the photo-dissociation of O_2 and self-sensitized pollutants, generating photochemically produced reactive intermediates (PPRIs) including hydroxyl radical ($HO^{\bullet}$), singlet oxygen ($^1O_2$) and excited triplet state. However, the diversity and complexity of water matrices, particularly the presence of natural organic matter (NOM), poses challenges to photochemical transformation of NOM. NOM can absorb UV light, scavenge the radicals/oxidants or enhance the reactive species formation, altering pathways for OMPs elimination.

Natural organic matter is a complex mixture of heterogenous compounds with various functional groups and molecular sizes, including aliphatic chains linked to substituted aromatic rings and attached functional groups like amides, carboxyl, hydroxyl, amine, and others. Notably, NOM features phenolic moieties (mono- or polyhydroxylated benzene units) known for their intriguing electron-donating, antioxidant properties in oxidation reactions. However, the specific role of these phenolic moieties in the formation of PPRIs, and their potential inhibitory effects in photolysis remains uncertain, thus establishing the focus of this study. To investigate this, Tannic acid (TA), gallic acid (GA), and catechin (CAT) were selected as representative surrogates for NOM containing phenolic moieties. Their impact on the photochemical transformation process was evaluated and compared with widely used Suwannee River NOM (SRNOM). Atrazine (ATZ) was selected as the probe OMP due to its susceptibility to photolysis and established photolytic kinetics data. In this investigation, a significantly higher concentration of $HO^{\bullet}$ was observed compared to $^1O_2$, and the triplet excited state ($^3NOM^*$). This finding suggests that the substituted phenols, particularly those with carboxylate-substitutions, played a substantial role in the formation of $HO^{\bullet}$. However, the inhibitory effects induced by these phenolic moieties were significant, mainly attributed to the direct photolysis inhibition caused by the inner filter effect. When compared with SRNOM, similar trends with less pronounced formation of PPRIs and inner filter effects were observed. Therefore, this study elucidates the role of phenolic moieties on the photochemical transformations, thereby deepening our understanding of the fate of OMPs in natural water.

3.18.P-Mo298 Comparison of nanofiltration and reverse osmosis membrane in the removal of pharmaceuticals from water

Jelena Šurlan[1]*, Nikola Maravić*[2]*,* ***Zita Istvan Šereš***[2]*, Natasa Durisic-Mladenovic*[3]*, Igor Antić*[3]*, Biljana Pajin*[2] *and João Crespo*[4]*, (1)Faculty of Technology Novi Sad, Unversity of Novi Sad, Serbia, (2)Faculty of Technology Novi Sad, University of Novi Sad, Serbia, (3)University of Novi Sad, Faculty of Technology, Serbia, (4)LAQV/REQUIMTE, Chemistry Department, NOVA School of Science and Technology, Universidade NOVA de Lisboa, Campus da Caparica, Portugal*

Presence of pharmaceuticals in water can have negative impact on human health, as well as the aquatic environment. Since pharmaceuticals are continuously introduced to water systems and conventional water treatments are not efficient enough in their removal, additional processes for their removal from water are required. Membrane separation processes, such as nanofiltration and reverse osmosis, could be efficient in the removal of pharmaceuticals from aquatic environment. The aim of this study was to compare the efficiency of nanofiltration and reverse osmosis membrane in the removal of four pharmaceuticals, acetaminophen, salbutamol, carbamazepine and bezafibrate, using dead end filtraton equipment. Two comercially available polyamide membranes, nanofiltration membrane with molecular weight cut off 150-300 Da and reverse osmosis membrane with molecular weight cut off 100 Da, were used for the removal of pharmaceuticals from a model solution. Efficiency of nanofiltration membrane in the removal of acetaminophen, salbutamol, carbamazepine and bezafibrate was 51.59%, 84.95%, 92,79% and 91.05%, respectively. However, higher removal efficiencies were observed with reverse osmosis membrane, with values of 92.71%, 86.29%, 96.53% and 94.99% for acetaminophen, salbutamol, carbamazepine and bezafibrate, respectively. Lower rejection rates of selected pharmaceuticals with nanofiltration membrane are due to the higher molecular weight cut off of the membrane. The greatest difference in rejection rates between nanofiltration and reverse osmosis membrane was observed for acetaminophen, due to the lowest molecular weight (151.16 Da). Salbutamol, carbamazepine and bezafibrate have higher molecular weights and therefore, the differences in the removal efficiencies between nanofiltration and reverse osmosis membrane were lower. In conclusion, reverse osmosis membrane was more efficient in the removal of selected pharmaceutical, however, nanofiltration membrane also had high removal efficiencies for pharmaceuticals with higher molecular weights.

3.18.P-Mo299 Effect of carbon nanoparticles ozonation on their properties and affinity to emerging contaminants

Aleksandra Bogusz[1]*, Bożena Czech*[2] *and* ***Patryk Oleszczuk***[2]*, (1)Institute of Environmental Protection National Research Institute, Poland, (2)Department of Radiochemistry and Environmental Chemistry, Maria Curie-Skłodowska University, Poland*

The release of nanomaterials (ENMs) to the environment can occur during the use of materials containing nanoparticles, their processing, disposal and storage. It is assumed that the main part of ENMs enters the environment with wastewater. During transport, ENMs may undergo various transformations, such as: oxidation and reduction, dissolution, adsorption, biotransformation, aggregation and deposition. These transformations can lead to changes in ENMS properties. Since ENMs first end up in the wastewater, it can be expected that they will undergo various transformations in the wastewater. Currently, there is insufficient knowledge about the type and extent of ENMs transformations during water and wastewater treatment. The impact of transformations that ENMs may undergo on their transport and toxicity is also unknown. Ozonation is currently one of the most commonly used methods of water and wastewater treatment. It can be expected that the properties of ENMs will change during ozonation. The main objective of this study was therefore to assess the changes that ENMs undergo under the influence of ozonation and how these changes affected the interaction of ENMs with pollutants. The effect of ozonation was tested on the following nanomaterials: graphene nanoflakes (hydrophilic, hydrophobic, neutral), carbon nanotubes (non-functionalized and functionalized), carbon nanotubes and graphene nanoflakes coated with Zn. Physical and chemical characterization included: elemental analysis (C, H, N), surface area assessment (SBET, pore volume, micropore volume and surface area, and mean pore width), FTIR spectroscopy and Raman spectroscopy. The adsorption affinity of ozonated and non-ozonated materials for triclosan was tested. It was noticed that the physico-chemical properties of ENMs changed after ozonation. These changes depended on the type of ENMs. As a result of ozonation, there was a change in the surface properties, especially of nanocomposites. Adsorption depended on the type of ENMs. Overall, however, ozonation decreased the adsorption affinity for most of the tested ENMs.

3.18.P-Mo300 Ozonation for wastewater treatment in water REUSE: organic matter reduction, micropollutants degradation and transformation products identification

Téo Ferreux[1]*, Geoffroy Duporte*[2]*, Elena Gomez*[2]*, Julie Mendret*[3]*, Linda Luquot*[4] *and Stéphan Brosillon*[3]*, (1)University of Montpellier, France, (2)HydroSciences Montpellier, University of Montpellier, CNRS, IRD, France, (3)European Institute of Membranes, University of Montpellier, CNRS, ENSCM, (4)Geosciences Montpellier, University of Montpellier, CNRS, France*

Water, a vital resource for the environment, human well-being, and economic development, is increasingly threatened by anthropic activities. Wastewater (WW) reuse after adapted treatment represents one of the existing solutions to decrease tension over water resources. However, it is associated with risks caused by the presence of micropollutants and pathogens. Ozonation is then considered as a potential tertiary WW treatment for the elimination of these pollutants. The aim of this study was to determine the effectiveness of ozonation as a cost-effective tertiary treatment for the removal of emerging contaminants and organic matter in the context of WW reuse. We also studied the formation of transformation products (TPs) by Non-Target Analysis (NTA).

Ozonation experiments were performed in a 3 L ozonation pilot glass stirred semibatch reactor (Vreactor = 3 L, 250 rpm) with TWW sampled from Claira wastewater tratment plant (WWTP). The total gas flow was 60 $NL.h^{-1}$ and the inlet ozone gas concentration ($[O_3]_{G,inlet}$) was 5 ± 0.2 $g.Nm^{-3}$. Water quality analysis were conducted based on global parameters such as Chemical Oxygen Demand (COD) and $UV_{254\ nm}$ absorbance... Target analyses and NTA were carried out using High Performance Liquid Chromatography coupled to a High-Resolution Mass Spectrometer (HPLC-HRMS) to follow the elimination of eight pharmaceuticals and two pesticides (native concentrations), and the formation of TPs in the treated wastewater (TWW).

Ozonation improved the water quality by effectively degrading the effluent organic matter (OM). COD decreased up to 25 %. UV_{254nm} absorbance decreased steadily between 0 and 0.4 $mg_{O3}.mg_C^{-1}$, where it reached a minimum value of 0.04. These results show that ozone oxidated OM and thus reduced the wastewater organic content. Finally, the decrease in OM aromaticity, as demonstrated by UV_{254nm} absorbance reduction, showed that ozonation modified OM by generating simpler molecular structures.

Micropollutants degradation was significant even at low ozone doses. Hence, the elimination was superior to 80 % for nine out of ten quantified compounds at an ozone dose of 0.074 $mg_{O3}.mg_C^{-1}$ (corresponding to 30 minutes of ozonation). However, micropollutants oxidation generated TPs that may be toxic. Some of these TPs have been identified using NTA, leading to a better understanding of the ozone process and its implications for WW reuse.

3.18.P-Mo301 A Nature-based Solution to Minimize Reverse Osmosis Concentrate Toxicity

Jan Christof Specker[1]*, Joana Casaca*[1]*, Tol Marsman*[1]*, Roy van Tol*[1]*, Sander Kamphorst*[1]*, Sarah Kraakman*[1] *and Michiel Kraak*[2]*, (1)University of Amsterdam (UVA), Netherlands, (2)University of Amsterdam, Institute for Biodiversity and Ecosystem Dynamics, Freshwater and Marine Ecology (FAME), Netherlands*

Reverse osmosis (RO) offers an excellent way to remove a plethora of recalcitrant contaminants from aqueous matrices such as drinking water. However, a substantial drawback is the produced waste stream, the RO concentrate. As the concentrate consists of the filtered pollutants, such as micropollutants or bacteria, its disposal has to be carried out in a safe and sustainable manner. Frequently, the concentrate is discharged into the open sea or into surface waters. Especially in water bodies with small volumes, the impact can be substantial with potential ecotoxicological effects. Hence, the handling and management of RO concentrate may benefit from cost-effective and sustainable remediation techniques. Therefore, this work presents a nature-based solution to treat RO concentrate with soil retention filters (RSF) to minimize its potential toxicity before discharging it into the environment.

RO concentrate was sampled from a drinking water facility in the Netherlands and was treated by RSF in the laboratory. The filters consisted of gravel and several layers of either sand and calcium carbonate or sand and biochar. The ecotoxicity of the RO concentrate before and after RSF treatment was studied by applying the acute toxicity daphnia assay, performed according to the OECD guideline 202 with *Daphnia magna*. Furthermore, pH, dissolved oxygen, and electrical conductivity were measured.

Ecotoxicological effects were observed for the untreated RO concentrate, albeit maximum RO concentration did not cause complete daphnid immobility. Treatment by RSF caused a complete effect removal, thus indicating that it is potentially safe to discharge the treated RO concentrate into the aquatic environment. Moreover, electrical conductivity was decreased by a factor of 1.5 and would meet therefore international water reuse guidelines.

This work shows that RSF could be a viable treatment for RO concentrate before it is discharged into the environment. Hence, RSFs offer a new option for water authorities to manage RO waste streams by safely discharging the concentrate. Moreover, the treated concentrate may be reused for green infrastructure irrigation. However, further research is required before any final conclusions can be made. Ecotoxicological effects need to be studied on additional species from several trophic levels including potential chronic effects. Furthermore, chemical target and non-target screening would be required as well as long-term performance of the RSF.

3.18.P-Mo302 Enhanced Removal of Stormwater Polar Organic Contaminants In Geomedia-Amended Biofilters
María Alejandra Cruz Bolaños[1]*, Jan Willem Foppen*[2]*, Enric Vázquez-Suñé*[1] *and Marc Teixidó*[1]*, (1)Geosciences, Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain, (2)Water Management, Faculty of Civil Engineering and Geosciences, Delft University of Technology, Netherlands*
Innovative drainage systems like green infrastructure (e.g., biofilters) are increasingly valued, designed, and implemented to mimic natural drainage regimes, maximize stormwater runoff capture and treatment, while enabling infiltration into the subsoil for aquifer recharge. Unfortunately, runoff can carry over 150 organic pollutants from vehicle-related sources, and highly polar contaminants (e.g., persistent, mobile, and toxic substances; in short: PMTs) remain challenging to remove in conventional infrastructure. To overcome treatment limitations, we assessed the transport and removal of vehicle-related pollutants such as 1H-benzotriazole, N'N-diphenylguanidine, and hexamethoxymethylmelamine, utilising batch experiments and laboratory biofilters amended with granulated activated carbon (GAC) and biochar. Experimental breakthrough curves demonstrated geomedia amendments can enhance polar organic contaminants removal during passive infiltration, particularly GAC with faster sorption kinetics and higher sorption capacity than biochar. However, contaminant sorption is subject to kinetic limitations and, thus, is sensitive to infiltration flow rates and hydraulic retention times. We inferred these effects could be intensified by dissolved natural organic matter fouling. A more recent biofiltration design is currently being studied to complement geomedia amendments and enhance polar contaminant treatment, even under intermittent dry/wet cycles, due to its benefits on hydraulic performance. Overall, our research contributes to improving polar organic pollutant removal technologies in environmental applications, and designing climate change-resilient biofilters with enhanced hydraulic and contaminant removal performances.

3.18.P-Mo303 Fungal Biomass in Wastewater: a Strategy for Pharmaceutical Removal
Oksana Golovko[1] *and Malin Hultberg*[2]*, (1)Swedish University of Agricultural Sciences (SLU), Sweden, (2)Department of Biosystems and Technology, Swedish University of Agricultural Sciences (SLU), Sweden*
Efficient removal techniques are urgently needed to remove emerging contaminants (EC), such as pharmaceuticals from wastewater, in order to protect water resources. A major source of pollution of inland waters are effluent discharges from wastewater treatment plants (WWTPs) because the existing treatment processes do not efficiently remove EC. Bioremediation based on white-rot fungi (mycoremediation) is particularly promising in decontamination because of the nonspecific nature of the ligninolytic enzymatic system, which can degrade a wide range of EC. Direct use of a colonized mushroom substrate is one method of employing oxidative enzymes. From a practical perspective, this would be less resource-intense than downstream processing and purification of the enzymes. Furthermore, locally produced plant biomass, such as wetland biomass, could be used to propagate the fungal mycelium. Another option may be submerged fermentation for production of mycelium directly in wastewater. Thus, this research focuses on developing novel, circular and resource-efficient mycoremediation strategies.

In one study, commercial mushroom spawn of Pleurotus ostreatus was used to develop a white-rot fungal pellet in water. Laccase activity could be induced by lignin and over time the added lignin accumulated in the pellet. The pellet was tested for removal of 11 different pharmaceuticals. The reduction of total sum of pharmaceuticals in the water phase ranged between 32-37% after 10 min of exposure. Concentration of the antibiotics azithromycin, erythromycin, sulfamethoxazole and trimethoprim was reduced to the highest extent while fluconazole was unaffected. Accumulation of pharmaceuticals in the solid phase, composed of spawn, hyphae and lignin, was correlated with the Kd of the compound. The size of the pellets allows harvest of the biomass by coarse filtration and the described concept holds promise as a low-cost and sustainable method for enzyme-based wastewater treatment.

3.18.P-Mo304 Capacity of biochars produced by cookstoves to remove pharmaceuticals and personal care products from hospital wastewater

***Brigitte Mukarunyana**, Chemistry, Umea University, Sweden*
In sub-Saharan Africa, agricultural and forestry residues are used in cooking but most of these biomasses are considered wastes and are not properly treated, in addition, carbonized materials resulting from cooking are often not valorized. The production of carbonized materials such as biochars may be a sustainable way of managing wastes given that they are renewable sources and their applications are various including energy production, soil amendment and water treatments. To treat wastewater, most hospitals apply conventional techniques that consume a lot of energy to provide oxygen to the treatment system, moreover, they were reported not efficient in removing pollutants like pharmaceuticals and personal care products (PPCPs). In response to that, adsorption has been applied and presented satisfactory results, especially with activated carbon. However, the latter was also reported as not cost-effective and thus became challenging to apply in developing countries. Biochars are therefore prime candidates with high potential for application in low-income countries since feedstock could be locally sourced, easy to produce and environmentally friendly. The study aimed to investigate the capacity of biochars produced by cookstoves in removing PPCPs from real hospital wastewater.

Wastewater samples were collected in one of the largest hospitals in Rwanda and were analysed before and after adsorption experiments on biochars using the LC-MS/MS method. The characterization of biochars produced by 3 different cookstoves using 3 feedstocks has been carried out using DRIFTS, Raman, XPS and BET. In total 28 PPCPs were detected and quantified. The averages of removal rates for all 9 biochars ranged between 14.2 and 65.5% Results from characterization, concentrations of detected PPCPs and the removal rates of biochars will be presented. Findings will contribute to the sustainable management of waste especially in countries with low income and also to increasing databases related to biochars and adsorption studies.

In conclusion, biochars produced by cookstoves removed PPCPs at different degrees, some were more efficient than others, and more biochar characterizations are needed to clarify what main parameters are involved in the removal of PPCPs.

3.18.P-Mo305 Identification of Cetirizine Metabolites in a Laboratory-scale Moving Bed Bioreactor System
***Jiexi Zhong**[1], Daniel Naschenweng[1], Selina Tisler[2], Ioannis A Fotidis[3] and Kai Bester[1], (1)Environmental Science, Aarhus University, Denmark, (2)University of Copenhagen, Denmark, (3)Department of Environment, Ionian University, Greece*
Cetirizine, a typical antihistamine, is barely removed from conventional wastewater treatment plants (WWTPs). Biofilm systems such as moving bed biofilm reactor (MBBR) are reported to be effective in removing these persistent micropollutants but no literature regarding it was published. This study aims to investigate how much cetirizine is emitted from WWTPs and whether MBBRs are effective in removing cetirizine via biodegradation.

Removal of cetirizine in conventional wastewater treatment was conducted by comparing in- and effluent wastewater. Additionally, a monitoring of 80 WWTP effluents from multiple EU countries was conducted. Laboratory-scale degradation tests were performed in Erlenmeyer flasks with AnoxKaldnes™ Z400 carriers. Un-spiked effluent wastewater containing cetirizine was used for the biodegradation kinetic test while the cetirizine metabolite identification experiment was conducted with spiked solutions. Changes in the metabolite concentration over time were observed to deduce the transformation pathways. All measurements were conducted using high performance liquid chromatography followed by high resolution mass spectrometry.

Cetirizine in effluent wastewater ranged between 1 to 10 µg/L in EU countries (found in 114 of 120 wastewater samples) and was persistent in a conventional WWTP. In contrast to the conventional wastewater treatment process, MBBR demonstrated its ability to remove cetirizine. Up to 20% cetirizine in un-spiked wastewater effluent was removed in MBBR incubation over 160 h whereas no cetirizine degradation was observed in flasks containing carriers with no biomass. In the meantime, eight metabolites were identified and their concentration increased over time. Cetirizine *N*-oxide was found to be the dominant metabolite in the MBBR incubation and was formed via N-oxidation of cetirizine. The presence of cetirizine *N*-oxide was frequently detected in EU countries (found 119 of 120 samples). Bio-transformation is involved in the removal process with MBBR. A possible transformation scheme was proposed to illustrate how cetirizine was transformed to its secondary or tertiary metabolites. The bio-transformation feature of MBBR suggesting biofilm systems could be used as a tertiary step in wastewater treatment system.

3.18.P-Mo306 Ecotoxicological mixture risk assessment of 35 pharmaceuticals in wastewater effluents following post-treatment with ozone and/or granulated activated carbon
***Francis David Spilsbury**[1], Vaidotas Kisielius[2], Kai Bester[2] and Thomas Backhaus[3,4], (1)Institutionen för biologi och miljövetenskap, University of Gothenburg, Sweden, (2)Environmental Science, Aarhus University, Denmark, (3)Biological and Environmental Sciences, University of Gothenburg, Sweden, (4)Institute for Environmental Research, RWTH-Aachen University, Germany*
Reducing the risk posed by mixtures of pharmaceuticals is a goal of current initiatives such as the European Green Deal to reduce anthropological environmental impacts. Wastewater effluent typically contains large numbers of active pharmaceutical

ingredients (APIs). For most APIs, existing technology commonly used in many wastewater treatment plants (WWTP) have removal rates below 20%, adding to the toxic burden of receiving waters.

We present an environmental risk assessment of mixtures of 35 APIs in effluent samples from 82 European WWTPs using the concentration addition model, and identify the respective risk-driving APIs. This is then compared to a corresponding mixture risk assessment of effluent samples from the Danish Hillerød WWTP subjected to post-treatment of varying doses of ozone (0.15–1.05 mgO_3/mg DOC) and/or granulated activated carbon (GAC).

All 82 WWTP effluent samples exceeded risk thresholds by at least a factor of 30, with a median RQ_{SUM} of 92.9, highlighting the need for effluent post-treatment. Antibiotics, analgesics and anti-depressants were among the top risk drivers with 99% of the average mixture risk attributable to azithromycin, diclofenac, venlafaxine, clarithromycin and mycophenolic acid. Effluent mixture risk was reduced by ozonation in a concentration-dependent manner, decreasing below threshold levels to a median RQ_{SUM} of 0.83 following treatment with 0.65 mgO_3/mg DOC. Fresh GAC was also effective at reducing the mixture risk, with a median final RQ_{SUM} of 0.04, however no additional reduction in API mixture risk was achieved with ozonation plus GAC treatment (median RQ_{SUM} = 0.07).

This is the first study to present a risk assessment of pharmaceutical mixtures in effluent comparing “classical” WWTP processes with additional post-treatment with ozone and/or GAC. We demonstrate the need for additional WWTP treatment technologies, and the efficacy of GAC and ozonation in decreasing the risk to the aquatic environment from pharmaceutical mixtures to below acceptable threshold limits.

3.18.P-Mo307 Rapid Small Scale Column Tests for the retention of very polar transformation products of commonly used pesticides on granular activated carbon

Tom Galle[1], *Denis Pittois*[2], *Michael Bayerle*[2] *and Jimmy Roussel*[2], *(1)Erin, Luxembourg Institute of Science and Technology (LIST), Belvaux , Luxembourg, (2)Erin, Luxembourg Institute of Science and Technology (LIST), Luxembourg*

Very polar transformation products rather than parent compounds are currently contaminating ground waters that serve for drinking water production. In Luxembourg, the ban of s-metolachlor and metazachlor in drinking water protection zones, whose transformation products are widely present in ground waters at levels beyond 100 ng/L, has led to a switch to alternatives that pose hardly less risk for the resources. Drinking water suppliers have started to employ granular activated coal treatment to mitigate the pollution without knowing the efficiency of the coals to retain these polar compounds. As several candidates have been identified that will pose problems in a near future by leaching to the water table it was urgent to evaluate their behavior on activated coal columns and to test different types of coal material. A Rapid Small Scale Column Test (RSSCT) device was established with two parallel lines driven by HPLC pumps and a large fraction collector. Seven different coals of different origin were tested with tracer compounds like diatrizoic and chlorobenzoic acid to evaluate their general retention capacity. From this set of coals the currently used coals by the drinking water suppliers as well as an additional reference were tested for 26 parent compounds and transformation products that are potentially expected or are currently already polluting ground water resources. The tests lasted for 3 days passing 82 m^3/kg GAC and showed tenfold differences in breakthrough thresholds for diatrizoic acid between the coals. The very polar transformations products followed their log D at pH 7 with breakthroughs of chlorothalonil RA471811>flufenacet-ESA>metazachlor-OA being the most critical. The comparison to running full-scale columns showed that the latter had breakthroughs that occurred 1.5 to 2.6 times faster than on the RSSCT systems.

3.18.P-Mo308 Seasonal monitoring of granular active carbon filter regeneration effects on organic micropollutant removal during drinking water treatment

Petra Nováková[1], *Helena Švecová*[2] *and Roman Grabic*[3], *(1)University of South Bohemia in České Budějovice, Czech Republic, (2)University of South Bohemia in České Budějovice, Faculty of Fisheries and Protection of Waters, Czech Republic, (3)University of South Bohemia in Ceske Budejovice, Faculty of Fisheries and Protection of Waters, Czech Republic*

Threats from organic micropollutants (MPs) remaining in drinking water after treatment are becoming more urgent withtheir increasing environmental concentrations. Drinking watertreatment plants (DWTP) commonly implemented granular activecarbon (GAC) filters for MP removal improvement. However, theaging and overloading of GAC filters supposedly lead to a drop in water quality.

We performed comprehensive research on the effect of the GAC system on drinking water quality, combining two methods basedon liquid chromatography hypnated with mass spectrometry (LC-MS). The studied technology was a DWTP fed by surface waterfrom a reservoir. We analyzed water samples and passive polarsamplers (POCIS) taken from different treatment points and compared the GAC filter with and without regeneration. Thesampling campaign was repeated four times in different seasonsfor a more detailed view of treatment changes with the age of theGAC. The first part of the analysis was a routine target methodcovering about 50 MPs of interest and revealing an expectedinstant treatment improvement with a regenerated GAC filter in the first sampling campaign. The following two campaignsnoticed a decreasing trend and growth of the MP concentrationpassing through the treatment system. Finally, there was no significant difference between the newly regenerated filter and theold one in the last campaign. After this hypothesis confirmation, we evaluated results from non-target analysis gained by high-resolution MS in combined full scan and data-independent acquisition mode. All detectable m/z signals were assessed and filtered for the final mass list. This list was used for compoundidentification and the complex evaluation of treatment along thetechnology line and with the age of the GAC filter.

3.18.P-Mo309 Sorption of Persistent, Mobile, and Toxic (PMT) and very Persistent very Mobile (vPvM) substances onto pyrogenic carbonaceous materials

Jiaqi Xu*, Jordi Cama and Marc Teixidó, Geosciences, Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain*

Chemical pollution, specifically arising from trace organic contaminants (TOrCs) such as persistent, mobile, and toxic (PMT) and very persistent, very mobile (vPvM) organic chemicals poses a global environmental concern. The escalating urbanization, characterized by increasing impervious surfaces amplify this issue, leading to the deposition and accumulation of pollutants in stormwater. Although green infrastructure aims to manage urban runoff, its efficacy in removing polar contaminants, especially PMT/vPvM substances remains inadequate. This study evaluates 20 cost-efficient PCMs (including biochars and granulated activated carbon GAC) and a suite of 34 PMT/vPvM substances to study the adsorption process under different experimental condition. Results indicate GAC as the effective adsorbent due to its physical properties, while MSP700 biochar demonstrates commendable competitiveness with GAC. Futhermore, sorption preferences based on the charges of adsorbates highlight the need for the specialized treatment for the different charge compounds. This study contributed to advancing knowledge for the development of treatment technologies targeting emerging contaminants in urban environments.

3.18.P-Mo310 TKIdentification – Occurrence and Fate of Tyrosine Kinase Inhibitors as a Novel Class of Pharmaceutical Residues in Municipal Wastewater and Surface Water in the Netherlands

Nick Zwart[1]*, Corine J. Houtman*[2]*, Timo Hamers*[3] *and Marja Lamoree*[3]*, (1)University of Amsterdam (UVA), Netherlands, (2)The Water Laboratory, Netherlands, (3)Vrije University Amsterdam, Netherlands*

The ever changing composition of contaminants in the aquatic environment poses a risk to water quality of surface or groundwater used in the production of drinking water. Mixtures of contaminants with the same mode of action can cause adverse effects which would remain undetected when considering single contaminants. To ensure safe drinking water, it is important to detect and identify potentially hazardous (mixtures of) chemicals (i.e. (novel) chemicals of emerging concern (CECs)) early on. Tyrosine kinase inhibitors (TKIs) are cytostatic drugs used in the treatment of cancers where (non) receptor tyrosine kinases (mediators of cell proliferation, migration and cell cycle progression) act as driver. First marketed in 2001, there are currently over 40 TKIs prescribed in the Netherlands, with more TKIs under development. Despite their ubiquitous use, the impact of environmental TKIs on ecology and human health has not been investigated. The accurate risk assessment of environmental TKIs depends on insight into the presence, fate and composition of the mixture of bioactive TKI residues which include (human) metabolites and breakdown/transformation products (TPs). To determine the introduction of TKIs into surface water via sewage, fourteen TKIs in the influent, effluent, and receiving surface water up/downstream from the effluent discharge points of three municipal wastewater treatment plants in the Netherlands will be quantified by LC-HRMS. Samples from locations with high concentrations of TKIs will be selected for the subsequent identification of unknown bioactive TKI TPs and metabolites, later in the project, using high-throughput effect-directed analysis (HT-EDA) expanded with newly developed bioassays, suspect screening, and enhanced non-target screening. The measured environmental TKI concentrations will help direct further investigation into the presence and fate of TKIs in the Dutch (drinking) water cycle, enable toxicological testing of the mixture and eventually contribute to a more accurate risk assessment of TKI residues in the aquatic environment.

3.18.P-Mo311 Influence of UV and UV LED disinfection treatment of wastewaters on the fate of micropollutants and water toxicity

Lucie Blahova[1]*, Michal Bittner*[1]*, Tim Schwarzenberger*[2]*, Kumiko Oguma*[3]*, Jaroslav Lev*[4]*, Lucie Baborska*[4]*, Kateřina Bočková*[1]*, Jutta Eggers*[2] *and Ludek Blaha*[5]*, (1)RECETOX, Faculty of Science, Masaryk University, Czech Republic, (2)TZW DVGW (German Water Centre), Germany, (3)University of Tokyo, Japan, (4)ASIO TECH s.r.o., Czech Republic, (5)Recetox, Masaryk University, Czech Republic*

Water scarcity is a growing issue globally. Wastewater recycling and reuse can help to contribute to societal sustainability but assuring of microbiological and chemical safety of the recycled wastewater is of premier importance. In the present study, we report outcomes of the pilot study at the municipal wastewater treatment plant (WWTP) that compared innovative UV LED reactors and conventional low pressure Hg-based UV lamp (LP UV) for disinfection of pre-treated effluents. The study confirmed significant inactivation of bacteria by both types of disinfection indicating thus suitability for wastewater reuse. LP UV irradiation also affected concentrations of micropollutants resulting in variable patterns. For example, significant decrease of concentrations was observed for diclophenac, sulfomethoxazole or ciprofloxacin. On the other hand, for some micropollutants such as acetaminophen we observed increased concentration after UV irradiation. Moreover, overall estrogenity and androgenity of the water (measured by reporter gene in vitro assays) was observed after both LP UV and UV LED irradiations. Analysis of treated water showed release of micropollutants from their conjugated forms, which occur at concentrations comparable with parent compounds but they are rarely studied at WWTPs [1; 2]. The fate of conjugates - glucuronides, sulfates – was also studied in follow-up laboratory experiments. Deconjugation (followed by increases in concentrations of parent micropollutants) as well as parallel degradation of free micropollutant forms were confirmed by LC MS/MS in different time periods. These observations indicate anti-microbial efficiency but also potential risks for water quality of the UV disinfection treatment of effluents.

3.18.P-Mo312 Tracking and Removal of Organic Micropollutants in the Urban Water Cycle: the Role of Wastewater Treatment Plants

Cristina Postigo[1], *Miguel Angel Gómez-Nieto Prof*[1] *and Jorge Ignacio Pérez-Pérez Prof*[2]*, (1)Civil Engineering / Institute of Water Research (IdA), University of Granada (UGR), Spain, (2)Building Engineering and Engineering Projects, University of Granada (UGR), Spain*

Organic micropollutants (OMPs) are the main cause of water quality deterioration. OMPs include not only a huge variety of anthropogenic chemicals, but also the byproducts generated after natural (photolysis and biodegradation) and engineered processes (chemical, biological and disinfection treatments). Therefore, OMP mixtures present in water are very complex and diverse. The chemical diversity of OMP mixtures is related to pollution sources and engineered solutions that impact the water, the physical-chemical properties of the water itself, and meteorological events, among others. To fully characterize OMP mixtures, wide-scope non-targeted analytical strategies are needed. In this sense, advanced analytical techniques based on high resolution mass spectrometry (HRMS) detection in combination with chemometrics reveal as very useful tools for the comprehensive analysis of OMPs in water. As a case study, this methodology has been applied to evaluate the effect that the construction and operation of a wastewater treatment plant has on the water chemical quality of Genil River as it flows through the municipalities of Huetor Tajar and Villanueva de Mesía (Granada, Spain). For this, grab water samples collected along the river stream before and after known locations of non-treated water discharge and the wastewater treatment plant were collected before and after the wastewater treatment plant came into operation. To cover a wide range of chemicals in the analysis water samples were 200x concentrated through lyophilization, and the extracts obtained were analysed by liquid chromatography-HRMS using a quadrupole-time of flight analyser. Differences among samples and OMPs of interest will be identified by chemometrics. This work aims at assessing the effect of the newly built wastewater treatment plant in the water quality of the Genil River, revealing the OMPs that persist the water treatment, and further exploring their environmental risks, as well as their removal with currently used advanced treatments. Results addressing these objectives will be presented.

3.18.P-Mo313 Assessment of Illicit Drugs Use in Seoul, Capital City of South Korea for 21 Days by Wastewater-Based Epidemiology

Ha Hyun Lim[1] *and **Jeong-Eun Oh***[2]*, (1)Department of Civil and Environmental Engineering, Korea, Republic of (South), (2)Department of Civil and Environmental Engineering, Pusan National University, Korea, Republic of (South)*

The recent surge in drug-related crimes has become a serious societal concern both domestically and globally. To suppress and prevent drug offenses, it's imperative to understand the prevalence of illegal drug usage. The drug consumption has primarily been monitored through conventional methods such as surveys, seizure quantities, and prescription records, which have limitations in accurately gauging actual drug usage. To address this, Wastewater-Based Epidemiology (WBE) has emerged as an alternative method, widely adopted due to its ability to estimate drug consumption rates by analyzing drug residues in wastewater. While many countries used WBE for monitoring drug usage, previous domestic studies were limited to certain cities, conducted over a short period (within three days), or involved monitoring only for one day nationwide. Furthermore, the absence of previous monitoring studies in Seoul, capital city of South Korea, makes it crucial to monitor drug consumption patterns in the city, especially considering the significant surge in drug-related crimes. Therefore, illegal drug usage was investigated in Seoul, the capital city of South Korea, for 21days using WBE to assess illicit drug consumption patterns for the first time by region and social status. Out of the 22 compounds, 10 were detected. Among these, Methamphetamine showed a 100% detection rate, with an average consumption rate of 16.25 mg/day/1000 people, the highest among the detected substances. This study showed lower consumption rates than most other countries. Furthermore, Methamphetamine usage was similar to or lower than previous domestic research. Notably, Cocaine and MDMA, previously undetected, were identified in this study. The usage patterns of these illicit drugs did not exhibit specific daily patterns. While some compounds showed slightly higher consumption on weekends compared to weekdays, no statistically significant differences were observed (Mann-Whitney Rank Sum Test, $p>0.05$). Moreover, Methamphetamine and MDMA displayed stable daily consumption patterns. Methamphetamine and MDMA consumption rates varied significantly by region ($p<0.05$), correlating positively with average annual income and education levels ($p<0.05$).

3.18.P-Mo314 Water Monitoring along Railway Tracks in Germany

Sabrina Michael[1]*, Markus Zingelmann*[2]*, Majo Karthe*[2]*, Martin Sonntag*[2] *and Sonja Szymczak*[1]*, (1)Environment and Sustainable Mobility, German Centre for Rail Traffic Research at the Federal Railway Authority, Germany, (2)Beak Consultants GmbH, Germany*

In general, rail transport shows a lower emission of pollutants compared to other modes of transport. However, it has an impact on the environment and especially on natural resources near the tracks, e.g. surface and groundwater bodies. Organic and inorganic substance emissions from todays and past rail operations and associated infrastructure maintenance works, as well as abrasions are of particular importance. The study focuses on released pollutants and their emission into adjacent groundwater, surface water and into the soil. The results are important for closing current knowledge gaps and creating a basis for a comprehensive environmental risk assessment and the derivation of prevention strategies. Five monitoring sites have been set up along the German railway network. Two of these focus on identifying potential impacts and emissions from railway tracks into nearby surface waters. In addition, the pollutant load in seepage water and groundwater (inflow and outflow) can be determined at all monitoring sites. The monitoring design consider both, relevant emissions from vegetation control and constant input from abrasions. Since 2021, water samples have been taken at least twice a year at all locations and analysed using standardized methods. The results show that the railroad operation emits heavy- and semi-metals in particular into the surface water and groundwater. Following vegetation control and the subsequent application of herbicides, glyphosate and its metabolite AMPA, flumioxazine and flazasulfuron were detected in downstream surface waters as well as in seepage water itself. Herbicides were only detected in surface waters if the precipitation occurred less than 10 days after the vegetation control. Other herbicides (e.g. atrazine, bromacil or pelargonic acid) or organic substances were only detected in traces in the soil around the track. The study forms an important part of the official monitoring concept and gains a deeper understanding of the release of pollutants along railway tracks into the surrounding environment. These investigations are an important contribution to the derivation of prevention strategies for track wastewater treatment and to the sustainable development of rail transport as such.

3.18.P-Mo315 Estimation of the usage of drugs of concern in the Southern Ontario, Canada, through wastewater-based surveillance

Diana M. Cardenas-Soraca[1], *Sandra Salic*[1], *Lily Warkentin*[1], *Paola A. Ortiz-Suarez*[1], *Cheryl Chong*[1], *Rashne Vakharia*[1], *Leslie Bragg*[2] *and Mark R. Servos*[2], *(1)Department of Biology, University of Waterloo, Canada, (2)Biology, University of Waterloo, Canada*

Wastewater-Based Surveillance (WBS) is a powerful tool for assessing and monitoring drug consumption within our communities. This approach has played a crucial role in the public health decisions, especially during the COVID-19 epidemic. However, implementing WBS programs face challenges, such as lack of reliable strategies to normalize the mass load per capita as well as the complexity of extracting these compounds from the wastewater.

To overcome these issues, an analytical method combining solid phase extraction (SPE) with liquid chromatography tandem mass spectrometry (LC-MS/MS) was developed to analyze a 19 of drugs of concern. The method achieved limits of detection from 0.7 to 49.3 ng/L for LSD and methamphetamine respectively. The final method was applied to wastewater collected from January 2022 to February 2023 across several wastewater treatment plants in Southern Ontario revealing varied drug concentrations ranging from 20 to 5000 ng/L. This data is important for comparing per capita drug usage and provide objective insights for health policymakers.

3.18.PC Next-Generation Urban Water Management: Improved Understanding of the Fate of Micropollutants, Transformation Products, Pathogens, and Antimicrobial Resistance

3.19 Passive Sampling: Analysis, Transport, Fate and Monitoring of Persistent, Mobile and Toxic Substances in the Environment

3.19.T-01 PASSIVE SAMPLERS FOLLOWED MASS SPECTROMETRIC TECHNIQUES FOR AN EFFICIENT EVALUATION OF HONEY BEE CHEMICAL EXPOSOME

María Murcia Morales[1], *Maria del Mar Gómez Ramos*[1], *Jose Antonio Martinez*[1], *Francisco José Díaz-Galiano*[1], *José Luis Oller-Serrano*[1], *Cristian Valderrama Conca*[1], *Jozef van der Steen*[2], *Ivo Roessink*[3], *Flemming Vejsnæs*[4] *and* ***Amadeo Rodriguez Fernández-Alba***[5], *(1)University of Almería, Spain, (2)AlveusAB, Netherlands, (3)Wageningen University & Research (WUR), Netherlands, (4)Danish Beekeepers Association, Denmark, (5)Chemistry and Physics Department, University of Almería, Spain*

Honeybee (*Apis mellifera*) health has been severely impacted by multiple environmental chemical stressors including pesticide exposure, environmental contaminants and other endogenous or exogeneous chemicals. Their impact on bee health is therefore a complex multifactorial problem which requires a holistic investigative approach. Many studies have been directed on such but with important limitations related to very limited analytical scopes, not enough sensitivity, or strong thump in the colonies in long term monitoring studies due to the use of live animals or parts of the beehive for the analysis. Furthermore, the need of standardization hinders the comparability of the results in different studies and varying environments.

In this study, a non-biological passive sampler based on Tenax-TA is described: the APIStrip (Adsorb Pesticide In-hive Strip). The use of this non-invasive sampling device is harmless for colony: the human interaction is minimal, and no resources are subtracted from honeybees. Of particular importance is the capability of standardization and the accumulation of chemicals for periods of time (typically 15 days) that facilitates an extensive monitoring at trace concentration levels of both target and non-target chemicals. The extraction of these APIStrips followed by low- and high-resolution mass spectrometry analysis report an extensive and unmatched data of chemicals present in the colony. Preliminary tests demonstrated the high efficacy, sensitivity, representativeness, and reproducibility of the APIStrip-based sampling.

Our findings raise the interest in using APIstrip as passive sampler followed by mass spectrometry techniques allowing an extensive evaluation of target (such as pesticides) and non-target compounds. This study not only presents a robust analytical methodology utilizing APIStrips for hive environment assessment but also sheds light on the diversity of organic compounds present in beehives across different areas and temporal settings. Both together resets a clear picture of the chemical environmental exposures of bees in the beehive.

3.19.T-02 Identifying persistent, mobile and toxic (PMT), and very persistent and very mobile (vPvM) substances in stormwater systems using passive samplers

***Fabienne Maire**[1] and Lena Mutzner[2], (1)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Dübendorf, Switzerland, (2)Urban Water Management, Eawag - Swiss Federal Institute of Aquatic Science and Technology, Switzerland*

Urban stormwater runoff from impervious areas has been recognised as a significant contamination source for various organic and inorganic pollutants in aquatic ecosystems. However, data are scarce regarding environmental pollution levels, particularly for persistent, mobile and toxic (PMT), and very persistent and very mobile (vPvM) substances.

For future monitoring programmes to incorporate critical organic substances, a data-driven approach to support the selection of priority substances alongside systematic, transferable monitoring tools is necessary. In the water phase, passive sampling was highlighted as a promising tool for measuring dissolved organic micropollutants, including PMT/vPvM substances.

In this study, we aim to identify PMT/vPVM priority substances that could potentially occur in stormwater systems in a comprehensive literature review and assess the effectiveness of two different passive sampling receiving phases from AttractSPE®, hydrophilic-lipophilic balance (HLB) and styrene-divinylbenzene reversed phase sulfonated (SDB-RPS) disks, for the set of identified potential urban stormwater contaminants.

Based on current literature, a list of fourty target analytes was compiled. The list of targets, comprising thirty PMT/vPvM substances, was supplemented by ten high-risk (occurrence >50%, risk quotient > 1) stormwater pollutants previously identified in urban areas. In a laboratory-scale experiment, the applicability of passive samplers for stormwater monitoring will be evaluated for the selected substances. In agreement with previous studies on a set of hydrophilic organic contaminants, we hypothesize that both AttractSPE® SDB-RPS and HLB disks are well-suited sampling phases for the chosen PMT/vPvM substances. Minor differences in sample uptake are expected due to slight differences in sampler properties, potentially showing slightly higher mass accumulation on the HLB disks.

Our systematic approach to identifying PMT/vPvM substances has revealed 47 substances that are highly likely to occur in urban stormwater and can be quantified using LC-HRMS/MS. As an initial set of target analytes, fourty substances could be prioritised when measuring urban stormwater for PMT/vPvM substances.

3.19.T-03 Passive sampling calibration for persistent and mobile chemicals

***Emma Knight**, Ian John Allan, Jan Thomas Rundberget and Bert van Bavel, Norwegian Institute for Water Research (NIVA), Norway*

Passive sampling techniques have been widely used for the monitoring of contaminants in water bodies, yet advancements in targeting persistent and mobile substances remain limited. This study focused on evaluating the performance of a polar organic chemical integrative sampler (POCIS) investigating analytes from three different chemical classes considered to have persistent and mobile substances. A laboratory calibration using two types of passive sampling HLB discs (HLB 1 and HLB 2) sandwiched between 5 µm pore size stainless steel membranes and POCIS rings were used to measure the uptake rates for ten analytes over a 28-day period. The discs were made of different materials: HLB 1 disc was made of 90 % sorbent and 10 % binding agent and HLB 2 was made of loose HLB sorbent packed between a glass fibre membrane. In the experimental setup, two stainless steel containers, each holding approximately 96 L, were filled to around 80 L capacity. These containers were then spiked with analytes at a concentration of 0.05 ng/mL, encompassing three different classes of contaminants: four per- and poly-fluoroalkyl substances (PFAS), one triazine, and five triazoles. Over the 28-day period, duplicate water samples were taken daily and HLB samplers removed either in triplicate or a singular replicate depending on the passive sampler configuration on days 1, 2, 4, 7, 14 and 28. Extracted samplers and water samplers were analysed using UPLC-MS. Results for the benzotriazoles showed higher sampling rates for HLB 1 (137-643 mL/d) compared to HLB 2 (58-232 mL/d), indicating there is a difference between the disc properties on the uptake of contaminants into the sampler. The sampling rates also indicate that the HLB 1 configuration may be more sensitive to water turbulence compared to the HLB 2 configuration. Therefore, understanding and accounting for these differences in disc properties and their influence on uptake dynamics is crucial for accurately monitoring persistent and mobile substances in the aquatic environment.

3.19.T-04 Combination of Passive Samplers, Bioassays and Nontargeted Screening as a Tool for a Decision Making

Roman Grabic[1]*, Andrea Vojs Staňová*[2]*, Kateřina Grabicová*[3]*, Branislav Vrana*[4]*, Zuzana Toušová*[5]*, Marie Smutna*[6] *and Klara Hilscherova*[6]*, (1)University of South Bohemia in Ceske Budejovice, Faculty of Fisheries and Protection of Waters, Czech Republic, (2)Faculty of Fisheries and Protection of Waters, Research Institute of Fish Culture and Hydrocenoses, University of South Bohemia in České Budějovice, Faculty of Fisheries and Protection of Waters, Czech Republic, (3)University of South Bohemia in České Budějovice, Faculty of Fisheries and Protection of Waters, Czech Republic, (4)Recetox, Masaryk University, Czech Republic, (5)RECETOX, Faculty of Science, Masaryk University, Czech Republic, (6)RECETOX, Masaryk University, Czech Republic*

Passive samplers were recognized as low-cost tools for obtaining more representative information on water pollution than grab or 24-hour composite samples. Because we cannot detect all chemicals present even in the extract, the bioassays remain the only tool for biological effect evaluation. However, there is a need to identify effect drivers, which can be forwarded to the next decision-making stage. Several approaches combine targeted and nontargeted analysis with bioassays to the effect´s explicability of the mixtures. We applied fractionation in 2D to reduce the complexity of the mixture and used affinity clean-up for selective extraction of unknowns of interest.

Commercially accessible AttractSPE®Discs HLB were deployed in WWTP effluent for two weeks. The initial extract was separated at the Arion polar C18 column into 10 fractions. The battery of bioassays was applied to investigate the effect of individual fractions. The active ones were offline fractionated at the Arion phenyl-butyl column and analyzed with bioassays identically to 1D fractions. All 1D separated fractions, 2D separated active fractions, and initial samples were analyzed by a nontargeted acquisition method combining liquid chromatography separation with full scan high-resolution and data-independent MS2 mass spectrometry. Selective affinity-based purification was applied to decrease the complex extract's matrix effect further and improve the detectability of effect drivers with a two-stage nontargeted screening workflow.

The complexity of the mixture was lowered by fractionation from about 4100 features to 2800 features in 1D fractions. This separation also affected the bioassays themself as extract cytotoxicity was lowered. The AhR effect was found in two consecutive fractions, further fractionated in 2D. The second dimension showed a good recovery of the 1D observed effect. The number of features detected in all 2D active fractions ranged from 975 to 1900 for F7 fractions and 580 to 1450 for F8 fractions, which was unsuitable for effect driver identification.

The affinity purification seems promising as the fraction's complexity level was lowered much more than in the case of fractionation only. The two-stage acquisition workflow allows for highly selective identification of TTR ligands. Applying affinity-based purification as an additional step to fractionation helps reduce the extract's complexity and enables the successful identification of effect drivers in the mixture.

3.19.P Passive Sampling: Analysis, Transport, Fate and Monitoring of Persistent, Mobile and Toxic Substances in the Environment

3.19.P-We190 Investigation of mutagenic aromatic amines in municipal wastewaters using passive sampling

Branislav Vrana[1]*, Simona Krupčíková*[1]*, Marek Stiborek*[1]*, Zdeněk Šimek*[1]*, Anna Goellner*[2] *and Melis Muz Massei*[2]*, (1)Recetox, Masaryk University, Czech Republic, (2)Department of Effect-Directed Analysis, Helmholtz Centre for Environmental Research (UFZ), Germany*

Aromatic amines (AAs) represent an environmentally important group of contaminants, including known and suspected mutagens. They enter surface waters from different sources directly from industrial emissions or indirectly as metabolites of pesticides and have the potential to endanger aquatic ecosystems. Municipal wastewaters (WW) present a not yet-investigated potential emission source of AAs. AA from sources in the indoor environments, emitted to municipal WW, may significantly contribute to their presence in receiving water bodies. Our study aimed to test a representative method for monitoring AAs in WW and recipient surface water using a combination of passive sampling (PS) with targeted analysis and suspect screening.

Three PS variants were tested for monitoring AAs in influent and effluent of a municipal wastewater treatment plant (WWTP) serving the city of Brno, Czech Republic. The uptake of AA to HPS was compared with their content in 24-hour composite water samples. The targeted analysis of samples on LC/tandem mass spectrometry included about 50 AAs with potential to cause adverse effects. Further, suspect screening of AAs on samples was performed using LC/high resolution mass spectrometry to contribute to prioritisation for further targeted developments. Finally, unknown AA patterns accumulated in samplers deployed in WWTP influent and effluent will be compared using non-target screening methods in order to evaluate the AAs that could be eliminated/treated and the newly generated AAs during the treatment process as transformation products.

All samplers accumulated a comparable number of AAs in targeted analysis, and integrative uptake was observed up to 28 days in both influent and effluent of the WWTP. For compounds present simultaneously in water and PS in at least 50% of the samples, sampling rate (R_s) estimation was performed. Robustness of R_s was assessed by comparing their calculated values for compounds occurring in both WWTP influent and effluent. Finally, removal efficiency of AAs in the wastewater treatment was assessed using the sampler variant with robust R_s values. Our study demonstrates the possibility for obtaining coherent results with passive samplers despite the differences in their construction. The sampler variant fitted with agarose diffusive hydrogel layer with the broadest range of accumulated compounds is especially attractive for suspect screening or non-targeted analysis of aquatic contaminants.

3.19.P-We191 Exposure assessment to organophosphate esters, phthalate esters and alternative plasticizers from recycling workers in Colombia using t-shirts as passive samplers

***Boris Johnson-Restrepo**[1], Jessica Paola Mercado-Paez[1], Fredys Sanchez-Catalán[1], Aleix Balasch Garcia[2] and Ethel Eljarrat[2], (1)Environmental Chemistry Research Group, University of Cartagena, Colombia, (2)Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain*

Clothing may be an important contributor to our daily exposure to various chemicals. Wearing clothes in polluted places could be a hidden source of potentially harmful substances. Human on daily lives, clothes constantly interact with the environment, accumulating a range of chemicals. These can come from diverse sources such as air pollution, household dust, and other envrionment sources. Sampling was conducted at the Industrial Park Recycling in Cartagena, Colombia, where there are workers engaged in the plastic recycling activities. T-shirts made from 100% cotton were provided to volunteer workers from this area at the beginning of their workday. From each t-shirt it was cut a piece of 14 × 20 cm2, and afterwards sliced into pieces of 1 × 1 cm^2. Extraction was performed using pressurized liquid extraction (PLE). Hexane:acetone (1:1) was used as the extraction solvent, and two static extractions were performed at 1600 psi and 50 °C, resulting into an extract around 35 mL. The extracts were injected in an online sample purification and analysis method based on turbulent flow chromatography (TFC) coupled to liquid chromatography (LC) and a triple quadrupole (QqQ) tandem mass spectrometry (MS-MS). On this study, concentrations of 16 OPEs, 11 PAEs and 3 alternative plasticizers were measured in cotton T-shirt samples. In this study, 16 out of 20 OPEs analyzed were detected in cotton shirt samples previously worn by recyclers. The total average concentrations of Σ_{16}OPEs were (mean ± SD) 11.0 ± 12.7 ng/(dm²*h), with a median of 2.7 ng/(dm²*h), ranging from 1.06 to 43.4 ng/(dm²*h). The highest detection frequencies (%DF) were found to be ≥97% for five specific OPEs: TEP, TClPP, TPHP, TBOEP, and TEHP. These five chemicals accounted for 96% of the total OPEs. The total average concentrations of Σ10PAEs were (mean ± SD) 2,087 ± 2,470 ng/(dm²*h), with a median of 1,040 ng/(dm²*h), ranging from 201 to 11,143 ng/(dm²*h). Detection frequencies (%DF) were found to be 100% for six target PAEs: DEP, BBzP, DnOP, DiDP, DiNP, DHexP, and DEHP and for the rest of the phthalates, %DF ranged from 61% to 94%. Three out of ten chemicals were the predominant PAEs. These results showed that clothings are an important source to exposure to these chemicals. DEHP, DiNP, and DiDP were the predominant PEAs and DEHA, ATBC, and DINA were the most abundant Non-PAEs detected. On the other hand, TEP, TCIPP, TEHP, TPHP, and TBOEP were the most predomiant OPEs in the T-shirt samples.

3.19.P-We192 The IMPART project – a citizen science approach to using passive samplers to monitor for emerging contaminants

***Alexandra Kate Richardson Dr, BSc(Hons.), MRes**, Stav Friedman and Leon Barron Dr, Environmental Research Group, Imperial College London, United Kingdom*

The Imperial Monitoring using Passive Samplers to Assess River Tributaries (IMPART) project utilises a citizen science approach to monitoring local rivers for contaminants of emerging concern using a miniaturised 3D-printed passive sampler device (3D-PSD). The 3D-PSDs are manufactured from a methacrylate-based resin and hold up to five individual 9 mm sorbent disks. Seventeen citizen scientists were engaged from four community groups across three UK sites - Brent, Norwich, and Sheffield. Utilising their local river knowledge and experience, the citizen scientists were trained to deploy and retrieve the HLB-orientated 3D-PSDs (unaided) in locations of their choosing for seven days during September 2022. Water samples were collected, and field blanks were exposed by the citizen scientists during deployment and retrieval.

In total, 25 passive sampler devices were successfully deployed and retrieved by the citizen scientists and returned to Imperial College London for quantitative analysis with no device losses. Across all sites, 57 unique compounds were quantified on the passive sampler and 35 compounds were common to all three sites. Bisoprolol was quantifiable on the passive samplers across all 25 deployment sites over the range of 0.01 to 2.0 ng $disk^{-1}$. In the water samples, only 20 unique compounds were qualifiable above method LLOQ across all sites, demonstrating the increased sensitivity of passive sampling, even at a miniaturised scale, for the monitoring of contaminants at environmentally relevant concentrations. Across the three sites, the average mass on the passive sampler was 0.9 ± 1.4 ng $disk^{-1}$, 0.5 ± 1.1 ng $disk^{-1}$, and 0.5 ± 0.9 ng $disk^{-1}$ for Sheffield, Norwich, and Brent, respectively. Within each site, sources of pollution were clearly identifiable from the 2.5 to 4-fold increase in the total mass of contaminants accumulated onto the 3D-PSD. There were between four and three unique compounds per site and multivariate statistics are being explored to determine if it is possible to classify rivers based on their chemical profile which has been demonstrated in the London tributaries. This work demonstrates the applicability of the 3D-PSD to citizen science and community engagement projects.

3.19.P-We193 Polytetrafluoroethylene (PTFE) Membranes for Passive Sampling of Hydrophilic Compounds in Water: a Big Yes

***Naomi Reymond**[1], Vick Glanzmann[1], Céline Weyermann[1] and Nicolas Estoppey[2], (1)School of Criminal Justice, University of Lausanne, Switzerland, (2)Norwegian Geotechnical Institute (NGI), Norway*

Passive sampling techniques are particularly efficient to monitor organic contaminants across various aqueous matrices. One common type of passive samplers, Chemcatchers, utilises a sorbent covered by polyethersulfone (PES) membranes to sample hydrophilic micropollutants. However, numerous studies have recommended replacing this membrane due to its high analyte sorption capacity, especially for the less hydrophilic compounds.

This research project investigated the potential of polytetrafluoroethylene (PTFE) membranes in Chemcatcher-like passive samplers. Calibration of 44 hydrophilic micropollutants was conducted using this sampler design within a channel-system featuring four distinct water velocities ranging from 5 to 40 cm s^{-1}. LC-MS/MS analyses revealed that the sorbent (styrenedivinylbenzene – reverse phase sulfonate, SDB-RPS) accumulated compounds on average more than 2,000 times than the PTFE membrane. This emphasized the suitability of PTFE as a membrane material for hydrophilic micropollutant sampling.

Sampling rates (R_S) were determined for each analyte at varying water velocities, ranging from 0.027 L day^{-1} to 0.300 L day^{-1}. By establishing relationships with the mass transfer coefficient of the water-boundary layer (k_w) that depends on hydrodynamics, it became feasible to determine site-specific R_S. Additionally, the relative contributions of each phase (i.e., water boundary layer, membrane, and sorbent) to mass transfer was determined. Estimations showed that thicker PTFE membranes ($\geq$ 100 µm) would completely shift uptake control towards the membrane when the hydrodynamic conditions exceed 20 cm s^{-1}, thus enabling the prediction of R_S for any hydrophilic organic compound without the need for time-intensive calibration experiments in conditions usually encountered in rivers.

In summary, this project significantly enhances the understanding of the role of membrane characteristics and hydrodynamic conditions in passive sampling. This could potentially facilitate the prediction of R_S for hydrophilic micropollutants, contributing to the advancement of passive sampling techniques for environmental assessment and monitoring.

3.19.P-We194 Characterization of Emission Products Formed during Firing of Small Caliber Ammunition

*Arjan den Otter and **Wouter van de Steeg**, TNO, Netherlands*

During the firing of ammunition, emission products are formed to which the shooter and the environment will become exposed to. In order to judge which weapon-ammunition combination can best be used in certain situations to reduce the exposure of personnel as much as possible, it is important to know which parameters influence the formation of the emission products and the routes via which the emission products can leave the weapon. This study provides an overview of the various parameters that directly or indirectly influence the formation of emission products. Besides that two types of setups for experimental determination of emission products are described.

In one type of these setups, the emission is measured at the location where typically the head of the shooter is located and analyzed for a range of toxic compounds and for particles. Using this setup several weapon-ammunition combinations, the influence of using a silencer and firing single shots versus a burst of 10 shots were evaluated. Using another type of setup, the weapon can be fired in a confined space. Both during and after firing and homogenization, the emission products can be analyzed. The benefit of this setup is that the influence of parameters like ventilation on the experimental results is limited, facilitating comparison of different weapon-ammunition combinations studies at different locations.

During experiments it was shown that although the firings were identical, large concentration variations were measured between the individual firings, most likely due to variations in the burning process in the weapon or the ventilation flow. When a silencer was used, typically concentrations of emission products were higher than without silencer. Based on concentrations measured during these experiments, the main components of concern were carbon monoxide and fine dust (< 1 µm). For ammunition containing lead and antimony, these are components that need specific attention. Nitric oxide could become a substance of concern when shooting for a long time.

It is important that a standardized method for performing emission measurements under controlled conditions is available. This will enable comparison of the different research results and to draw more solid conclusions regarding the influence of various parameters on the formation of emission products. This will contribute to an improvement of the assessment of the risks to which a shooter is exposed to during firing of ammunition.

3.19.P-We195 Personal Exposures of Waste Collection Workers to Nitrogen Dioxide and Ozone During Day Time and Night Shift Hours on 24 Different Collection Routes

*Gizem Çınar and **Eftade Emine Gaga**, Environmental Engineering, Eskisehir Technical University, Turkey*

Waste collection workers are potentially exposed to health, environmental and safety risks due to various chemical and biological substances in the waste to be collected. The job descriptions of waste collection workers usually consist of driving truck, collecting and emptying waste containers or sacks and unloading waste at waste receiving facilities. Typical rear loader operations require manual lifting of materials into collection vehicles but a fully automated collection minimizes manual lifting and reduce exposure to contaminants. There is usually one or two more staff in the vehicle usually at the rear loader besides the driver. In this study, personal exposure to gaseous pollutants was determined in 70 employees working in municipal cleaning works, 24 of whom were drivers and 46 of whom were personnel collecting garbage behind the vehicle. Passive samplers were used to measure exposure concentrations of nitrogen dioxide (NO_2) and ozone (O_3). The workers carried the passive samplers with armbands on their arms only during working hours. During the personal sampling, the trucks collected waste along 24 different routes. The exposures of the driver and the workers in the back of the truck were compared and the route-dependent variability of the measured pollutants was analysed. When we analyzed the sampling routes separately according to the traffic density (low, medium, high), it was observed that the NO_2 exposure in the two groups was correlated with traffic density with higher concentrations on routes with higher traffic density. The results also showed that the exposure of workers at the rear loader to NO_2 was significantly higher than that of truck drivers ($P < 0.005$). The exposure of the workers was analysed based on the type of garbage collection (waste container, manual collection of garbage bags, both), and a statistical difference was observed ($P < 0.005$). There is a significant difference between the NO_2 exposure concentrations of drivers working in day and night shifts ($P < 0.005$).

Keywords: *Passive sampling, NO_2, Ozon, Waste collection, Exposure*

3.19.P-We196 Characterization of Covalent Organic Frameworks as Adsorbents for Pharmaceuticals in Water

Joana Campos Araújo[1]*, Gabriel Brantuas Arijón*[1]*, Beatriz Carneiro*[1]*, Laura M. Salonen*[2]*, Marta M Pazos Currás*[3] *and Begoña Espina*[4]*, (1)International Iberian Nanotechnology Laboratory, (2)CINBIO, Universidade de Vigo, Department of Organic Chemistry, Spain, (3)Universidade de Vigo, Departamento de Ingeniería Química, Edificio Isaac Newton Despacho 21 Planta baja, Campus Universitario As Lagoas-Marcosende, Spain, (4)International Iberian Nanotechnology Laboratory, Portugal*

In the present work, several covalent organic frameworks ($TpBD(CF_3)_2$, $TpBD\text{-}Me_2$ and TPB-DMTP) were challenged to adsorb several pharmaceuticals considered among the most important emerging pollutants in water: the antibiotics sulfapyridine, sulfamethoxazole and tetracycline and, the anti-inflammatory diclofenac. $TpBD(CF_3)_2$ was the best adsorbent for sulfonamides. The adsorption yields reach 70 and 88% for sulfamethoxazole and sulfapyridine respectively, showing rapid adsorption reaching equilibrium at 30 min. The pH plays a significant role in the adsorption mechanism, especially at basic pH where the target molecules are negatively charged, which suggests that there is an effect of repulsion of charges or that the formation of hydrogen bonds is prevented.

For the adsorption of tetracycline, $TpBD\text{-}Me_2$ proved to have the best potential to be used for adsorption as it retained a good adsorption efficiency (up to 90%) while not having to use the fluorinated material. When tested at different pHs, the adsorption of tetracycline by $TpBD\text{-}Me_2$ was more efficient at pH 6 when the pharmaceutical compound was at the dominant zwitterionic form.

For the adsorption of diclofenac, TPB-DMTP showed the highest adsorption capacity between the analysed COFs (up to 50 mg/g experimentally). This COF stands out for its higher surface area and larger pores. The adsorption of diclofenac by TPB-DMTP was more efficient at pH 6 than pH 9, pointing to a lower affinity of the COF for the deprotonated form.

Isopropanol was determined as the best desorption solvent for all pharmaceuticals, with percentages of recoveries between 65% and 100% being sulfapyridine and diclofenac the less and the most efficiently desorbed, respectively. Desorption kinetics indicated that the optimum time of desorption was between 15 min and 2 h depending on the pharmaceutical. This desorption capacity makes reuse possible in up to five successive cycles of adsorption-desorption, enabling the implementation of these materials for passive sampling more sustainable and cost-efficient.

Acknowledgement - The authors thank financial support through the project Charm (PTDC/QUI-OUT/2095/2021) funded by the FCT.

3.19.P-We197 Comparison of Recent Attract HLB to Established Biotage HLB and Empore SDB-RPS Phases for Passive Sampling of Pesticides

Emmanuel Schaad*, Sergio Cirelli and Aurea C. Hernández, University of Bern, Switzerland*

In recent years, passive sampling (PS) has been widely applied to monitor organic micropollutants in aquatic environments as a cost-effective tool. Its ability to enrich compounds in situ and providing a time-weighted average makes it a suitable alternative to costly automated sampling. Various PS phases have been studied and characterised regarding uptake of pesticides from water. However, with some phases having experienced shortages in production, alternative materials need to be investigated and compared to enable faster changes from one producer to another in case of discontinuation, even more so as there is no standardised material for PS with secured production.

This work investigates the recently introduced hydrophilic-lipophilic balanced (HLB) phase (Attract product line) from the French company Affinisep for uptake suitability of PPPs and compares it to the well-established HLB phase produced by Biotage and the widely applied polystyrene-divinylbenzene reversed-phase sulfonated (SDB-RPS) phase of Empore.

The samplers (47 mm disks, custom steel-plate housing) were calibrated for different hydrodynamic regimes (flowing vs. stagnant, continuous replenishment of spiked water) over a two-week period. In addition, all PS phases were evaluated in the field to compare in-situ calibration with the laboratory study. Furthermore, partition coefficients were determined via a shaking and equilibrating experiment. Additionally, the Affinisep HLB phase was further investigated to test its ability for sediment pore water sampling of PPPs for a future study using custom-made sheets.

Our data suggest that the more recently introduced HLB (Affinisep) phase is well suited to study a wide range of pesticides (69 analytes) with different $logK_{ow}$ (-1.7 to 5) compared to the well-established Biotage HLB and Empore SDB-RPS phase. Our kinetic uptake studies show that Affinisep HLB exhibits higher sampling rates compared to HLB from Biotage, resulting in larger analyte amounts sorbed to the disk overcomes issues of sensitivity. The data indicates the suitability for short-term deployments of this new PS phase.

Overall, this study provides new PS properties such as sampling rates and partition coefficients for a wide range of PPPs which will help improve existing uptake models.

3.19.P-We198 Accelerated solvent extraction (ASE) of passive samplers as an efficient tool for the monitoring of hydrophobic micropollutants in water

Ines Tascon[1]*, Fabienne Pfeiffer*[1]*, Céline Weyermann*[1] *and Nicolas Estoppey*[2]*, (1)School of Criminal Justice, University of Lausanne, Switzerland, (2)Norwegian Geotechnical Institute (NGI), Norway*

Water, as an essential resource, contributes to the growth of ecosystems and needs to be preserved and protected from potential harm. Persistent organic micropollutants, such as polychlorinated biphenyls (PCBs), polybrominated diphenyl ethers (PBDEs), and polycyclic aromatic hydrocarbons (PAHs), may cause harm due to their toxicity even in low concentrations. Monitoring these compounds in surface waters is crucial to preserve biodiversity, achieve good water quality, and investigate contaminated rivers to identify pollution sources.

To this end, the use of passive samplers to measure contaminant concentrations is becoming more widespread. Passive samplers offer high sensitivity, lack confounding matrix effects, and have a relatively easy deployment system. These samplers are usually extracted with Soxhlets, followed by purification of the extracts on chromatographic columns and quantification by gas chromatography-tandem mass spectrometry (GC-MS/MS). Currently, one of the biggest limitations of passive sampling for hydrophobic contaminants is the time- and resource-consuming analysis.

The aim of this work is to improve the efficiency of the current methodology, allowing passive sampling to become more routinely used for the monitoring of hydrophobic contaminants. An automated method, accelerated solvent extraction (ASE), has been tested and optimized to reduce the time and resources needed. For this purpose, samplers were spiked with target compounds under controlled conditions in the laboratory. In total, nine ASE methods were tested, and the results were compared with those obtained from Soxhlet extractions. The most efficient ASE method was chosen and will be tested on field samplers to assess the influence of environmental factors on the extraction. However, some PAH contaminations were detected. Thus, further optimization needs to be tested to avoid cross-contamination between samples, for example, by inserting more blank extractions between samples.

Improving the extraction of these passive samplers would facilitate their implementation on a larger scale for monitoring campaigns of micropollutants.

3.19.P-We199 Illicit drug epidemiology in Luxembourg using passive sampler based load balancing in wastewater treatment plants with different socio-economic population

Tom Galle[1]*, Denis Pittois*[2]*, Nicolas Villani*[3]*, Adèle Bourmaud*[3] *and Serge Schneider*[3]*, (1)Erin, Luxembourg Institute of Science and Technology (LIST), Belvaux , Luxembourg, (2)Erin, Luxembourg Institute of Science and Technology (LIST), Luxembourg, (3)Analytical toxicology – pharmaceutical chemistry service, National Health Laboratory (LNS), Luxembourg*

Establishing load profiles of illicit drugs for urban communities at the inlets of wastewater treatment plants is challenging in terms of temporal representativeness. The problem is addressed by operating relatively cumbersome flow-proportional monitoring with autosamplers over several days. Besides being logistically limiting in terms of numbers of plants that can be monitored, the stability of the compounds during the storage time in the samplers is one of the issues adding to uncertainty. Here we used our formerly introduced weekly sampling with passive samplers to calculate inlet loads for illicit drugs. The approach calibrates the passive samplers at the low concentration variability of the outlet and calculates the inlet load via the elimination. The latter is obtained by the ratio of inlet/outlet mass of a compound in the passive samplers following a normalization with an inert compound to compensate for sampling rate differences. The approach was successfully applied for pharmaceuticals, biocides and household chemicals and was now tested on illicit drugs. For this purpose 9 wastewater treatment plants serving communes with socio-economic differences were monitored for 4 individual weeks during 2 seasons. The socio-economic gradient was established with respect to median salary of the connected communes and the age-structure of the population. Passive samplers were placed at the in- and outlets of the chosen plants and grab samples were taken at each switch/collection of the passive samplers to allow for sampling rate determination. Many of the illicit drugs were completely eliminated during wastewater treatment, jeopardizing the calibration strategy of using the outflow as a reference. Instead, using a mix of pharmaceuticals and doable illicit drugs, sampling rates were determined within the range of log D at pH7 of the investigated compounds and delineated for the inlet. An uncertainty analysis revealed the the highest uncertainty did not reside in the monitoring or the analysis of the illicit drugs but the determination of the population equivalents during the monitoring periods. Median salary did only show a slight negative correlation with heroin but the age-group of young professionals (age 25-40) was correlated with the use of cannabis and cocaine (as measured by the metabolite benzoylecgonine)

3.19.P-We200 Prominent Features In Chemical, Physical And Ecotoxicological Analysis Of Seawater In The Genoa Harbor (Italy) By Means Of Passive Sampling Techniques

*Laura Caiazzo[1], Laura Cutroneo[2], Marco Capello[2], Maria Rita Montereali[1], Luisa Parrella[3], Simona Schiavo[3], **Sonia Manzo**[3], Marina Di Carro[4] and Emanuele Magi[4], (1)ENEA Casaccia Research Centre, Italy, (2)DISTAV University of Genoa, Italy, (3)ENEA PORTICI Research Center, Italy, (4)Department of Chemistry and Industrial Chemistry, University of Genoa, Italy*

Assessing the current state of the global ecosystem is essential to fully understand the situation of the marine environment. Passive Sampling (PS) techniques are increasingly used for the integrated assessment of time-weighted average concentrations of both inorganic and organic compounds in a range of matrices, including water.

In the framework of Italian PNRR project “Return”, the goal of this work is to monitor seawaters in Genoa harbour (NW Mediterranean Sea). PS will be exposed beginning in December 2023 with samplings being conducted once a season.

The so-called FL (Eastern entrance to the harbor near shipyards and mouth of the Bisagno stream), FB (inside the harbor in front of the Oil Terminal) and FP (Western entrance in front of the mouth of the Polcevera stream and sewage drain) are the three considered sampling sites. A wide range of anthropogenic chemicals may be present in seawater due to all the waterways connected to industrial and harbor activity and city and sewage discharges.

Organic chemicals will be sampled by Semi-Permeable Membrane Device (SPMD) and Polar Organic Chemical Integrative Sampler (POCIS) for lipophilic and hydrophilic compounds, respectively, and will be deployed for 21 days. Besides, Diffusive Gradients in Thin films (DGT) will be deployed for 7 days for metals and mercury sampling. When combined with the detection through high sensitivity and selectivity instrumentation at our disposal, such as GC-MS, LC-MS/MS, Hg-Analyzer and ICP-MS, this will enable the thorough assessment of the system studied.

On passive sampler extracts (polar, non-polar, metals) a battery of three bioassays with organisms belonging to different trophic levels (*Aliivibrio fischeri*, *Artemia salina*, *Dunaliella tertiolecta*) will be applied for the detection of ecotoxicological effects at the investigated locations.

Alongside the PS, sediment and water sampling will be also conducted at the end of the PS deployment. The detection of pollution at concentrations lower than ng/L will be possible thanks to the synergy of active and passive sampling systems. Physical measurements will be combined with water and sediment samplings, specifically temperature, conductivity, pH and oxygen, using a multiparametric probe (CTD).

The preliminary results of the first deployment will be presented. The chemical, physical and ecotoxicological characterization will enable a first assessment of the ecological risk due to the potential contamination of the water ecosystem.

3.19.P-We201 Passive sampling - results and comparison to national biota monitoring (within the WFD)

***Marcel Kotte**, Data and Information management, Ministry of Infrastructure and Water Management, Netherlands*

Under the European Water Framework Directive (WFD; 2000/06/EC), good chemical status must be achieved by 2027. To this end, European standards are set for priority substances, as laid down in the Priority Substances Directive (2013/39/EU). For eleven of these substances or groups of substances, which are poorly measurable in water, standards are also set in biota. Therefore Rijskwaterstaat (RWS), responsible for the main watersystem, has had a biota monitoring network operational since 2017.

If one or more biota EQS's are exceeded at a location, it should be considered whether or not upstream water bodies should also be monitored. For ethical, logistical and financial reasons, it is not desirable to monitor biota at all upstream locations. Moreover, many of the substances are ubiquitous and there is little scope for action if the substance is present at all sites. It may then not make sense to extend biota monitoring to upstream sites. Passive sampling (PS) could play a role in determining where other biota sampling should best take place.

In an earlier study RWS looked at the relative contents in the material used in the passive sampling (silicon sheets and Speedisk). A comparison of the calculated concentrations from the passive samplers and the concentrations measured in biota has now also taken place. During SETAC 2024 both kind of results will be presented.

During SETAC 2024 recommendations for the incorporation of passive sampling within future monitoring of RWS will also be presented.

3.19.P-We202 Calibration and field deployment of Ceramic Passive Samplers for monitoring of PFAS in groundwater

*Efthymios Chrysanthopoulos[1], Sergio Santana-Viera[2], Martha Perdikaki[3], Antonia Merola[2], Diego Schmidlin[4], **Sandra Perez Solsona**[5], Eike Marie Thaysen[2], Enric Vázquez-Suñé[4], Andreas Kallioras[3] and Silvia Lacorte[2], (1)National Technical University of Athens, Greece, (2)Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain, (3)National Technical University of Athens, School of Mining and Metallurgical Engineering,*

(4)Geosciences, Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain, (5)Onhealth, Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain
Groundwater contamination by per- and polyfluoroalkyl substances (PFAS) poses significant risks to human health and the environment. This study introduces Ceramic Passive Samplers (CPS) as an innovative and cost-effective strategy for monitoring PFAS in groundwater. The calibration process involved testing different sorbents, optimizing deployment times, and evaluating extraction conditions. CPS were calibrated over 30 days, demonstrating a linear calibration for all PFAS with sampling rates ranging from 1-10 mL/d. Stability assessments confirmed PFAS stability in water, crucial for CPS uptake. Deployments in highly polluted river basins, Besòs (Spain) and Kifissos (Greece), revealed CPS efficacy in detecting PFAS, with PFOA and PFOS as primary contaminants.

Twenty-five PFAS were analyzed, with CPS calibrated for the seven main PFAS. Oasis and Porapak sorbents showed optimal affinity and recoveries during calibration. CPS, deployed in boreholes for 30 days, exhibited no fouling, indicating sustained PFAS uptake. PFAS concentrations were calculated based on mass accumulation during deployment, revealing good agreement between CPS and grab sampling. The study validates CPS as a reliable method for PFAS monitoring, offering time-integrated concentrations without clogging issues and high analytical sensitivity.

3.19.P-We203 Passive sampler derived profiles and mass flows of Perfluorinated Alkyl Substances (PFAS) across the Fram Strait in the North Atlantic

*Matthew Dunn[1], Simon Vojta[1], Thomas Soltwedel[2], Wilken-Jon von Appen[2] and **Rainer Lohmann**[3], (1)University of Rhode Island, (2)Alfred Wegener Institute Helmholtz-Center for Polar and Marine Research, Germany, (3)Graduate School of Oceanography, University of Rhode Island*
Per- and polyfluorinated alkyl substances (PFAS) are a family of pollutants of high concern due to their ubiquity and negative human health impacts. The long-range marine transport of PFAS was observed during year-long deployments of passive tube samplers in the Fram Strait across three depth transects. Time weighted average concentrations ranged from 2.4-360 pg L^{-1}, and 10 different PFAS were regularly observed. PFAS profiles and concentrations were generally similar to those previously characterized for polycyclic aromatic hydrocarbons (PAHs) at these sites. The detection of several anionic PFAS in “old” water demonstrated that they are not perfect water mass tracers, but are also transported to depth via settling particles. Mass flows of PFAS through the Fram Strait in and out of the Arctic Ocean were basically similar (97 29 Mg $year^{-1}$ northward flow, 107 39 Mg $year^{-1}$ southward flow). For FOSA, export from the Arctic Ocean via the Fram Strait exceeded import by Atlantic Water, likely due to preferential transport and deposition in the Arctic Ocean. These observations suggest that PFAS in the Arctic are governed by the same feedback loop previously described for PAHs in the region – with additional atmospheric transport delivering volatile PFASs to the Arctic, which then get exported via water masses.

3.19.P-We204 Atmospheric Passive Sampling Technique for Gas-Phase Perfluoroalkyl Carboxylic Acids

***Cora Young**[1], Eric Vanhauwaert[2], Trevor VandenBoer[3], Hayley Hung[4] and Chubashini Shunthirasingham[5], (1)York University, Canada, (2)Department of CHemistry, York University, Canada, (3)Chemistry, York University, Canada, (4)Air Quality Processes Research Section, Environment and Climate Change Canada, Canada, (5)Environment and Climate Change Canada, Canada*
Perfluoroalkyl carboxylic acids (PFCAs), a sub-class of PFAS, are toxic compounds found ubiquitously in the environment. Studies have shown that atmospheric transport of PFCAs is an important transport mechanism which has sparked an interest in atmospheric measurements. Despite this, measuring mixing ratios of gaseous (g) PFCAs in the atmosphere has been an analytical challenge due to artifacts and biases, high maintenance, location limitations, and cost. Calibrated passive air samplers (PAS) alleviate these issues by offering a cheap, power-free, and low maintenance alternative. Atmospheric acids (e.g., nitric acid) have previously been measured by nylon PAS, which is selective for acids through chemisorption. Custom-built PFCAs (g) passive diffusion-based samplers employing nylon collection filters and polypropylene protective filters were comprehensively calibrated using a 1 m^3 chamber and were then deployed for measurements in the field. The PAS were deployed in several field locations: two remote locations (Saturna Island, British Columbia and Tadoussac, Quebec), as well as indoor and outdoor sites in Toronto, Ontario. Mixing ratios from PAS in outdoor urban air in Toronto were compared to orthogonal measurements to validate this new sampling method. The samples were quantified offline using ion chromatography with conductivity detection (IC-CD) or mass spectrometry (IC-MS) or gas chromatography mass spectrometry (GC-MS) via a novel derivatization technique. Our custom-built PAS were able to measure mixing ratios of TFA as low as 0.1 pptv over a 2-month period, demonstrating their ultra-trace measuring capabilities.

3.19.P-We205 Investigating the Uptake of Gaseous Aromatic Amines to Textiles

***Özge Edebali**[1], Lisa Melymuk[2], Marek Stiborek[3] and Branislav Vrana[3], (1)Faculty of Science, RECETOX, Masaryk University, Czech Republic, (2)RECETOX, Masaryk University, Czech Republic, (3)Recetox, Masaryk University, Czech Republic*
Aromatic amines (AAs) are mutagenic and/or carcinogenic compounds with environmental and industrial importance. AAs are found in indoor environments, originating from sources such as human activities like cooking, smoking, and hair dyeing. The risks associated with AAs in indoor spaces are amplified due to their often-elevated concentrations and the substantial amount of time people spend indoors. Furthermore, the impact of indoor contaminants extends beyond human exposure, as AAs indoor contaminants can be introduced into aquatic environments through cleaning and laundering of textiles. Indoor contaminants

can both deposit and sorb onto indoor textile surfaces such as carpets, curtains, and clothing. When textiles are laundered, sorbed chemicals can be released to wastewater and potentially affect receiving water bodies.

Recognizing the role of textiles as inadvertent indoor passive samplers (PS), we characterized the uptake of AAs from the gaseous phase of indoor air by cotton, wool, and polyester textiles under controlled conditions. A solvent extraction method for AAs in textiles was developed, relying on methyl tert-butyl ether, which demonstrated a higher extraction efficiency for AAs compared to acetonitrile and acetone. AA uptake to textiles was investigated using a series of chamber experiments to quantify textile-air partitioning. Textiles were uniformly spiked with a mix of AAs and placed in a glass chamber to equilibrate with the air inside. The chamber design allowed for the controlled extraction of a known volume of air by a vacuum pump. The analytes present in the air were sampled on a Tenax sorbent tube, and textile-air partitioning coefficient was calculated based on the concentrations in both the textile and the air. Textile-air partitioning coefficients for AAs showed a positive correlation with the octanol-air partition coefficient.

3.20.A Pharmaceuticals in the Environment – Risk Assessment, Regulation, and New Insights Into the Science Globally

3.20.A.T-01 Global Megatrends: the critical role of pharmaceuticals in health and environment

Stewart Owen[1]*, Rachel Moreby*[1]*, Samuel K Maynard*[2] *and Irene Bramke, PhD*[3]*, (1)AstraZeneca UK Ltd, United Kingdom, (2)Global Sustainability, AstraZeneca UK Ltd, United Kingdom, (3)AstraZeneca, Netherlands*

The role of pharmaceuticals in human and environmental health are critical to a sustainable future. Indeed health is a human right and access to medicines is key to the '*right to the highest attainable standard of health*'. But pharmaceutical residues are present in the environment and there is potential for harm to wildlife. We also know healthcare has a significant carbon footprint, whilst poor public health likely has an even bigger footprint. Therefore, healthcare's impact on climate, biodiversity and pollution becomes a very complex problem; yet is critical to address the Megatrends and sustainability challenges. How do we secure the right to health while minimising the environmental burden arising from all aspects of healthcare?

There is growing ambition to reduce the carbon costs of medicines. But exclusively carbon-focuessed approaches ignore other potential risks. For example; the potential for ecotoxicity, or environmental presence of residues after patient excretion are not addressed within strategies merely to reduce the carbon emissions. If we were to have to prioritise, which should we choose, a low carbon but high environmental presence or a higher carbon footprint but lower environmental presence medicine? And who should make that choice, a medic, an environmental or life cycle scientist, or a procurement specialist? Does selecting one medicine over another (where the potential risk of either may be characterised with a high degree of uncertainty) increase potential for regrettable substitution? Is this direction of travel proposed compatible with the patients right to health?

In the near future, if legislation changes, the right to the highest available standard of health for European patients may well be different to that of other parts of the world. Is the SETAC community equipped for this critical role that our life cycle assessment and fate & effect scientists will need to play? Are we training enough people? Are we targeting research in the areas to help clarify these societal concerns? The social and economic challenges of the Megatrends aim to ensure a healthy (European) population as the basis of a sustainable future. How we manage the environmental risk assessment of pharmaceuticals and the wider sustainability of medicines is critical to managing these Megatrend challenges ahead, and particularly important when '*putting health at the centre of climate change action*'.

3.20.A.T-02 Pharmaceutical Contamination of European River Systems

Jun Li[1]*, John Wilkinson*[2] *and Alistair Boxall*[3]*, (1)Department of Environment and Geography, University of York, United Kingdom, (2)Environment and Geography, University of York, United Kingdom, (3)University of York, United Kingdom*

While numerous studies have assessed the occurrence of different active pharmaceutical ingredients in surface waters in different regions of the world, these are often non-comparable due to differences in the analytical methods used. To address this challenge, a recent study applied a standardised approach to monitor the occurrence of a range of APIs in rivers from 104 countries (Wilkinson et al., 2022). While the study provided important insights into spatial variations in API exposure, as only one sampling timepoint was used, it provided no information on how concentrations varied temporally. Thie large-scale study was therefore performed to explore the spatial and temporal variability of concentrations of 56 APIs in river systems across Europe. The 56 target APIs were selected based on detection frequencies in the previous global monitoring study (Wilkinson et al., 2022) or had been prioritised by the Prioritisation and Risk Evaluation of Medicines in the Environment (PREMIER) project. A total of 281 sampling sites, spread across 31 European counties, were selected to cover a broad range of river types in terms of river size, river location and land use in order to capture spatial variation across European landscapes. A total of 2356 samples (including 172 field blank samples) were then collected at four timepoints (Summer, Autumn, Winter and Spring, 2022-2023) across a 12 month period. Based on preliminary findings for the four countries Albania, Austria, Belgium, and Cyprus, Belgium exhibits the highest level of pollution with seasonal average cumulative concentrations of 5.4 μg/L across all sites, whereas Austria holds the lowest level (1.0 μg/L). Temporal variations in API concentrations and the number of API detections varied between countries. This result could potentially be attributed to a combination of factors, including population density, pharmaceutical usage, chemical properties (hydrophobicity, degradation rate), WWTP removal efficiency and hydrology (flow rate, DOC).

3.20.A.T-03 Temporal Analysis of EcoPharmacoVigilance Data; Insights from Measured Environmental Concentrations of Active Pharmaceutical Ingredients (APIs) since 1996

Irene Bramke, PhD[1], *Samuel K Maynard*[2], *Rachel Moreby*[3] *and Stewart Owen*[3], *(1)AstraZeneca, Netherlands, (2)Global Sustainability, AstraZeneca UK Ltd, United Kingdom, (3)AstraZeneca UK Ltd, United Kingdom*

Advances in the sensitivity and throughput of monitoring analytics and the growing interest in PiE (Pharmaceuticals in the Environment) are continuing to deliver an exponential increase in MECs (measured environmental concentrations) gathered and reported in the scientific literature. The EcoPharmacoVigilance (EPV) process implemented at AstraZeneca has identified over 46,000 aquatic MECs dating back to 1996 that are made publicly accessible via an online dashboard. Temporal analysis of this data allows insights into global and regional trends of reporting and environmental risk over more than two decades.

The EPV process implemented at AstraZeneca was published in 2013. Under this process, MECs reported for our portfolio (and some legacy) small molecule APIs were extracted from the published, peer-reviewed literature. Of the totality of aquatic MECs, data reported for *surface water* (30,530 MECs) were subjected to further analysis. This analysis shows that amounts of reported water monitoring data has been rising steeply over the past two decades, first in Europe followed by the US (since 2008) and other global regions. The vast majority, 99.3% of *surface water* MECs reported to date (Q2 2023) indicate a low or insignificant risk (risk quotients derived using PNECs from published ERAs and grouped by risk according to Fass guidance).

Where AstraZeneca APIs were tested for, quantifiable concentrations were typically detected on half of all occasions. Mean, median and 95th %ile risk quotients calculated for discrete 3-year reporting periods are well below 1 when taking the full data set into account. When excluding non-detects, the corresponding conservative risk quotients of quantified concentrations are also below 1, with two exceptions; the 95th %ile RQ of 1.18 for 2002 to 2004 and the mean RQ of 1.26 for 2020 to 2022.

Based on this preliminary analysis of temporal trends, the available data does not indicate a global increase in surface water risk.

Further analysis of this data (and any additional data reported during year 2023) will investigate;

- Temporal trends at finer (year by year) resolution, for specific (insignificant, low, moderate, high) risk groups and for discrete global regions (e.g. Europe, USA, Asia)
- Focused analysis of specific, data rich APIs.

This will provide insights into global regions of heightened concern and impacts of the quality of data reporting on the utility of existing monitoring data for risk assessment and management.

3.20.A.T-04 DISTRIBUTION, BIOACCUMULATION AND ECOLOGICAL RISK ASSESSMENT OF CONTAMINANTS OF EMERGING CONCERN IN THE FRESHWATER-SEDIMENT-FISH SYSTEM

Diana Manjarrés[1], *Nadin Ulrich*[2], *Ralf-Uwe Ebert*[3], *Nicola Montemurro*[4], *Annika Jahnke*[5] *and Sandra Perez Solsona*[6], *(1)Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain, (2)Department of Ecological Chemistry, Helmholtz Centre for Environmental Research (UFZ), Germany, (3)Ecological Chemistry, Helmholtz Centre for Environmental Research (UFZ), Germany, (4)Department of Environmental Chemistry, Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain, (5)Department of Exposure Science, Helmholtz Centre for Environmental Research (UFZ), Germany, (6)Onhealth, Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain*

Contaminants of emerging concern (CECs), including pesticides and pharmaceutically active compounds (PhACs), cover a diversity of substances with broad physico-chemical properties. Their extensive use has resulted in their presence in diverse aquatic ecosystems, impacting water quality. Some of these compounds have the ability to accumulate in the tissues/organs of aquatic organisms, generating adverse effects on their endocrine or reproductive system. The discharge of effluents from wastewater treatment plants (WWTP) has been identified as a significant source of PhACs contamination, with concentrations that can reach effect thresholds, indicating possible adverse ecological effects. This study evaluated the ecological risk and bioaccumulation potential of 32 CECs in a Spanish river, particularly in organs/tissues of common carp (plasma, muscle, skin, liver, kidney, brain, and heart). In addition, environmental concentrations in freshwater and sediment were assessed at five sampling sites upstream and downstream of the WWTP. The highest total concentrations (ΣCECs) for water and sediments were six and eighteen times higher for the sampling sites downstream of the WWTP (R4: 12.4 µg L^{-1} and R3: 30.1 µg L^{-1}) compared to those upstream (R1: 2.08 µg L^{-1} and R2: 1.66 µg L^{-1}). Half of the contaminants were detected in fish tissues and organs (5M1H-benzotriazole, amantadine, benzotriazole, bisoprolol, BPA, BPS, BPF, caffeine, cotinine, diazepam, hydrochlorothiazide, metoprolol, desmethylvenlafaxine, sotalol, terbutryn, and venlafaxine), and the highest mean concentrations ocurred for amantadine in kidney (158 ng g-^{1} w. w), and liver (93 ng g^{-1} w.w) and for terbutryn in brain (50 ng g^{-1} w.w). Experimental bioaccumulation factors (BCFs) indicated substantial bioaccumulation potential (greater than 500) for amantadine, diazepam, and terbutryn in the kidney, liver, and brain. Individual risk quotients (RQs) suggested that 63% of the contaminants had a low risk for common carp, but caffeine and terbutryn showed elevated RQs for fish (RQmax 11 for caffeine and 10 for terbutryn). The mixed risk quotient (MRQ) revealed medium risk for most carp (between 2 and 14) and elevated risk for downstream sites (between 2 and 30). These results underscore the need for comprehensive risk assessments that span multiple environmental compartments to better to understand the actual exposure levels of an aquatic ecosystem.

3.20.A.T-05 Engaging Citizen Scientists to Support Monitoring of Contaminants of Emerging Concern in Coastal Environments

Jasmin Uhlhorn[1]*, Alex Ford*[2]*, Keng Tiong Ng*[3]*, Leon Barron Dr*[4] *and Thomas Miller*[5]*, (1)Brunel University London, United Kingdom, (2)University of Portsmouth, United Kingdom, (3)Imperial College London, United Kingdom, (4)Environmental Research Group, Imperial College London, United Kingdom, (5)Brunel University, United Kingdom*

Contaminants of emerging concern (CECs) are detected in the environment as a result of widespread anthropogenic activity. With wastewater discharges serving as one common entry route of pharmaceuticals into water bodies. Therefore, it is important to understand the influence of wastewater treatment plant (WWTPs) discharges and combined sewer overflow (CSO) events on the presence of CECs and is herein analysed for a coastal environment in the UK with input from 5 different WWTPs. Citizen scientists collected samples from 22 different sites within the Chichester and Langstone harbours. Two primary and two minor sampling campaigns were conducted aimed to capture seasonal variations and evaluate potential CSO event impacts during periods of drought and heavy rainfall. In addition, biota samples from 6 species representing important ecological groupings were collected and analysed to better understand the potential for bioaccumulation. A targeted liquid chromatography tandem mass spectrometry (LC-MS/MS) method was employed to analyse 149 compounds covering pharmaceuticals, pesticides, and recreational drugs. An additional 341 analytes were screened to extend the suite of chemicals monitored. The analysis revealed the occurrence of over 150 compounds and patterns in CEC concentrations with influences from WWTP discharges and CSO events. During dry weather conditions, concentrations of specific pharmaceuticals exhibited a consistent profile in the low ng L^{-1} range, indicating a continuous input from anthropogenic sources. An increase in concentrations was detected during wet weather conditions for selected sites. Moreover, CSO events were identified and captured as drivers of short-term spikes in CEC concentrations at sites close to these discharge points. Notably, some compounds that were previously not detectable at these sites emerged temporarily after CSO events. For other compounds previously detected, concentrations increased up to hundred-fold, with some concentrations reaching up into µg L^{-1} range. This study provides an insight into the presence of CECs and the findings emphasize the significance of considering both WWTP discharges and CSO events in assessing the environmental fate of pharmaceuticals and other CECs in coastal environments and highlights the collaborative integration of local citizen scientists that can support regional mitigation efforts.

3.20.B Pharmaceuticals in the Environment – Risk Assessment, Regulation, and New Insights Into the Science Globally

3.20.B.T-01 Understanding the Variability of Poultry Litter on the Degradation Rates of Veterinary Medicines and Feed Additives.

Bethany Adams[1]*, Laura Carter*[2]*, Paul Kay*[2]*, Phil Rooney*[3]*, Edward Haynes*[4] *and Chris Sinclair*[4]*, (1)University of Leeds, United Kingdom, (2)School of Geography, University of Leeds, United Kingdom, (3)FERA, United Kingdom, (4)Fera Science Ltd., United Kingdom*

The potential environmental impact of veterinary medicines and feed additives is assessed through an environmental risk assessment as part of the regulatory process. Simulating manure degradation can be used as an approach to refine environmental exposure and currently the guidance provided by the European Medicines Agency in 2016 only requires testing in one source of manure per animal type. Most of the research exploring degradation of veterinary medicines has been conducted on pig slurry or cattle manure, leading to an specific to these 'liquid' manures. In comparison, poultry litter is relatively understudied. The variability of poultry litter properties and the potential effect of this variability on the rate of degradation of veterinary medicines is relatively unknown. Subsequently, the current guidance on the number and type of litters to be used may not accurately evaluate the true environmental risk posed by these compounds. A series of experiments have been designed to explore the impact of poultry litter collected from different farms on the degradation of five veterinary antibiotics: tiamulin, trimethoprim, sulfadiazine, monensin and salinomycin. Three litter types that differed in the type of chickens reared and the type of bedding material were collected from three separate farms and used in simulated degradation studies performed according to the harmonised experimental guidance published by the European Medicines Agency in 2011. Results revealed that the rates of degradation for salinomycin differed significantly ($p = 2.0 \times 10^{-16}$) between the poultry litters, in the litter collected from one farm, salinomycin was persistent (DT50 >1000 days) and in the litters from other farms it degraded rapidly (DT50 <1). Our results suggest that we need to better understand how the variability in the chemical and biological properties of poultry litters can influence degradation processes. Based on these initial findings, a number of litters from different farms may be needed to perform manure degradation studies to deliver a comprehensive, and realistic environmental risk assessment.

3.20.B.T-02 Acidification increases the toxicity of diclofenac to aquatic organisms

Katarzyna Bethke*, Klaudia Kwidzińska, Weronika Koczur, Anna Białk-Bielińska and Magda Caban, Department of Environmental Analysis, University of Gdansk, Poland*

Pharmaceuticals and their metabolites are among the challenges of modern ecotoxicology and environmental chemistry. Even at low concentration levels, they can be dangerous to non-target aquatic organisms. It turns out that the toxicity of pharmaceuticals can be affected by global warming effects, such as an increase in average temperature and a decrease in pH in water bodies. The direction of toxicity change with acidification is problematic to predict due to diverse chemical structure and mode of action of pharmaceuticals.

We therefore decided to investigate the effect of acidification of water bodies on changing the toxicity of diclofenac, a drug from the non-steroidal anti-inflammatory group. Toxicological tests were conducted against two model organisms: *Daphnia magna* and *Lemna minor*. Acute and chronic tests were carried out in accordance with OECD guidelines 202, 221 and 211. These tests allowed, among other things, the determination of EC_{50} parameters, thus confirming the negative effect of lowering the pH on the toxicity of diclofenac to the test organisms (mortality, inhibition of growth or reproduction). Interestingly, quantitative analysis of diclofenac (HPLC - DAD) during tests with *L. minor* confirmed the degradation of the pharmaceutical during the test, which was not observed during tests with *D. magna*. The enhanced toxicity to the duckweed may therefore be due to exposure to any of the diclofenac derivatives. It is possible that changing the pH of water bodies also alters the toxicity of pharmaceutical degradation products. To date, there has been little work on the effects of changing the toxicity of pharmaceuticals on aquatic plants, so this study adds to the body of knowledge on the subject and confirms the need for further experiments on the effects of climate change on the toxicity of pharmaceuticals and their derivatives.

3.20.B.T-03 Fish Show Altered Reproductive Behaviours in the Wild Following a Whole-Lake Exposure to an Estrogenic Pharmaceutical

Erin McCallum[1]*, Karen A. Kidd, PhD*[2]*, David T. Callaghan*[3]*, Andrew R. Majewski*[4] *and Paul J. Blanchfield*[4]*, (1)Swedish University of Agricultural Sciences (SLU), Sweden, (2)McMaster University, Canada, (3)University of Manitoba, Canada, (4)Fisheries and Oceans Canada, Canada*

Reproductive behaviour has become a key endpoint in studies assessing the impacts and risks of endocrine disrupting chemicals and pharmaceuticals to wild fish populations. Yet, it is exceedingly difficult to test whether widely accepted behavioural responses observed in the laboratory are also manifested in the same way under natural conditions in the field, and what the repercussions of this might be for exposed populations. To close this gap, we measured the reproductive behaviour of male fathead minnows (*Pimephales promelas*) from video recordings taken over multiple years before, during and after the synthetic estrogen ethinylestradiol (EE2; used in birth control pills and hormone therapies) was added to a lake in a whole-lake exposure study. In line with previous laboratory EE2-exposure studies, we found that males from the EE2-exposed lake reduced the amount of time they spent tending to their nest when compared to fish from reference lakes. However, in contrast to prior laboratory studies, we found that males from the EE2-exposed lake showed increased nest defence as measured by aggression towards conspecifics. We also found that social dynamics at the nest changed in the EE2-exposed lake, where more non-reproductive conspecifics were present during nesting and interrupted the focal males. We evaluated the expression of male secondary sex characteristics alongside behaviour and found that males from the EE2-exposed lake showed marked reductions in secondary sexual characteristics compared to males from reference lakes in the final years of exposure. We will connect our new behavioural findings to already established physiological and population-level effects measured during this whole-lake exposure study. Our findings contradict the generally held view of reduced spawning aggression by estrogen-exposed males, and we highlight that the complex ecological and behavioural interactions that occur in natural systems provide a challenging but necessary arena in which to pursue ecotoxicological studies.

3.20.B.T-04 Antibiotic and Emerging Antibiotic Resistance Assessment in the Ebro Delta and the Albufera of Valencia reservoirs (Spain)

Maria Garcia Torné[1]*, Irene Falcó*[2]*, Esteban Abad*[3]*, Gloria Sánchez*[2]*, Marinella Farre*[3] *and Marta Llorca-Casamayor*[4]*, (1)Institute of Environmental Assessment and Water Research (IDAEA-CSIC), Spain, (2)Control of Food Intake Group, Aquaculture Institute of Torre de la Sal, Spanish National Research Council (IATS-CSIC), Spain, (3)Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain, (4)Environmental Chemistry, Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain*

Urban rivers are impacted ecosystems which may play an important role as reservoirs for antibiotic-resistant (AR) bacteria. The primary goal of this work was to assess antibiotics, the prevalence of antibiotic resistance through the study of antibiotic resistance genes (ARGs) and bacteria (ARBs), in two protected reservoir areas in Spain, the Ebro Delta (NE of Spain), which is the biggest river in the north of Spain, and the Albufera of Valencia, a freshwater lagoon on the Gulf of Valencia (E of Spain).

Main antibiotics groups were assessed by ultra-performance liquid chromatography coupled with high-resolution mass spectrometry (UPLC-HRMS). ARGs were detected using qPCR to assess aquatic habitats' emerging microbial contaminants vulnerability and ARBs like *Escherichia coli* were grown by cultivation methods.

The main results of suspect screening showed the presence of β-lactams, tetracyclines, macrolides, sulfonamides, quinolones and DHFR inhibitors. The further analysis for the unequivocal identification confirm the presence of quinolones such as ciprofloxacin and ofloxacin, the macrolides such as clarithromycin, tetracyclines such as tetracycline, and sulfonamides including sulfamethoxazole, and trimethoprim. Antibiotics were detected in almost all the samples with some seasonal variations, were the concentrations were ranging between the MLOQ and 104.9 μg/L. In the case of bacteria, despite the microbial load decreases in effluent compared to influent wastewater (2-3 log10 on average), the reductions between upstream and downstream wastewater do not comply with the latest European standards, Regulation (EU) 2020/741 of the European Parliament and of the Council on minimum requirements for water reuse.

3.20.B.T-05 Refining the Predicted Environmental Concentration (PEC) of human pharmaceuticals; effect of region-specific dilution factors and wastewater volumes

Rachel Moreby[1]*, Samuel K Maynard*[2]*, Irene Bramke, PhD*[3] *and Stewart Owen*[1]*, (1)AstraZeneca UK Ltd, United Kingdom, (2)Global Sustainability, AstraZeneca UK Ltd, United Kingdom, (3)AstraZeneca, Netherlands*
To classify environmental risk of a human pharmaceutical when completing an environmental risk assessment, the PEC resulting from patient use is compared to the Predicted No Effect Concentration. There are various methods of calculating the PEC which require the assessor to estimate the environmental concentration using the quantity of Active Pharmaceutical Ingredient (API) intended for patient use. However current methods use default values for wastewater production (V_{ww}) and dilution factor of wastewater by surface water flow (DF) regardless of where the pharmaceutical product is sold and ultimately excreted. The European Medicines Agency (EMA) default values are from technical guidance dated 2003, yet in the last 10 years at least two papers have been published estimating region specific values for both DF and V_{ww}. The purpose of this study is to apply these region-specific values when calculating the PEC, to assess the impact of using default versus refined values, and how this may affect the environmental risk classification of an API.

2022 sales data of 41 AstraZeneca APIs were assessed, and the highest per capita sales were identified for each. These data were used to calculate the PEC as per the equation in the Fass guidance for the four combinations of default or refined DF and V_{ww} values. 36 APIs reported a reduction in PEC when refined with both region-specific values, resulting in 4 APIs being assigned to a lower risk category. 5 APIs reported an increased PEC when fully refined, but none changed risk category. PEC values were more sensitive to the DF than V_{ww} parameter, resulting in an average difference to the default PEC of 18%. Regional analysis was conducted for one API, which showed that when refining both DF and $V_{ww,}$ Saudi Arabia reported high environmental risk, despite per capita use 2 orders of magnitude below that of the country with the highest per capita sales. The PEC derived using default EMA values is generally more conservative than regional specific PECs and full refinement results in a decrease in PEC for more than 80% of APIs assessed. It was also highlighted that refinement using region-specific DF and V_{ww} values must be combined with country-specific sales, as regions of highest per capita sales may not always be where an API poses the highest environmental risk. This offers potential risk management opportunities, as it would allow assessors to prioritise and target such efforts based on locally predicted risk.

3.20.P Pharmaceuticals in the Environment – Risk Assessment, Regulation, and New Insights Into the Science Globally

3.20.P-Th344 Metabolites Are Overlooked in Environmental Risk Assessment and Monitoring of Pharmaceuticals: The Case Study of Pantoprazole

Finnian Freeling[1]*, Dominic Armbruster*[1]*, Karsten Nödler*[2] *and Thomas A Ternes*[3]*, (1)TZW: DVGW-Technologiezentrum Wasser (German Water Centre), Germany, (2)TZW: DVGW Water Technology Center, Germany, (3)G Qualitative Hydrology, German Federal Institute of Hydrology (BfG), Germany*
After application, pharmaceuticals and their metabolites are excreted via urine and feces. Since many compounds cannot be completely eliminated by conventional wastewater treatment plants (WWTPs), they are regularly detected in receiving waters. To date, approaches to environmental monitoring as well as risk assessments for regulatory purposes focuse on the parent compounds of pharmaceuticals. For instance, the environmental risk assessment of medical products for human use in the EU largely ignores transformation in regulatory authorization procedures, allowing for a so-called total residue approach in which the environmental fate and toxicity of metabolites are assumed to be covered by that of the original pharmaceutical. Pantoprazole (PPZ) is a top-selling PPI worldwide. Despite the large consumption volumes, concentrations of PPZ in urban waters are comparatively low, which can be explained by the extensive metabolization of PPZ in the human body. By screening urine from a PPZ consumer and WWTP effluent for the presence of known PPZ metabolites by high resolution mass spectrometry, 4’-O-demethyl-PPZ-sulfide (M1) was identified as the most promising PPZ related compound for environmental analysis. M1, which, to the best of our knowledge, has not been described yet as a human metabolite of PPZ, was found to be ubiquitously present in WWTP influents and effluents (up to 3 µg/L) as well as in wastewater-impacted surface waters (up to 1.4 µg/L) in Germany. On average, the concentrations of M1 were about 30 times higher than those of the parent compound PPZ in the analyzed surface water samples. Concentrations of M1 in suspended particulate matter from the Rhine River at Koblenz showed a strong increase between 2005 and 2015 and were highly positively correlated with the annual prescription volumes of PPZ in Germany. Laboratory scale adsorption experiments demonstrated that post-treatment with activated carbon can substantially improve the removal of M1 during wastewater treatment. Laboratory ozonation experiments revealed fast removal of M1 but also the formation of several transformation products during the ozonation of M1. The presented study shows that information on the absorption, distribution, metabolism, and excretion of medicinal products after administration must be taken into account in comprehensive monitoring programs in order to adequately describe their environmental occurrence and relevance.

3.20.P-Th345 A Refined Read-Across Approach to Support Environmental Assessment of Data-Poor Pharmaceuticals

Tim Verslycke*, Ifeoluwa Bamgbose and Janet Vo, Gradient*
Environmental assessments are required for market approval of new active pharmaceutical ingredients (APIs) in the US and the EU. However, ecotoxicological information to support such assessments is often lacking, particularly for drugs that were approved prior to the implementation of environmental assessment regulations and for new drugs that qualify for a categorical exclusion. Evaluating environmental risks of drugs lacking ecotoxicity data typically requires the use of quantitative structure-activity modeling (QSAR) or read-across approaches. QSAR ecotoxicity modeling can be unreliable for APIs and requires expert application and interpretation. Therefore, in 2012, we proposed a simple read-across approach based on drug therapeutic class and an experimental aquatic toxicity dataset containing 184 APIs belonging to 14 therapeutic classes

(Verslycke *et al.*, 2012; SETAC Europe Annual Meeting, Berlin, Germany). In 2023, we updated our 2012 therapeutic class read-across approach using an expanded experimental aquatic toxicity dataset containing 314 APIs (Bamgbose *et al.*, 2023; SETAC North America Annual Meeting, Louisville, USA). Here, we propose a further refinement of our read-across approach by using subclasses that consider human therapeutic target and presence/absence of that target in ecological taxa (algae, invertebrates, or fish).

3.20.P-Th346 Exposure Assessment of Pharmaceuticals in the Northern Adriatic Sea: Emission Inventory and Environmental Modelling

Loris Calgaro[1], *Elisa Giubilato*[1], *Elena Semenzin*[1] *and Antonio Marcomini*[2], *(1)University Ca' Foscari of Venice, Italy, (2)Ca' Foscari University of Venice, Italy*

Pharmaceuticals are fundamental to effectively treat a multitude of diseases both in humans and animals but, at the same time, there is evidence of risks to the environment and, particularly in relation to antimicrobial resistance, to human health caused by the environmental release of these chemicals during their manufacture, use and disposal. However, the monitoring of pharmaceuticals in the environment is still limited, especially for coastal waterbodies. The use of predictive exposure models has been identified as a complementary, cost-efficient tool to support the investigation of the behaviour and environmental fate of these contaminants and the assessment of associated risks.

The Northern Adriatic is a narrow and shallow sea, where the variety of temperature, salinity, and sedimentation patterns leads to the presence of different and unique habitats for marine species. This area is also subjected to several anthropogenic pressures, such as high nutrient loads from agricultural activities, discharges of urban/industrial wastewaters, and in general a diversity of anthropic activities (such as tourism, transport of freights and people, mining, aquaculture, etc.) leading to the release of various types of pollutants. Among these pressures, the discharge of active pharmaceutical compounds raises particular concern, especially due the lack of information regarding their concentration in water and sediments.

The aims of this work, developed within the iNEST project, are: (i) to develop an emission inventory of several active pharmaceutical ingredients in the study area, (ii) to use state-of-the-art modelling tools to investigate the environmental distribution and fate of these contaminants in the Northern Adriatic, with particular attention to the processes involved in their natural attenuation, and (iii) to define a risk-based priority list of contaminants specific to the case study area, taking into consideration the overall mass balance of the target pollutants.

The emission inventory was developed by integrating pharmaceutical sales data for human consumption obtained from each Regional authority within the Northern Adriatic drainage basin with river flow, census and geographical information through statistical data treatment and GIS-based spatial analysis. In addition, a preliminary modelling exercise was carried out by applying the newly-developed ChemicalDrift model, a chemical transport module part of the open-source Lagrangian framework OpenDrift.

3.20.P-Th347 Can the Enantiomeric Fraction of Chiral Pharmaceuticals be used to Identify Septic Tank Discharges?

Maike Wilschnack[1], *Elise Cartmell*[2], *Vera Jemina Sundström*[1], *Kyari Yates*[1] *and Bruce Petrie*[1], *(1)Robert Gordon University, United Kingdom, (2)Scottish Water*

Pharmaceuticals are emerging contaminants in the environment and they are found in various water sources worldwide in the ng to µg L^{-1} range. They are often chiral, existing as at least two enantiomers. Enantiomers are mirror images of each other with identical chemical structures but different spatial arrangements. Pairs of enantiomers (S-(+) and R-(-)) can demonstrate enantioselectivity in their environmental occurrence, fate, and toxicity. Consequently, enantioselective analysis is an important tool in risk assessment and source identification for chiral drugs.

Concentrations and enantioselective composition of 28 chiral pharmaceuticals and metabolites were determined in septic tank wastewater and river microcosms. Enantioselective separations were achieved using a UHPLC-MS/MS system and a ChiralPak IG-U and a InfinityLab Poroshell 120 Chiral-V column, respectively.

No significant difference was found between the enantiomeric composition of septic tank influent and effluent for chlorpheniramine, citalpram and naproxen, suggesting that no enantioselective degradation occurs. In line with its enantiopure dispension, R-(-)-naproxen was either not detected in septic tank wastewater or found in substantially lower concentrations than S-(+)-naproxen. Enantioselective degradation of pharmaceuticals is typically observed in conventional wastewater treatment systems (WWTS). Concentration data shows no or limited removal of pharmaceuticals through septic tanks. Overall, the unchanged entantiomeric composition in septic tank wastewater and limited reduction of total concentrations, indicate that pharmaceuticals are removed to a lesser degree in septic tanks than in conventional WWTSs.

Pharmaceuticals are degraded in abiotic and biotic river microcosms in light conditions over 13 days. The degradation processes of chlorpheniramine and citalopram are not enantioselective. Inversion from S-(+)- to R-(-)-naproxen was not observed. Overall, the similarity between abiotic and biotic microcosms suggests that in river water, microbial degradation is negligible over other degradation processes, such as photodegradation.

Potentially, the unchanged entantiomeric composition in septic tank wastewater, can be used to distinguish between pharmaceutical discharges from septic tanks and conventional WWTSs in the environment.

3.20.P-Th348 Seasonal study of the presence of pharmaceuticals in A Coruña estuary (NW Spain)

***Jorge Lejo-Santiago**[1], E Concha-Graña[2], P López-Mahía[2] and S Muniategui-Lorenzo[2], (1)University Institute of Research in Environmental Studies (IUMA), University of a Coruña, Spain, (2)Universidade da Coruna, Spain*

In last years an increase in the presence of potentially toxic compounds known as contaminants of emerging concern (CEC) was observed due to the population growth and industrial development. Among them the pharmaceutical compounds and their metabolites are highly spread. Their presence in the environment is related with two main sources, firstly wastes from laboratories, hospitals and agriculture, and secondly, their excretion after their consumption, which appears in wastewaters. Not all organic pollutants are removed at WWTPs, so some pharmaceuticals are being found in the water. The aim of this work is to study the presence and behavior of 56 pharmaceuticals using liquid chromatography coupled to triple quadrupole mass spectrometry (LC-MS/MS (QqQ)) for their determination. The seasonal study was performed collecting samples from the A Coruña estuary (NW Spain) making a radial of 5 points during 2022, analyzing each point in every season. 16 pharmaceutical compounds including antibiotics, NSAIDs, cardiovascular drugs and psychiatric drugs among others were found in levels from 0.1-67.5 ng/L with different occurrence and behavior. Pharmaceuticals were found in all samples, 5 of them (Azithromycin, Carbamazepine, Clarithromycin, Diclofenac and Erythromycin) are proposed to be regulates by the EU. It appears that in summer and spring are the seasons with the higher concentration of analytes in the water. Antibiotics and NSAID were found in specific places while the rest of therapeutic classes seems to be more distributed.

Acknowledgment: This work is part of the project “Presence, behaviour and risk assessment of pharmaceuticals in marine ecosystems” (PHARMASEA) (ref. PCI2021-121987) supported by MCIN/AEI/10.13039/501100011033 and the European Union “NextGenerationEU/PRTR”. 3.20.P-Th349 Evaluation of the Occurrence and Fate of Pharmaceuticals in North and South Mediterranean Intermittent River Basins

***Olga Gómez Navarro**[1], Anna Maria De Girolamo[2], Armin Lorenz[3], Taha-Hocine Debieche[4], Samia Khadhar[5], Francesco Gentile[6], Serge Chiron[7] and Sandra Perez Solsona[1], (1)Onhealth, Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain, (2)Water Research Institute - Italian National Research Council (IRSA-CNR), Italy, (3)University of Duisburg-Essen (Uni DUE), Germany, (4)Geological Engineering Laboratory (LGG), University of Mohamed Seddik Benyahia, Algeria, (5)Laboratory of Georessources, Technopole of Borj Cedria, University Carthage, Tunisia, (6)Department of Agricultural and Environmental Sciences, University of Bari Aldo Moro, Italy, (7)University of Montpellier, France*

Most river basins are subjected to several anthropogenic inputs, including wastewater treatment plant (WWTPs) discharges and urban/storm runoff waters, which collectively affect water quality. Despite the use of WWTPs to manage and treat wastewater, their effluent may still contain contaminants, including pharmaceuticals, as conventional WWTP do not fully eliminate them. This study analyzed the presence of pharmaceuticals in five countries: Spain, France, Italy, (North Mediterranean) and Algeria and Tunisia (South Mediterranean). In Tunisia and Algeria, WWTPs are sometimes over-exploited and industries often release wastewater directly into river basins. In addition, the lack of regulations regarding pharmaceutical concentration in surface water and the limited monitoring makes it interesting to investigate their presence and impact. Hence, different intermittent rivers from each site were sampled and possible differences between the North Mediterranean and the South Mediterranean basins were investigated. A total of 82, mainly pharmaceuticals and other organic contaminants, selected based on their occurrence and ubiquity in the aquatic environment were screened and quantified using high-resolution mass spectrometry (Q-Exactive-Orbitrap-MS). The presence and potential differences in contamination levels across the five countries were investigated. The studied river basins from France and Algeria reported lowest concentrations while the basin in Tunisia reported the highest concentrations. The most remarkable class were the industrial compounds where significant differences between Tunisia and the four other countries were observed. As for Italy, the highest concentrations belonged to the antihypertensive group. Regarding specific contaminants, caffeine concentrations were outstanding in Tunisia compared to the rest of countries, and Italy presented remarkable concentrations of irbesartan and valsartan acid, a sartan group metabolite. A prioritization list based on compounds with the highest frequency of predicted no-effect concentration (PNEC) exceedance was compiled and a risk assessment approach was performed. Tunisia was the country with the highest concentration for the majority of the prioritized compounds, emphasizing the need and requirement of attention for regulations and researchers for further monitoring efforts.

Acknowledgement - This study has been financially supported by the EU through the PRIMA project (INWAT 201980E121).

3.20.P-Th350 Solid-phase extraction and chromatographic determination of diazepam, alprazolam and clonezapam in wastewater samples

*Silumko Nzube and **Vernon Somerset**, Cape Peninsula University of Technology, South Africa*
Pharmaceutical pollutants entering the aquatic environment have become a growing environmental concern. These pharmaceuticals are unique pollutants because of their special characteristics and behaviour that cannot be simulated with other organic pollutants. The untreated wastewater effluent that contains pharmaceuticals poses considerable threat to the aquatic ecosystem because of the negative effects of non-target organisms in the water. Recent years have seen a growing concern about the benzodiazepines, as emerging pollutants, and their effects on the aquatic environment. These compounds are nowadays widely detected in sewage wastewater. It is important to increase the emphasis on the characteristics of the benzodiazepines in order to differentiate them from industrial chemical compounds. In this study various solid phase extraction techniques have been employed focusing on isolation of benzodiazepines in wastewater matrices. Employing this methodology has shown improved detection and analysis of diazepam and clonezapam as benzodiazepines.

Preliminary results have shown the diazepam concentrations to range between 1 to 9 ppm in seasonal wastewater samples analysed, with higher concentrations during the winter season. In the case of clonezapam and alprazolam, concentrations ranged between 0.4 to 2 ppm. Seasonal characteristics of the benzodiazepines are discussed along the trends observed for the water quality characteristics of the final treated wastewater.

3.20.P-Th351 Anthropogenic Gadolinium And Correlations of Pharmaceuticals Along River Wutach (Black Forest Germany)

*Andreas Weis[1] and **Thomas Schiedek**[2], (1)Geosciences, TU Darmstadt, Germany, (2)Hydrogeology, Technical University Darmstadt, Germany*
In the recent years more and more reports revealed, that pharmaceuticals and residues from medical treatments reach sewage treatment plants via wastewater. However, the processes in the sewage plants are not suitable to degrade or retain those compounds, thus detectable quantities of such compounds travel through the sewage plants, and are discharged into river water. From there they can reach by exchange processes groundwater and from sewage sludge applications the soil zone. Gadolinium (Gd) and pharmaceuticals against modern industrial society diseases (such as antiepileptic drugs, pain relievers, antibiotics as well as beta-blockers) and contrast agents (e.g. for x-ray and magnetic resonance imaging MRI) can usually be detected in traces in almost every river in densely populated regions with state of the art medical treatment facilities. The highest concentrations are usually antidiabetics, x-ray agents, antihypertensives (drops blood pressure) and diuretics, as well as Gd as contrast agent for MRI. In general, there are only a few studies on anthropogenic Gd accumulation and pharmaceuticals in natural catchment areas, almost no reports in Germany. Thus, in this study we investigated the occurrence and distribution of such pharmaceuticals and Gd in the relatively natural catchment of the river Wutach in the Southern Black Forest. We took 21 samples from various locations along the river. From the concentrations, correlations were checked and mass fluxes were calculated. First results show, that even in the natural Wutach Valley all target compounds could be detected in traces, only in the spring area with very low anthropogenic impact (few farm houses, no hospital etc.) no excess of Gd could be found and pharmaceuticals were below detection limit. With the occurrence of the hospital in the catchment, an anthropogenic excess of Gd in the river water can be calculated, even for locations up-stream of the hospital (excretion at home after application). Correlations found are probably “spurious correlations”, but it can be concluded, that patients with diabetes may have high blood pressure and take pain reliever, patients with schizophrenia take antidepressive medicaments, combinations of pharmaceuticals are subscribed to control blood pressure (e.g. candesartan and hydrochlorothiazide). A weak correlation of candesartan and 4(5)-methylbenzotriazole (dishwasher incredient) may point to the excretion of blood pressure control medicaments mostly at home.

3.20.P-Th352 Perils of Pet Pollution: Monitoring of Companion Animal Parasiticides in English Surface Waters

***Isla Thorpe**[1], Andrew Beckerman[2], Caroline Dessent[3], Carmel Ramwell[4], Susan Zappala[5] and Alistair Boxall[3], (1)Environment and Geography, University of York, United Kingdom, (2)School of Biosciences, University of Sheffield, United Kingdom, (3)University of York, United Kingdom, (4)Fera Science Ltd., United Kingdom, (5)Joint Nature Conservation Committee (JNCC), United Kingdom*
Parasiticides are commonly and extensively used to treat pets. With 21 million cats and dogs within the UK alone, there is growing concern over the potential impacts of these chemicals in the environment. In the UK, 31 active ingredients are used as parasiticide treatments in pets and, following use, these can enter the environment via down the drain emission from wastewater treatment plant (wwtp) effluent discharges and direct emissions from dogs swimming in the aquatic environment. However, only a limited number of studies have focused on determining the concentrations of pet parasiticide compounds in freshwater systems, with most focusing on a small number of compounds namely, fipronil and imidacloprid. Furthermore, data are lacking on concentrations within sediment in the aquatic environment. Levels of aquatic environmental exposure for a broad range of parasiticides due to their use within and on pet parasiticides are, therefore, largely unknown. This monitoring study was therefore performed to generate exposure data for companion animal parasiticides in English surface waters and to understand the relative importance of different pathways of release of these substances to the environment. Approximately 350 water and sediment samples will be collected across 23 sampling sites across 12 different locations across England. Seven sampling locations have been selected to capture the contribution of dogs swimming to parasiticide concentrations in the aquatic environment and five sampling locations have been selected to determine the influence of wwtp effluents on levels of exposure. The concentration of a broad range of compounds from a number of chemical classes including neonicotinoids, isoxazolines and macrocyclic lactones will be determined. The monitoring campaign is on-going. The current focus of this work is to undertake targeted analysis of the sediment and water samples to determine the concentration of pet parasiticide

compounds associated with down the drain and direct emission pathways to the aquatic environment. The study will generate knowledge on exposure of these understudied substances which will then help to support the assessment of the potential environmental risk posed by pet parasiticides.

3.20.P-Th353 Occurrence and Human Exposure Assessment of Pharmaceutically Active Compounds (PhACs) in Indoor Dust Collected from Spanish Homes, Schools and Offices

*Silvia Royano[1], Adrián de la Torre[2], Irene Navarro[1] and **María Ángeles Martínez**[1], (1)Center for Energy, Environmental and Technological Research (CIEMAT), Spain, (2)Center for Energy, Environmental and Technological Research (CIEMAT), Madrid, Spain*

The increasing consumption of medicines could raise the presence of pharmaceutically active compounds (PhACs) in the environment and lead to health problems. Although PhACs occurrence in other environmental compartments has already been studied, little is known about their presence in indoor locations. The presence of any of these compounds in the indoor dust is of great concern since we spend most of our time in indoor environments, and this may be a source of human exposure to these compounds.

To address this issue, 85 indoor dust samples were collected in central Spain from 14 homes, 23 offices, and 48 schools, from kindergartens (n=21) and high schools (n=27), during 2022. Then, the presence of 23 analytes belonging to several groups of PhACs as antibiotics, β-blocker agents, psychiatric drugs, analgesics, anti-inflammatories, lipids regulators, fungicides and anthelmintics were determined. Indoor dust samples (1g) were spiked with deuterated internal standards and extracted by the QuEChERS method consisting of a mixture of Milli-Q water and acetonitrile acidified with 1% acetic acid in the presence of magnesium sulfate and sodium acetate. Instrumental analysis was carried out with a UHPLC-MS/MS system. Chromatographic separation was made by an ExionLC system coupled to a Triple Quad™ 3500 MS/MS system for the MS/MS analysis. The method was validated according to SANTE/2020/12830 and SANTE/11312/2021 criteria and method limits of quantifications ranged between 10 and 50 ng/L. Recovery for deuterated standards were always between 70 and 120%.

Suspended and deposited dust was collected separately in schools and offices, but no statistically significant differences were found between both types of dust. Acetaminophen, clotrimazole, thiabendazole and the metabolite anhydroerythromycin were quantified in >50% of the samples with median concentrations of 166 ng/g, 75 ng/g, 25 ng/g and 2 ng/g, respectively. 13 PhACs were quantified in less than 9% of the samples with concentrations ranging between 10 ng/g and 630 ng/g. In contrast, 9 PhACs were below LODs in all cases. Concentration differences between locations were investigated, resulting in acetaminophen being the main PhAC quantified in most of the samples, especially in homes. Interestingly, the presence of other target analytes such as thiabendazole highlights possible non-pharmacological sources.

The present study is part of the project PID2019-105990RB-I00 funded by MCIN/AEI/10.13039/501100011033.

3.20.P-Th354 Aquatic-to-Terrestrial Transfer of Pharmaceuticals: Insights from Riparian Spiders

***Natalia Ivone Sandoval Herrera**[1], Daniel Cerveny[2], Tomas Brodin[3] and Erin McCallum[2], (1)Department of Wildlife, Fish, and Environmental Studies, Swedish University of Agricultural Sciences (SLU), Sweden, (2)Swedish University of Agricultural Sciences (SLU), Sweden, (3)Wildlife, Fish and Environmental Studies, Swedish University of Agricultural Sciences (SLU), Sweden*

The presence of pharmaceuticals in surface waters, and their effects on wildlife, has been widely reported, yet the risk of exposure for aquatic organisms and transference to terrestrial systems has been poorly characterized. Pharmaceuticals can be transported from aquatic systems to land when terrestrial predators such as riparian spiders, birds, or bats feed on emergent insects, or drink contaminated water. Riparian spiders can be effective sentinels to monitor aquatic to terrestrial contaminant flux because they are widespread, abundant, relatively sedentary, occupy high trophic levels, and are important prey for vertebrates. Here, we assessed the pharmaceutical load of riparian spiders from 26 sites across Sweden. The samples were collected as part of a community science project where high school students were trained to collect spiders from riparian zones and water samples from the closest water body. We screened both types of samples (totaling 565 spider samples and 220 water samples) for 95 pharmaceutical compounds. Across all sites, we detected pharmaceuticals in 50% of the spiders and in 40% of the water samples. In water, we found 60 different pharmaceuticals from 20 therapeutic drug classes, the most frequent were antihypertensives, antibiotics, and antidepressants. Similarly, in spiders, we detected 59 compounds from 15 classes mostly antihypertensive, anxiolytics, and antidepressants. The compounds with the highest concentrations in water were the stimulant caffeine, and the analgesics paracetamol and codeine. In spiders, the most common were the analgesic paracetamol, antibiotic trimethoprim, and the corticosteroid beclomethasone. We found 44 compounds shared between spiders and water samples, most of which were quantified in concentrations significantly higher in spiders, as much as 1000 times greater. The detection of a diverse range of pharmaceuticals, including some at concentrations significantly elevated in spiders compared to water, underscores the potential for biomagnification within the aquatic-terrestrial interface. Our study not only reveals the widespread exposure of aquatic and riparian organisms to pharmaceuticals but also highlights the need for further investigation on the pathways through which contaminants move across ecosystems and the potential risks this poses to wildlife.

3.20.P-Th355 Assessing the environmental fate of novel peptidomimetic antimicrobial molecules

***Owen Daniel**, Thomas Thiebault, Fabrice Alliot and Elodie Guigon, METIS - UMR 7619, France*

Antibiotics are molecules used to treat bacterial infections that have led to major improvements in human and veterinary medicine. However, the overuses and misuses of antibiotics caused the development of antimicrobial resistance (AMR). Due to poor absorption, large amounts of antibiotics and transformation products (TP) are excreted and can be emitted in the environment, either directly or *via* wastewater treatment plants effluents. In the environment those compounds impact both human and environmental health by contributing to the spread of AMR and affecting natural bacterial communities. There is therefore an urgent need of innovative molecules that are effective against antimicrobial-resistant bacteria and safe for the environment. Antimicrobial peptides (AMP) are antibiotics molecules naturally produced by organism for defending against infectious disease. Peptidomimetic compounds are derived from AMP and mimic their antimicrobial activities but without their drawbacks (toxicity, poor stability). 4 peptidomimetics molecules have recently been synthetized from *S. aureus* PepA1 toxin. These new compounds are cyclic pseudopeptides (Pep) and could be good candidates for clinical evaluation. Therefore several of their characteristics need to be evaluated, including their environmental fate and impacts on microbial communities. Firstly, natural attenuation processes (i.e. hydrolysis, photolysis, biodegradation, adsorption) are assessed in batch scale. These controlled experimental conditions allow to isolate each process and thus to understand their kinetics under various environmental conditions, their degradation pathways and major TP. Peps concentrations are measured by HPLC-MS/MS whereas degradation pathways and transformations products are characterized by HPLC-HRMS. As Peps are huge molecules (>1000 g/mol), TP could be toxic and more stable than their parents as it is the case for vancomycin, another AMP. It is therefore important to characterize Peps TP too. However, batch conditions are simple and poorly represent environmental fate of chemicals. Consequently a mesocosm experimentation will be carried out. Results obtained in batch will be used to develop an appropriate methodology and to simplify those obtained in mesocosms. The combination of batch and mesocosms will allow to understand Peps environmental fate and impacts on microbial communities, thereby reducing environmental and health risks if those compounds are commercialized.

3.20.P-Th356 Biosorption of Pharmaceutical Compounds under Acidogenic and Methanogenic Condition during Anaerobic Digestion: Effect of pH and Glycerol Co-fermentation

***Rodrigo Braz Carneiro**[1], Marcelo Zaiat[2] and Álvaro J. Santos-Neto[3], (1)São Carlos Institute of Chemistry, University of São Paulo (USP), Butantã, Brazil, (2)São Carlos School of Engineering, University of São Paulo (USP), Brazil, (3)São Carlos Institute of Chemistry, University of São Paulo (USP), Brazil*

Biosorption and biodegradation have been identified as the main mechanisms for removing pharmaceuticals compounds (PhCs) in wastewater treatment plants. Depending on the compound, biosorption on sludge can represent a relevant factor in its removal, and according to its magnitude, it can represent a potential risk when sludge is disposed in the environment. Sorption behavior can be estimated with the sorption coefficient (K_D), which is dependent on the characteristics of the contaminant and the type of sludge. This work aimed to evaluate the biosorption of different PhCs in a two-phase (acidogenic-methanogenic) anaerobic bioreactor. The reactor operation was divided into two operational phases: the first treating lab-made sewage (169 days) and the second using glycerol (GOH) as co-substrate (80 days). PhCs belonging to different classes were selected: the antibiotic sulfamethoxazole (SMX); the anti-inflammatory drugs naproxen (NPX) and diclofenac (DCF); the analgesic acetaminophen (ACT); the beta-blocker metoprolol (MTP); and the antiepileptic carbamazepine (CBZ). Samples of acidogenic and methanogenic biomass were removed from the reactor and PhCs were extracted from the biofilm by ultrasonic solvent extraction with methanol and acetonitrile, prior to the solid phase extraction and analysis by liquid chromatography coupled with mass spectrometry. As main results, three types of PhCs biosorption behavior were observed. SMX and ACT were not detected in the acidogenic and methanogenic sludge as they are more hydrophilic (low $logD_{ow}$ at any pH). CBZ and MTP showed low sorption - low K_D values (71 – 149 and 23 – 76 L kg^{-1}TSS for CBZ and MTP, respectively), also evidenced by the $logD_{ow}$ values that do not vary with the decrease in pH in the acidogenic reactor. Finally, NPX and DCF showed moderate to high sorption and were influenced by the pH of the medium. With the GOH co-digestion, the acidogenic reactor pH decreased from 5.5 to 4.2, increasing $logD_{ow}$ of these compounds and, thus, influencing biosorption, also demonstrated by the K_D values in the acidogenic reactor (NPX: 229 – 1843, DCF: 702 – 5950 L kg^{-1}TSS, without and with GOH, respectively). The results proved that acidogenesis and methanogenesis act differently on the PhCs biosorption. The GOH co-fermentation acted specifically on the biosorption of NPX and DCF, due to the lowering of the pH by the organic acids production.

3.20.P-Th357 Degradation Studies of Some Pharmaceuticals Present in Sewage Sludge

***Lembit Nei**[1] and Egge Haiba[2], (1)Tallinn University of Technology , Tallinn, Estonia, (2)Tartu College, Tallinn University of Technology, School of Engineering, Estonia*

Soil pollution has a clear impact on food quality. At the same time the global deficit of fertilizers is present and due to the war in Ukraine the situation is worsening. Still, a number of possible resources of nutrients have not found appropriate application in agriculture, as for example sewage sludge (SS), which is one of the most promising sources of P, N and organic matter. SS usage as an agricultural fertilizer has a number of limitations. Amongst them persistent organic pollutants (POPs) have a special role due to their ability to undergo plant uptake and *via* this affect living organisms.

Intensive studies involving the fate and possible means of eliminating POPs present in SS are going on, but due to the complexity of these compounds no major success has been achieved. In some cases promising results have been gained *via* SS composting with different bulking agents. Our work has been concentrated on studying the degradation of several widely used

POPs, as for example pharmaceuticals, during composting. We have shown, that the degradation rate of pharmaceuticals and personal care products, as in the case of carbamazepine (CBZ) and triclosan (TCS), depends on composting conditions.

3.20.P-Th358 Unravelling the Dynamics of a Photolabile Pharmaceutical in the River Rhine: Real-Life Degradation Rates and the Impact of Sunlight Variability

Enpei Li *and Kevin S. Jewell, German Federal Institute of Hydrology (BfG), Germany*

Pharmaceutical contaminants, including the photolabile diclofenac (DCF), pose a risk to the environment in rivers and streams, sometimes exceeding proposed standards. However, the lack of real-world degradation constants creates a knowledge gap that hinders effective management. Accurate numbers from river conditions are lacking, despite extensive laboratory research. Our study addresses this issue by developing a method to determine the degradation rate constants of the DCF using high-resolution monitoring data from rivers. Routine monthly monitoring is insufficient due to the rapid turnover of DCF, which requires higher temporal resolution. Through near daily non-target screening (NTS) data integration and modelling, our goal is to calculate degradation rate constants and assess seasonal and annual changes in DCF load.

We first calibrate the daily NTS data to monthly DCF concentration monitoring to ensure accuracy and reliability. With the calibrated NTS data, we modelled DCF load to reconstruct the DCF time series by assuming first-order degradation based on sunshine duration and discharge. We successfully reproduce the weekly to seasonal variations of DCF concentration at two Rhine stations (km 359 and km 590). Our calculated degradation rate constant (0.14 h^{-1}) agrees with laboratory studies, and with this calculation we extended the temporal coverage of the daily DCF concentration to 2012. Comparing the annual variation in DCF load from both data and model to the variation in sunlight, we find that more than 63% of the DCF load variation is due to the variation in sunlight.

In conclusion, the half-life of DCF in our study area is approximately 5 hours. Sunlight changes dominate DCF load variations over the last decade, overshadowing changes in consumption patterns. The approach will be extended to other photolabile substances and integrated into river hydrodynamic models for broader spatial coverage.

3.20.P-Th359 Pharmaceutically Active Compounds (PhACs) in sediments and fish from a fluvial ecosystem. Tagus River case study

Silvia Royano[1], Adrián de la Torre[2], Irene Navarro[1] and ***María Ángeles Martínez[1]****, (1)Center for Energy, Environmental and Technological Research (CIEMAT), Spain, (2)Center for Energy, Environmental and Technological Research (CIEMAT), Madrid, Spain*

The presence of pharmaceutically active compounds (PhACs) in river waters is well established, but their mobility to other compartments may endanger the quality and health of the whole ecosystem. The present study addressed the presence of 22 PhACs and one metabolite in river sediments (n=28) and fish samples (n=24) collected from the Tagus River watershed during 2020, 2021, and 2022.

PhACs were analyzed in both matrices by an adapted QuEChERS extraction method and SPE clean-up step. Instrumental analysis was carried out by ultrahigh performance liquid chromatography tandem mass spectrometry (UPLC-TqMS/MS) followed by quantification with deuterated standards.

For the validation of the analytical method for both matrices, samples with no PhAC levels were processed as previously described. Limits of quantifications meeting SANTE/2020/12830 and SANTE/11312/2021 criteria ranged between 1 to 50 ng/g for sediments and between 10 to 50 ng/g dry weight (dw) for fish. 9 PhACs were quantified in at least one sediment sample while only clotrimazole PhAC was found above LOQ in fish. Quantification frequencies were higher than 50% for azithromycin, clarithromycin, clotrimazole, irbesartan, miconazole, o-desmethylvenlafaxine, and venlafaxine in sediments. No temporal (2020-2021-2022) tendencies ($p>0.05$: Kruskal-Wallis test) were found. According to results obtained in surface water sampled in the same period, areas with the highest PhACs concentration in river water showed the highest PhAC levels in sediments and biota, revealing a possible mobility between these environmental compartments. In addition, PhACs with elevated Kow and Koc values as clotrimazole were found in both matrices with a median concentration of 20 ng/g in sediments and 12 ng/g dw in fish samples.

In accordance with the proposal for amending the Water Framework Directive, five PhACs will be included as Priority Substances. However, environmental quality standards (EQS) are not defined for sediment and biota for either of them. Nevertheless, the proposal identifies azithromycin and clarithromycin as substances that tend to accumulate in sediment and/or biota matching with the results of this study.

The present study is part of the project PID2019-105990RB-I00 funded by MCIN/AEI/10.13039/501100011033.

3.20.P-Th360 A microcosm to elucidate the mobility of wastewater derived pharmaceuticals in soils and their effects towards respiration - a combined fate and effect study

John Nightingale[1]*, Andrea Lorena Garduno Jimenez[2] and Laura Carter[3], (1)University of Leeds and Fera Science Ltd, United Kingdom, (2)University of Leeds, United Kingdom, (3)School of Geography, University of Leeds, United Kingdom*

The increasing adoption of wastewater reuse in agricultural irrigation, driven by climate change and water scarcity, is a sustainable solution for water management, however, inadvertently introduces a suite of emerging contaminants into soils. Contaminants including pharmaceuticals such as antibiotics, anti-depressants and anti-inflammatories are widely detected in soils following wastewater irrigation. Nevertheless, our understanding of terrestrial fate and effects of these contaminants in soils are still within their infancy. This gap is particularly critical given the potential impact of antibiotics on soil microbial communities. To address this, a combined microcosm was developed to investigate the leaching behaviour of pharmaceuticals in two arable soils (silty clay loam and a sandy loam). The microcosm includes a 30 cm soil profile and an automated system to analyse CH_4, CO_2, N_2O, NO, and NO_2; at regular time intervals; automation was provided via an Arduino chip and solenoids. Over the duration of two months, the columns were exposed to simulated irrigation events using synthetic wastewater spiked with antibiotics (azithromycin, trimethoprim, lincomycin, and sulfadiazine). Preliminary results show that exposure to environmentally realistic concentrations (100-1000 ng/L) of azithromycin, trimethoprim, lincomycin, and sulfadiazine, resulted in a 17 – 50 % increase in CO_2 respiration and no alterations to CH_4 production. Given that the system currently evaluates synergistic effects, a repeat experiment is underway to explore the effects of individual antibiotics on the production of gas emissions from soils. . Furthering this leaching data will be predicted using the best available models, in the attempt to bridge gaps between current risk assessments (manure and biosolid applications) and future agricultural practices. Overall, this research offers vital insights into the terrestrial fate and effects of pharmaceuticals in agricultural soils, contributing to a more nuanced understanding of the environmental implications of using reclaimed wastewater in agriculture.

3.20.P-Th361 Prioritisation of fish testing requirements for human pharmaceuticals – a quantitative impact analysis

Samuel K Maynard[1]*, Andrew Ross Brown*[2]*, Alison Nimrod Perkins*[3]*, Stewart Owen*[4]*, Charles Tyler*[5] *and Anja Coors*[6]*, (1)Global Sustainability, AstraZeneca UK Ltd, United Kingdom, (2)Exeter University, United Kingdom, (3)Lilly, (4)AstraZeneca UK Ltd, United Kingdom, (5)University of Exeter, United Kingdom, (6)ECT Oekotoxikologie GmbH, Germany*

Among the approximate 3500 Active Pharmaceutical Ingredients (APIs) on the market in the EU many were approved for use prior to 30th October 2005 and as such were not subject to the requirement for environmental risk assessment. As part of the ongoing revision to the general pharmaceutical legislation (proposal for directive repealing direction 2001/83/EC) there is a proposal for the European Medicines Agency, in conjunction with other agencies, to prepare a risk-based prioritisation of these so-called “legacy” APIs, for provision of environmental data and risk assessments. A recent publication by Coors et al., 2023 has proposed an approach whereby a decision tree is utilised to determine if vertebrate ecotoxicity testing of pharmaceuticals is necessary. If this decision tree was implemented as part of such a risk-based prioritisation system for these legacy APIs, a significant saving of fish tested could be realised. Here we demonstrate the potential impact in terms of animals, capacity and financial savings. Using the database of APIs and ecotoxicology data availability collected during the IHI PREMIER Project, we show that implementing the approach published by Coors et al., for all APIs without fish chronic data, could save up to $30m and 240,000 fish. Furthermore such an approach optimises capacity at contract research facilities to conduct hundreds of fish early life stage studies on other APIs allowing risk of more than 1000 legacy APIs to be clarified more quickly and using less fish. More detailed analysis will be presented showing different scenarios of different levels of prioritisation of APIs. In future, additional savings could be made through implementation of this approach for new APIs and integration of *in silico and in vitro* tools to further refine potential for fish sensitivity. This analysis has indicated the benefits beyond bioethics of the prioritisation of data generation activities, allowing more expedited environmental assessments and effective utilisation of vertebrate testing resource where it provides the best value and most effective environmental protection.

3.20.P-Th362 Ecological risk assessment of human pharmaceuticals detected in Japan and establishment of ecotoxicity database

Hiroshi Yamamoto[1,2]*, Haruna Watanabe*[1,2]*, Takahiro Yamagishi*[1,2]*, Yoshikazu Ninomiya*[2]*, Norihiro Kobayashi*[3]*, Takashi Yamada*[3] *and Akihiko Hirose*[3,4]*, (1)Health and Environmental Risk Division, National Institute for Environmental Studies (NIES), Japan, (2)University of Tokyo, Japan, (3)National Institute of Health Sciences, Japan, (4)Chemical Evaluation and Research Insitute, Japan*

Guidance for environmental risk assessment (ERA) of new human pharmaceuticals were published in 2016 by Japan Ministry of Health, Labour and Welfare with referring first version of Guideline on the environmental risk assessment of medicinal products for human use published by European Medicines Agency (EMA) in 2006 but the risk assessment is voluntary-base and the comprehensive ecological risk of pharmaceuticals have not been conducted in Japan mainly due to the lack of ecotoxicity data. Therefore, we conducted the short-term (sub-)chronic aquatic toxicity tests using three species, zebrafish (*Danio rerio*), *Ceriodaphnia dubia*, and green alga (*Raphidocelis subcapitata*) for 30+ out of 100 pharmaceuticals detected in rivers and effluent of wastewater treatment plants in Japan. Some of newly obtained data were compared with the existing acute/chronic data. Both acute/chronic ecotoxicity data were also collected from European public assessment reports (EPAR, EMA), Drugs@FDA database (FDA), pesticides ERA related materials (MOE, Japan), Safety Data Sheets (SDS) of pharmaceutical companies, and research articles. These data were curated by chemicals and toxicologists in our research group based on our expertise in ecotoxicity. 1095 test data for 363 pharmaceuticals had already been published in open database (Yamada et al., Fundamental Toxicological Sciences, 8(7):195-204, 2021) and additional 3309 test data for 255 pharmaceuticals are planning to be added in the database and be donated to OECD QSAR Toolbox by the end of 2024. Based on this database, the ecological risk assessment was conducted using the monitoring data of our research team in rivers and effluent of wastewater treatment plants all over Japan and the 100+ pharmaceuticals were ranked with their hazard quotient calculated by the measured environmental concentration (MEC) divided by the predicted no effect concentration (PNEC).

3.20.P-Th363 Ecological Risk Assessment of Individual PPCPs and Their Mixtures in Korean Surface Waters
***Jun Yub Kim** and Sang Don Kim, School of Earth Science and Environmental Engineering, Gwangju Institute of Science and Technology (GIST), Korea, Republic of (South)*
The ubiquitous presence of pharmaceuticals and personal care products (PPCPs) in water bodies, even at low concentrations, is concerning due to their pseudo-persistence and toxicity. This study assessed the ecological risks of individual PPCPs and their mixtures in Korean surface waters. Using Liquid Chromatography-High Resolution Mass Spectrometry (LC-HRMS), 137 PPCPs were monitored in four major rivers over a year, revealing concentrations from a few ng/L to 42,733 ng/L for metformin. The Risk Quotient (RQ) methodology, including an analysis of the frequency with which the Measured Environmental Concentration (MEC) exceeds the Predicted No-Effect Concentration (PNEC), referred to as RQ_F, was used to evaluate potential impacts on aquatic life. After considering the frequency of PNEC exceedance, the RQF values generally decreased, but clotrimazole still exhibited the high RQ_F of 17.4 with 99.6% of its MECs exceeding PNECs. The Hazard Index (HI) for PPCP mixtures was calculated using the lowest PNECs from all available aquatic organisms and three trophic levels, yielding HI values of 24.02 and 11.37, respectively. This suggests that focusing solely on three trophic levels might underestimate the ecological risks of PPCPs, especially to sensitive species like insects, which share vulnerabilities with PPCPs and pesticides. A comparison between the Maximum Cumulative Ratio (MCR) and HI revealed that the risk is primarily associated with individual PPCPs, particularly clotrimazole. Subsequently, the RQ based on the Sum of Toxic Units (RQ_{STU}) was calculated, indicating that fish are the most sensitive group in assessing ecological risks of PPCP mixtures, with an RQ_{STU} value of 6.45. This study highlights the urgent need for comprehensive ecological risk assessments of PPCPs due to their significant threat to aquatic environments and potential impact on human health.

3.20.P-Th364 A biomarker-based investigation of the effects of metformin and guanylurea on the Mediterranean mussel, Mytilus galloprovincialis
***Ayesha Rafiq**, Paola Valbonesi, Marilin Profita and Elena Fabbri, Biological, Geological and Environmental Sciences, University of Bologna, Italy*
Metformin (MET) is a first line oral therapy for diabetic patients, and their number is expected to reach 643 million by 2030, which represents over 11% of the population between 20 and 79 years old. Accordingly, researchers have found that MET is released into aquatic bodies in higher amount than other drugs in terms of weight. MET is mainly transformed to guanylurea (GUA) and both may adversely affect organisms living in aquatic environments. Only a few data are available for marine species, thus the current study was conducted to examine the effects of MET and GUA in adult marine mussel *Mytilus galloprovincialis* after a 3-day exposure to environmentally realistic concentrations (0.5, 5 and 10 ng/L). Six biomarkers were evaluated, including lysosomal parameters (lysosomal membrane stability, LMS; lysosome to cytoplasm ratio, LYS/CYT; lipofuscin, LF; neutral lipid, NL), and oxidative stress enzyme (glutathione-S-transferases, GST and catalase, CAT) activities. Further biomarkers will be assessed, e.g. neurotoxicity stress enzyme (acetylcholinesterase, AChE) and lysosome membrane stability in digestive gland. According to the results, the highest tested concentration (10 ng/L) of MET and GUA had a significant effect on mussel LMS. Reduction in LMS is an early warning signal of damage to cells in *Mytilus* species. MET at 10 ng/L also significantly increased the accumulation of end products of lipid peroxidation (LF content). Mussels exposed to all tested concentrations of GUA showed a significant dose-dependent increase in CAT activity in both digestive gland and gills, as well as in GST activity in gills. The GST activity was also increased in digestive glands exposed to GUA, with a bell-shaped trend reaching significance at 5 ng/L. When MET was applied, CAT activity was significantly decreased in both gills and digestive gland at 10 ng/L; at the same concentration GST activity showed significant decrease only in gills. Overall, the parent compound MET has shown major effects on lysosomal parameters, meanwhile, the metabolite GUA impacted mainly the activity of oxidative stress enzymes both in gills and digestive glands of mussels. The European 4th WATCH list has prioritized MET and GUA as monitoring substances in surface waters; according to the findings of this study, more investigation is recommended on the occurrence of MET and GUA also in the marine environment, where they can affect living organisms.

3.20.P-Th365 Hazards of Cardiovascular Drugs in the Aquatic Environment: Impact on Growth and Vascular System Development in Zebrafish (Danio rerio) Embryos
***Giulia Cafiero**[1], Katharina Brotzmann[2] and Thomas Braunbeck[3], (1)Environmental Risk Assessment, Wageningen University & Research, Netherlands, (2)University of Heidelberg, Germany, (3)Centre for Organismal Studies, University of Heidelberg, Germany*
Antihypertensive drugs are a class of therapeutic agents commonly detected in the environment. β-Blockers, such as metoprolol, and angiotensin II-receptor blockers, such as valsartan, stand out as the most common detected cardiovascular drugs in freshwater and marine samples. The veterinary drug carazolol is a β-blocker that has been co-detected with metoprolol and valsartan and represents 2 % of the cardiovascular drugs found in environmental samples. While few studies have described the effects of metoprolol in fish and little data have been reported for valsartan, no data is available on the (eco)toxicity of carazolol. In the present study, some knowledge gaps about the (eco)toxicity of metoprolol, valsartan and carazolol are filled by data obtained from experiments on the zebrafish embryo model.

For all compounds, the Fish Embryo Acute Toxicity (FET, OECD 236) test was conducted in 3 replicates with wild-type zebrafish (Danio rerio) Embryos. Teratogenic effects were recorded and the median lethal concentration (LC50) and median effect concentration (EC50) were calculated. Growth and heart-beat rate were considered as additional endpoints. Effects on the development of the vascular system were observed through the transgenic Danio rerio Tg(kdrl:GFP) strain. Vascular

system malformations were analysed at 120 hpf through fluorescence microscopy. Preliminary results of metoprolol showed 50 % lethality at 700 mg/L, 120 hpf. At ≥ 300 mg/L, hatched embryos presented scoliosis and lordosis of the spine and motility decreased to 0. Measurements of the body length of hatched larvae revealed a trend of inhibition in growth (≥ 500 mg/L). At 72 hpf, individuals exposed to ≥ 300 mg/L of metoprolol showed cardiac effects. Preliminary morphological observations on the Tg(kdrl:GFP) line did not reveal any obvious malformations on the blood vessels at 120 hpf.

Subsequent tests will shed light on the (eco)toxicity of carazolol and provide standardised data through the execution of FET tests on valsartan and metoprolol. Effects on growth, behaviour, as well as endocrine and antioxidant systems caused by cardiovascular drugs have been reported in non-target organisms. So, it is indispensable to produce base evidence of ecotoxicity through established in vivo models. Experiments with the vascular fluorescent transgenic line Tg(kdrl:GFP) will show its effectiveness as an ecotoxicologal tool for screening drugs for their potential to impair the vascular system development.

3.20.P-Th366 Toxicity of Diclofenac Towards Baltic Cyanobacteria and Their Biochemical Response

Klaudia Kwidzińska[1]*, Magda Caban*[1]*, Hanna Mazur-Marzec*[2]*, Anna Aksmann*[3]*, Martyna Zalewska*[3] *and Justyna Kobos*[2]*, (1)Department of Environmental Analysis, University of Gdansk, Poland, (2)University of Gdansk, Poland, (3)Faculty of Biology, University of Gdansk, Poland*

Cyanobacteria occurring in the Baltic Sea are constantly exposed to the pharmaceutical contaminants. One of the pharmaceuticals detected in the Baltic Sea that is of particular concern is diclofenac - DCF. Cyanobacteria play an important role in the ecosystem and significantly affect the condition of entire water reservoirs. On the one hand, they constitute the basis of the food chain and produce oxygen in quantities significant for the entire globe. On the other hand, they create problematic blooms during which they release toxins that are harmful to humans and animals. Increased blooms may cause hypoxia and deteriorate the condition of ecosystems, and ultimately lead to eutrophication of the entire water reservoir. The aim of this study is to investigate the impact of DCF on several different species of cyanobacteria occurring in the Baltic Sea. The study took into account not only the effect of this pharmaceutical on the growth of cyanobacteria in reference ecotoxicological tests, but also determined other endpoints, such as changes in the profile of photosynthetic pigments and toxins produced by them, observation of changes in the size and number of cells using flow cytometry, and growth assessment by optical density. The release of reactive oxygen species in response to stress caused by the presence of DCF has also been studied. The results showed high resistance of unicellular cyanobacterial species Synechocystuis salina and Microcystis aeriuginosa in reference ecotoxicological tests. In turn, according to preliminary tests, multicellular cyanobacteria with a filamentous structure were more sensitive; their growth was inhibited at a DCF concentration of several mg L-1. In some of the tested cyanobacterial cells, despite no effect on cell growth, a biochemical response was observed, i.e. increased secretion of toxins or an effect on photosynthesis.

3.20.P-Th367 Pharmaceutical Pollution Drives Changes in the Composition and the Functionality of the Aquatic Microbial Biotic and Abiotic Communities

Marina Barbudo-Lunar Ms.[1]*, Chiara Trombini Dr.*[2]*, Carmen Michan*[3]*, Jose Alhama*[4] *and* ***Julian Blasco***[5]*, (1)Dpt. Biochemistry and Molecular Biology, ceiA3, Universidad de Córdoba, Spain, (2)Ecology and Coastal Management, Institute of Marine Sciences of Andalusia, Spanish National Research Council (ICMAN-CSIC), Spain, (3)University of Córdoba, Spain, (4)Biochemistry and Molecular Biology, University of Cordoba, Spain, (5)Institute of Marine Sciences of Andalusia, Spanish National Research Council (ICMAN-CSIC), Spain*

Pollution is a worrying problem today that affects all ecosystems. Aquatic ecosystems are among the most affected as they are a sink for pollutants from various sources. Among the main chemical pollutants threatening the stability of aquatic ecosystems, pharmaceuticals stand out due to their exponential increase in use for both human treatment and intensive livestock farming. As environments are exposed to multiple stressors, we have used multispecies assays, including the bivalve *Scrobicularia plana*, in artificial controlled microcosms to assess the specific impact of different pharmacological compounds on the microbiome. Their effects on both the abiotic and biotic matrices of the ecosystems were analyzed using metagenomic techniques. We used 16S rDNA sequencing to determine changes in the structure, diversity, and functionality of bacterial populations from sediments and the digestive gland of bivalve molluscs. Here we present the effects of the drugs carbamazepine (CBZ), an anticonvulsant used to treat epilepsy and bipolar disorder, and sulfamethazine (SMZ), a synthetic antibiotic of the sulfonamide family, when exposed individually and in combination to a concentration of 1 μg/L, which is an environmentally relevant concentration, for 10 days. An unexposed control was also included. Overall, the phylum with the highest number of identifications in all samples was Proteobacteria. The families Ectothiorhodospiraceae and Flavobacteriaceae were highly represented in both types of samples. Exposure to SMZ resulted in a significant decrease in families related to nitrogen fixation, such as Thioalkalispiraceae and Xanthomonadaceae. In addition, CBZ had an antagonistic effect on SMZ. At the functional level, there was a significant decrease in "anoxygenic photoautotrophism" after single exposure to SMZ compared to the control. The changes observed in the microbiome can be used as biomarkers of environmental exposure to these drugs.

3.20.P-Th368 Green microalgae respond differently to the toxicity of diclofenac. An study with Scenedesmus quadricauda and Ankistrodesmus falcatus

*Laura Cruz-Castillo, Miriam Hernández Zamora and **Fernando Martínez-Jerónimo**, Instituto Politécnico Nacional Escuela Nacional de Ciencias Biológicas, Mexico*

Each year, 1443±58 tons of diclofenac are consumed worldwide. This non-steroidal anti-inflammatory drug's high consumption and incomplete metabolism have caused it to be widely distributed in aquatic environments, posing a risk to microalgae and ecosystems. This study aimed to evaluate the effect of diclofenac on population growth, in the concentration of photosynthetic pigments, and the main biomolecule composition in *Scenedesmus quadricauda* and *Ankistrodesmus falcatus*. Bioassays were performed in PCG medium for *S. quadricauda* and Bold´s Basal Medium for *A. falcatus* with 0.1, 1, 10, and 100 mg L^{-1} diclofenac, incubating with constant aeration and continuous illumination at 25°C for 96 hours. The population growth of *A. falcatus* was inhibited by 43, 55, and 99% with 1, 10, and 100 mg L^{-1} diclofenac, respectively, while *S. quadricauda* showed no significant growth change at any drug concentration. However, in *S. quadricauda*, an increased frequency in atypical cells was observed as the concentration of diclofenac was augmented. In *A. falcatus*, the concentration of carotenoids and chlorophylls *a* and *b* increased significantly with 1 and 10 mg L^{-1} diclofenac, respectively, compared with the control. Lipid concentration in *A. falcatus* exposed to all concentrations of diclofenac was higher than the control, and proteins increased by 152 and 217% with 1 and 10 mg $L^{-1,}$ respectively; carbohydrates increased by 190% with 10 mg L^{-1} diclofenac. For *S. quadricauda* exposed to diclofenac, the concentration of chlorophylls *a* and *b* was similar to that determined in the control. However, carotenoid and lipid content decreased significantly in all drug concentrations, and the protein concentration increased by 271, 338, and 339 %, respectively, for the concentrations of 1, 10, and 100 mg L^{-1}. In comparison, carbohydrates increased by 204 and 207% with 10 and 100 mg L^{-1} of diclofenac. The results confirm the adverse effects of diclofenac on primary producers despite the differences in toxic responses. It was also evidenced that different endpoints should be studied in aquatic biota for a complete assessment of drugs toxicity as emerging concern pollutants.

3.20.P-Th369 Does DCF influence antioxidant enzyme system in Baltic cyanobacteria? Biochemical response of the cells to environmental emergent pollutant

*Klaudia Kwidzińska[1], **Magda Caban**[1] and Ewa Mulkiewicz[2], (1)Department of Environmental Analysis, University of Gdansk, Poland, (2)Faculty of Chemistry, University of Gdansk, Poland*

The presence of pharmaceuticals in the environment is a global challenge. Diclofenac (DCF) is a pharmaceutical which deserves special attention due to its low removal rate in wastewater treatment plants (WWTPs), the high frequency of its detection in natural waters and proven negative impact in low concentrations on non-target wild-living organisms.

The Baltic Sea, is a diverse, closed and shallow basin, and is one of the most polluted seas by various anthropogenic compounds. Enhanced eutrophication is one of the causes of the formation of cyanobacteria blooms. Cyanobacteria, just like other organisms occurring in the Baltic Sea, are chronically exposed to pharmaceuticals including DCF. Currently, there is limited knowledge on the pharmaceutical effect on cyanobacteria, while some works are available on selected green algae and diatoms. Available literature data indicate higher resistance of cyanobacteria to pharmaceuticals compared to, for example, green algae, due to their overall high adaptive possibilities. The study of the impact of pharmaceuticals on phytoplankton focuses mostly on the growth inhibition endpoint in acute studies, which gives information about the general toxicity but not about biochemical changes occurring in cells.

Taking all this into account, the aim of the research was primarily characterization of the antioxidant enzyme system in *Synechocystis salina*, *Microcystis aeruginosa*, *Nodularia spumigena*, *Aphanizomenon flos-aquae* - the dominant species of cyanobacteria occurring in the Gulf of Gdańsk, the Polish part of the Baltic Sea. The presence of enzymatic activity of glutathione reductase (GR), superoxide dismutase (SOD), catalase (CAT), and peroxidases (GPx) was examined. The antioxidant enzyme system of target cyanobacteria species was never previously described. As the Baltic cyanobacteria are chronically exposed to DCF present in the environment, the biochemical response (induction/inhibition of selected antioxidant enzymes) of the cells was studied.

3.20.P-Th370 Application of flow cytometry for testing of pharmaceuticals toxicity toward cyanobacteria

*Klaudia Kwidzińska, Katarzyna Bethke and **Magda Caban**, Department of Environmental Analysis, University of Gdansk, Poland*

Pharmaceuticals are among the challenges of modern ecotoxicology. Three decades of its monitoring shows that they are present in all water types. The huge number of pharmaceuticals, its diverse characteristics and mode of action cause problems with testing of toxic effect on water organism, which also are represented with thousands of species. Thereby, the reference test organisms are taken for ecotoxicology. The water microorganisms are mostly represented by green algae. Cyanobacteria are much less often the targets, despite their high impact on the environment caused by blooms creation.

In this work we decided to present the application of flow cytometry for testing the cell number during test of pharmaceuticals to cyanobacteria. The Synechocystis salina and Microcystis aeruginosa were taken as representants of unicellular cyanobacteria. The ampicillin antibiotic was taken as target and acute 96h test was performed. This substance was found to have EC50 lower than 10 mg/L. The performance of flow cytometry measurement shows that despite the cell number the results of this analysis can show how the basic parameters and cell characteristic can be changed by toxicants. Preliminary studies with staining by fluorescein diacetate were performed. The correlation between cell number and optical density shows perfect agreement, what mean that they can be alternatives. As conclusion, the advantages and disadvantages of flow cytometry for unicellular cyanobacteria counting was presented.

Acknowledgement - Financial support was provided by the National Science Center (Poland) under grants UMO-2019/35/B/NZ9/00253.

3.20.P-Th371 Antibiotics and its Associated Risk in an Indonesian Reservoir

***Miranti Ariyani*[1]*, Nynke Hofstra[2], Milou van de Schans[3], Pieter van Oel[4] and Carolien Kroeze[5], (1)Wageningen University and Research (WUR), Wageningen, Netherlands, (2)Water System and Global Change Group, Wageningen University & Research, Netherlands, (3)Wageningen University and Research (WUR), Wageningen Food Safety Research, Netherlands, (4)Water Resources Management Group, Wageningen University & Research, Netherlands, (5)Environmental System Analysis Group, Wageningen University & Research, Netherlands*

While various classes of antibiotics have been detected in rivers and reservoirs worldwide, there is limited knowledge of antibiotic occurrence and their risk in the surface waters of Southeast Asia. This is due to the unavailability of data on consumption of antibiotics and a lack of environmental monitoring. This study aims to provide insight into the occurrence and ecological risk associated with various classes of antibiotics in the Cirata reservoir in Indonesia. For this, we analyzed 65 types of antibiotic residues including the antibiotic classes of tetracyclines, fluoroquinolones, macrolides, sulfonamides, lincosamides, diaminopyrimidines, and amphenicols in water and sediment samples. Our assessment of wet-season samples shows that at least 14 types of antibiotic residues with concentrations ranging from below the limit of quantitation to hundreds of ng/L were present in the water samples. Also, a relatively high concentrations (µg/kg) of 5 types of antibiotic residues were present in the sediment. The individual preliminary risk assessment of the highest antibiotics concentration present in the water and sediment samples shows that fluoroquinolones and tetracyclines poses critical risk for the prevalence of antimicrobial resistance development. Meanwhile, their risk to the aquatic organism such as phytoplankton and crustacean is unlikely. Further assessment on the mixture of antibiotic residues in relation to ecological risk should be performed to provide a more comprehensive impact. The information provided in this study is helpful to define further ecological impact of antibiotics on the supporting services provided by the reservoir, the sources, and effective strategies for dealing with ecological impacts and antimicrobial resistance on local as well as regional scales.

3.20.P-Th372 Pharmaceutical pollution in agriculture: Impacts & risks of antidepressants on soil health and crop production

***Isla Eunice Stubbs*[1]*, Sylvia Toet[2] and Alistair Boxall[1], (1)University of York, United Kingdom, (2)Environment and Geography, University of York, United Kingdom*

Recent environmental concerns regarding pharmaceutical pollution have primarily focused on its impact on aquatic ecosystems, neglecting its effects on agricultural soils. The heightened use of reclaimed wastewater and biosolids in agriculture intensifies soil exposure to pharmaceuticals. Given the increasing reliance on reclaimed wastewater due to climate change, urgent research is imperative to understand the chronic, low-level exposure of agricultural soils to pharmaceuticals. This comprehension is vital for informing environmental risk assessments, guiding land management practices, and addressing the role of reclaimed wastewater in climate change adaptation. Limited research exists on the impacts of pharmaceuticals on soil, microbial communities, and crops. This review aims to assess the current knowledge on contaminants of emerging concern (CEC), with a specific focus on antidepressants. The investigation will evaluate both predicted and measured effects of individual pharmaceuticals and their mixtures on soil health, microbial communities, and crops.

This literature review will delve into the abundance, types, and levels of antidepressants found in agricultural systems, considering the diverse range of pharmaceuticals in circulation including, but not limited to, sertraline, venlafaxine, citalopram and fluoxetine. Current studies predominantly focus on antidepressant impacts in aquatic systems, and so the basis of the extent of terrestrial exposure will build from this. The study will explore the routes and mechanisms through which antidepressants may cause adverse effects on various ecosystem processes and compartments, including crop health, soil microbial processes, and the physical and chemical properties of the soil. Emphasis will also be placed on the acknowledgement and assessment of CEC mixtures, as well as the individual risk of the chemical on the environment. Through this literature review, we aim to contribute to the advancement of knowledge on pharmaceutical pollution in agricultural systems, assessing the potential challenges and risks posed by antidepressant contamination.

3.20.P-Th373 Are there alternatives to PFAS pharmaceuticals?

***Gunther Speichert*[1]*, Gerd Maack[1], Petra Mußler[2], Johanna Greinke[2] and Michael Müller[2], (1)German Environment Agency (UBA), Germany, (2)Institut für Pharmazeutische Wissenschaften, Albert–Ludwigs–University Freiburg, Germany*

The national authorities of Denmark, Germany, the Netherlands, Norway, and Sweden are currently proposing a comprehensive restriction covering a wide range of perfluorinated and polyfluorinated alkyl compounds (PFAS). By definition (fluorinated methyl (CF_3-) or methylene (-CF_2-) carbon atom without any H/Cl/Br/I atom attached to it), some active pharmaceutical ingredients (APIs) in human and veterinary medicinal products (HMP/VMP) can also be categorised as PFAS. Exemptions from the restriction should only be provided for uses that are considered necessary for health, safety or are critical for the functioning of society.

Many medicinal products are necessary for human and animal health and it is, therefore, likely that they will be exempted from the restriction. This means, other ways to reduce the use of PFAS-APIs need to be considered. Often, there are several APIs for the same indication. For example, the *World Health Organisation's Model List of Essential Medicines* lists therapeutic alternatives for numerous APIs, to be used if the API recommended in the first instance is not readily available for certain reasons. The DrugBank databank also offers a service to identify potential therapeutic alternatives.

We have identified 70 approved PFAS APIs in the DrugBank. For the majority of these, non-PFAS alternatives are available. How they and their alternatives were identified and some prominent examples will be presented on the poster. The second aim of the project was to identify which PFAS-types (e.g. CF_2 or CF_3) are present and what are the reasons for the fluorination. The majority of the PFAS-APIs contain a CF_3 group (84 %), which is remarkable as the CF_3 group is a terminal group and often not directly involved in binding to the active site. The final degradation product of most of the identified CF_3 groups is trifluoroacetic acid (TFA), an already nearly ubiquitous anthropogenic substance found in almost all compartments, even in rain and drinking water. Due to the existence of non-PFAS alternatives for the majority of the PFAS-APIs investigated, the inclusion of CF_3 in APIs in the current scale is questionable.

The results can be used by researchers involved in drug discovery to reconsider whether the inclusion of the CF_3 group is really necessary for the functionality of the drug, but can also be used by doctors and pharmacists to select more sustainable pharmaceuticals.

3.20.P-Th374 Demonstrating the environmental benefits of greener alternative pharmaceuticals in a hazard driven regulatory landscape

Rebecca Jayne Brown[1]*, Grace Panter*[1]*, Céline Gerard*[2] *and Céline Delierneux*[2]*, (1)wca environment Ltd., United Kingdom, (2)Estetra SRL, Belgium*

Pharmaceuticals have a critical role in the health and well-being of society, providing lifesaving treatments, helping patients to manage long term health conditions, and enhancing general quality of life. There are however environmental risks associated with increasing concentrations of pharmaceuticals in the environment (PiE). Recognising this, in March 2019 the European Commission (EC) published a Strategic Approach comprising multiple initiatives to address pharmaceutical pollution ranging from regulatory proposals aimed at controlling or managing emissions (i.e., end of pipe measures), to more proactive approaches to reduce input or adverse effects at source by designing pharmaceuticals which have a more favourable environmental profile, the “Greener Pharmaceutical” concept. A problem with the Strategic Approach is that hazard-based approaches aimed at reducing pharmaceutical emissions are not aligned with promoting innovation of greener alternative pharmaceuticals. This is demonstrated through a case study with the novel natural oestrogen estetrol (E4) which has been shown to be a greener alternative to 17α-ethinyloestradiol (EE2) for use as a human contraceptive. E4 is demonstrated as having a more favourable environmental profile compared with EE2 (being less persistent and having lower potential for bioconcentration) and risk quotients (RQ) calculated according to European Medicine Agency (EMA) guidelines are <1 for use as a contraceptive (compared with RQ of 3.9 for EE2 in an equivalent product). Nevertheless, the lower potency of E4 for the oestrogen receptor means higher doses are prescribed with the potential for higher environmental concentrations despite a lower risk for aquatic organisms. For E4, conservative Predicted Environmental Concentration (PEC) in surface water are up to 31 ng/L (i.e. not accounting for removal in the Sewage Treatment Plant), compared with 0.066 ng/L for EE2. This is a concern based on EC proposals for generic environmental quality standards (EQS) of 25 ng/L for total pharmaceutical concentrations in groundwater. We therefore recommend that potency is a consideration for developing generic EQS for pharmaceuticals.

3.20.P-Th375 Pharmaceuticals Strategy for Europe: A Call for Continuous Improvement towards Environmental Protection

Sam Harrison[1]*, Catherine Barnett*[1]*, Maria D Pavlaki*[2]*, Stephen Lofts*[1]*, Sarah Roberts*[1]*, Madalena Vieira*[3]*, Stephen James Short*[4]*, Susana Loureiro*[5] *and David Spurgeon*[1]*, (1)UK Centre for Ecology & Hydrology (UKCEH), United Kingdom, (2)University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Portugal, (3)University of Aveiro, Portugal, (4)Pollution, UK Centre for Ecology & Hydrology (UKCEH), United Kingdom, (5)CESAM-Centre for Environmental and Marine Studies and Department of Biology, University of Aveiro, Portugal*

In 2020, the European Commission (EC) launched its *Pharmaceutical Strategy for Europe*, with broad goals to ensure equitable access to affordable medicines, support competitiveness, innovation and sustainability, enhance crisis preparedness, and ensure the EU has a strong voice in the world. A key step in its implementation was the acceptance by the EC of a draft Regulation and Directive in April 2023, for which a stakeholder consultation period has, in November 2023, just ended. This legislation will ultimately replace the current European Medicines Agency regulation, which has seen little update since publication in 2006. Broadly speaking, its aims align with that of the Pharmaceutical Strategy for Europe, with explicit reference to aspects such as environmental sustainability and anti-microbial resistance. In this poster presentation, we will highlight enhancements in environmental protection offered by this legislation and reflect on areas where there are still gaps and room for improvement.

Examples of enhancements include a requirement to consider the whole lifecycle of products, the ability for authorities to refuse market authorisation based on the risk of environmental harm, the requirement for retrospective risk assessment of products already on the market, and the requirement for continually updated risk assessments. In addition, manufacturers must flag when substances are PBT (persistent, bio-accumulative, toxic), vPvB (very persistent, very bio-accumulative), PMT (persistent, mobile, toxic), vPvM (very persistent, very mobile) or endocrine disrupting.

Despite this enhanced protection, there are important aspects that are not addressed. For example, the risk posed by chemical mixtures, which could be included through the development of a robust mixtures assessment framework. Whilst endocrine disruption is explicitly mentioned, there is room for improvement in testing for other sub-lethal effects, such as neurotoxicity (affecting behaviour), immune modulation and genotoxicity leading to inter- and trans-generational effects. In general, environmental heterogeneity (in space and time) is not accounted for, requiring the better use of data on the effects of, for example, pH and DOC on bioavailability and climatic scenarios on temporal dynamics. Integration of these aspects would lead to better understanding, supporting strengthened environmental protection for pharmaceutical products.

3.20.P-Th376 Proposal for of a threshold approach to PBT/PMT assessment of active pharmaceutical ingredients (APIs)

Gemma Janer, PhD[1]*, Irene Bramke, PhD*[2]*, Andreas Häner*[3]*, Milica Glogovac*[4] *and Joanne Elmoznino*[5]*, (1)Novartis Pharma, Spain, (2)AstraZeneca, Netherlands, (3)Group SHE, F. Hoffmann-La Roche Ltd., Switzerland, (4)Novartis Pharma, Switzerland, (5)Pfizer*

The EU Commission proposal for a new EU pharmaceutical legislation foresees the need to evaluate PBT (including vPvB) and PMT (including vPvM) criteria for active pharmaceutical ingredients (APIs), and considers possible risk mitigation measures associated with these criteria. According to the current EMA guidance, PBT criteria are required to be evaluated regardless of the predicted environmental concentrations (PECs). However, consumption of different APIs and hence the respective PECs range widely. At one end, APIs are used at extremely low daily doses of few µg/day and/or for rare diseases. At the other end of the range, APIs are administered at a level of g/day and/or to very large patient populations. The PBT/PMT criteria (under REACH and CLP) are useful for identifying substances of heightened concern when similar levels of release to the environment are compared, but may not when these differ by many orders of magnitude.

Under current EMA guidance, PBT screening of APIs generally stops after the generation of log D_{OW} data, as the action trigger of log Dow >4.5 is rarely exceeded. In the absence of any corresponding action trigger, future PMT screening would require adsorption/desorption studies (and sometimes also sediment/soil transformation tests) to be conducted for all APIs, including those that do not reach the current, exposure-based action limit (PEC = 0.01 µg/L) for Environmental Risk Assessments (ERA). Both study types are costly and require the use of radiolabeled material.

We present science-based options to establish PEC thresholds to trigger PBT and/or PMT screening. The proposed approach is conservatively designed to ensure that any potential risks a) of secondary poisoning (main concern for PBT substances) and b) to groundwater/drinking water (main concern for PMT substances) will not be missed.

Secondary poisoning risks were evaluated following ECHA guidance documents for hypothetical APIs with reasonably extreme bioaccumulation factors, toxicity, and K_{OC}. Similarly, groundwater risks were evaluated following the draft EMA ERA guideline (2018) for hypothetical APIs with reasonably extreme Kd sludge/soil values and DT50 values. Different PEC triggers and $PNEC_{oral}$ values were used.

The results of these simulations support that the current exposure action limit is an appropriate trigger for PMT assessment, while for PBT assessment, we propose a combined trigger based on exposure levels and mammalian toxicity data.

3.20.P-Th377 Toward a greener pharmacy: preparation of factsheets on potential environmental risks of pharmaceuticals products to support the environmentally conscious prescription of medicines

Stefano Polesello[1]*, Vitalia Murgia*[2]*, Mattia Gianni*[3]*, Luisa Mattoli*[3]*, Giada Fodaroni*[3]*, Grazia Ferrara*[4]*, Marianna Rusconi*[1]*, Massimo Mercati*[3] *and Emiliano Giovagnoni*[3]*, (1)Water Research Institute - Italian National Research Council (IRSA-CNR), Italy, (2)Associazione Italiana Medici per l'ambiente ISDE, Italy, (3)Aboca SpA, Italy, (4)Apoteca Natura SpA, Italy*

In recent decades, the combination of "pharmaceuticals" and "personal care products" (PPCPs) have been recognized as contaminants of "emerging concern" due to their persistent presence in the environment.

Many PPCPs are rapidly dispersed in the environment, but their extensive and universal use determines a pseudo-persistence in aquatic and soil environments with serious ecological impacts on aquatic organisms, thus also posing a risk of selective pressure that can lead to a reduction in biodiversity. The concern for the detection of PPCPs in the environment derives from their ubiquitous presence in bodies of water, soil, and biota.

For Active Pharmaceutical Ingredients (APIs), the concern is greater for some of their peculiar characteristics. They are substances designed to act at very low doses, to "last" for a long time, with considerable stability that limits their biodegradability and for this reason they persist for quite a long time in the environment.

In this project 300 compounds used in pharmaceutical products (such as APIs, preservatives, artificial sweeteners, dyes) will be searched in water samples. Data from the literature about their persistence, toxicity and bioaccumulation will be collected. In some specific cases, for substances considered particularly relevant, for which ecotoxicity data are not present, experimental studies will be carried out. All the data will be organized in technical sheet reporting a calculated a new presumed level of potential environmental risk. This database of concise fact sheets of PPCPs will be consulted on the web or via App for mobile devices by health professionals. The database can enable doctors, pharmacists and veterinarian, while ensuring that every patient gets the treatment they deserve, to also maintain the focus on the protection of the environment and biodiversity. Several educational initiatives will be implemented to spread the evidence that will emerge by this project which will be also open to researchers and academics of various disciplines. This work has been funded by the European Union - Next Generation EU program. PNRR, Mission 4, Component 2, Investment 1.4 - National Biodiversity Future Center (NBFC) – CUP n° B63D21015220004.

3.20.P-Th378 Use Pharmaceutical PNECs with Caution

Neil Parke[1]*, Alison Nimrod Perkins*[1] *and Michael Lee*[2]*, (1)Lilly, (2)Lilly, United States*

In recent years, substantial effort has been made to measure concentrations of pharmaceuticals in the aquatic environment. By comparing measured environmental concentrations (MECs) to predicted no effect concentrations (PNECs), locales at risk from pharmaceutical micropollutants can be identified. However, not all PNECs are created equal. There are several published or presented assessments where poorly-derived PNECs were used to identify risks from MECs. PNECs considered poorly-derived include those based on predicted toxicity when empirical data is available or those based on unreliable ecotoxicity data. Examples are presented and discussed, including some reported PNECs that are orders of magnitude different from PNECs based on high quality data. Researchers should critically evaluate PNECs before using them to determine whether an MEC is safe or a concern. Elements of that critical evaluation are discussed. PNECs for pharmaceuticals should be derived using standard methodology (e.g., EPA Water Quality Standards Methodology or EU Water Framework Directive) using the best available, empirical, most recent, and preferably chronic ecotoxicity data. It is recognized that there is currently not a comprehensive database with ecotoxicity data on pharmaceuticals and not all pharmaceuticals have ecotoxicity data. Available sources for data to develop PNECs will be presented. Finally, when PNECs are used to identify risks, their origin and basis should be transparent. Only high quality PNECs should be used to make decisions by risk assessors and policy makers.

3.20.P-Th379 Towards a Greener Pharmaceutical. A Comparative Study of the Environmental Risk of Ciprofloxacin and its Alternative CIP-Hemi from Human to River.

Qiyun Zhang, Ph.D. candidate[1]*, Morten Suk*[2]*, Max Sabbe*[3]*, Raed Al Halabi*[4]*, Laure Bombeke*[5]*, Kristof Demeestere*[6]*, Klaus Kümmerer*[2] *and Karel De Schamphelaere*[1]*, (1)Ghent University - GhEnToxLab, Belgium, (2)Leuphana University Lüneburg, Germany, (3)Ghent University, Belgium, (4)Bioscience Engineering, University og Ghent, Belgium, (5)Laboratory of Environmental Toxicology and Aquatic Ecology, Environmental Toxicology Unit (GhEnToxLab), Belgium, (6)Ghent University (UGent), Belgium*

Ciprofloxacin (CIP) stands out as one of the most extensively used fluoroquinolones globally, used for its diverse antibiotic applications against both gram-negative and some gram-positive bacterial infections. Despite its established medical efficacy, the release of ciprofloxacin into the natural environment raises significant concerns due to its slow biodegradation and the potential for fostering antibiotic-resistant bacteria. Attempts have been made to explore chemical alternatives to replace ciprofloxacin, aiming for comparable medical effectiveness with reduced environmental impacts, based on the safe and sustainable by design concept. This research seeks to conduct a comparative study on the environmental risk posed by CIP and its derivative, CIP-Hemi, from patient to river. Given several data gaps in this pathway, particularly concerning CIP-Hemi, toxicity tests were executed on cyanobacterium *Microcystis aeruginosa* following the ozonation and photodegradation experiments. These experiments aim to assess the influences of the above-mentioned processes on the ecotoxicity of CIP and CIP-Hemi. The mixtures of daughter molecules resulting from these antibiotics after each process will be examined, noting that either of the tested processes leads to the complete mineralization of these compounds. Regarding the remaining stages, information is compiled through an extensive literature review. Due to similarities in the chemical structure between CIP and CIP-Hemi, some data regarding the toxicity of CIP can be extrapolated to CIP-Hemi, an approach that was utilized for the remaining stages. The previously mentioned experiments and the literature review will be used to assess and compare the risks of CIP and CIP-Hemi.

3.20.P-Th380 Ecological Impacts of the Pharmaceutical Pollutant Oxazepam on Roach (Rutilus rutilus) Behavior in Natural Environments: Integrating Landscape Use and Resource Selection

Natalia Ivone Sandoval Herrera[1]*, Erin McCallum*[2]*, Henrik Baktoft*[3]*, Christer Brönmark*[4]*, Daniel Cerveny*[2]*, Lars-Anders Hansson*[4]*, Gustav Hellström*[2]*, Kai Hulthén*[4]*, Anders Nilsson*[4] *and Tomas Brodin*[5]*, (1)Department of Wildlife, Fish, and Environmental Studies, Swedish University of Agricultural Sciences (SLU), Sweden, (2)Swedish University of Agricultural Sciences (SLU), Sweden, (3)DTU AQUA National Institute of Aquatic Resources, Denmark, (4)Lund University, Sweden, (5)Wildlife, Fish and Environmental Studies, Swedish University of Agricultural Sciences (SLU), Sweden*

Effects of pharmaceutical contaminants on non-target organisms, such as fish, have been widely reported particularly for commonly prescribed anxiolytics like benzodiazepines. Oxazepam, for example, has been shown to alter fish behavior and physiology, including activity patterns, foraging, and predator-prey interactions. While laboratory-based studies have provided initial insights into the effects of oxazepam on fish behavior, research in natural field settings is essential for assessing the ecological relevance of these findings. Here, we evaluated the effects of an environmentally relevant concentration of oxazepam on roach (Rutilus rutilus) behavior, in a natural environment, combining cutting-edge approaches that increase the ecological realism of the study. We used a slow-release internal implant to deliver the pharmaceutical, and high-resolution acoustic telemetry to track fish movement in the system. We evaluated changes in roach swimming activity, activity patterns, and habitat selection. We found that exposed fish were active 50 % more time than control fish, although their diel activity patterns were not different. Exposed fish swam 40% faster on average, however, they spent more time encamped— a behavior where fish are active but in a repetitive and small space— than exploring or transiting, hence this difference in speed was not reflected in their use of space. Exposed fish in fact had a more constrained and aggregated distribution in the landscape than control fish, associated with a preference for areas with the presence of macrophytes. Our results support previous findings on the increase in swimming activity of fish exposed to oxazepam. Moreover, our approach incorporating landscape use and resource selection provides a more comprehensive picture of the full extent of pharmaceutical effects on fish behavior. Our findings highlight the importance of considering ecological context in behavioral ecotoxicology studies to better understand the risks associated with pharmaceutical contamination at population and ecosystem levels.

3.20.P-Th381 From Science to Practice: Ecotoxicological Insights in Malaria Vector Control in Burkina Faso
***Andre Patrick Heinrich**[1], Hermann Sié Pooda[2], Christophe Roberge[3], Rolf-Alexander Düring[4] and Karine Mouline[5], (1)Justus Liebig University Giessen, Germany, (2)Centre International de Recherche-Développement sur l'Elevage en zone Subhumide (CIRDES), Burkina Faso, (3)MedinCell, France, (4)Institute of Soil Science and Soil Conservation, Research Centre for BioSystems, Land Use and Nutrition (iFZ), Justus Liebig University Giessen, Germany, (5)Institut de Recherche pour le Développement (IRD), France*
In the ongoing battle against malaria in Sub-Saharan Africa, innovative and contextually appropriate vector control methods are crucial. Our study in Burkina Faso explores a novel vector control strategy with the endectocide ivermectin to control Anopheles mosquitoes. Using ivermectin-treated cattle, we also integrate the One Health mindset that interlinks human, animal, and environmental health. This strategy, a part of our ANIVERMATE project, aims not just for scientific efficacy but also on its alignment with local agricultural and environmental practices.

Central to our research is the utilization of long-acting ivermectin formulations in cattle, offering a dual benefit of sustained mosquito control and enhanced animal health. However, ecotoxicological guidance of this strategy, particularly considering the well-documented environmental impact of ivermectin, is pivotal. Our work includes proposed risk mitigation measures, such as the use of "fosses fumières" – traditional manure storage pits. These pits are crucial in the local farming cycle and represent a potential site for environmental interaction with ivermectin residues. To understand how dung of treated cattle would be used under field conditions, we also surveyed farmers from three adjacent villages on their use of dung (as a fertilizer) and regarding their agricultural routines.

Our findings emphasize the necessity of aligning scientific innovations with the realities of local farming practices. We delve into the dynamics of ivermectin excretion and degradation in cattle dung and explore tailored risk mitigation measures that aim to protect the unique environmental conditions of West African agroecosystems.

Our research, supported by a robust modeling dataset, demonstrates the potential of ivermectin-treated cattle for malaria vector control. Bridging advanced vector management with ecotoxicological awareness, our study aligns with the One Health concept, emphasizing an integrated approach for ecosystem health, animal welfare, and community well-being. This method not only targets effective malaria control but also contributes to sustainable health practices in Sub-Saharan Africa.

3.20.P-Th382 Bioaccumulation of pharmaceuticals and metabolome investigation in trout – from egg to young-of-the-year fish
***Kateřina Grabicová**[1], Ning Zhang[2], Roman Grabic[3] and Tomáš Randák[1], (1)University of South Bohemia in České Budějovice, Faculty of Fisheries and Protection of Waters, Czech Republic, (2)Faculty of Fisheries and Protection of Waters, South Bohemian Research Center of Aquaculture and Biodiversity of Hydrocenoses, University of South Bohemia in České Budějovice, Faculty of Fisheries and Protection of Waters, Czech Republic, (3)University of South Bohemia in Ceske Budejovice, Faculty of Fisheries and Protection of Waters, Czech Republic*
The emissions of micropollutants from wastewater treatment plants (WWTPs) into the receiving surface water is a recognised threat to the aquatic environment. The adverse effects of released chemicals on aquatic organisms belong to the most accented ones. In this study, brown trout (*Salmo trutta*) eggs were deployed to a natural stream, where treated wastewater contributed up to 25% of the total stream flow. The eggs placed upstream of the WWTP served as a reference locality. The bioaccumulation of selected pharmaceuticals and their metabolites in three developmental stages of brown trout (fish egg, yolk sac fry and young-of-the-year fish) was studied using liquid chromatography with high-resolution mass spectrometry. Besides the bioaccumulation, the changes in metabolome and exposome were evaluated. Fifteen pharmaceuticals were found with clear bioaccumulation trends with time since hatching. The highest concentrations were observed for antidepressants sertraline and its metabolite norsertraline, trazodone and for cardiovascular drug telmisartan. It was proven that individual developmental stages bioaccumulated different pharmaceuticals with different intensities. Based on the non-targeted screening, significantly changed signals (up-and downregulated) increased with exposure time. Some endogenous and exogenous compounds in exposed fish differ from fish from the reference locality. The treated wastewater caused bioaccumulation and has a negative impact on the metabolome in the early developmental stages of brown trout. The study was conducted under project No. 20-04676X (Czech Science Foundation).

3.21.A Polymers and Their Chemicals: Environmental Fate, Hazards, and Risk Assessment

3.21.A.T-01 A Draft Framework for Risk-Based Prioritization & Evaluation of Additives & Polymer-associated Chemistries (APAC)

Craig Warren Davis[1]*, Laura Maurer*[2]*, Hesbon Nyambego*[1]*, Kate Serrano*[1]*, Silvia Maberti*[1] *and Trent A. Key*[3]*, (1)ExxonMobil Biomedical Sciences, Inc., (2)Toxicology & Environmental Science, ExxonMobil Biomedical Sciences, Inc., (3)Environmental Property and Solutions, ExxonMobil Global Services Company*

Widespread global use of polymers and plastic has led to increased stakeholder interest in the health & environmental assessments of these materials. Formal frameworks (i.e., RISK21, Canadian ERC) may require specific data types, developed with prescribed methods, and largely focused on non-polymeric substances. These data are not always available and can result in inaction, or conservative decision making. This is due to the propensity for regulatory or policy decisions to rely primarily on hazard information, without comprehensively considering exposure information. Assessing risk and making risk-based decisions requires deliberate consideration of a complex, and often dynamic, suite of information. For risk assessments that are highly challenging (e.g., large numbers of substances), approaches which screen and prioritize data inputs is a practical methodology for parsing out and addressing complexity in a stepwise approach. This framework for screening and prioritizing additives and polymer-associated chemistries (APAC) was developed to parameterize the large, diverse set of chemistries that are utilized in the manufacture and processing of polymers by considering relative chemical hazards and potential polymer-related exposure profiles together to form the initial basis for a practical and informed risk assessment. The framework leverages existing datasets, mines global databases, and utilizes predictive modeling methodology in a tiered approach to move toward the future goal of fit-for-purpose polymers risk assessments, and is intended to be an accessible approach for all stakeholders with interest in polymers risk assessment. To evaluate the utility of the framework for a large, diverse dataset, a preliminary analysis utilizing the UN database was performed. Substances were assigned to hazard and exposure tiers (based on the nature of available data for each substance) and a matrix was developed to visualize the level of quantitative risk assessment which could be performed for the database. It is estimated that at a minimum Tier 1 hazard and exposure assessments may be conducted for ~ 83.8% of substances from information identified or which may be available. For the remaining substances, risk-based screening may be possible with additional data sources and/or further manual curation.

3.21.A.T-02 The Role of UV Light on the Aquatic Leaching and Transformation of Plastic Additives

Frank Menger[1]*, Mara Römerscheid*[2]*, Eric Carmona Martinez*[3]*, Stefan Lips*[4]*, Ole Klein*[5]*, Deedar Nabi*[6]*, Daria Bedulina*[7] *and Lars Michael Hildebrandt*[8]*, (1)Department of Organic Environmental Chemistry, Helmholtz-Zentrum Hereon, Germany, (2)Department of Exposure Science, Helmholtz Centre for Environmental Research (UFZ), Germany, (3)Department of Effect-Directed Analysis, Helmholtz Centre for Environmental Research (UFZ), Germany, (4)Deparment of Bioanalytical Ecotoxicology, Helmholtz Centre for Environmental Research (UFZ), Germany, (5)Inorganic Environmental Chemistry, Helmholtz Center Hereon, Germany, (6)GEOMAR Helmholtz Center for Ocean Research Kiel, Germany, (7)Alfred Wegener Institute Helmholtz-Center for Polar and Marine Research, Germany, (8)Department of Inorganic Environmental Chemistry, Helmholtz-Zentrum Hereon, Germany*

Functional additives enhance the performance, functionality and stability of plastic products. When released, these additives can, however, become of significant environmental concern. For example, floating plastic can pose a threat to aquatic environments through leaching of chemicals. Solar radiation is expected to affect the leaching of such floating material; the ongoing processes are complex and currently poorly understood. In this work, eight different plastic consumer products were leached under UV radiation under controlled laboratory conditions simulating eight months of environmental weathering to study the release of additives and the formation of possible photo-transformation products. A broad analytical toolbox was employed covering metal(loid), microplastic, target and non-target analysis to characterize the leachates comparing UV-treated and dark control samples. Environmental concerns were estimated using different toxicity tests based on e.g. algae, snails and human cell-lines. The leachates were found to exhibit a multi-stressor scenario by containing small plastic particles, diverse elements and organic additives. Some leachates were found to pose toxic concerns. However, the observed effects could not easily be linked to the analytical data due to possible analytical blind spots and its complexity. More detailed investigations into possible transformation products using high-resolution mass spectrometry revealed the presence of several tentatively identified structures that could explain parts of the anticipated analytical gaps. This research highlights the need for a broad analytical toolbox to study the role of solar radiation in already complex natural leaching processes and concludes that cross-discipline research projects are crucial to the understanding of threats posed by environmental plastic pollution.

3.21.A.T-03 Exploring Past and Present Inputs of Organophosphate Ester Plastic Additives in the French Atlantic Coast by Sediment Core Analysis

Javier Castro-Jiménez, PhD[1]*, Yalanda Putu Yulikayani*[2]*, Nadège Bely*[3]*, Charles Pollono*[3]*, Jacek Tronczynski*[2]*, Nicolas Briant*[4] *and Anne Grouhel-Pellouin*[5]*, (1)Chemical Contamination of Marine Ecosystems, IFREMER, France, (2)IFREMER, (3)IFREMER, France, (4)IFREMER, RBE-BE-LBCM, France, (5)IFREMER, RBE-BE-ROCCH, France*

Organophosphate esters (OPEs) flame retardants and plasticizers present multiple environmental sources, exhibit a number of hazardous effects and are among the most abundant organic plastic additives found in the marine environment. Due to their generally high octanol-water partition coefficients, most OPEs have the tendency to bind to suspended particulate matter, accumulating in sediment over time. The study of their vertical profiles in dated sediment cores allows the retrospective investigation of their deposition and exposure history. However very few investigations reported on the vertical distribution of OPEs in marine sediment cores. In this work we (1) investigated the occurrence of parent OPEs (tri-OPEs) and their major degradation metabolites (di-OPEs) in horizons covering the last 50-100 years from three sediment cores collected in the Gulf of Biscay (North-East Atlantic Ocean) and, (2) explored the vertical profiles of these contaminants to assess historical and present concentrations and exposure trends in the study area. Sediments cores were collected on board of the R/V Thalia (IFREMER) in May 2022 (campaign ROCCHSED2022, DOI: 10.17600/18002069.) in three sites subject to different anthropogenic pressures by using an interface corer equipped with stainless steel tubes. Once in the lab, the cores were sliced into 1 cm horizons and dated. OPEs were extracted by sonication, extracts cleaned-up by solid phase extraction and quantified by isotopic dilution LC-ESI-MS/MS. An increasing north-to-south OPE loading trend was observed, with core 22-04 (southernmost site) exhibiting the highest median concentrations of 2.3 and 0.4 ng g^{-1} dw for ∑tri-OPEs and ∑di-OPE, respectively. This core showed also the highest detection frequency (50-78%). Our results show that OPEs seem to be present in the area already in the early 50’s, although only few compounds (mostly alkyl-OPEs) were detected at low concentrations (pg g^{-1} dw level). Although some general trends were observed for ∑tri-OPEs in the core 22-04, a high concentration variability was observed over time, pointing to heterogeneous input patterns. Vertical profiles of individual tri- and di-OPEs are under evaluation for this sediment core as well as the other two sites, and may help better assessing the past and present inputs of OPEs in the area. Relative distribution of individual OPEs along the vertical profiles and tri-/di-OPE ratios will be also discussed in the presentation.

3.21.A.T-04 Current Levels of Microplastic Pollution Impact Wild Seabird Gut Microbiomes

***Gloria Fackelmann**[1,2], Christopher Pham[3], Yasmina Rodriguez[3], Mark Mallory[4], Jennifer F Provencher[5], Julia Baak[6] and Simone Sommer[7], (1)Department of Cellular, Computational and Integrative Biology, University of Trento, Italy, (2)Institute of Evolutionary Ecology and Conservation Genomics, University of Ulm, Germany, (3)IMAR/OKEANOS, Universidade dos Açores, Portugal, (4)Department of Biology, Acadia University, Canada, (5)Ecotoxicology and Wildlife Health Division, Environment and Climate Change Canada, Canada, (6)McGill University, Canada, (7)Institute of Evolutionary Ecology and Conservation Genomics, Ulm University, Germany*

Given the large amounts of microplastics in the environment, their long-lasting nature, and the countless wildlife species exposed to microplastic pollution throughout their life histories, it is imperative to understand how wildlife health is impacted by microplastics in their current environmental concentrations, which are only projected to rise in time. Despite its vital role in host health and its propensity to change in taxonomic and functional diversity and composition in animals subjected to anthropogenic and environmental stressors, the gut microbiome represents a new avenue in microplastics research that has not been thoroughly explored as a possible impact point for microplastic pollution. Here, we studied the gut microbial response in two different parts of the gastrointestinal tract to varying degrees of microplastic ingestion in two different seabird species known from long-term monitoring to ingest (micro)plastics: the northern fulmar, *Fulmarus glacialis* (*n* = 27; a bioindicator for plastic pollution) and Cory’s shearwater, *Calonectris borealis (n* = 58*)*. This study is the first to describe impacts of environmentally relevant concentrations of microplastics ingested by wildlife species on the diversity and composition of the gut microbiome. Using this multi-species study system, we found that effects of microplastics on gut microbial composition are species-specific, whilst effects on gut microbial diversity are shared between the two species. However, regardless of host species, our results show a decrease in commensals and increase in potentially pathogenic, antibiotic resistant, and plastic-degrading microbes associated with microplastic ingestion at concentrations already present in the environment. Since humans also ingest plastic particles (besides stool, microplastics have even been found in human placentas, blood and lungs), this study puts into question the potential effects microplastics may have on human microbiomes and thus human health.

3.21.A.T-05 Effects of Di-Butyl Phthalate and Di-Ethyl-Hexyl Phthalate at Environmental Doses on Health and Development of Bombus terrestris Microcolonies

***Justine Dewaele**[1], Charlotte Terzo[2], Sébastien Duterne[2], Yves Piquot[1], Denis Michez[2], Nina Hautekèete[1] and Virginie Cuvillier[1], (1)Univ. Lille, CNRS, UMR 8198 - Evo-Eco-Paleo, France, (2)Laboratory of Zoology, Research Institute for Biosciences, University of Mons, Belgium*

The urban environment can have a contrasted role on wild pollinator population settlement. It acts both as a refuge with high floral diversity and zero-phyto policies in Northern cities, but also presents severe constraints such as soil impermeabilization, heat islands and pollution. With the recent legislations implemented in Northern cities to reduce fossil fuel exhaust, the atmospheric pollution profile has changed, revealing organic volatile compounds from petrochemical industry, such as phthalates as main air pollutants. These molecules have endocrine disrupting effects on vertebrate models but have been less studied in invertebrates and especially in terrestrial invertebrates. In the context of the current insect decline crisis, it seems important to understand the impact of such ubiquitous molecules on their health and development as they can disrupt crucial hormonal regulations such as the ecdysteroid pathway. In this study, we exposed *Bombus terrestris* workers in microcolonies to Di-Butyl Phthalate (DnBP) and Di-Ethyl-Hexyl Phthalate (DEHP) alone and in mixture at environmental doses, found in and nearby the city of Lille, France. We investigated the effects of such exposure on microcolony health, worker mortality and larval development. Preliminary results show an increased in worker mortality caused by repeated exposure to DEHP alone and in the mixture, associated with a decrease in adult male production in microcolonies exposed to the mixture. Moreover, repeated exposure to DnBP affected worker lipid content, with increased mass in late stage larvae, suggesting transgenerational obesogenic effects of this molecule. Phthalate exposure seems thus to affect both adults and larvae of *B. terrestris*. It seems therefore important to understand the impact of those molecules on the health of insect populations and especially on bees which population trends show a severe decline since the past seventy years.

3.21.B Polymers and Their Chemicals: Environmental Fate, Hazards, and Risk Assessment

3.21.B.T-01 Recycled Polyethylene: A Closer Look at Chemical Complexity and Environmental Consequences

Eric Carmona Martinez[1,2], *Francesca Molinari*[3,4], *Elisa Rojo-Nieto*[5], *Thomas Backhaus*[2,6] *and Bethanie Carney Almroth*[7], *(1)Department of Effect-Directed Analysis, Helmholtz Centre for Environmental Research (UFZ), Germany, (2)Biological and Environmental Sciences, University of Gothenburg, Sweden, (3)Department of Biology and Environmental Sciences, University of Gothenburg, Sweden, (4)University of Exeter, United Kingdom, (5)Department of Ecological Chemistry, Helmholtz Centre for Environmental Research (UFZ), Germany, (6)Institute for Environmental Research, RWTH-Aachen University, Germany, (7)University of Gothenburg, Sweden*

Plastics, ubiquitous in our environment, present a significant challenge despite efforts to reduce their impact. Plastic pollution remains a pressing threat, with regulatory gaps and >13,000 chemicals used in production. Recycling of plastics is fraught with transparency issues, further contributing to environmental risks, particularly in low-income nations burdened by plastic waste from high-income countries. Mechanical recycling facilities emerge as sources of microplastic pollution, releasing toxic compounds into the environment. To address these challenges, we collected recycled plastic pellets from Global South recycling facilities, analysing them for potential toxicity and identifying substances requiring regulation. The study advocates for transparency and reduced chemical use in the plastics industry.

Materials and methods involve collecting HDPE samples globally, subjecting them to chemical analysis using LC-HRMS. The study employs a robust framework, including UAE and bioassays on *Raphidocelis subcapitata*, assessing the impact of plastic extracts on algal growth. Results reveal diverse contaminants in recycled plastics, with N-Ethyl-o-toluenesulfonamide and N,N-dimethyl-p-phenylenediamine as notable compounds. Pesticides, pharmaceuticals, industrial compounds, among others were detected through Targeted and Non-Targeted Screening analysis. The chemical trojan horse phenomenon suggests plastics could release absorbed chemicals into the environment, threatening biodiversity. Bioassays show growth inhibition and enhancement effects on microalgae, indicating potential environmental issues.

In conclusion, the study underscores the challenge of diverse chemical adsorption in recycled plastics and the complexity of mixture toxicity, making the identification of specific substances challenging. Suboptimal production practices enable potentially harmful trace substances to accompany consumer products, emphasizing the need for improved waste management and sustainable plastic practices.

3.21.B.T-02 Effect-Directed Analysis of Endocrine Disruptors in Plastic Food Packaging

Sarah Stevens[1], *Molly McPartland*[2], *Zdenka Bartosova*[3], *Johannes Völker*[4] *and Martin Wagner*[3], *(1)Norwegian University of Science and Technology (NTNU), Trondheim, Norway, (2)Biology, Norwegian University of Science & Technology (NTNU), Norway, (3)Norwegian University of Science & Technology (NTNU), Norway, (4)Innovative Environmental Services (IES) Ltd., Switzerland*

Plastics are chemically highly complex materials with more than 13,000 substances either used in the manufacturing of plastics (e.g., plasticizers, antioxidants) or non-intentionally added during production processes (e.g., reaction byproducts, impurities). Despite established evidence linking certain plastic compounds (e.g., bisphenols and phthalates) to endocrine disruption, the specific toxic compounds leaching from everyday plastic product remain largely unknown. Therefore, our study aims at identifying the endocrine compounds leaching from plastic food contact articles (FCAs) through an effect directed analysis. Four plastic products made of polystyrene (PS), polyvinylchloride (PVC) and polyurethan (PUR) were leached into a water-ethanol mixture for 10 days at 40°C according to European Regulation 10/2011/EU. Employing high-performance liquid chromatography, we separated the resulting plastic leachates into 60 fractions. Reporter gene assays for nuclear receptors relevant to human health, including peroxisome proliferator-activated receptor gamma (PPARγ), estrogen receptors alpha (ERα), and androgen receptor (AR), were used for analysis. For the identification of the causative chemicals, the active fractions were analyzed by non-target high-resolution mass spectrometry. For the PVC drinking tube, a single estrogenic fraction, constituting for 56% of the activity of the original leachate, was identified. This suggests that most of the estrogenic activity is induced by chemicals contained in one fraction eluting with 100% methanol. The two PUR hydration bladders exhibited three anti-androgenic fractions, each accounting for less than 10% of the original samples' activity. Ongoing efforts are focused on identifying chemical features within the active fractions. This research underscores that plastic FCAs leach endocrine disrupting chemicals into food simulants and by identifying the causative compounds, can enable monitoring the human exposure and better understanding downstream effects.

Acknowledgment - This project has received funding from the European Union’s Horizon 2020 research and innovation program under grant agreement No 860720.

3.21.B.T-03 Translating the hazards of additives in plastic mulch films to the risk of release

Michaela Reay[1], *Martine Graf*[2], *Maddy Murphy*[1], *Gupeng Li*[3], *Chanrong Yan*[4], *Richard P Evershed*[1], *David R Chadwick*[5], *Davey L Jones*[5] *and Charlotte E M Lloyd*[1], *(1)Organic Geochemistry Unit, School of Chemistry, University of Bristol, United Kingdom, (2)School of Natural & Environmental Sciences, Bangor University, United Kingdom, (3)Bangor University, United Kingdom, (4)CAU, (5)School of Environmental & Natural Sciences, Bangor University, United Kingdom*

Plastic mulch film supports improved food security, particularly in regions of marginal productivity. Associated with these films are organic and metal additives, which are not chemically bound, and thus susceptible to loss to the wider soil environment prior to polymer breakdown. There are known hazards associated with heavy metals and some additives (e.g., phthalates, organophosphites) included in plastics, yet the overall additive and metal content still remains relatively unknown, as does the potential risk of these components leaching to the wider environment. In this study, we analysed LDPE (n=47) and biodegradable (n=5) plastic mulch films from China for solvent-extractable additive content via GC-MS and metal content via TXRF. The mulches were then leached to explore the potential extent and composition of the chemical burden arising from organic compounds and metals. Lubricants (fatty acids, amides, alcohols) and antioxidants (Irgafos® 168, Irganox® 1076) were the most abundant additives. Plasticisers, both phthalate and non-phthalate, were present at lower abundances and, particularly for biodegradable films, were dominated by additive and polymer degradation products. The overall metal content was higher in biodegradable (7.9±0.7% *w/w*) than LDPE (0.88±0.17% *w/w*), dominated by Ca, Na and Al with only minor contributions from heavy metals (Fe, Zn, Ti, Cd). The average leached content from LDPE was 71.0±9.9 mg kg^{-1} (equiv. of 2.3% extractable from the new plastic) and 3024±146 mg kg^{-1} for biodegradable plastic (equiv. of 28% extractable from the new plastic). A total of 612 unique compounds were present in the leachate, yet >50 were present in the new films. The majority of the leachate content (80%) has not undergone any regulatory scrutiny, and thus are of unknown concern following release. As the contribution to the total metal content of heavy metals (i.e. high concern) was low, leaching of these metals into both acid and water was also low compared to other metals (7.7±0.7 g ha^{-1} and 27.5±10.5 g ha^{-1}, for LDPE and biodegradable mulches, respectively). Biodegradable mulches had higher leaching of both organic and metal additives, rasing the question of pollution swapping if used as an alternative to LDPE mulch. This work revealed the complexity of the chemical burden posed by both LDPE and biodegrdable mulch films, which is not fully reflected by the composition of the parent mulch and must be considered in future ecotoxicology assessments.

3.21.B.T-04 Occurrence of novel polymer additives in house dust and its association with allergic diseases

***Mauricius Marques dos Santos*[1]*, Melanie Kah*[2]*, Lokesh P. Padhye*[3]*, Emma Sharp*[2]*, Jia Shenglan*[4]*, Declan Fisher*[2] *and Shane Allen Snyder*[5]*, (1)Nanyang Environment & Water Research Institute (NEWRI), Nanyang Environment & Water Research Institute (NEWRI), Singapore, (2)University of Auckland, New Zealand, (3)Department of Civil and Environmental Engineering, University of Auckland, New Zealand, (4)Nanyang Technological University, Singapore, (5)Nanyang Environmental & Water Research Institute, Singapore*

Polymer additives are used to improve strength, durability, flexibility, and many other properties of materials and that account for more than 10,000 different chemicals currently used. Human exposure to such chemicals can occur through various pathways, and the study of environmental exposures have generated different causal links to adverse health consequences. Our work used house dust samples (n=191) from the Dustsafe Aotearoa project, New Zealand, together with household participants demographic and self-reported clinical conditions. Twenty-four house dust contaminant concentrations were determined as well as house dust extract (HDE) *in-vitro* nuclear factor kappa B (NFκB) activity. Out of 24 monitored chemicals, five bisphenol analogues (BP) (BPE, BPP, BPM, BPC, and BPG) were not detected in any of the dust samples. Six chemicals were detected in less than one third of the samples (atrazine, BPBP, BPAP, BPAF, BPTMC, and BPPH). Of the BPA and analogues groups, only Bisphenol S, Bisphenol A and Bisphenol BP were frequently detected (detection frequency of 99%, 60.6% and 35.2%, respectively). 1,3-diphenylenimine (DPG) showed the second highest median concentration in house dust of 735 ng/g (95% CI=598 ng/g - 831 ng/g) and a higher detection frequency of 99%. In this work, we report for the first time on the association of occurrence of the polymer additive 1,3-diphenylguanidine (DPG) in house dust and atopic dermatitis. Households with atopic dermatitis participants (n=58) had a median DPG concentration of 809 ng/g (95% CI=700 ng/g - 1,050 ng/g) versus 392 ng/g (95% CI=316 ng/g - 447 ng/g) of those of non-atopic dermatitis households (n=133). House dust extracts from homes with atopic dermatitis participants also showed a greater activation of NFκB response with bioactivity having a strong relationship with DPG concentrations. To verify the association of DPG with the observed induction of NFκB pathway, an effect-directed analysis of a pooled house dust extract was performed, and DPG-containing fractions were found to be responsible for 11.2% of the total observed NFκB activity, the major contributing hydrophilic fractions. While DPG is recognized as an allergen, to the best of our knowledge, this is the first report that associates its occurrence as an environmental contaminant with atopic dermatitis incidence, suggesting a potential risk from human exposure to house dust containing high concentrations of DPG.

3.21.B.T-05 Hazard Assessment of 6PPD-quinone across fishes of commercial, cultural, and ecological importance

***Markus Hecker*[1]*, Catherine Roberts*[2]*, David James Montgomery*[3]*, Summer Selinger*[3]*, Hannah Mahoney*[3]*, Francisco da Silva*[4]*, Justin Miller*[5]*, Eric Stock*[5]*, Alper James Alcaraz*[2]*, Jonathan Karl Challis*[3]*, Neil Mochnacz*[6]*, Andrew Chapelsky*[6]*, Lynn Weber*[3]*, David M. Janz*[7]*, Steve Wiseman*[5] *and Markus Brinkmann*[2]*, (1)Toxicology Centre and School of the Environment and Sustainability, University of Saskatchewan, Canada, (2)Toxicology Centre, University of Saskatchewan, Canada, (3)University of Saskatchewan, Canada, (4)Toxicology, University of Saskatchewan, Canada, (5)University of Lethbridge, Canada, (6)Department of Fisheries and Oceans, Canada, (7)Western College of Veterinary Medicine and Toxicology Centre, University of Saskatchewan, Canada*

Stormwater runoff from urban landscapes has recently been linked to mass mortalities of coho salmon in the U.S., also dubbed urban runoff mortality syndrome (UMRS). The chemical responsible has been identified as N-(1,3-dimethylbutyl)-N′-phenyl-p-phenylenediamine-quinone (6PPD-Q), a transformation product of the rubber tire antioxidant 6PPD. This presentation summarizes a series of studies that assessed the acute toxicity of 6PPD-quinone across eight other fishes of commercial, cultural, and ecological importance in North America, and to characterize the specific mechanisms that drive toxicity using acute and sub-chronic experiments with select fishes. Acute toxicity differed greatly among species: No mortality occurred for Arctic char (AC), brown trout, bull trout, westslope cutthroat trout, and white sturgeon even at the highest measured concentrations (>13 ug/L), while lake (LT), brook, and rainbow (RBT) trout were sensitivity to 6PPD-Q exposure with LC50 values between 0.33 and 0.59 ug/L. Furthermore, sub-chronic exposures of RBT and LT demonstrated teratogenic effects in both larval RBT and LT. Experiments with primary cultures of RBT gill cells suggest that the mechanism of toxicity may be related to uncoupling the mitochondrial electron transport chain. Comparative cardiac ultrasound, electrocardiography and blood gas analysis revealed significant decreases in hemoglobin oxygenation and sympathetic stimulation in sensitive RBT but not insensitive AC, further supporting this hypothesis. Whole transcriptome analysis in RBT identified several molecular toxicity pathways that may explain the apical effects described above. Further research supporting development of a comprehensive toxicity pathway model supporting risk assessment of 6PPD-quinone across fishes is underway.

3.21.P Polymers and Their Chemicals: Environmental Fate, Hazards, and Risk Assessment

3.21.P-We206 Predicting the Environmental Implications of Tire Compounds: Property Estimation and Environmental Modelling

Cassandra Johannessen[1]*, Dave Bowman*[2] *and Xianming Zhang*[1]*, (1)Chemistry and Biochemistry, Concordia University, Canada, (2)Validation, Prototyping and Manufacturing Institute, Brock University, Canada*

Tires, as an integral part of modern transportation, undergo constant wear and tear, releasing a complex mixture of tire-derived chemicals (TDCs) into the environment. This release process contributes to the dispersion of TDCs across various environmental compartments, including soil, water bodies, and air, as recent monitoring work has demonstrated. However, the environmental distribution, transport mechanisms, and transformation processes of these compounds are not well understood. This is partly due to insufficient information on their physico-chemical properties, which are crucial for understanding their environmental behaviour. Furthermore, the full range of chemicals released from tire pollution is still unknown, adding complexity to environmental impact assessments. This project seeks to address these research gaps by first estimating the missing physico-chemical properties of TDCs. To do so, a list of >200 compounds known to be used in synthetic rubber has been extracted from the PubChem database. To enhance the scope of this work, we conducted non-target analysis (NTA) on tire-wear particle (TWP) leachate extracts to identify additional TDCs, thus broadening our dataset for more comprehensive property prediction and fate modelling. NTA was conducted on both non-polar and polar TWP extracts using two-dimensional gas chromatography-mass spectrometry (GCxGC-ToF-MS) as well as liquid chromatography-high resolution mass spectrometry (Orbitrap LC-HRMS). To estimate the physico-chemical properties for each chemical, this project leveraged prediction software tools such as the Estimation Programs Interface (EPI) Suite, OPEn structure–activity/property Relationship App (OPERA), and BIOVA COSMOtherm. The partitioning tendencies of the TDCs were evaluated through interpretive chemical space plots. Environmental effect metrics, such as the fish bioconcentration factor and the acute oral systemic toxicity in rats were also predicted. Subsequently, this work applied level III steady-state fugacity models as environmental fate assessment tools to better understand the distribution, transformation, and persistence of these contaminants in different environmental matrices. This work will allow for the prioritization of these compounds in future environmental monitoring campaigns and empirical toxicity assessments as well as guide the refining of their chemical management strategies.

3.21.P-We207 Plasticizers and flame retardants in rubber recycling and recreational surfaces

Aleix Balasch Garcia*, Teresa Moreno and Ethel Eljarrat, Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain*

Granulated vulcanised elastomeric materials as crumb rubber sourced from used tyres present both a serious environmental challenge and new technological opportunities. These materials are chemically complex and therefore difficult to recycle, and also can contain toxins and are present in huge quantities. This work will focus in used-tyres used as turn infill and as base layer for playgrounds, mainly made of styrene-butadiene rubber (SBR), as well as ethylene propylene diene monomer (EPDM) that is used as wear layer in playgrounds. The aim of the study is to assess the occurrence of organophosphate esters (OPE) and phtalates in these materials, as these compounds are used as plasticizers and flame retardants, and some of them have been demonstrated to present a risk for human health.

In the first part of the study, OPEs were analysed in different EPDM and SBR samples providen by Barcelona City Council, being the same materials used in the playgrounds. Additional experiments are being carried out to look for degradation by the daylight during a 3-month period were carried out, with the analysis of OPEs and also of phtalates and alternative compounds to phtalates.

Fifteen out of the 20 analysed OPEs were detected in EPDM and SBR samples, with concentrations ranging between 71.2 and 2460 ng/g for the EPDM and SBR samples used in playgrounds (red, green, yellow, blue and black), and between 8.89 and 118 µg/g in SBR used in sport, showing a huge difference between both kind of samples.

It was found that for most cases OPE concentration increased after crushing the sample, as extraction efficiency is also increased. That was an exception for SBR samples used in sport fields, as those ones were coated with painting. That resulted into a reduction of concentration after crushing the sample, as the amount of coating was diluted, giving a more realistic result about the bulk concentration.

In samples from playgrounds, there were five dominant OPEs: TEP, TCEP, TPHP, TNBP and TCIPP, while in the case of sport samples the TEHP was the dominant congener. It is crucial to note that TEP, TPHP, and TCIPP present non-carcinogenic risks, while TCEP, TNBP, and TEHP pose both carcinogenic and non-carcinogenic risks. This underscores the need for additional studies to assess whether the use of these materials in recreational surfaces could indeed pose health risks.

3.21.P-We208 Exploring Toxicity of Tire Particles and Tire-Related Chemicals with Bioassays on High-Performance Thin-Layer Chromatography Plates

Alan J Bergmann[1]*, Thibault Masset*[2]*, Florian Breider*[2]*, William Dudefoi, PhD*[3]*, Kristin Schirmer*[3,4,5]*, Benoit J.D. Ferrari*[1] *and Etienne Vermeirssen*[1]*, (1)Swiss Centre for Applied Ecotoxicology, Switzerland, (2)Central Environment Laboratory, Ecole Polytechnique Fédérale de Lausanne – EPFL, Switzerland, (3)Environmental Toxicology, Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (4)Laboratory of Environmental Toxicology, Ecole Polytechnique Fédérale de Lausanne – EPFL, Switzerland, (5)ETHZ, Institute of Biogeochemistry and Pollutant Dynamics, Switzerland*

Tire and road wear particles (TRWP) contain complex mixtures of chemicals and release them to the environment, and potential toxic effects of these chemicals still need to be characterized. We used a currently available surrogate for TRWP, cryogenically milled tire tread (CMTT), to isolate and evaluate effects of tire-associated chemicals. We examined organic chemical mixtures extracted and leached from CMTT for the toxicity endpoints genotoxicity, estrogenicity, and inhibition of bacterial luminescence. The bioassays were performed after chromatographic separation on high-performance thin-layer chromatography (HPTLC) plates. CMTT extracts were active in all three HPTLC-bioassays with two estrogenic zones, four genotoxic zones, and two zones inhibiting bacterial luminescence. Two types of aqueous leachates of CMTT, simulating either digestion by fish or contact with sediment and water, contained estrogenic chemicals and inhibitors of bacterial luminescence with similar profiles to those of CMTT extracts. Of eleven tested tire-associated chemicals, two were estrogenic, three were genotoxic, and several inhibited bacterial luminescence. 1,3-Diphenylguanidine (DPG), transformation products of N-(1,3-dimethylbutyl)-N'-phenyl-p-phenylenediamine (6PPD), and benzothiazoles were especially implicated through comparison to HPTLC retention factors in the CMTT samples. Other bioactive bands in CMTT samples did not correspond to any tested individual chemicals. Tire particles contain and can leach complex mixtures of chemicals to the environment. While some known chemicals contribute to estrogenic, genotoxic, or antibacterial hazards, unidentified toxic chemicals are still present and deserve further investigation. In summary, HPTLC showed that few chemicals were responsible for the detected effects and implicated known chemicals as likely causative toxicants. Our work expands the understanding of potential adverse effects from tire particles and helps improve the link between those effects and the responsible chemicals.

3.21.P-We209 Monitoring and Modelling of Phenylenediamine Antioxidants and Their Transformation Products in Urban Snow – An Important Medium Linking Tire Additive Emissions and Aquatic Loadings

Joshua Onyeka Osagu[1]*, Meng Qin*[1]*,* ***Cassandra Johannessen***[1]*, James Barnwell*[1]*, Dave Bowman*[2] *and Xianming Zhang*[1]*, (1)Chemistry and Biochemistry, Concordia University, Canada, (2)Validation, Prototyping and Manufacturing Institute, Brock University, Canada*

Chemical emissions from tires are an emerging environmental concern. They can have toxic or harmful effects on organisms in aquatic ecosystems. Snow acts as a natural filter, trapping and removing various pollutants from the atmosphere, including chemicals from traffic emissions. However, as snow melts and runoff occurs, these chemicals can be released back into the environment, potentially contaminating aquatic environment. To understand the role of snow in trapping chemicals additives in tires, a monitoring study was conducted to characterize concentrations of chemical trapped in road site snow and developed model simulations to characterize chemicals processes in snow. The snow model was incorporated into the Multimedia Urban Model to study the implication of snow melt on the chemicals' mass flow within urban environment. The study found that the concentrations of tire additives in snow were significantly influenced by traffic levels. The highest concentrations were found in snow from high traffic roads. The study also identified a number of transformation products of tire additives in snow, which suggests that these chemicals can undergo chemical changes in the environment. The study's findings highlight the importance of understanding the fate and transport of tire additives in snow, particularly in northern cities where snow plays a major role in the urban water cycle.

3.21.P-We210 Green Analysis of Additives from Plastic Samples by In-Tube Extraction Dynamic Headspace Coupled to GC-MS/MS

E Concha-Graña, V Fernández-González, C Moscoso-Pérez, P López-Mahía and ***S Muniategui-Lorenzo****, Universidade da Coruna, Spain*

The analysis of plastic additives is necessary to evaluate the real risk (for the environment and the human health) posed by the presence of plastics in the environment. The European Chemical Association (ECHA) characterized over 400 substances used as plastic additives. Some additives like bisphenol A (BPA), Tinuvin328, Tinuvin 327, and many phthalates have been identified by ECHA as substances of very high concern (SVHC).

In this work, In-tube extraction dynamic headspace sampling (ITEX-DHS) combined with gas chromatography (GC) and mass spectrometry (MS/MS) method was optimized for the analysis of about 50 plastic additives from plastic samples. Multivariate and univariate approaches were used to optimize the many parameters affecting the extraction and desorption efficiency. Quantitation of target analytes was performed by matrix matched calibration, using isotopically labelled standards as internal standards.

Good analytical performance characteristics were obtained: trueness was between 70-128%, the intermediate precision between 3-24%, with good sensitivity (quantitation limits of the method ranging from 0.2 ng g^{-1} (DnOP) to 0.37 µg g^{-1} (Ionox

100)). The greenness of the optimized method was calculated using AGREE software, obtaining an overall score of 0.82 (in a range from 0 for the less green, and 1 for the greenness) due mainly to be a solvent-less and fully automatic method.

This is the first approach using ITEX-DHS for the quantitative analysis of about additives from plastics, and supposes a good alternative for the reliable quantitative analysis and monitoring of additives from plastics and microplastics.

3.21.P-We211 Human and Environmental Exposure by Synthetic Antioxidants: Insights from Wastewater

*Corina Meyer[1], Mara Lisa Baer[2] and **Juliane Hollender**[3], (1)Swiss Federal Institute of Aquatic Science and Technology (Eawag), Switzerland, (2)Institute of Biogeochemistry and Pollutant Dynamics, ETH Zurich, Switzerland, (3)Environmental Chemistry, Environmental Chemistry, Eawag, Swiss Federal Institute of Aquatic Science and Technology, Switzerland*

Synthetic antioxidants (SAOs) are of widespread use in everyday life products, including polymeric materials, medicinal face masks, personal care products and food. They act by preventing oxidative reactions and extending product shelf life. As antioxidants are additives and not chemically bound to their substrates, leaching from materials and detection in wastewater treatment plants (WWTPs) has been reported. Correspondingly, uptake by humans is expected through contact to materials. However, little is known about the human and environmental exposure of antioxidants. Therefore, this study aims (i) to identify SAO metabolites in untreated wastewater to get some insight into human exposure and (ii) to analyze the abatement behavior of the parent compounds and their metabolites through the different treatment steps in WWTPs to understand the environmental exposure. A MS/MS library of SAO metabolites was generated by human liver S9 incubation experiments, combined with online-SPE-LC-HRMS/MS analysis. This library, containing about 1000 potential metabolites, was compared to influent samples of three Swiss WWTPs, leading to approximately 50 matches. Using machine learning and *in silico* fragmentation tools, structure elucidation was so far possible for one compound (fenozan), which was confirmed by a reference standard. This result gives first hints with regard to human exposure towards SAOs. To further elucidate exposure pathways, medicinal face masks were analyzed by the same analytical method. Their extracts contained over 30 different antioxidants. Total SAO concentrations of around 100 μg per mask were found. Current analyses examine the wearing of face masks as uptake pathway. Besides the detection of metabolites in untreated wastewater, knowledge about the abatement of parent SAOs through the different treatment steps in WWTPs is missing. Thus, the same three WWTPs, equipped with an advanced treatment step (ozonation or granular activated carbon filtration), were sampled and analyzed by online-SPE-LC-HRMS/MS after every treatment step to assess environmental exposure by WWTPs. Results indicate incomplete abatement of some SAOs. Overall, humans and the environment seem to be exposed to synthetic antioxidants and further research is required to understand the uptake of SAOs into the human body, their metabolism and their behavior in wastewater treatment.

3.21.P-We212 Halogenated Flame Retardants in Dust collected from Indoor Environments: Homes, Offices, Kindergartens and High Schools

***Adrián de la Torre**[1], Irene Navarro[2] and María Ángeles Martínez[2], (1)Center for Energy, Environmental and Technological Research (CIEMAT), Madrid, Spain, (2)Center for Energy, Environmental and Technological Research (CIEMAT), Spain*

In March 2023, the European Chemicals Agency (ECHA), released its Regulatory Strategy for Flame Retardants and identified aromatic brominated flame retardants as candidates for an EU-wide restriction. In this report, a high exposure potential to consumers during article service life was associated with the use of items such as textiles, household furniture, electronic equipment or even toys through skin contact or indoor dust ingestion. To address this issue the present study investigates the occurrence of 51 flame retardants (FR) including polybrominated diphenyl ethers (PBDEs), novel brominated flame retardants (DBDPE, BTBPE, HBBz, PBEB) and dechloranes (Clordane Plus, Dec 602, 603, 604 and Declorane Plus (DP)) in indoor dust samples collected from homes, offices, kindergarten and high schools from Spain. The validated analytical method (SRM2585) including extraction (hexane:acetone; 3:1 v/v), fractionation (florisil column), purification (acid silica column), HRGC-MS/MS (Agilent 8890-7010c) analysis and isotope dilution for quantification, was applied to 85 settled (<0.5 m) and suspended (>0.5 m) dust samples.

Brominated targeted analytes presented high quantification frequencies (Qf) in all indoor environments, with a pollutant pattern dominated by $\sum_{42}$PBDEs (445 ng/g, 100%; median, Qf) followed by DBDPE (244 ng/g, 100%), BTBPE (6.77 ng/g, 40%) and HBBZ (2.47 ng/g, 51%). However, for dechloranes, only DP was quantified in 81% of the samples (10.2 ng/g). Interestingly, no differences ($p>0.05$ Mann-Whitney test) were obtained between suspended and settled dust in terms of FR content. Positive correlations ($r_s>0.4$, $p<0.01$; Spearman test) were found between BDE-209, DBDPE and DP suggesting that BDE-209 substitution is taking place, but also reflecting similar application areas, and/or behavior once sloughed off from consumer products. Important differences were found between indoor environments. Dust obtained from homes and offices presented higher PBDEs and DBDPE ($p<0.05$; Kruskal-Wallis test) concentrations compared to samples collected from kindergartens and high schools. Finally, data obtained were used to determine estimated daily intakes (EDI) via dust ingestion and dermal absorption for toddlers and adults at central and upper percentiles. Calculated EDI levels even at worst case scenario were below available reference dose (RfD) values in all cases.

The present study is part of the project PID2019-105990RB-I00 funded by MCIN/AEI/10.13039/501100011033.

3.21.P-We213 In-Vehicle Exposure of Southern California Commuters to Tris(1,3-dichloro-2-propyl) phosphate
David C. Volz[1]*, Aalekhya Reddam*[1]*, Nicholas Herkert*[2] *and Heather M. Stapleton*[2]*, (1)Department of Environmental Sciences, University of California Riverside (UC Riverside), (2)Nicholas School of the Environment, Duke University*
Tris(1,3-dichloro-2-propyl) phosphate (TDCIPP) is an additive, organophosphate-based flame retardant (OPFR) introduced within vehicle parts to meet a stringent, federal-level flammability standard within the United States. As TDCIPP is a semi-volatile organic compound, TDCIPP migrates from end-use products, resulting in human exposure to TDCIPP-contaminated air and/or dust within the interior of vehicles. To our knowledge, human OPFR exposure as a function of total commute time had not been evaluated prior to 2019. Therefore, the overall objective of our first, one-week study in 2019 was to leverage silicone wristbands to monitor personal OPFR exposure within a subset of commuter vs. non-commuter undergraduate students (N=88) at the University of California, Riverside. Out of 22 OPFRs analyzed, 13 OPFRs were detected on at least 62 wristbands (70% detection rate). Among these 13 OPFRs, TDCIPP was the only OPFR that was significantly predicted by total commute score, suggesting that longer commutes were associated with increased human exposure to TDCIPP. Therefore, the overall objective of our second, two-week study in 2020 was to determine if a decrease in interior car dust resulted in mitigation of personal TDCIPP exposure for participants (N=49) who spend a significant amount of time in their personal vehicles. Once participants enrolled in the study, participants were distributed across four groups that determined when the participants wiped their car interiors during the two-week study. Interestingly, there was no significant difference in wristband TDCIPP concentrations among the different wiping groups despite concentrations being higher than those of non-commuters. Moreover, when all of the no-wipe and wipe data were pooled to enhance statistical power, we detected no significance difference in TDCIPP concentrations between these two groups. Therefore, findings from our 2020 study suggest that the correlation between TDCIPP exposure and longer commutes within our 2019 study may have been attributed to direct partitioning from vehicle parts into wristbands via car interior air. Given that Americans within densely populated regions across the United States spend one or more hours commuting on a near-daily basis, there is a critical need to understand the potential human health implications of chronic TDCIPP exposure within vehicles, particularly within traffic-congested areas such as Southern California.

3.21.P-We214 Time Trends of Flame Retardant Additives in Cars
Petra Svobodová[1]*, Lisa Melymuk*[2] *and Rozarka Jilkova*[1]*, (1)Faculty of Science, Masaryk University, RECETOX, Czech Republic, (2)RECETOX, Masaryk University, Czech Republic*
Vehicles are a unique indoor environment as they are full of synthetic materials, textiles and electronics, many of which contain a complex mixture of additive chemicals to impart safety and appearance properties. In addition, vehicles are subject to significant external impacts through variations in temperature and radiation that can influence the emission, degradation and fate of plastic additives.

We investigate the presence of brominated and organophosphate flame retardant (FR) additives in vehicles and evaluate the influence of vehicle age on the profile and levels of FRs detected. Vehicle dust was used as a surrogate matrix to indicate FR use in vehicle parts. Ten individual vehicles of two models of a Czech brand were tested. The two models were selected because vehicle assembly occurs at European sites, suggesting compliance with EU chemical regulations. The model years spanned 1996 to 2021.

We expected a shift in the composition of FRs over the 25 year span of vehicles, yet this was not broadly supported by the dust concentrations. Distinct differences were only seen in the levels of polybrominated diphenyl ether (PBDE) congeners associated with the penta-BDE commercial mixture. In the oldest car from 1996, the concentration of BDE 47 was ~1000x higher than in all subsequent vehicles, attributed to past use of penta-BDE in vehicle foams. However, no time trends were observed for other FRs. BDE 209 was measured at levels of 97.2-39201 ng/g in car dust (median 3260 ng/g), with the highest value found in a car from 2009, and no significant differences according to car age, nor any evidence of a transition to alternative FRs. The elevated levels of FRs in vehicles emphasize their substantial use in vehicle components, and the lack of a transition away from deca-BDE indicates a lag time between regulation and implementation. Further, the ongoing presence of lower levels of lower brominated PBDEs (10-100 ng/g range) may indicate contributions from recycled car parts or substantial debromination of BDE-209.

3.21.P-We215 Effect-based strategy for identification and assessment of potential health effects of hazardous organic chemicals in indoor environments
Nathalie Struwe[1]*, Maria Bernander*[2]*, Ulrika Eriksson*[3] *and Maria Larsson*[4]*, (1)Orebro University, Sweden, (2)Volvo Car Corporation, Sweden, (3)Örebro UniversitySchool of Science and Technology, Oerebro University, Sweden, (4)MTM Research Centre, Orebro University, Sweden*
People spend most of their time in different indoor environments, such as their homes or transportation vehicles. There is a

concerning lack of information about what hazardous chemicals that could be found in these environments, as well as the effects that they have on the human health. Since additives in plastic can migrate from the material, it is likely that plastic could be an important source of several airborne chemicals found in indoor environments. Polycyclic aromatic compounds (PACs) is a group of chemicals associated with traffic emissions, plastic additives and being formed during manufacturing or recycling of plastics. In this project, chemical characterisation of synthetic materials and indoor air in car cabins will be performed. The aim is to develop methods for screening and identification of hazardous chemicals and their sources. Different groups of PACs, e.g., polycyclic aromatic hydrocarbons (PAHs), alkyl-PAHs and oxy-PAHs will be targeted, as well as other groups such as pesticides and plasticisers. This will be complemented with bioanalytical *in vitro* tests for measurement of different effects, like hormone like effects and genotoxicity. Samples will be collected inside and outside the car whilst driving on the countryside vs in the city, and whilst heating up the car to 70 degrees Celsius in a climate chamber. In addition, materials from the inside of the cars will be extracted, and emission tests of individual materials will also be done to identify sources of chemicals. These samples will be analysed using 1) targeted- and non-targeted chemical analysis, 2) a battery of *in vitro* reporter gene assays covering important mechanisms of toxicity and, 3) effect-directed analysis (EDA) to identify potential toxic airborne chemicals. The results from this study will increase the knowledge about the identity, sources and the combination effects of chemicals present in the car cabin environment as well as appropriate methods to screen for the chemicals.

3.21.P-We216 A novel biomonitoring platform with caged lumpfish (Cyclopterus lumpus) eggs for spreading of rubber- and plastic-associated chemicals from urban run-off into a harbour area in Central Norway
***Bjørn Henrik Hansen*[1]*, Julia Farkas[2], Andy Booth, PhD[2], Ida Beathe Overjordet[1] and Lisbet Sorensen[2], (1)SINTEF, Norway, (2)SINTEF Ocean, Norway*
Some rubber and plastic materials are known to contain a high proportion and diverse range of potentially hazardous chemicals, many of which have been shown to leach out and partition to environmental matrices (water, sediments, soils) in laboratory studies. However, knowledge on the fate and bioavailability of these chemicals in the marine environment remains scarce, limiting the potential for conducting accurate and robust risk assessment and effective policy development and implementation. In the present study, we deployed fertilized lumpfish (*Cyclopterus lumpus*) eggs (1 dpf) at two urban harbour areas and a reference site close to the city of Trondheim for 17 days to study uptake of rubber- and plastic-associated chemicals, as well as a wide range of legacy pollutants, using gas chromatography tandem mass spectrometry analysis. We found accumulation of UV stabilizers (benzophenone and benzothiazoles), plasticizers (n-butylbenzenesulfonamide), reagents, and polymer synthesis precursors (bisphenol A, acetophenone, phthalide, and phthalimide) in eggs deployed in the harbour areas. Several of these compounds were detected in concentrations above quantified legacy contaminants in the same study areas. Although high survival was observed in eggs exposed at all sites, a significantly higher presence of embryotoxicity was observed in the harbour-exposed eggs than in the reference site. Further studies are needed to investigate which pollutant(s) are driving the observed embryotoxicity. The current study demonstrates the use of a novel biomonitoring platform using caged fertilized lumpfish eggs to assess the uptake and toxicity of rubber- and plastic-associated chemical pollutants directly in the marine environment.

3.21.P-We217 Identifying and Mitigating Hot Spots of Salmon Exposure to Toxic Road Runoff in Metro Vancouver
***Simon Drew*[1]*, Mason D. King[2], Katie Moloney[3], Sonya Reger[4], Tim Frederick Mainguy Rodgers, PhD[5], Ritu Saha[3], Gopal Sharma[3], Yanru Wang[6], Tanya Brown[7] and Rachel C Scholes[6], (1)University of British Columbia, Canada, (2)Department of Biological Sciences, Simon Fraser University, Canada, (3)Civil Engineering, University of British Columbia, Canada, (4)Department of Fisheries and Oceans, Canada, (5)Civil Engineering, University British Columbia, Canada, (6)Department of Civil Engineering, University of British Columbia, Canada, (7)Fisheries and Oceans Canada, Canada*
Recent research has revealed that *N*-(1,3-dimethylbutyl)-*N′*-phenyl-*p*-phenylenediamine-quinone (6PPD-quinone), a transformation product of the rubber antiozonant 6PPD, which is present at high concentrations in car tires, is acutely toxic to some salmonids. In particular, 6PPD-quinone has been linked to coho salmon mortality in streams heavily affected by road runoff.

Our project, Salmonid Toxic Runoff Exposure and Mitigation (STREAM), is investigating the transport and fate of 6PPD-quinone and other toxic road runoff compounds (TRRCs) to water courses used by salmonids, their impacts, and potential mitigation measures to reduce levels in streams. Our objectives are to: 1) identify hot spots of increased salmon exposure to TRRCs, 2) assess the removal of TRRCs from stormwater by green infrastructure and 3) Improve the design of green infrastructure for TRRC removal.

This poster presents preliminary data from the first year of our project for each of these objectives. We will present data from a field survey of salmonid-bearing streams across the Metropolitan Vancouver, a large urban area with populations of sensitive species that our data indicate may be exposed to road runoff. We will also show results assessing the efficacy of stormwater retention ponds in reducing loadings of TRRCs to receiving water bodies, revealing preliminary information on whether they act as secondary sources of 6PPD-quinone to streams. Finally, we will suggest design, operation, and management interventions to improve the ability of green infrastructure systems to reduce loadings of TRRCs to salmon-bearing streams while maintaining their ability to meet water-quantity objectives. Together, the results of our project will help storm water managers, urban planners, and engaged community members protect salmonids across the Metro Vancouver area and beyond.

3.21.P-We218 Investigating Alternative Environmental Sources of Toxic Tire Additives

***Leland Bryshun**[1], Markus Brinkmann[2] and Kerry McPhedran[1], (1)University of Saskatchewan, Canada, (2)Toxicology Centre, University of Saskatchewan, Canada*

2-((4-Methylpentan-2-yl) amino)-5-(phenylamino) cyclohexa-2,5-diene-1,4-dione (6PPD-Q) has been shown in recent years to cause mortality in North American freshwater fish species. 6PPD-Q is a transformation product formed from an additive found in rubber tires. The major focus of scientific efforts concerning 6PPD-Q contamination pathways has since been on paved roads. However, over half the road network in Canada consists of unpaved roads. Additionally, employment of recycled tire material is increasing as recycling initiatives mature and expand in scope. The use of recycled material could potentially increase the inputs of 6PPD-Q into the environment beyond paved roads. We hypothesize that (1) unpaved road networks can act as a source for 6PPD-Q in the environment and that (2) recycled tire products have the potential to leach 6PPD-Q under environmental conditions. To investigate this, we collected gravel from the surface of unpaved roads in and around Saskatoon, Saskatchewan, Canada. Chemical extractions and 72-hour leachate studies will be performed on the collected road surface to detect and quantify tire additive concentrations in the leachate. We also performed a long-term leaching study to detect 6PPD-Q that has leached out of the recycled materials under environmental conditions. To accomplish this, we are collecting rainwater and meltwater that has infiltrated through layers of recycled rubber material, then quantifying the 6PPD-Q concentrations found in the leachate. During these studies, we expect to quantify environmentally relevant concentrations of 6PPD-Q in the collected leachate and gravel road dust. Preliminary results suggest that leachate from recycled material contains concentrations of 6PPD-Q lethal to certain fish species. Identifying 6PPD-Q in unpaved roads could lead to unpaved roads being considered as reservoirs for tire particles and related toxic leachates. Furthermore, detecting 6PPD-Q in recycled material leachate could change how recycled materials are utilized in the environment. The results of these novel studies will fill a critical knowledge gap concerning the potential environmental sources of 6PPD-Q and other tire additives.

3.21.P-We219 The Fate of 6PPD-quinone in Soil and Water-Sediment Systems using a 14C Radiotracer

***Rory Mumford**[1], Daniel T Evans[2] and Pete Yeomans[2], (1)Environmental Fate and Metabolism, Smithers, Shawbury, Shrewsbury, United Kingdom, (2)Environmental Fate and Metabolism, Smithers, United Kingdom*

6PPD-quinone (6PPD-Q), a transformation product of the antiozonant and antioxidant 6PPD (N-(1,3-Dimethylbutyl)-N′-phenyl-phenylenediamine), is believed to be carried from tire and road wear particles (TRWP) into watercourses. Some publications have identified 6PPD-Q as a contributor to Urban Runoff Mortality Syndrome (URMS) of a single specific fish species, Coho salmon.

The potential mobility of 6PPD-Q in soils and sediments has been investigated using the OECD 106 test guideline (Adsorption - Desorption Using a Batch Equilibrium Method) and ^{14}C-radiolabelled 6PPD-Q. This study is used to indicate how likely a compound is to move through soils.

Additionally, the transformation of 6PPD-Q has been investigated according to OECD test guidelines 307 (Aerobic and Anaerobic Transformation in Soil), OECD 308 (Aerobic and Anaerobic Transformation in Aquatic Sediment Systems) and OECD 309 (Aerobic Mineralisation in Surface Water – Simulation Biodegradation Test). These studies were selected to allow us to gain an understanding of the transformation and partitioning of 6PPD-Q in the key environmental compartments.

Initial results were presented at SETAC North America (Louisville, November 2023). This presentation summarises the findings, including identification and quantification of transformation products generated during these aforementioned studies.

3.21.P-We221 Chronic effects of three tire rubber-derived contaminants on zebrafish embryos

***Stefano Magni**[1], François Gagné[2], Riccardo Sbarberi[3], Camilla Della Torre[1], Christian Gagnon[2] and Andrea Binelli[3], (1)Biosciences, University of Milan, Italy, (2)Environment and Climate Change Canada, Canada, (3)Biosciences, Università degli Studi di Milano, Italy*

Tires are considered an important source of *non*-conventional plastic particles originated at the tread/asphalt interface. Consequently, about one billion of abraded tires (17 million tonnes) reach the end-of-life every year worldwide. This type of environmental pollution is amplified by the wide plethora of chemicals, adsorbed during the activities of transport means or used as additives in the rubber mixture, which, in turn, could have negative implications on biota. Therefore, the aim of this study was the evaluation of the chronic toxicity (sub-lethal effects) by three tire rubber-derived contaminants in the embryos of the freshwater model *Danio rerio* (zebrafish). In detail, we exposed the selected specimens from 0 to 120 hours post fertilization (hpf) at 1,3-dimethylbutyl-N′-phenyl-1,4-benzenediamine (6PPD), an additive used as antioxidant in tires, 6PPD-quinone (6PPDq), the main 6PPD metabolite, and 1,3-diphenylguanidine (DPG), an accelerator of rubber vulcanization. These three chemicals were tested at the environmentally relevant concentration of 500 ng/L. We certified both the exposure concentrations, as well as the stock solutions (1 mg/L), of selected substances through Liquid Chromatography-High Resolution Mass Spectrometry. During the exposure the eventual acute effects (coagulation of eggs, lack of somite formation and heart breath), as well as sub-lethal abnormalities (scoliosis, development delay, edemas and malformations), were daily registered. Since in all experimental groups no acute toxicity was observed, with an average value of embryos viability of 94.2 ± 1.4 %, we processed the samples for the chronic effect evaluation. We used an integrated ecotoxicological approach of a biomarker suite coupled with gel free proteomics to identify the possible mechanism of action (MoA) of selected chemicals.

3.21.P-We222 Tire Related Additive Chemicals in Road Run-Off & Recipient Waters, Snow and Sediment Samples from Six Nordic Countries

***Natascha Schmidt**, Linda Hanssen and Vladimir Nikiforov, Climate and Environmental Research Institute NILU, Norway*

Tire related additive chemicals, such as the antioxidant 6PPD (N-(1,3-dimethylbutyl)-N'-phenyl-p-phenylenediamine), one of its transformation products 6PPD-Q (6PPD-Quinone), and the crosslinking agent HMMM (Hexa(methoxymethyl)melamin) can leach out of tires and enter the environment. While there is a growing amount of literature available concerning the occurrence of these chemicals in specific geographic areas and/or specific time intervals (e.g., during rain events), data from large screening studies is currently missing. Here, we present data on the occurrence of tire related additive chemicals in road run-off and recipient waters, snow and sediment samples from Norway, Sweden, Iceland, Faroe Islands, Finland and Denmark. Samples were collected during spring 2023 and were analyzed using liquid chromatography–mass spectrometry (LC/MS).

HMMM was the predominant compound in water samples, including snow samples, due to its relatively high water solubility. On the other hand, 6PPD, which tends to adsorb to particulate matter, was predominant in sediment samples. Tire related additive chemicals were present in all samples, but strong differences in concentrations were observed according to sample types and sampling location. The highest concentration observed for a single compound was 11.5 µg/L HMMM in a road run-off sample. Nordic countries are potentially particularly prone to contamination from tire related chemicals, due to the frequent use of studded tires, which can enhance the production of tire and road wear particles (TRWP). Poor road conditions and the application of road salts in cold climate regions can further increase the emissions of TRWP into the environment and thereby also the emissions of tire related additive chemicals.

3.21.P-We223 Application of a Multispecies Approach to Assess the Effects of Car Tires Leachate Toxicity on Freshwater and Terrestrial Environments

*Alessio Gomiero[1], Veslemøy Navrestad[1], Adrián Jaén-Gil[2], Farhan R. Khan, PhD[3], Matthew Cole[4], Mark Hahn[5], Bryan D. James[6], Lisbet Sorensen[7] and **Stefania Piarulli**[7], (1)Norwegian Research Centre (NORCE), Norway, (2)NORCE Norwegian Research Centre, Norway, (3)Climate, Norwegian Research Centre (NORCE), Norway, (4)Plymouth Marine Laboratory, United Kingdom, (5)Biology, Woods Hole Oceanographic Institution, (6)Woods Hole Oceanographic Institution, (7)SINTEF Ocean, Norway*

The contact between tyre and road surface causes shear and heat in the tyre. Both processes result in the generation of wear particles. Several studies have suggested that wear and tear from car tyres is an important source of microplastics in the environment. On the other hand, tire materials are complex mixtures, as various chemicals are used during the production of tires. Besides the rubber itself, fillers, reinforcement agents, processing aids, accelerators and retarders, adhesives, and activators may be added. Once released in the environment these particles may undergo leaching processes releasing a cocktail of different chemicals which may cause deleterious effects to the aquatic life. Even if such type of pollution has been widely investigated for marine environments, limited is the knowledge on freshwaters and terrestrial organisms. In this study, tyre material has been ground, size fractionated and leached (1 g/l) under natural like conditions using freshwater and terrestrial compatible leaching medium. A dilution series (0.1 to 100%) was performed, and leachates exposed to the green microalgae R. subcapitata, the rotifer B. plicatilis, the freshwater protozoan Euplotes spp, the zebrafish D. rerio, the crustacean D. magna and three terrestrial plants (S. saccharatum, L. sathivum and S. alba). A battery of different endpoints across the different species including survival and hatching success are assessed, as well as other relevant biomarkers such as oxidative stress, DNA damages and general cell functioning. The LC50, EC10, EC20 and EC50 is calculated for all investigated biological models. Distinctive species-specific pattern of responses is observed at sub-lethal level. This work is expected to help establishing baseline knowledge for supporting the environmental risk assessment of tyre wear particles leachates in the freshwater and terrestrial ecosystems.

3.21.P-We224 Echoes of Ecosystems: Comparing Phthalate Exposure in Sentinel Bottlenose Dolphins (Tursiops truncatus) Residing in Sarasota Bay, Florida and Barataria Bay, Louisiana

***Miranda Dziobak**[1], Randall S Wells[2], Amanda Moors[3], Emily C Pisarski[4], Ed Wirth[4], Christina N Toms[5], Leslie B Hart[1], Ryan Takeshita[6] and Cynthia Smith[6], (1)Department of Health and Human Performance, College of Charleston, (2)Mote Marine Laboratory, Chicago Zoological Society's Sarasota Dolphin Research Program, (3)National Institute of Standards and Technology (NIST), (4)National Oceanic and Atmospheric Administration (NOAA), (5)Chicago Zoological Society's Sarasota Dolphin Research Program, (6)National Marine Mammal Foundation*

Phthalates are a class of endocrine disrupting chemical additives commonly used to increase desirable properties of consumer goods (e.g., plastics, personal care products, cleaning products, pesticides). Phthalates are not chemically bound to the products they modify, so they easily contaminate the environment, and have been documented in air, soil, water, and biota. Environmental phthalate contamination has been linked with urbanization and land use. The objective of this study was to compare phthalate exposure between geographically distinct populations of bottlenose dolphins (*Tursiops truncatus*) inhabiting estuaries where phthalate contamination likely differs (potentially related to bay features, such as land use, hydrology, proximity to urban centers, wastewater treatment practices). Dolphin urine collected during catch-and-release health assessments conducted in Sarasota Bay, Florida, USA (2010-2019; n= 51) and Barataria Bay, Louisiana, USA (2011-2023; n= 47) was screened for seven phthalate metabolites: monoethyl phthalate (MEP), mono(2-ethylhexyl) phthalate (MEHP), mono-2-ethyl-5-hydroxyhexyl phthalate (MEHHP), mono-(2-ethyl-5-oxohexyl) phthalate (MEOHP), monobenzyl phthalate (MBzP), monoisobutyl phthalate (MiBP), and monobutyl phthalate (MBP). All metabolites were detected in at least one dolphin from both locations except MiBP, which was not detected in Sarasota Bay dolphins. Overall, the percentage of individuals with detectable urinary phthalate metabolite concentrations was higher in Sarasota Bay than Barataria Bay (~75% vs ~47%, respectively). The most commonly detected metabolites in Sarasota Bay dolphins were MEHP and MEP, while MEHP and MBzP were most common among Barataria Bay dolphins. Among dolphins sampled at both locations, differences in metabolite detection were not observed relative to sex or age class, suggesting widespread phthalate exposure vulnerability. Differences in exposure prevalence and detected metabolite profiles (i.e., MEP vs MBzP) may suggest geographic differences in environmental contamination, potentially attributed to human influence. MEP detection in humans, for example, is often associated with dermal exposure from personal care product use, so environmental exposure may be linked to anthropogenic activity. Additional studies are warranted to investigate potential relationships between exposure variation and habitat utilization to better understand the influence of urbanization on environmental contamination.

3.21.P-We225 Phthalates Contamination of Wild Pollinators in an Urban and Peri-urban Context

Virginie Cuvillier[1]*, Nina Hautekèete*[1]*, Yves Piquot*[1]*, Justine Dewaele*[1] *and Nicolas Visez*[2]*, (1)Univ. Lille, CNRS, UMR 8198 - Evo-Eco-Paleo, France, (2)Lasire, University of Lille, LASIRE, France*

The rising science of urban ecology showed that cities could be wild bee-friendly, pointing out that urban areas can show higher abundance and diversity compared to adjacent rural areas. However, growing urbanization comes with harsher constraints (habitat fragmentation, heat island effect, pollutants…). In the actual context of general pollinator decline, it seems useful to better understand the relative contribution of the different urban parameters to the sustainability of wild bee populations, in order to support this welcome urban biodiversity. Among urban parameters, exposure to urban atmospheric pollutants and their effects on insect health have been poorly investigated. Moreover, recent regulations on transport emissions have changed the toxic profile of the atmosphere of Western cities towards a now majority release of volatile chemicals, among which phthalates are well represented. Proven endocrine disruptors for many vertebrate models, very little is known about terrestrial insects exposed to phthalates except that their cuticle is an efficient trap for these lipophilic contaminants, suggesting that they could accumulate these contaminants when evolving in a contaminated environment. In the present work, we addressed this hypothesis by measuring the cuticular contamination of bumblebees caught in different urban and peri-urban sites. Due to their foraging activity, bumblebee workers make numerous trips back and forth from their nest, within a radius of a few hundred meters, and are therefore considered sentinels of their immediate environment. We measured the magnitude of contamination of bumblebee workers and compared the phthalates mixture they bear on their cuticle with that absorbed by passive sensors installed nearby. Three collection sessions were carried out over the pollination period to study the effect of average temperature. Results confirm the massive contamination of bumblebee populations with ~80% of the total number contaminated with at least one phthalate and ~30% contaminated with more than 5 phthalates, DEHP and DBP being the dominant contaminants. They also highlight the great variability of this type of contamination, not easy to relate to local conditions.

3.21.P-We226 Spatial Distributions and Ecological Risk Assessment of Phthalate Esters in the Surface Water of the St. Lawrence River and Estuary in Canada

Amina Ben Chaaben[1]*, Mathieu Babin*[1]*, Haritha Yespal Subha*[1]*, Frank Wania*[2]*, Hayley Hung*[3]*, Magali Houde*[4]*, Liisa Jantunen*[5]*, Huixiang Xie*[1] *and Zhe Lu*[1]*, (1)Institut des Sciences de la Mer de Rimouski (ISMER), University of Quebec at Rimouski (UQAR), Canada, (2)Department of Physical and Environmental Sciences, University of Toronto, Canada, (3)Air Quality Processes Research Section, Environment and Climate Change Canada, Canada, (4)Aquatic Contaminants Research Division, Environment and Climate Change Canada, Canada, (5)Atmospheric Science and Technology, Environment and Climate Change Canada, Canada*

Phthalate esters (PAEs) are a group of chemicals widely utilized as plasticizers in plastic production to enhance flexibility and durability. Additionally, they are used in a broad range of consumer products, including cosmetics, medical devices, and toys. However, as they are not chemically bound to plastics, they can easily escape into the environment and pose risks to ecosystems. Due to the vast global production of plastics, numerous studies have found PAEs to be ubiquitous in various environmental matrices. PAEs are also considered endocrine disruptors and can interfere with the normal functioning of hormones, leading to adverse health effects in organisms. As a result, the United States Environmental Protection Agency (EPA) has designated six PAEs as priority pollutants due to their harmful impacts on human health and the environment. To this date, there is no data on PAEs reported in the St. Lawrence Estuary, the main habitat for the endangered St. Lawrence beluga whale. We also do not know if these chemicals could drain into this system via rivers like the St. Lawrence River. To this end, this study aims to investigate the spatial distributions of nine PAEs in the surface waters of the St. Lawrence River and Estuary and assess their ecological risks in water. Sampling was conducted in summer 2022. Surface water samples were collected from 30 coastal sites and 15 offshore sites in the St. Lawrence River and Estuary. Air and water field blanks were also collected. Samples were analyzed as soon as possible after collection. The aqueous dissolved phase was extracted via solid-phase extraction while the particles were ultrasonically extracted. Analysis was done with GC-MS/MS. Results from the aqueous dissolved phase showed the detection of the nine PAEs and the total PAEs ranged from 6 to 565 ng/L. The concentrations of the coastal sites were higher than those of the offshore sites. Di-n-octyl phthalate, one of the six priority PAEs identified by EPA, was detected in 87% of the sampling sites. An ecological risk study was conducted in water and the results showed that some PAEs (eg., Diisobutyl phthalate (DiBP)), could have a high risk for species like crustaceans and fish. This study establishes a baseline for monitoring PAEs in the St. Lawrence River and Estuary.

3.21.P-We227 Associations Between Building Characteristics and Plasticizers in Indoor Settled Dusts

Sabina Vancova[1]*,* ***Paula Marcinekova***[1]*, Rozarka Jilkova*[2] *and Lisa Melymuk*[3]*, (1)Recetox, Masaryk University, Czech*

Republic, (2)Masaryk University, RECETOX, Czech Republic, (3)RECETOX, Masaryk University, Czech Republic
Phthalates are plastic additives typically detected among the highest levels in indoor settled dusts. These dusts represent an important potential exposure route to people, especially young children, but can also offer insight into the properties of the indoor environment associated with elevated levels of indoor plasticizers. In this study we profiled house dust in 120 Czech homes for a broad set of plastic additives, including 17 phthalate esters. Eight phthalates were broadly detected, with bis(2-ethylhexyl) phthalate (DEHP) and dibutyl phthalate notably detected in all dust samples. Phthalates in dust were strongly dominated by diethyl phthalate, with a median of 1800 ng/g in dusts, and individual concentrations up to 41 µg/g. DEHP was detected in all dusts with a median of 98 ng/g.

To assess the drivers of indoor plasticizers levels, we investigated the association between individual and total phthalates in indoor dusts, and indoor and outdoor home characteristics, including degree of urbanization and population density, type of home or apartment, primary building and flooring materials, and composition of the household. While phthalate levels indoors have been associated, in particular, with the use of PVC flooring, we found that building age and ventilation were most relevant to phthalate levels indoors. In addition, we explored seasonal variations in dust within the homes, in a subset of homes using monthly dust samples, which identified the combined effects of temperature, heating use and seasonal changes in ventilation on indoor plasticizer levels.

3.21.P-We228 Dietary exposure of Japanese people to phthalates and their substitutes
***Naohide Shinohara**[1], Tomoko Oguri[2], Mai Takagi[3], Jun Ueyama[4] and Tomohiko Isobe[3], (1)National Institute of Advanced Industrial Science and Technology (AIST), Japan, (2)The National Institute of Advanced Industrial Science and Technology, Japan, (3)National Institute for Environmental Studies (NIES), Japan, (4)Graduate School of Medicine, Nagoya University, Japan*
Introduction
Phthalates have been widely used as plasticizers for plastic products. In recent years, many countries have imposed restrictions on the use of some kinds of phthalates, especially in the food industry. For a long time, di(2-ethylhexyl) phthalate (DEHP) was the most widely used plasticizer. However, more recently, di(2-ethylhexyl) adipate (DEHA), di(2-ethylhexyl) terephthalate (DEHT), trioctyl trimellitate (TOTM), acetyl tributyl citrate, (ATBC) and 1,2-cyclohexane dicarboxylic acid diisononyl (DINCH) have been developed and used as alternatives to DEHP. Nevertheless, there is little clarity regarding the exposure of Japanese people to phthalates, including these substitutes. In this study, as part of our research on the pharmacokinetics of chemicals derived from food, we measured the dietary concentrations of phthalate-related substances and their substitutes and recorded the results.

Methods
We conducted an intervention study in which a totally of 100 healthy men and women were asked to consume the same diet for five days on five separate occasions. The meals were analyzed as yin meals, and after each meal, some water was added to the samples, which were then mixed and lyophilized. The samples were analyzed for DINCH, DEHA, DINA, DEHT, TOTM, ATBC, 2,2,4-trimethyl-1,3-pentanedioldiisobutyrate, and phthalate degradation products (2-ethyl-2-hexanol and texanol) using GC–MS (Agilent 5973-6890) and GC–TOFMS (Agilent 7200 Q-TOF). For substances without corresponding d-body, the samples were analyzed with 2 µg of analyte protectant, PEG300, per injection (1 µL).

Results and Discussion
When analyzed without PEG300, the recoveries for substances with its d-body were 85%–105%; however, for other substances, the recoveries were much higher than 100%, with some substances exhibiting recoveries of approximately 150%. When analyzed with PEG300 as an analyte protectant, the recoveries were improved to approximately 100%. The GC–MS analysis showed that DEHP (N = 72) was detected in 99% of the diet samples, with a median concentration of 0.048 µg/g-food per actual weight of the diet samples. Besides DEHP, di-n-butyl phthalate was detected in more than 50% of the dietary samples (detection rate: 67%, median: 0.0061 µg/g-food).

Acknowledgments
The authors would like to thank all the participants for their cooperation in the intervention study. This study was funded by the General Promotion Fund for Environmental Research (JPMEERF20205003).

3.21.P-We229 Investigation of the effects of rotenone, bisphenol A and dibutyl phthalate in Schizosaccharomyces pombe strains
*Consuelo Alvarez-Herrera[1], **Sara Maisanaba**[1], María Llana-Ruíz-Cabello[1], Ana María Colino[1], Raquel Rojas[1], Oscar Herrero[2] and Guillermo Repetto[1], (1)Universidad Pablo de Olavide de Sevilla, Spain, (2)Campus UNED Las Rozas, Spain*
Different compounds widely used in everyday products present multiple risks to environmental and human health. Among them, the pesticide rotenone and the plasticizers bisphenol A and dibutylphthalate are very relevant. The aim of this work was to investigate their effects independent of endocrine disruption and complex I inhibition. For this purpose, the fission yeast *Schizosaccharomyces pombe* was selected, an experimental model lacking complex I of the mitochondrial electron transport chain, and estrogenic receptors.

The cytotoxicity, oxidative stress and the possible potentiation of the effects were evaluated with the wild strain. The main mechanisms of action were investigated in strains with deleted genes, to detect stress (pmk1, sty1) and interference with microtubules (mph1) or DNA (rad3). The protection by exclusion pumps was evaluated globally and for the specific transporters Bfr1, Pmd1, Mfs1 and Caf5 and also for the transcription factor Pap1.

The main results observed were: a) rotenone presented low toxicity in *S. pombe* due to the lack of its main target and because a marked protection by the transporters Bfr1, Pmd1, Caf5 and Mfs1, being oxidative stress the predominant mechanism of action; b) bisphenol A also induced general stress according to Pmk1 and Sty1A, reducing cell growth and increasing oxidative stress. c) dibutylphthalate presented low toxicity and marked protection by the Bfr1, Caf5 and Pmd1 transporters. Finally, potentiation of their effects was observed, particularly for rotenone by the fungicide carbendazim and the antimetabolite drug hydroxyurea. Given that the compounds evaluated present complex adverse effects and that their combination may causes potentiation, for their uses, more exhaustive controls and regulations should be considered.

3.21.P-We230 A Comprehensive Analysis of Phthalates Microplastics Effects on Developing Zebrafish: Genomic, Organ Development, and BMP Pathway Insights

Abdulkhalik Mansuri[1]*, Krupa Kansara*[2] *and Ashutosh Kumar*[3]*, (1)Ahmedabad University, India, (2)Biological and Engineering Discipline, Indian Institute of Technology – Gandhinagar (IITGN), India, (3)Biological and Life Sciences, Ahmedabad University, India*

The escalating global plastic pollution crisis, driven by projections of a two-fold increase in plastic production by 2050, has triggered widespread accumulation of plastic waste, particularly microplastics, in diverse ecosystems. Of particular concern is the leaching of chemicals from these microplastics, with a significant focus on phthalates, commonly used as plasticizers in various products. Phthalates pose a substantial threat to aquatic life and ecosystem health. This study utilizes zebrafish, a well-established model organism for toxicity assessments, to comprehensively investigate the impact of phthalates on aquatic organisms. Zebrafish larvae exposed to three prominent phthalates, DEP (diethyl phthalate), DBP (dibutyl phthalate), and DEHP (di-ethylhexyl phthalate), exhibit reduced survival rates, with DBP demonstrating the highest toxicity among them. These exposures also result in various malformations, including pericardial edema, spinal deformities, yolk sac edema, and tail malformations, with DBP showing the most pronounced effects. The study further reveals that phthalate exposure triggers a significant increase in intracellular reactive oxygen species (ROS) production in zebrafish larvae, with the highest ROS induction in DBP-exposed larvae, correlating with higher mortality rates and malformations. The research extends to examine histopathological consequences in adult zebrafish exposed to DBP and DEP, revealing structural modifications in vital organs, including liver lesions, alterations, necrosis, and cellular degeneration. Additionally, the study investigates genetic expression patterns in zebrafish larvae exposed to phthalates. Several genes associated with organ development, dorsoventral patterning, and cardiovascular development display downregulation in response to phthalate exposure, reinforcing the developmental impact of these chemicals. Beyond these fundamental observations, the study delves into the intricate mechanisms underlying the effects of phthalates. It explores the influence of phthalates on the Bone Morphogenetic Protein (BMP) pathway during zebrafish development. Staining methods, including alizarin, calcein, and alcian blue, are employed to evaluate bone development. These analysis provide valuable insights into how phthalates disrupt bone development and interfere with the BMP pathway in zebrafish.

3.21.P-We231 Plastic additives: trophic level ecotoxicity for enhanced Life Cycle Assessment Impact

Carla Ofélia Silva[1,2]*, Naiara Machado Casagrande*[1,3]*, Ana Candeias*[3]*, Paula Sobral*[1,3] *and Graça Martinho*[1,3]*, (1)MARE - Marine and Environmental Sciences Centre, ARNET - Aquatic Research Network Associate Laboratory, Portugal, (2)NOVA.ID.FCT, Caparic, Portugal, (3)NOVA School of Science and Technology, NOVA University Lisbon, Portugal*

Plastic waste poses a significant environmental challenge, drawing considerable research, media, and policy attention primarily focused on its visible impact. The plastic industry incorporates various additives, such as plasticizers, to achieve desired product properties. Consequently, plastics serve as potential vectors for the release of these additives into the aquatic environment, posing ecotoxicological risks. Despite the prevalence of these additives in aquatic ecosystems, there are substantial knowledge gaps concerning their ecotoxicological effects, especially in the context of Life Cycle Impact Assessment (LCIA). There is a lack of characterization models for additives to assess their environmental impact on the plastic life cycle. In our literature review, we identified ecotoxicity data for 75 additives used in the plastic industry, a very small fraction compared to the extensive range of additives reported. This study aims to address this gap by providing aquatic ecotoxicity data aiming to calculate EF specifically for plastic packaging additives. We conducted a battery of ecotoxicological tests involving species from tree trophic levels, to estimate effects such as growth inhibition of algae *Pseudokirchneriella subcapitata*, acute immobilization of invertebrate *Daphnia magna*, as well as the toxicity assessment of the luminescent bacteria *Vibrio fischeri*, following OECD guidelines and the requirements to produce relevant data for LCIA advances. These data are crucial for a better understanding of the environmental impact of plastic additives on aquatic ecosystems, contributing to LCIA by refining and expanding the available sets of effect factors. Advancements in this area enhance plastic life cycle assessment, enabling the identification of toxicity associated with additives and the estimation of their chemical footprint. The findings of this study not only expand the number of covered additives used in plastic packaging but also support initiatives aiming to minimize environmental hazards associated with plastic waste, informing sustainable practices in plastic production.

3.21.P-We232 Differences in Modulating Phenanthrene Bioavailability and Toxicity in Parhyale hawaiensis by Microplastics: Short- and Long-Term Effects

*Ibrahim Lawan[1], Mariana A. Dias[2], **Cassiana Carolina Montagner**[3], Alastair Robert Lyndon[4] and Theodore Henry[1], (1)Heriot-Watt University, United Kingdom, (2)Institute of Chemistry, Universidade Estadual de Campinas (UNICAMP), Brazil, (3)Universidade Estadual de Campinas (UNICAMP), Brazil, (4)Institute of Life and Earth Sciences, Heriot-Watt University, United Kingdom*

Polycyclic aromatic hydrocarbons (PAHs) and microplastics (MPs) are environmental pollutants that interact with marine organisms and pose unknown risks. MPs sorb PAHs and influence their environmental fate; however, the short- and long-term effects of sorption on PAH bioavailability and toxicity require further investigation. We examined the bioavailability and toxicity of phenanthrene (Phe), a PAH, to determine the effect of sorption on three environmentally prevalent MPs – polyamide (PA), polyethylene (PE), and polyethylene terephthalate (PET) – in the tropical marine amphipod *Parhyale hawaiensis*. Adult *P. hawaiensis* (8 – 12 months) were exposed to different concentrations of Phe with and without MPs for short-term (96 h) and long-term (21 d) durations. In short-term exposures, the presence of MPs reduced Phe toxicity, reflected in higher median lethal concentrations (LC_{50}), without significant differences among the MP polymer types. Conversely, MPs did not reduce Phe toxicity in long-term exposures based on *P. hawaiensis* mortality and moulting frequency. Furthermore, behavioural ecotoxicity tests in long-term exposures indicated that the presence of MPs did not reduce the toxic effects of Phe on growth, foraging behaviour, or condition factor indices. These findings suggest a change in Phe bioavailability based on exposure duration, with MPs influencing short-term exposures but exhibiting a limited impact on Phe toxicity in long-term scenarios. The observed changes in sorption-desorption interactions between MPs and toxicants over time highlight the need to further investigate their environmental implications

3.21.P-We233 Mixture Toxicity of a Lipophilic and a Hydrophilic Pesticide with Microplastics and a Perfluoroalkyl Substance

***Sam van Loon**[1], Ge Xie[2], Claus Svendsen[3], Nienke Catarina Schut[4], Eva Sprokkereef[4] and Cornelis A.M. van Gestel[2], (1)Amsterdam Institute for Life and Environment (A-LIFE), Vrije University Amsterdam, Netherlands, (2)Amsterdam Institute for Life and Environment (A-LIFE), Vrije Universiteit Amsterdam, Netherlands, (3)UK Centre for Ecology & Hydrology (UKCEH), United Kingdom, (4)University of Amsterdam (UVA), Netherlands*

In natural environments, organisms are never exposed to just a single substance, but always to mixtures of chemicals. Ubiquitous substances like microplastics (MPs) and per- and polyfluoroalkyl substances (PFAS) are expected to be found in any global environment, and therefore are always present in the mixture of compounds that organisms are exposed to. This especially is the case in soils, which act as a sink for many chemicals. Therefore, it is important to assess how these compounds may contribute to the toxicity of other xenobiotics to organisms. MPs are considered to contribute to the translocation of xenobiotics into the organism by adsorbing these compounds followed by desorption once the particles have entered the organism, thereby facilitating exposure to xenobiotics. PFAS may also be hypothesized to influence the toxicity of other compounds, by causing immunotoxicity, or induction of cytochrome P450 enzymes involved in the biotransformation of xenobiotics inside the organism, or by affecting the uptake of (lipophilic) chemicals due to their amphiphilic properties. This study aimed to examine the effects of MPs and PFAS on the toxicity of pesticides to the soil dwelling springtail *Folsomia candida*. A hydrophilic pesticide, imidacloprid (log K_{ow} 0.57), and a lipophilic pesticide, chlorpyrifos (log K_{ow} 4.7), were used to elucidate the effect of lipophilicity on the potential facilitation of exposure by MPs. Single compound toxicity tests were performed to assess the effects of selected compounds on the reproduction of *F. candida*. EC_{50}s of linear low density polyethylene (LLDPE) MPs, perfluorobutane sulfonamide (FBSA), imidacloprid, and chlorpyrifos were 2.9%, 1.2 mg kg^{-1} dry soil, 0.3 mg kg^{-1} dry soil, and 0.1 mg kg^{-1} dry soil, respectively. Three ternary mixture toxicity tests were planned to assess the combined effect of MPs and FBSA with either of the pesticides, as well as of FBSA with both pesticides. Test concentrations were designed to range from 0.25 to 4 TU, and by varying the concentration of each component it was aimed at including all binary and ternary mixtures of the four test compounds. The ternary mixture experiments are currently ongoing. Results of two experiments will be presented at the meeting in May 2023.

3.21.P-We234 Ecotoxicological effects of ketoconazole combined with virgin and aged microplastics in Daphnia similis

*Keila Ishii[1], Fábio Florenzano[2], Flávio Silva[1] and **Teresa Paiva**[3], (1)Universidade de São Paulo (USP), Brazil, (2)Materiais, Universidade de São Paulo (USP), Brazil, (3)University of São Paulo (USP), Brazil*

Currently, many studies seek to understand the action of xenobiotic agents on organisms in aquatic environments. Among the xenobiotic agents studied, microplastics are materials often identified in water bodies, which have adsorptive capacity and toxicological synergistic action when associated with other chemical species. Plastics exposed to degrading environmental conditions have altered physicochemical properties, which is called the aging process, generating structural changes with effects on adsorption phenomena and consequently on toxicological effects. Thus, the present study aimed to understand the relationship of toxicological effects that virgin (MPv) and aged (MPe) polyethylene microplastics, associated or not with ketoconazole (CTZ) fungicide, may represent for aquatic organisms, using the *Daphnia similis* organism as the experimental model. The chemical composition and surface morphology of the microplastics were analyzed using FTIR-ATR and SEM techniques, respectively, while the toxicity of MPv and MPe, isolated or associated with CTZ, was determined using oxidative stress biomarkers in *D. similis* under acute test. The physical and chemical changes caused by the aging of the MP were observed, obtaining evidence of the aging of the material, given the appearance of oxygenated groups and greater wrinkled surface. The microplastics with CTZ were more lethal, reinforced by the higher enzymatic activities of superoxide dismutase (SOD), glutathione S-transferase (GST) and malondialdehyde (MDA). Comparing MPv and MPe associated with CTZ, there

was higher mortality by MPv + CTZ than MPe + CTZ, although the latter caused greater oxidative stress and SOD activation. It was seen that the association between microplastics and the drug was more toxic to the organism than each xenobiotic separately, requiring further evaluations to compare damage between virgin and aged plastics.

3.21.P-We235 Weathered Nanoplastics Cause Zebrafish Developmental Stress and Augment Bisphenol A-driven Estrogenicity

Astrid Saraceni[1], *Andrey Ethan Rubin*[2], *Yair Wexler*[3], *Yoav Gothilf*[3], *Patrizia Bovolin*[1] *and Ines Zucker*[2], *(1)Department of Life Sciences and Systems Biology, University of Turin, Italy, (2)Porter School of the Environment and Earth Sciences, Raymond and Beverly Sackler Faculty of Exact Sciences, Tel Aviv University, Israel, (3)Department of Neurobiology, George S. Wise Faculty of Life Sciences and Sagol School of Neuroscience, Tel Aviv University, Israel*
Session chairs and colleagues: Eric Carmona Martinez, Elisa Rojo-Nieto, Bethanie Carney Almroth

Plastic pollution has become a critical issue at the global level during the last decades. Plastics can fragment into smaller pieces, to which all living organisms are continuously exposed, through different routes. Plastic fragments in the environment are classified based on their dimension, the smallest being micro- (diameter < 5 mm) and nano-plastics (NPs) (diameter <100 nm). Most laboratory studies in this field use commercial virgin micro/nanospheres when assessing the impact of exposure to these particles on model organisms. However, fragmented plastics in the environment are not perfectly spherical, and vary in their physicochemical characteristics compared to pristine (non-weathered) plastic particles due to exposure to solar, mechanical, thermal, and biological degradation. In this study, we first compared the response of zebrafish embryos to two physical models of polystyrene (PS) NPs, including commercial virgin nanobeads and laboratory-weathered NPs. The laboratory-weathered NPs are originating from single-use plastic products that, after fragmentation, undergo an accelerated weathering protocol. Through morphological, behavioral, and molecular techniques, we observed that weathered NPs more deleteriously affect embryo development, glucocorticoid-dependent stress response, and locomotor activity than commercial beads. As a second step, we investigated if the weathered NPs may operate as a vector to coexisting pollutats, using Bisphenol A (BPA) as a chemical model substance. After assessing BPA sorption capacity on weathered NPs, we exposed the zebrafish embryos to the particles with and without BPA, and we performed a gene expression analysis, which revealed that zebrafish embryos exposed to BPA-sorbed NPs had increased stress and estrogenic responses. Our findings suggest that exposure to PS NPs can impact the development of living organisms, thereby intensifying their stress response. Additionally, using weathered NPs combined with coexisting contaminants could be an effective tool to evaluate the risks associated with exposure to nanoplastics and related pollutants and to simulate human and wildlife exposure scenarios relevant to the environment.

3.21.P-We236 Inflammatory-gene expression and DNA damage effects in zebrafish adults after nanoplastic and benzo[a]pyrene exposure.

Joana Antunes[1], *Isabella Bramatti*[2], *Paula Sobral*[1], *Vasco Branco*[2,3] *and Marta Martins*[1], *(1)MARE - Marine and Environmental Sciences Centre, ARNET - Aquatic Research Network Associate Laboratory, Portugal, (2)Research Institute for Medicines (iMed.Ulisboa), Faculty of Pharmacy, Universidade de Lisboa, (3)Egas Moniz Center for Interdisciplinary Research (CiiEM); Egas Moniz School of Health &Science, Campus Universitário, Portugal*

Nanoplastics (NPs) and benzo[a]pyrene (B[a]P) represent emerging environmental pollutants that have attracted significant attention due to their potential adverse effects on ecosystems. Nanoplastics, characterized by their small size and extensive surface area, pose unique challenges in terms of dispersion, transport, and ecological impact. These NPs, often derived from the breakdown of larger plastic materials, can accumulate in several environmental compartments, raising concerns about their implications for aquatic and terrestrial life. On the other hand, B[a]P, a polycyclic aromatic hydrocarbon (PAH), is a well-known environmental contaminant resulting from incomplete combustion of organic matter, such as fossil fuels and tobacco. With recognized carcinogenic and mutagenic properties, B[a]P has been a subject of regulatory scrutiny and research to understand its distribution, persistence, and potential ecological consequences.

In the present study, the toxicological effects of NPs, B[a]P, and their mixtures in zebrafish adults (*Danio rerio*) were investigated. Three different treatments were considered: a) NPs via dietary intake of *Daphnia magna* previously contaminated with 25 nm diameter polystyrene nanoparticles at a concentration of 500 $\mu g.mL^{-1}$; b) waterborne exposure to B[a]P at 25 nM; and c) a combination of both contaminants. After 28 days and 3 months of exposure, DNA damages were analyzed in fish blood through the comet assay, and the genes associated with inflammation were assessed in the fish liver through RT-PCR analysis.

Results from this *in vivo* bioassay provide insights into the potential consequences of simultaneous exposure to NPs and B[a]P, addressing concerns related to aquatic ecosystems and human health.

3.21.P-We237 Deciphering toxicological effects: the interplay between nanoplastics, industrial residues and aquatic environment

Vera Maria[1], Joana Santos[2] and ***Ângela Barreto***[1], *(1)Departament of Biology & CESAM, University of Aveiro, Portugal, (2)Department of Biology & CESAM, University of Aveiro, Portugal*
The persistent discharge and buildup of plastic particles in ecosystems stem primarily from the widespread industrial application of plastics and the insufficient management of plastic waste. In the environment, where various contaminants coexist, plastics may serve as vectors, facilitating their transport to organisms. Nevertheless, a substantial void in knowledge exists regarding the intricate interplay of nanoplastics (NPls) and co-contaminants. The aim of this study is to investigate whether the toxicological impact of phenmedipham (PHE, herbicide) and amitriptyline (AMI, antihistaminic) on zebrafish (*Danio rerio*) embryos is modified in the presence of polystyrene NPls. Fish embryonic test (FET), behavior and biomarkers were explored. Analyzed endpoints: mortality, heartbeat, hatching, malformations appearance, locomotor performance, oxidative stress, neurotransmission and energy budget. The combined exposures of PHE or AMI with NPls did not affect embryos development, showing that the presence of NPls did not modulate the PHE or AMI toxicity. NPls induced hyperactivity, PHE induced hypoactivity, and AMI had no effect. The behavioral assessment showed a simple independent action (hyperactivity) for 0.015 mg/L NPls + 20 mg/L PHE and an interaction effect (hypoactivity) for the 0.015 (or 1.5) mg/L NPls + 0.03 mg/L AMI. NPls increased catalase activity and PHE increased glutathione S-transferases activity. On the combination 0.015 (or 1.5) mg/L NPls + 20 mg/L PHE (or 3 mg/L AMI), cholinesterase activity was inhibited. Additionally, the mixture of 1.5 mg/L NPls + 20 mg/L PHE increased both catalase and glutathione S-transferases activities. Increased total glutathione levels were found in 0.015 mg/L NPls + 0.03 mg/L AMI. The joint presence of NPls and PHE resulted in a greater impact on various biochemical endpoints compared to individual exposures, indicating an elevated effect of the combined exposures. This phenomenon was not observed in the case of the mixture NPls + AMI. Divergent interaction effects, including no interaction, synergism, and antagonism, were identified between NPls and PHE or AMI. This study underscores the significance of considering the influence of NPls on the bioavailability and toxicity of different types of co- contaminants in the evaluation of the environmental behavior and risks associated with NPls.

3.21.P-We238 Hazard Assessment of Polyhydroxybutyrate Nanoplastics and Caffeine on In Vivo and In Vitro Models of Xenopus Laevis

Fábio Miguel Ribeiro Gomes[1], Miguel Oliveira[2] and ***Isabel Lopes***[2], *(1)University of Aveiro, Portugal, (2)University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Portugal*
Pollution is a major impacting driver on wildlife populations, especially amphibian´s due to their high susceptibility to xenobiotics. Plastic contaminants have been a target of extensive risk assessment research, mainly because of their environmental persistence. Polyhydroxybutyrate (PHB), a bio-based and biodegradable polymer, lacks full assessment for its ecological impact, particularly on its nano-sized particles. In addition to its individual exposure threat, nanoparticles may serve as vectors, facilitating the transfer and release of adsorbed contaminants to organisms. Caffeine, the world's most consumed psychoactive drug, is ubiquitously present and prevalent in aquatic environments. Amphibians are both prey and predators of freshwater ecosystems, playing a key role in population dynamics. Nonetheless there is a lack of knowledge regarding amphibians' sensitivity to emerging to contaminants. Thus, this works aims to: assess the individual and combined effects of caffeine and PHB-NPs to early life stages of *Xenopus laevis*; determine the adequacy of *in vitro* assays as non-animal alternatives for first tiers of amphibian aquatic stages risk assessment. Hence, the toxicity of caffeine and PHB-NPs was assessed individually and in mixture, in 96-h assays with embryos and tadpoles of *X. laevis*, and in 72-h assays with A6 e XTC-2 cell lines of *X. laevis*. The present study provides the first experimental evidence of cytotoxic impact initiated by novel bio-nanoplastics and caffeine exposure, either as a single contaminant or in combination, to amphibian *in vitro* models. Caffeine proved strong effects on survivorship, malformations, heartbeat, and body growth, on both early life stages, while PHB-NPs displayed no toxicity on *X. laevis*. PHB-NPs and caffeine co-exposure displayed no apparent interaction on *in vivo* models, while on *in vitro* assays both examples of antagonism and synergism were observed. Embryos were consistently more sensitive than tadpoles to caffeine, with LC_{50} of 196 and 226 mg/L, respectively. Live models were more susceptible to caffeine than both A6 (587 mg/L) and XTC-2 (864 mg/L) cell lines, while for PHB-NPs the opposite was observed. Even though PHB is regarded as a biodegradable and biocompatible polymer, our results indicate that PHB-NPs displayed cytotoxic potential. Thus, it is pivotal to further explore the effects of PHB-NPs on *in vivo* models, in order to better understand its suitability as an environmental-friendly alternative.

3.21.P-We239 Nanoplastics and Pharmaceuticals: Unraveling the Hidden Ecotoxicological Web

Ângela Barreto[1], *Joana Santos[2], Ana Rita R. Silva[3] and Vera Maria[1], (1)Departament of Biology & CESAM, University of Aveiro, Portugal, (2)Department of Biology & CESAM, University of Aveiro, Portugal, (3)CESAM & Department of Biology, University of Aveiro, Portugal*
Plastic waste pollution poses a significant environmental challenge, yet research regards contamination by nanoplastics (NPls) remains limited. NPls, apart from their potential toxicity, can also act as vectors for other harmful contaminants, impacting aquatic and terrestrial ecosystems. However, there is a notable knowledge gap in understanding the interactive effects of NPls on mixtures with pharmaceuticals. The main of this study is to investigate how the toxicological effects of the pharmaceutical diphenhydramine (DPH) changes in the presence of polystyrene NPls. Considering both aquatic and terrestrial ecosystems, ecotoxicological model species *Daphnia magna* (aquatic compartment) and *Folsomia candida* (terrestrial compartment) were used. Commercial polystyrene NPls (44 nm) served as the NPls model. In *D. magna*, immobilization and biochemical endpoints were assessed after 48 hours. For *F. candida*, reproduction, survival, and biochemical responses were evaluated after 28 days and behavior after 48 hours. In *D. magna*, DPH + NPls showed a synergistic pattern for oxidative damage (increased lipid peroxidation) at ecologically relevant concentrations. The concentration causing a 50% of effect (EC_{50}) for *D. magna*

immobilization was 3.9 mg/L for DPH alone. In the mixture, with increasing NPls concentration, the DPH EC_{50} for immobilization decreased to 0.001 mg/L. In general, DPH + NPls exhibited more pronounced toxic effects than anticipated based on individual exposures, suggesting synergy between the mixture components. In *F. candida*, DPH effects on survival and reproduction were independent of NPls presence. However, for avoidance behavior, the effects of mixtures depended on NPls concentration (0.015 mg/kg: interaction - no avoidance; 600 mg/kg: no interaction - avoidance). Glutathione-*S*-transferases activity increased after DPH + NPls exposure (synergism), while the rise in lipid peroxidation seen at 0.015 mg/kg NPls was absent in mixtures. Effects of the binary mixtures varied with endpoints and concentrations. This study revealed interactive effects between NPls and DPH, leading to harmful impacts on both *D. magna* and *F. candida*. These findings provide valuable insights for informed decisions by society and policymakers concerning plastics and pharmaceuticals, underscoring the importance of environmental risk assessment when considering contaminant mixtures.

3.21.P-We240 Contribution of additive-related effects to LDPE microplastics toxicity for aquatic organisms: a case study with model metal and organic additives

*Valentina Perc[1], Anita Jemec Kokalj[2], Damjana Drobne[2], Axel Müller-Köhn[3], Annegret Potthoff[4], **Dana Kühnel**[5] and Alisha Fiona Zoons[6], (1)Biotechnical faculty, University of Ljubljana, Slovenia, (2)University of Ljubljana, Biotechnical Faculty, Slovenia, (3)Fraunhofer Institute for Ceramic Technologies and Systems (IKTS), Germany, (4)Fraunhofer Institute for Ceramic Technologies and Systems IKTS, Germany, (5)Helmholtz Centre for Environmental Research (UFZ), Germany, (6)Biotox, Helmholtz Centre for Environmental Research (UFZ), Germany*

Microplastic particles (microplastics) often contain an unknown quantity of known as well as unidentified chemicals in addition to the polymer material. Intentionally added chemicals may leach from the polymer matrix under environmental conditions, subsequently entering water bodies. There they may exert toxic effects on aquatic organisms and contribute to the overall chemical load. However, studying such effects is challenging due to the complexity of mixtures that are released, as for most commercial polymers the identity and amount of additives are undisclosed.

Here we present an approach to produce well-defined additive-loaded microplastics applicable to subsequent aquatic ecotoxicity testing. We used ZnO, and commercially available LubioÒ products as model additives, both being relevant in industrial applications as UV-stabilizers and polymer antiaging systems, respectively.

A common amount of a nanoscale ZnO (5 wt%, NanoTek) or LubioÒ (3.5 wt%) was homogeneously distributed in LDPE (DOW 410E), and polymer sheets were casted. These were subjected to cryo-milling, yielding micron-scaled irregular shaped particles. Powders were sieved to obtain comparable particle fractions of > 300 µm, 140 µm-300 µm, and < 140 µm for all samples. In addition to 3 different microplastics (additive-free, ZnO loaded, and LubioÒ loaded), also the single additives were tested. Microplastics were produced from unaged polymers as well as from polymers aged under accelerated UV conditions. They were extensively characterized before ecotoxicity testing regarding the leaching of the known additives. We performed toxicity testing with two aquatic ecotoxicity models; freshwater crustacean *Daphnia magna* and protozoan *Tetrahymena thermophila*.

As expected, the ZnO nanoparticles were acutely toxic (induced immobility) to *D. magna* and slightly cytotoxic to *T. thermophila*. LubioÒ additives did not exert high cytotoxicity in *T. thermophila*, whereas a slight toxicity of the LubioÒ was observed in daphnids. None of the microplastics (additive-free / additive-loaded; unaged / aged) was acutely toxic to both organisms. This is an indication that the concentrations of individual additives as used in our study are too low to pose an acute risk to aquatic organisms. Additionally, our results show that the presented approach for preparing microplastics with defined additive content is promising to distinguish the effects posed by microplastics and additives.

3.21.P-We241 Do Microplastics Affect the Toxicity of Metals to Duckweed?

***Guiqi Zhao**[1] and Philippe Juneau[2], (1)Department of Biological Sciences, University of Quebec in Montreal (UQAM), Canada, (2)Department of Biological Sciences, Ecotoxicology of Aquatic Microorganisms Laboratory, EcotoQ, GRIL, TOXEN, Université du Québec à Montréal (UQAM), Canada*

Microplastics (size from 1 µm to 5 mm) have been frequently detected in different water bodies. Because of their unique surface characteristics, they are considered as good carriers of various contaminants in aquatic environment. However, there are few studies focusing on the combined effects of microplastics and metals on freshwater organisms. Under this context, the aim of this study was to evaluate the effect of an environmentally relevant concentration of microplastics on the toxicity of two metals to freshwater macrophyte.

We investigated the individual and combined effect of 10 mg/L polystyrene microplastics with two different sizes (< 100 µm and >100 µm) and two metals (0.1 mg/L cadmium and 1.5 mg/L zinc) on *Lemna minor*. Plant growth, photosynthetic activity, pigment contents were determined after 7 days of exposure. Results showed that individual microplastics promoted growth of *L. minor*, with the larger tested microplastics increasing the fresh weight by up to 26%. Although Cd alone did not inhibit the growth, combination of microplastics and cadmium decreased the plant growth significantly. We noticed that the combination of the smaller microplastics and Cd induced a weaker inhibition of growth and photosystem II activity than larger microplastics and Cd. No significant changes in pigment contents between the Cd alone and the mixture of Cd and microplastics were observed compared to the control. The combined effect of Zn and microplastics mainly affected photosystem II activity and increased the non-photochemical quenching dissipation compared to Zn alone.

Therefore, the interaction between microplastics and metals and their combined toxicity to aquatic plants need to be considered when assessing the environmental risk of microplastics and metals to freshwater ecosystem.

3.21.P-We242 Toxic effects on zebrafish caused by micro- and nanoplastic: a review

Lina Sofia Lundin[1] *and Steffen H. Keiter*[2]*, (1)Orebro University, Sweden, (2)MTM Research Centre, Orebro University, Sweden*

Lina Lundin1, Steffen Keiter1

Plastic pollution in the marine environment has become increasingly prevalent, causing devastating effects on a myriad of inhabitants, both small and large. Annually, approximately 19-23 million tons of plastic find their way into the oceans. The breakdown of these plastics results in the formation of micro- and nanoplastic particles (MPs and NPs). Given the ubiquity of sources and their persistence in the aquatic environment, these particles are globally distributed in various environments including some areas far from emission sources. Therefore, the impact of MPs and NPs on aquatic organisms, along with the potential repercussions for ecosystem functioning, has been a topic of discussion for over a decade. For the investigations of the possible environmental consequences of plastic pollution, studies on plenty of different test organisms were conducted such as zooplankton, mollusks, marine worms, and fish. Among these various test organisms, the zebrafish (*Danio rerio*) represents one of the most common test organisms to investigate environmental pollution and more frequently used to investigate the toxic effects of MPs and NPs. However, the challenge lies in synthesizing the increasing volume of new research in this field. This study aimed to combine results of different studies to find consistencies, irregularities, as well as to summarize and to find gaps in the currently available research data using a semi-structured literature research. Results of the study reveal an alarming amount of negative consequences for zebrafish caused by MPs and NPs, such as heart problems, decreased locomotor function, accumulation in brain, liver, pancreas, gallbladder, intestines, and eyes. Noteworthy contributions of this study include the correlation of size of particles with certain toxicological endpoints as well as the importance of the life stage. Additionally, these various scientific data suggest that the lack of clear guideline for studying MPs and NPs effects in zebrafish impedes the creation of a comprehensive overview, emphasizing the need for a shared methodology to facilitate clearer comparisons.

3.21.P-We243 Impact of Micro(nano)plastics on Amphibian Cell Lines

Carolina Frazão[1]*, Mónica Almeida*[1]*, Miguel Tamayo-Belda*[2]*, Ricardo Pinto*[3]*, Isabel Lopes*[1] *and* ***Miguel Oliveira***[1]*, (1)University of Aveiro & Centre for Environmental and Marine Studies (CESAM), Portugal, (2)University of Madrid (UAM), Spain, (3)Chemistry, Aveiro Institute of Materials (CICECO), Portugal*

The low cost, versatility, and durability of plastic materials led to its increased production, resulting in its environmental presence. Once in the environment, abiotic and biotic processes have been shown able to promote their degradation/fragmentation to microplastics (100 nm < MP < 5 mm) and nanoplastics (NP < 100 nm). A decrease in size often increases the bioavailability and reactivity of the particles. This becomes highly relevant to the potential impact that small particles may induce on biota. The increased concern over plastic pollution led to a shift in the plastic industry towards the development of bioplastics. Despite their reported biodegradable nature, when disposed of uncontrollably, bio-based plastics will accumulate in the environment and fragment into MP and NP. Whether bio-based plastics are more eco-friendly than conventional fuel-based is still to be proved. Among the organisms that may be affected by MPs and NPs are amphibians, a group of organisms already under anthropogenic pressure worldwide. However, ethical constraints limit the tests that can be employed to understand the hazards of MP and NP to amphibians. Therefore *in vitro* cellular models based on established cell lines are of great significance for the risk assessment of MP and NP. This study aimed to evaluate the cytotoxic effects of micro(nano)plastics of two fuel-based polymers (polymethylmethacrylate (PMMA), and polystyrene (PS)) and a bio-based polymer (polylactic acid (PLA)) on two amphibian cell lines A6 (adult *Xenopus laevis* kidney epithelial cell line) and XTC-2 (tadpole *Xenopus laevis* carcass fibroblast cell line). The selected cell lines were exposed to NP (from 0 to 400 mg/L) and MP (from 0 to 200 mg/L) obtained through laboratory synthesis (PMMA) or fragmentation of larger particles (to produce environmentally relevant shapes – PS and PLA) and the cell viability was assessed, through 3-[4,5-Dimethylthiazol-2-yl]-2,5-diphenyltetrazolium bromide (MTT) assay, up to 72 hours. A fluorescent dye (perylene) was added to PMMA NP to track and localize the NPs after their internalization in the cells. No significant effects on A6 cell viability were observed after exposure to PMMA NP, while cell viability decreased after exposure to PLA MP (200 mg/L). XTC-2 viability decreased at the highest concentration of PMMA NP (400 mg/L) containing perylene and PLA MP (200 mg/L), while PS MP induced no significant effects on cell viability.

3.21.P-We244 Effects of Field-collected Microplastic Particles on Zebrafish (Danio rerio) Embryos

Lisa Bauer[1]*, Liv Charlotta Richter*[1]*, Patrick Heinrich*[1] *and Thomas Braunbeck*[2]*, (1)Centre of Organismal Studies, University of Heidelberg, Germany, (2)Centre for Organismal Studies, University of Heidelberg, Germany*

Given the global increase in plastic production, the assessment of the environmental impact of plastic waste has become a major issue in ecotoxicology. In particular, smaller fragments known as microplastics (MPs) have been detected in multiple aquatic ecosystems, where − due to their small size and poor biodegradability − MPs can easily be ingested by organisms and passed on within food nets. Ingestion of MPs has been speculated to pose not only physical risks, but to also pose chemical risks through sorption and transfer of anthropogenic environmental pollutants such as pharmaceuticals and pesticides. Thus, the ingestion of MPs has been associated with adverse effects on mortality, growth, feeding activity, endocrine function and the immune system. As many of the mechanisms underlying toxic effects of MPs are still unclear, further research is needed to assess the risk of MPs to aquatic organisms.

As a non-protected vertebrate model, wildtype zebrafish embryos were used to study the biological effects of organic extracts from MPs collected in European coastal marine waters by partners within the JPI Oceans RESPONSE project (https://www.response-jpioceans.eu/). The MP samples mainly consisted of a 100-200 µm size fraction of samples collected in the Tyrrhenian Sea, Adriatic Sea and the Bay of Biscay. Organic contaminants included in the MP samples were extracted by hexane. The endpoints investigated comprised acute toxicity, effects on ethoxyresorufin-*O*-deethylase activity by aryl hydrocarbon receptor-mediated induction of cytochrome P450-dependent monooxygenases (CYP1A), acetylcholinesterase activity and changes in the optokinetic response. Taken together, these experiments provide insight into MP-induced toxic mechanisms and effects in zebrafish embryos, which may help to improve the assessment of the environmental hazard and risk by MPs.

This study has received financial support within the JPI-Oceans-associated project RESPONSE from the German Ministry for Education and Science (BMBF) under contract no. 03F0853A.

3.21.P-We245 Qualitative and Quantitative Assessment of Microplastics Derived from Ship Paint during Hydroblasting: Estimation of Global Microplastics Emissions from an International Research Vessel study

Taekhyun Kim[1,2], *Soeun Eo*[1,2], *Won Joon Shim*[1,2] *and Moonkoo Kim*[1,2], *(1)Korea Institute of Ocean Science and Technology (KIOST), Korea, Republic of (South), (2)University of Science and Technology (UST), Korea, Republic of (South)*

As global concerns over microplastic (MP) pollution continue to grow, the International Maritime Organization (IMO) has highlighted the potential risks of MP derived from ship paint, particularly during hull cleaning processes. Despite the growing awareness, there remains a significant data gap in quantifying the extent of MP emissions specifically derived from these cleaning activities. Our study aims to address this data gap by evaluating MP particles generated during hydroblasting, a common hull cleaning technique.

After collecting samples from hydroblasting on globally operating research vessels, we identified the polymers constituting the paint using Fourier-Transform Infrared Spectroscopy (FTIR), and then measured the weight of particles smaller than 5 mm. Each particle was classified as a polymer such as alkyd, acrylate, epoxide, urethane, or polyester/polyether using FTIR. The weight of the paint particles was measured by multiplying the particle's volume with its density. Additionally, the value for the paint’s plastic components was cited to be 54.9%. To develop an MP emission factor, we estimated the amount of paint applied by multiplying the wetted surface area with coating film thickness, and the density of the paint. As a result, from the total paint applied (485.2 kg), 60.5 kg (12.5%) was generated as paint, and 33.2 kg (6.8%) as MPs from hydroblasting. The MP emission factor was calculated as 0.00926 kg/m^2, which is the value of 33.2 kg divided by the Wetted Surface area of 2161.8 m^2. To estimate the global emission of MPs from ships, we multiplied these emission factors by the total wetted surface area of global ships (326,126,497 m^2), considering the hull cleaning frequency which is once or twice every five years, corresponding to 0.2 or 0.4 times per year. As a result, the MP emission was approximately 604~1,208 tons in 2023. Additionally, we estimated the global MP emissions from 2011 to 2023, categorizing by ship type, including bulk carriers, oil tankers, container ships, general cargo, and other types of vessels. The quantity of MP emissions has shown a consistent upward trend over the period.

This data is not only used for risk assessment regarding the global MP emissions from ships, but also contributes to the development of ship cleaning regulations. To obtain more accurate MP emission values, analysis by the frequency of hull cleaning and by year of operation is necessary.

3.21.P-We246 Exposures to spherical, fibrous, and fragmented microplastics induced alterations of bioaccumulation, microbial immunity, and epigenetic signature in the mussel Mytilus galloprovincialis

Kiyun Park[1], *Won-Seok Kim*[2], *Ji-Won Park*[2] *and Ihn-Sil Kwak*[2], *(1)Fisheries Science Institute, Chonnam National University, Korea, Republic of (South), (2)Department of Ocean Integrated Science, Chonnam National University, Korea, Republic of (South)*

Plastic wastes are globally recognized as the fastest-growing source of pollution worldwide and are therefore an environmental concern of high priority. Microplastic (MP) pollution has become a major global concern due to the widespread use and discharge of plastics into the environment. However, very few studies have assessed the potential variations in the toxicity of MPs according to their shape and size. Therefore, our study sought to identify the biotoxic effects of spherical, fiber-shaped, and fragment-shaped polyethylene terephthalate MPs of different sizes at different concentrations on the Mediterranean mussel *Mytilus galloprovincialis*. The survival rate after exposure to small-sized MPs was lower than that observed for the larger type MPs. Bioaccumulation of MPs was different depending on the exposure periods and MP shapes. Interestingly, the fiber-shaped MPs underwent morphological modifications in the mussel body upon uptake. MP exposure also increased the global DNA methylation levels (i.e., an epigenetic signature), expression of the microbiota immunity-related toll-like receptor gene, and alteration of the gut microbial composition in the mussel. These findings indicated that MPs of different shapes and sizes at different concentrations can alter the bioaccumulation sensitivity of mussels according to the exposure periods, and the balance of gut immunity and epigenetic process. Furthermore, our results demonstrated that MPs of different shapes, particularly fiber types, can undergo morphological modification in mussel tissues, thus posing a hazardous threat.

3.21.P-We247 SUSPECT SCREENING OF EMERGING CONTAMINANTS ADSORBE ONTO MICROPLASTICS IN SEAFOOD: A POTENTIAL ROUTE OF HUMAN EXPOSURE

*María Dolores Márquez-Medina, Soledad Rubio and **Noelia Caballero-Casero**, Analytical Chemistry, University of Córdoba, Spain*

Microplastics are highly persistent and ubiquitous, with the ability to accumulate emerging contaminants (ECs). When marine organisms ingest microplastics, these ECs can be transferred through the food chain, potentially reaching humans through the consumption of fish and shellfish. Given that oceans and seas are the primary food resource for humanity, establishing regulations is imperative to ensure food safety for citizens by monitoring the presence of specific chemicals.

This study introduces a novel suspect screening analytical methodology to assess human exposure to microplastic pollutants by identifying ECs in marine foods. The sample treatment involves the use of SUPRAS, representing a paradigm shift in processing due to its numerous opportunities for improving process yields, selectivity, sustainability, and economics. Supramolecular solvents (SUPRAS) are green nanostructured liquids formed spontaneously in colloidal suspensions of amphiphilic compounds through sequential self-assembly and coacervation. SUPRASs exhibit outstanding properties for analyte extraction and sample cleanup, allowing for the removal of major matrix components while effectively extracting the target compounds.

High-resolution mass spectrometry (HRMS) was employed for detection, annotation, and identification of ECs in marine foods. To explore the potential relationship between microplastic distribution throughout the water column and their intake, various edible marine species from different levels of the water column were analyzed using the developed workflow. Microplastics discovered during the analysis underwent a leaching test, and the resulting leachate was examined using SUPRAS-HRMS. Similarly, muscle tissues were examined using the developed workflow for the identification of ECs.

ECs identified at confidence levels 3-1 (Schymanski's scale) in muscle tissue were cross-checked with those identified in the leachate of microplastics to elucidate potential relationships between microplastics and the presence of ECs in edible marine organisms. This study enhances our understanding of the mechanisms of EC migration and the contribution of microplastics to contamination in marine species, thereby assessing the potential risk of exposure to ECs through diet.

3.21.P-We248 The effect of PET microplastics on transcriptomic profile of porcine pituitary – an in vivo study

***Iwona Bogacka**[1], Karol Mierzejewski[2], Monika Golubska[3], Ismena Gałęcka[4], Jarosław Całka[4] and Aleksandra Kurzyńska[3], (1)Department of Animal Anatomy and Physiology, Department of Animal Anatomy and Physiology, University of Warmia and Mazury in Olsztyn, Poland, (2)Department of Animal Anatomy and Physiology, University of Warmia and Mazury in Olsztyn, Poland, (3)University of Warmia and Mazury in Olsztyn, Poland, (4)Department of Clinical Physiology, University of Warmia and Mazury in Olsztyn, Poland*

Over the years, the environment has been contaminated with millions of tons of plastic. There are different types of plastics that are produced for a single use, and the most dominant include polyethylene, polypropylene, polystyrene, polyvinyl chloride, polyamide and polyethylene terephthalate (known as PET). Microplastics (MPs) and nanoplastics (NPs) have deleterious influence on mammalian endocrine components, including the pituitary gland – organ having an essential role in many physiological functions such as growth, reproduction, metabolism or stress response. Thus, the aim of this study was to determine the *in vivo* effect of PET microplastics on the global transcriptomic profile of the pituitary gland.

The experiment lasted four weeks and was carried out on 8-week-old, sexually immature gilts (n = 15). Animals were divided into three groups: 1) control – receiving empty gelatin capsule, 2) experimental LD – receiving a low dose of PET MPs (0.1 g/pig/day), and 3) experimental HD – receiving a high dose of PET MPs (1 g/pig/day). High-throughput mRNA sequencing was performed on the NovaSeq 6000 Illumina platform.

The study revealed 145 differentially expressed genes (DEGs) in the pituitary of piglets from the LD group (exposed to a low dose of PET) . Among these genes, 32 were downregulated and 113 were upregulated. The DEGs were mostly involved in immune response events – leukocyte mediated immunity (*IL12B, RAC2, CRP, IL13, GZMM*), T cell mediated cytotoxicity (*IL12B, GZMM*), regulation of mast cell activation (*RAC2, IL13*). In addition, the study revealed 176 DEGs in the pituitary of piglets from the HD group (exposed to a high dose of PET). The expression of 47 of these genes was downregulated while 129 was upregulated. The DEGs were involved in processes related to neuroinflammation (e.g., *CXCL8*, *IL-13, CSF3, LIF, AHRR, GFAP, GZMM),* apoptosis processes (e.g., *ELFN2*, *GDA*, *SFTPA1*, *ABHD16B*, *PITX3*), or associated with pituitary function or hormone regulation (e.g., *RXFP1, CBLN1, LIF, AVPR2).*

This comprehensive analysis highlights the complex molecular responses in the pituitary gland exposed to PET microplastics and indicates possible links to inflammation, apoptosis and hormone regulation. These findings recognize the urgent need for further research to fully understand the impact of microplastic pollution on reproductive health and endocrine function.

Supported by the National Science Centre of Poland, Grant No. 2021/43/B/NZ7/01093.

3.21.P-We249 Effect of microplastics in diet on the transcriptome profile of the ovary in sexually immature gilts
Selahattin Bahadır Şahin[1], *Karol Mierzejewski*[1], *Aleksandra Kurzyńska*[2], *Monika Golubska*[2], *Ismena Gałęcka*[3], *Jarosław Całka*[3] *and Iwona Bogacka*[4], *(1)Department of Animal Anatomy and Physiology, University of Warmia and Mazury in Olsztyn, Poland, (2)University of Warmia and Mazury in Olsztyn, Poland, (3)Department of Clinical Physiology, University of Warmia and Mazury in Olsztyn, Poland, (4)Department of Animal Anatomy and Physiology, Department of Animal Anatomy and Physiology, University of Warmia and Mazury in Olsztyn, Poland*
As plastics have recently become widely used in industry, agriculture, and daily life, the production of plastics and their products continues to increase dramatically. When plastic waste enters the environment, it breaks down into small pieces (particles<5 mm) called microplastics (MPs). It was reported that MPs could pass through the intestinal barrier and enter into the circulatory system as well as accumulate in various tissues, including those of the reproductive system. Therefore, the aim of this study was to describe the effects of MPs on the ovary.

The *in vivo* experiment was performed on 8-week-old immature gilts (n =15) divided into following groups: 1) control, 2) group treated with a low dose of PET MPs (0.1g/animal/day) for 4 weeks, 3) group treated with a high dose of PET MPs (1g/animal/day) for 4 weeks. The transcriptomic profile was analyzed by RNA-Seq.

The study demonstrated that the low dose of PET MPs affected the expression of 12 genes (3 downregulated while 9 upregulated) in the ovary. According to GO analysis, the differentially regulated genes (DEGs) were engaged mostly in process related with apoptosis (e.g. *ADAMTS2, PRLR, SOX4*). The KEGG analysis showed that the DEGs were involved in the regulation of PI3K−Akt signaling pathway, oxytocin signaling pathway and prolactin signaling pathway. In turn, the high dose of PET MPs altered the expression of 146 genes (103 downregulated while 43 upregulated) in the ovary. The DEGs were engaged for instance in the regulation of inflammatory response (*IL-17B, CXCL9, CXCL10*) or apoptosis process (e.g. *SOX2, ATOH1, PIP5KL1*). In addition, the KEEG analysis revealed that the high dose of PET MPS induced changes in the expression of genes regulating steroid hormone biosynthesis, chemokine signaling pathway and

cytokine-cytokine receptor interaction.

The results of this study comprehensively describe for the first time the effects of different doses of PET MPs on immature ovaries. The PET MPs alters genes involved in key regulatory processes in the ovary, such as signal transduction, apoptosis, immune response, and hormone synthesis. Our study provides a basis for further exploring the molecular mechanism of reproductive disorders induced by exposure to PET MPs in females.

Supported by the National Science Centre of Poland, Grant No. 2021/43/B/NZ7/01093

3.21.P-We250 PET microplastics affect metabolism of neurotransmitters in the hypothalamus
Karol Mierzejewski[1], *Aleksandra Kurzyńska*[2], *Monika Golubska*[2], *Ismena Gałęcka*[3], *Jarosław Całka*[3] *and Iwona Bogacka*[4], *(1)Department of Animal Anatomy and Physiology, University of Warmia and Mazury in Olsztyn, Poland, (2)University of Warmia and Mazury in Olsztyn, Poland, (3)Department of Clinical Physiology, University of Warmia and Mazury in Olsztyn, Poland, (4)Department of Animal Anatomy and Physiology, Department of Animal Anatomy and Physiology, University of Warmia and Mazury in Olsztyn, Poland*
The escalating global production of plastics has led to widespread environmental pollution. Microplastics (MPs), small particles created when plastics break down, are a growing problem that has been detected in numerous consumer products. Our recent study shows that PET plastic particles can be transported by extracellular vesicles (EVs), which are crucial mediators of intercellular communication. In view of the potential infiltration of plastic particles via EVs into the central nervous system, we decided to determine the effect of PET MPs on the hypothalamus – pivotal regulator in the hypothalamic-pituitary-adrenal and hypothalamic-pituitary-gonadal axes.

The experiment was performed on immature gilts (n = 15). Animals were divided into three groups: 1) control, 2) group receiving a low dose of PET MPs orally (0.1 g/pig/day), and 3) group receiving a high dose of MPs (1 g/pig/day) for 4 weeks. The transcriptomic profile of hypothalamus was determined using RNA-Seq method.

The analysis revealed 82 differentially regulated genes (DEGs) in the hypothalamus of piglets that received a low dose of PET MPs. The GO analysis assigned these DEGs to processes such as inositol phosphate biosynthetic process (*CD244*), regulation of ERBB signaling pathway (*PDE6H*) or receptor recycling (*TRAT1*). In turn, a high dose of PET MPs changed expression of 128 genes. These DEGs were assigned to processes such us catecholamine metabolic process (*DBH, PNMT*), cytokine production (*CD244*, *C5AR2*, *CLEC7A*). Furthermore, KEEG analysis showed that these DEGs were engaged in pathways such as tyrosine metabolism (*DBH*, *PNMT*), Cushing syndrome (*CYP11A1*, *STAR*, *CYP21A2*) or steroid hormone biosynthesis (*CYP11A1*, *CYP21A2).*

These results suggest that exposure to PET MPs induce changes in gene expression
in the hypothalamus, affecting processes related to neurotransmitter synthesis, immune response, and endocrine function. The findings contribute to our understanding of the molecular responses to microplastic exposure.

Supported by the National Science Centre of Poland, Grant No. 2021/43/B/NZ7/01093.

3.21.P-We251 The chemical composition of oxo-"degradable" plastics and their use in Switzerland

Helene Wiesinger[1], Magdalena Klotz[1], Zhanyun Wang[2], Melanie Haupt[1], ***Christopher Oberschelp**[1]* *and Stefanie Hellweg[1], (1)ETH Zurich, Switzerland, (2)Technology and Society Laboratory, Empa – Swiss Federal Laboratories for Material Science and Technology, Switzerland*

Oxo-"degradable" plastics (oxo-plastics) are plastics containing pro-oxidant additives that allegedly promote fragmentation and subsequent biodegradation. However, oxo-plastics, in reality, do not completely biodegrade under environmental or industrial composting conditions, thus contributing to microplastic pollution. Moreover, they can disrupt recycling processes. The Single-Use Plastics Directive in the European Union prohibits the placing on the market of "all plastics containing additives that, through oxidation, lead to fragmentation" (therewith targeting oxo-plastics). In this study, we investigated the occurrence of oxo-plastics in Switzerland and their chemical makeup based on a literature and patent review as well as XRF screening of real samples.

In Switzerland, intentional use of oxo-plastics is not widespread, as larger stakeholders are environmentally conscious and intentionally avoid such products. However, smaller users and distributors of intentional oxo-plastics products exist. Accessing information on oxo-plastics material flows is difficult, as manufacturers and stakeholders do not provide data, and trade statistics do not reveal imports of pro-oxidant additives or oxo-plastic products.

Many substances can act as pro-oxidant additives. The assumption of Fe, Mn, and Co salts being the main pro-oxidant additives is based on limited primary literature. Furthermore, several commercial pro-oxidants also have other functionalities in polymers, thus unintentionally rendering some conventional plastics as "oxo-plastics." The difficulty in differentiating conventional plastics from oxo-plastics was also observed in the XRF screening, where no differences between oxo-plastics and conventional plastics could be observed.

Based on the study's findings, it is recommended to establish a precise definition for oxo-plastics, considering the multi-functionality of many "pro-oxidant" additives. Additionally, the development of practical methods for identifying oxo-plastics is crucial. Implementing regulations on labeling degradable products may contribute to proper disposal practices.

3.21.P-We252 Beyond the Surface: Spotlight on Plastic Metal(loid) Additive Leaching and Unseen Contaminants

***Ole Klein**[1], Lars Michael Hildebrandt[2], Mara Römerscheid[3], Annika Jahnke[3] and Daniel Pröfrock[4], (1)Inorganic Environmental Chemistry, Helmholtz Center Hereon, Germany, (2)Department of Inorganic Environmental Chemistry, Helmholtz-Zentrum Hereon, Germany, (3)Department of Exposure Science, Helmholtz Centre for Environmental Research (UFZ), Germany, (4)Inorganic Environmental Chemistry, Helmholtz-Zentrum Hereon, Germany*

It is known that the leaching of plastic additives, not chemically bound to the polymer backbone, accelerates due to the sunlight-induced weathering of plastics. As a result, these compounds, which in some cases are harmful to the environment, can be increasingly released e.g. from micro plastic particles - resulting in enhanced hazard potential. Since the mechanisms of how fast and to which extent additives migrate out of polymers are complex, it is important to be able to clearly differentiate between the actual leaching of additives and the release of other (micro) contaminants, such as impurities introduced during production or other metal(loid) inclusions.

For this study, eight plastic consumer products (CPs) covering three polymer types (PE, PET and PVC) were subjected to accelerated weathering and leaching in double-distilled water for ten days under ultraviolet (UV) light and the chemical composition (with emphasis on the metal(loid) fingerprint) of the UV leachates was compared with the multi-elemental fingerprint in the corresponding dark control (DC) samples. In addition to these commercial materials, custom-made plastic samples (CMs) with known and well-defined additive profiles were analyzed after application of the same leaching protocol.

Results showed both CPs and CMs exhibited increased UV leachate concentrations by a factor of 0.1 – 1276.6 compared to DCs, indicating weathering effects from simulated sunlight. Antimony (Sb) concentrations exceeded EU Drinking Water Framework Directive limits, raising concerns. However, CP data alone couldn't confirm if leached Sb solely originated from additives like SbO_3 (flame retardants) or other sources. However, a comparison of CP and CM results revealed additives may not be the sole cause of elevated leachate concentrations, emphasizing the need to assess releases of other contaminants from plastic products beyond additives.

3.21.P-We253 Linking Composition to Toxicity in UV-Weathered Plastic Leachates: An Assessment Using Diverse Cell Lines

*Deedar Nabi, **Aaron J Beck**, Deniz Tasdemir and Eric P. Achterberg, GEOMAR Helmholtz Center for Ocean Research Kiel, Germany*

The ultraviolet (UV) component of solar weathering significantly influences the leaching behavior of plastics and the photo-transformation of plastic additives. This study explores the correlation between UV-induced compositional changes in plastic leachates and their consequent toxicity. We analyzed leachates from eight consumer plastics exposed to UV radiation and dark conditions using liquid chromatography-mass spectrometry (LC-MS). The leachates were then assessed for toxicity in five human cancer cell lines: liver, skin, lung, colon, and breast tissues. Our analysis identified 12 additives belonging to classes such as flame retardants, plasticizers, antioxidants, and stabilizers. The occurrence of these additives varied distinctly with the type of plastic and treatment condition (UV vs. dark). UV exposure altered the chromatographic profiles of the leachates, by increasing complexity and introducing new peaks at lower retention times, suggesting the formation of more bioavailable transformation products. Further investigation in the US EPA Comptox database revealed that the identified additives exhibit significant activity across various cellular assays, indicating potential biological effects ranging from endocrine disruption to impacts on liver metabolism. Laboratory toxicity assessments of leachate samples showed differential toxicity across cell lines, with the liver cell line (HEP G2) showing the highest susceptibility and the colon cell line (HCT-116) the least. This variance highlights the importance of exposure pathways, where liver cell lines, indicative of systemic toxicity and metabolism, exhibiting greater susceptibility to leachate toxicity compared to colon cell lines, which represent gastrointestinal exposure. Notably, the presence of a high number of detected additives in some plastic products did not always correspond to increased toxicity, suggesting that while parent additives may contribute to toxicity, other factors, such as transformation products, (non)microplastics, inorganic components, and fractions that are not amenable to LC, could play more significant roles in the observed toxic effects. Taken together, this study underscores the critical need for comprehensive analytical approaches to unravel the complex interactions between UV-weathered plastic leachates and biological systems for better environmental and health risk assessments.

3.21.P-We254 Are Marine Plastics a Sink or a Source of Organic Chemicals in the North Pacific Ocean?

*Christoph Rummel[1], **Elisa Rojo-Nieto**[2], Beate Escher[3], Maria Koenig[3], Martin Krauss[4], Cedric Abele[5] and Annika Jahnke[6], (1)Helmholtz Centre for Environmental Research (UFZ), Germany, (2)Department of Ecological Chemistry, Helmholtz Centre for Environmental Research (UFZ), Germany, (3)Department of Cell Toxicology, Helmholtz Centre for Environmental Research (UFZ), Germany, (4)Department of Effect-Directed Analysis, Helmholtz Centre for Environmental Research (UFZ), Germany, (5)Environmental Science, Stockholm University, Sweden, (6)Department of Exposure Science, Helmholtz Centre for Environmental Research (UFZ), Germany*

Plastics contain a diverse mixture of additives, processing aids, and other organic chemicals, partly of concern, to meet the desired material performance. Once emitted to the aquatic environment, these chemicals can leach from the polymer. In contrast, the high sorption capacity of some polymers, *e.g.* Polyethylene, renders plastics a passive sampling phase when exposed to environmental matrices. Hence, when floating in the ocean, marine plastic litter constantly (de)sorbs organic compounds from/into the surrounding sea water until equilibrium is reached. In this study, we evaluated if marine plastics in the North Pacific Ocean represent a sink or a source of organic contaminants in ambient waters. For this purpose, marine plastics were sampled in the Pacific Ocean during the expedition SO268/3 of RV SONNE and, if identifiable, matching new products were purchased.

We investigated the co-occurring processes of chemical (de)sorption by effect analysis of chemical mixtures that were solvent-extracted from field-weathered marine plastics and dosed into different cell-based reporter gene bioassays. The observed effects were compared to those from solvent extracts of new plastic products corresponding to the field samples. Moreover, the new plastic products were artificially weathered in a custom-made weathering wheel under UV light and Dark Control conditions. The retrieved plastics were solvent-extracted, and the aqueous leachates were up-concentrated by solid-phase extraction. Both types of extracts were dosed into the bioassays. Finally, chemical analysis of organic pollutants and plastic-associated chemicals was performed by LC-HRMS (Q-Exactive Plus quadrupole-Orbitrap) with subsequent effect modelling to identify mixture toxicity drivers.

The results showed a diverse picture of reporter gene induction caused by either field-weathered plastics (presumably by sorbed chemicals and remaining additives) or by the new products (presumably caused by additives), depending on the product type. Samples for outdoor exposure appeared to be a source of (elevated) effects, whereas, *e.g.,* food-contact material tended to sorb organic chemicals from the surroundings. By chemical analysis and subsequent modelling we could partially explain the observed effects. Our study underlines the relevance of weathering for the leaching of chemicals of concern from marine plastics.

3.21.P-We255 Post-consumer recycling plastics (PCR), a safe alternative to pristine plastic bags? A case study: Degradation and toxicity of PCR vs pristine plastic bags.

*Bettie Cormier[1], Emma Ludvigsen[2], Hoda Daneshvar[2], Stefania Piarulli[3], Lisbet Sorensen[3], Andy Booth, PhD[3], Maria T. Hultman[4], Tania Gomes[5] and **Martin Wagner**[1], (1)Norwegian University of Science & Technology (NTNU), Norway, (2)NTNU, Norway, (3)SINTEF Ocean, Norway, (4)Norwegian Institute for Water Research (NIVA), Norway, (5)Norwegian Institute for Water Research (NIVA), Oslo, Norway*

The production and use of plastics has increased consistently over the past seven decades, leading to increased levels of plastic pollution across the globe. Accordingly, growing public and political awareness has led to many policy responses, including the ongoing negotiations of the global plastics treaty. Among a range of mitigation actions to reduce the quantity of newly produced plastics released to the environment, recycling of plastic waste has emerged as one of the viable options. From a circularity perspective, recycled materials appear to be a good alternative to the use of fossil-fuel derived pristine plastics to produce plastic consumer products, as well as decreasing the overall volume of plastic waste. However, knowledge remains limited on the degradation rates and mechanisms of the post-consumer recycled plastics (PCR) and their potential impacts on aquatic organisms. In this study, we investigated and compared the impacts of simulated UV (sunlight) exposure on the photodegradation of pristine and PCR (printed and non-printed) polyethylene plastic bags, as well as the potential toxicity of partially photodegraded microplastics on *Daphnia magna*. From an ecological perspective, *D. magna* is a key species in freshwater environments, including Norway. The plastic bags (pristine, PCR, PCR printed) were artificially degraded in a UVC chamber. Microplastics (non-degraded and degraded) were characterized using FTIR and Coulter Counter to investigate the influence of the recycling process on its degradation. The chemical composition (non-intentionally added substances and additives) before and after degradation was assessed by non-target screening of methanol extracts using UPLC-MS/MS and direct analysis of particles by TD/py-GC-MS. Toxicity studies were performed following OECD 211, by exposing *D. magna* to extracts of non-degraded or degraded plastic bags (pristine and PCR). This study is expected to contribute to a better understanding of the impacts of the recycling plastic process on the durability and impacts of recycled plastics in terms of their degradation and toxicity.

3.21.P-We256 Aquatic Toxicity Assessment of Chemical Mixtures from Recycled Plastics

Francesca Molinari[1]*, Eric Carmona Martinez*[2]*, Agathe Bour*[1] *and Bethanie Carney Almroth*[1]*, (1)University of Gothenburg, Sweden, (2)Department of Effect-Directed Analysis, Helmholtz Centre for Environmental Research (UFZ), Germany*

The recycling of synthetic plastic products is offered as one of the potential solutions to the global plastic crisis although there are several environmental issues concerning the plastic recycling industry. Recycled plastics can contain thousands of chemicals including non-intentionally added substances and contaminants such as traces of pharmaceuticals or pesticides. In this study, we assessed the aquatic toxicity of high-density polyethylene (HDPE) recycled plastic pellets coming from 11 facilities in the global south. A Liquid chromatography High Resolution Mass Spectrometry (LC-HRMS) with target analysis gave an indication of the substances contained in the plastics. The compounds within the plastics were extracted by using hexane, acetonitrile, and methanol. Zebrafish, Chironomid larvae and the phytoplankton *R. subcaptitata* were then acutely exposed to two DMSO extract concentrations equivalent to 16g/L and 3.3g/L of plastics. Nine of the 11 plastics showed toxic effects in at least one model organism. Phytoplankton was the most sensitive organism, affected by 7 of the 11 extracts when exposed to the highest concentration and by 4 of the extracts at the lowest. Chironomid larvae were also affected. One of the chemical extracts in particular, caused 88% mortality of the larvae. No apparent deleterious effects were observed in Zebrafish embryos, exposed at the embryo stage.

Our results suggest that the increased use and subsequent dispersion in the environment of recycled plastics has the potential to cause disruptive effects on phytoplankton and invertebrate populations. This study could have management implications regarding the import of recycled plastics.

3.21.P-We257 Assessing the Ecotoxicological Impact of Plastic-Associated Chemicals from Consumer Products on the Marine Environment: Using In Vitro Studies with Halibut (Hippoglossus hippoglossus) Hepatocytes

Maria T. Hultman[1]*, Prem Chand*[2]*, Cassandra Rauert*[3]*, Pradeep Dewapriya*[4]*, Kevin Thomas*[3] *and Tania Gomes*[5]*, (1)Norwegian Institute for Water Research (NIVA), Norway, (2)Ecotoxicology and risk assessment, Norwegian Institute for Water Research (NIVA), Norway, (3)University of Queensland, Australia, (4)University of Queensland, ., Australia, (5)Norwegian Institute for Water Research (NIVA), Oslo, Norway*

The increasing amount of microplastics resulting from fragmentation and degradation of marine litter are well documented, but the environmental risks of plastic-associated chemicals are emerging as a much lesser understood threat to the marine environment. The aim of this study was to investigate the toxic effects of plastic-associated chemicals in a marine fish species relevant to the Norwegian environment. To address this effectively, a reproducible, cost-effective and ethically, New Approach Methodologies (NAMs) using *in vitro* methods was implemented using primary liver (hepatic) cells from the Atlantic Halibut (*Hippoglossus hippoglossus*). The toxicity of leachates originating from five different consumer products were assessed, namely shoe soles, balloons, ”end-of-life” tyre granulates, washing gloves and a polyethylene terephthalate (PET) bottle. These consumer products were chosen based on previously identified toxicity (shoe soles > balloons > tyre granulates ≈ washing gloves > PET bottle) in marine organisms at different stages of development (embryo, juvenile, adult) and trophic levels (bacteria, algae, copepods, oysters, mussels, sea urchins and fish).The primary hepatocytes were exposed for 48 and 96 hours to the five leachates, after which effect responses as cell viability, endocrine disruption, oxidative stress and detoxification were assessed. Chemical analyses using non-target Gas-chromatography-Mass-spectrometry and Inductively Coupled Plasma Mass Spectrometry were also performed on the leachates, identifying the presence of several plastic-associated chemicals in each product. The outcome of this study will further fill the data gaps on the toxic mode of action of chemical additives in fish liver cells, further supporting the hazard and risk assessment data produced in the MicroLEACH project. The MicroLEACH project was funded by the Norwegian Research Council, project. No. 295174.

3.21.P-We258 Comparative Toxicity of Conventional versus Compostable Plastic Consumer Products: an in-vitro Assessment

*Tiantian Wang[1], Mahboubeh Hosseinzadeh[1], Alcira Reyes Rovatti[2], Amparo López-Rubio[2] and **Cinta Porte**[1], (1)Environmental Chemistry, Institute for Environmental Assessment and Water Research, Spanish Research Council (IDAEA-CSIC), Spain, (2)Food Safety and Preservation, Control of Food Intake Group, Aquaculture Institute of Torre de la Sal, Spanish National Research Council (IATS-CSIC), Spain*

The accumulation of plastics in the environment, and in particular of single-use items, is one of the greatest threats caused by human activity. In recent years, biodegradable/compostable plastics (BPs) have been promoted as green alternatives to reduce plastic waste pollution through on-site biodegradation. However, few studies have investigated the toxicity of BPs in ecosystems and the consequences of incomplete degradation in the environment. This study evaluates the toxicity of the methanolic extracts of BPs compared to conventional plastics (both virgin and recycled), and explores the potential influence of plastic photodegradation and composting on toxic responses using a battery of in vitro assays conducted in PLHC-1 cells. The extracts of BPs, but not those of conventional plastics, induced a significant decrease in cell viablility (< 70%) in PLHC-1 cells after 24 hours of exposure. Toxicity was enhanced by either photodegradation or composting of BPs. Extracts of conventional plastics, and particularly those of recycled plastics, induced 7-ethoxyresorufin-O-deethylase (EROD) activity and micronucleus formation in exposed cells, indicating the presence of significant amounts of CYP1A inducers and genotoxic compounds in the extracts, which was enhanced by photodegradation. These findings highlight (a) the importance of investigating the effects of degradation mechanisms, such as sunlight and composting, on the toxicity of BPs, and (b) the need to investigate the composition of newly developped formulations for BPs, as they may be as harmful as the conventional ones.

3.21.P-We259 Impacts of conventional and alternative plastic leachates on Hordeum vulgare: a comparative study in soil and hydroponic environments

***Amy C M Wright**, Bas Boots, Thomas C Ings and Dannielle S Green, Life Sciences, Anglia Ruskin University, United Kingdom*

There is a current shift in agriculture towards hydroponics to reduce land and water use and address global food demand. Despite the increased yields offered by hydroponics, concerns have emerged regarding potential adverse effects of polymer leachates, released from plastic agricultural equipment upon degradation, on plant growth, particularly within hydroponic systems. Additives (leachates) from biodegradable polymers have received little consideration. Chemical compositions of biodegradable plastics are often kept confidential by manufacturers, but evidence suggests that during degradation, these plastics can release toxic additives into soil ecosystems. This study focuses on the impact of plastic leachates on spring barley (*Hordeum vulgare*) in soil and hydroponic systems. The leachate of selected plastics (conventional: PE, PP; alternative: biodegradable PE, PLA; and Control) are tested for their effects on the development of spring barley. Leachate concentrations are set at 0.25% (w/v) to mimic lower environmental concentrations. The hypothesis posits that barley seeds exposed to leachate from plastics at germination stage and throughout early plant development stages will exhibit reduced growth. Two experiments are conducted: a 30 day edaphic study, focusing on germinating seeds in leachate from plastics and transferring them to uncontaminated soils, while an 8 day hydroponic study, examined seeds germinated under normal conditions and exposed to plastic leachate in a hydroponic setup. Both experiments assessed effects on plant growth, biomass, chlorophyll content, and oxidative stress. Preliminary findings indicate that, in the edaphic study, leachates of conventional plastics decreased shoot growth by 11%, while leachates of alternative plastics led to a more substantial reduction of 22-23%. In the hydroponic study, leachates resulted in a 29-45% reduction in shoot biomass and an 11-70% reduction in root biomass. Multivariate analyses will be employed to establish relationships between chemical composition of the leachates and observes responses for each plastic type. This research contributes valuable insights into the potential ecological risks associated with plastic leachates in agricultural systems. The outcomes of this study aim to contribute to the ongoing discourse on mitigating the environmental impact of plastic pollution in modern farming techniques.

3.21.P-We260 Sex hormone disruption potentials of several biodegradable plastics of human use in H295R cell lines

***Eunhye Kim**[1], Ah-Reum Jo[2], Mike Williams[3] and Kyungho Choi[2], (1)School of Public Health, Seoul National University, Seoul, Korea, Republic of, (2)School of Public Health, Seoul National University, Korea, Republic of (South), (3)Commonwealth Scientific & Industrial Research Organisation (CSIRO), Australia*

Biodegradable plastics are generally recognized as a safer and more sustainable alternative to petroleum-based plastics. While some studies have reported the presence of endocrine-disrupting chemicals in biodegradable plastic products, current knowledge on the endocrine disruption effects and mechanisms of biodegradable plastics remains limited. In the present study, we utilized human adrenocortical carcinoma (H295R) cells to evaluate the sex hormone disruption potential of major biodegradable plastics manufactured for direct human contact. Biodegradable plastics tested in this study, intended for human use, included a sanitary bag (n=1), hygiene gloves (n=2), a plastic cup (n=1), a straw (n=1), and a plate (n=1). These products were made from plastics such as polybutylene adipate terephthalate (PBAT), polylactic acid (PLA), and a PBAT+PLA polymer. Products made from high-density polyethylene (HDPE) were included for comparison. The products were shredded into small pieces and extracted using acetone. Sex hormone levels were measured after exposure to the extracts of these samples. Moreover, expression levels of key genes involved in sex hormone synthesis were measured, including *star*, *hmgr*, *cyp11a1*, *cyp11b2*, *cyp17a1*, *3βhsd2*, *cyp19a1*, *cyp21a2*, *17βhsd1*, *and 17βhsd4*.

In H295R cell experiments, exposure to eight plastic extracts generally led to increased 17ß-estradiol (E2) levels. However, statistical significance was not always observed. Particularly, the PLA plastic cup extract exhibited a significant 1.46-fold

increase at the highest concentration (5 mg/mL) compared to the solvent control. For testosterone (T) levels, a significant decrease was observed in HDPE sanitary bag and PBAT hygiene gloves extracts. For most products, a significant upregulation of the *cyp19a1* gene was observed in H295R cells.

The results of this study demonstrate that biodegradable plastics may influence sex hormone homeostasis, potentially through alteration of aromatase activity. Effects toward anti-androgenicity observed in the biodegradable plastics were similar to those reported for some phthalates, typical components of PVC plastics. Further investigations are warranted on the environmental health implication of this *in vitro* observation.

[Acknowledgment] This research was supported by Korea Environment Industry & Technology Institute (KEITI) and funded by Korea Ministry of Environment (MOE) Project No. 2020002960006.

3.21.P-We261 Characterising the Chemical Additive Content of Agricultural Plastic Mulch Film

Charlie Monkley[1], *Michaela Reay*[1], *Richard P Evershed*[1] *and Charlotte E M Lloyd*[1,2], *(1)Organic Geochemistry Unit, School of Chemistry, University of Bristol, United Kingdom, (2)School of Geographical Sciences, University of Bristol, United Kingdom*

The cultivation of arable land presents unique regional challenges, such as crop demand, climate pressures or limited economic capacity. The use of plastic mulch film is a globally adopted agricultural practise that can aid in relieving such challenges. Mulch film is a ‘plasticulture’ application where film is stretched over the soil surface to maintain a humid microclimate at the crops / fruits soil-root zone, whilst protecting seedlings from pests. However, the introduction of mulches to agroecosystems comes with an anthropogenic chemical load, whose ecotoxicological legacy is yet to be assessed. Therefore, extraction and analytical methods were developed to characterise both the polymer and organic additive content in commercially available mulches, intended for field application.

Methods were developed for a low-density polyethylene (LDPE) mulch and a biodegradable polylactic acid (PLA) / polybutylene adipate-*co*-terephthalate (PBAT) blend. Proprietor confidentiality meant no information was available on the additive content of the films. A non-targeted characterisation approach was therefore adopted, which also allowed for the identification of non-intentionally added substances (NIAS). Microwave assisted solvent extraction and dissolution-precipitation were used to retrieve the additive content from the LDPE and PLA/PBAT mulch respectively. Extracts were analysed using gas chromatography-mass spectrometry (GC-MS) and spectral libraries, to characterise the extractable content of the films. Thermal desorption (TD)-GC/MS was additionally tested for comparable qualitative screening of additives. An array of chemicals were identified including: plasticisers (citrates, adipates), slip agents (fatty amides), antioxidants (hindered phosphates, hindered phenols), antistatics (fatty esters), lubricants (fatty alcohols, alkanes) and transformation products of both additives and polymer. Cyclic oligoesters were especially abundant polymer derivatives in the PLA/PBAT mulch, with comparable total concentrations (3.03 ± 0.03 mg g^{-1}) to the extracted additive content (4.37 ± 0.12 mg g^{-1}). Additionally, confirmation of the mulches polymeric compositions, or revelation of unreported polymeric components, was achieved through fourier transform infrared (FTIR) spectroscopy and ^{1}H nuclear magnetic resonance (NMR). Ongoing research investigates the lifetime and transformation of mulch film derived organics in agricultural soils, at environmentally relevant concentrations.

3.21.P-We262 Mulches in Agriculture: Tackling Contaminant Transport to Soil and Crops

Costanza Scopetani[1], *Giulia Selvolini*[1], *Agnese Bellabarba*[1], *Tania Martellini*[2], *Giovanna Marrazza*[1], *Carlo Viti*[1], *Alessandra Adessi*[1] *and Alessandra Cincinelli*[2], *(1)University of Florence, Italy, (2)Department of Chemistry “Ugo Schiff”, University of Florence, Italy*

Mulching is an agricultural technique aiming at improving crop quality; this practice often involves the use of polyethylene based films, that typically contain additives such as phthalates known to disrupt various endocrine functions.

The potential environmental and health hazards posed by plastic mulching arise from the possible transfer of the pollutants carried by these films to the soil and subsequently to soil biota and edible crops.

In response to these challenges, biodegradable plastic mulches have been produced as an alternative. Their biodegradable nature allows them to remain in the fields, contributing to a reduction in plastic waste and in the costs associated with collection, treatment, and disposal. Despite these advantages, concerns arise regarding the potential release of substances from biodegradable mulches, raising questions about their impact on biodiversity and human health.

To assess the impact of mulches on contaminant transport, we analyzed soil and crop plants exposed to different mulching materials.

A small field experiment was conducted to replicate realistic mulch usage conditions where strawberries plants were cultivated using four different types of mulches, biodegradable and non. Soil and strawberries were collected for GC-MS analysis and are currently undergoing an extraction process that will enable us to detect and quantify phthalates, acetyl tributyl citrate and other plastic additives.

Our results will determine whether biodegradable and non-biodegradable mulches pose risks to agricultural soils and whether there are significant differences between them in terms of contaminant transport.

3.21.P-We263 Metallic Additives Leaching and Extractions from Biodegradable Plastics Used in Fishing Gears and Potential Materials: Are They Truly More Environmentally Friendly?

Waranya Wataniyakun[1]*, Mya Schouwenburg*[2] *and Lisbet Sorensen*[3]*, (1)Arctic University of Norway (UiT), Norway, (2)Northern Analytical Laboratory Service (NALS), University of Northern Britsh Columbia, Canada, (3)SINTEF Ocean, Norway*

Additives are chemical compounds added into polymer synthesis to enhance performance, functionality, and properties of polymers. Each additive plays a different role in improving the final plastic product. Additives are categorized into four groups, namely functional additives, colorants, fillers, and reinforcements. Since they are not chemically bounded to the final material, additives could leach out of it. More focus has been given to organic additives in comparison to metallic ones due to their affiliations to chemical toxicity, with some falling into the same groups as persistent organic pollutants. However, in several studies, it was observed that while organic additives reached an equilibrium after approximately 14 days, leaching of metallic additives showed an increasing continuance. Metallic additives are cheaper than organic ones, with better heat and weathering resistance properties. Although certain metals have been banned from use, due to recycling of plastics, these toxic metals could still be present in trace amounts in newer products. Given their durability, lost fishing gears made of nylon could remain in the ocean for up to 600 years. In addition to visible impacts such as ghost fishing or ingestion, leaching of toxic additives is yet another potential problem that could intensify throughout the food chain. Biodegradable have increasingly been discussed as potential replacement materials for nylon with the advantage of a significant reduction of environmental impacts in case of loss. This study aimed to investigate the leaching pattern of metallic additives, and the total metallic additives content in nylon and five other biodegradable plastics. Of these, two materials, namely polybutylene succinate co-adipate-co-terephthalate (PBSAT) and Poly(butylene succinate-co-adipate) (PBSA) have been produced as fishing gears and have been tested in several fishing trials. The other three polymers, namely polybutylene succinate 1 and 2 (PBS) and polycaprolactone (PCL) are potential materials or potential blending materials for fishing gears given their individual physical properties. Each one of them was microwave digested at an elevated temperature to quantify the total metallic additive presence. Five different leaching experiments ranging from 6 hours to 31 days were set up at two different temperatures for each material at a concentration of 1 gL-1. Both leachates and extracts were diluted prior to analysis and quantification using ICPQQQ-MS.

3.21.P-We264 Biofilms enhance the adsorption capacity of Cd on weathered microplastics generated from mulching material (both biodegradable PLA and conventional PE)

Xiao Xiao[1]*, Mark Hodson*[2] *and Brett Sallach*[3]*, (1)Environment and Geography, University of York, York, United Kingdom, (2)University of York, United Kingdom, (3)Department of Environment and Geography, University of York, United Kingdom*

Biodegradable polylactic acid (PLA) mulch has been developed to replace conventional polyethylene (PE) mulch in agriculture as a response to growing concerns about plastic pollution. Under some management practices mulches are ploughed into the soil at the end of their use which can lead to the production of plastic fragments including microplastics (MPs). Microplastic mulch residues can also form following degradation of the mulches due to exposure to UV radiation and the weather. Cadmium (Cd) contamination of agricultural soils is an ongoing challenge due to the use of Cd-bearing phosphate fertilisers. Cd can adsorb to MPs. During MP formation, exposure in the natural environment can lead to the formation of biofilms on MPs, which may further impact their adsorption of contaminants. The aim of this study was to investigate the adsorption of Cd on both pristine and naturally weathered MPs (PLA and PE) generated from mulching material. We determined the biofilm content of the MPs to help explain our results. Therefore, large sheets of PE and PLA mulches were prepared and hung outside to age naturally from 3rd April in 2022 to 2nd August in 2023. Both pristine and weathered mulches were cut into small pieces using scissors, shredded to generate MPs using a blender and sieved to less than 2 mm. The PE formed platy particles whilst the PLA formed fibres. This generated the following sample types: pristine PE pieces (PPE), pristine PLA fibre (PPLAF), weathered PE pieces (WPE) and, weathered PLA fibre (WPLAF). Pristine and weathered PLA mulches were also cut to produce similar shaped particles to the PE using scissors (pristine PLA pieces, PPLAP, and weathered PLA pieces, WPLAP). 50 images of each MP type were captured using microscope and then analysed using imageJ. We carried out adsorption experiments to investigate the potential for different MPs to adsorb Cd. In the subsequence experiement, for each MP type, triplicate samples of four pieces of MP were analysed to determine the amount of biofilm on their surface by the crystal violet staining method. Our results suggest that, even when surface area per unit mass is taken into account PLA is more sorptive to Cd than PE. This may have implications for Cd bioavailability in Cd-bearing soils where PE mulches have been replaced by PLA mulches. Further, our results suggest that as MPs weather and biofilms develop on them, Cd mobility will be further decreased.

3.21.P-We265 A recipe for plastic: Expert insights on plastic additives in the marine environment

Thomas Maes[1]*, Fiona Preston-Whyte Ms.*[1]*, Stephanie Lavelle*[2]*, Alessio Gomiero*[3]*,* ***Andy Booth, PhD***[4]*, María Jesús Belzunce*[5]*, Juan Bellas*[6]*, Steven Brooks*[7]*, Adil Bakir*[8]*, Lisa Inès Devriese*[9]*, Christopher Pham*[10] *and Bavo De Witte*[11]*, (1)GRID-Arendal, United Kingdom, (2)GRID-Arendal, Norway, (3)Norwegian Research Centre (NORCE), Norway, (4)SINTEF Ocean, Norway, (5)AZTI, Spain, (6)Vigo Oceanographic Center of the Spanish Oceanographic Institute, Spanish National Research Center (IEO-CSIC), Spain, (7)Norwegian Institute for Water Research (NIVA), Norway, (8)Centre for Environment Fisheries and Aquaculture Sciences (Cefas), United Kingdom, (9)Ocean & human health, Flanders Marine Institute (VLIZ), Belgium, (10)IMAR/OKEANOS, Universidade dos Açores, Portugal, (11)Marine Research, Institute for Agriculture and Fisheries*

Research (ILVO), Belgium
The production and consumption of plastic products had been steadily increasing over the years, leading to more plastic waste entering the environment. Plastic pollution is ubiquitous and comes in many types and forms. To enhance or modify their properties, chemical additives are added to plastic items during manufacturing. The presence and leakage of these additives, from managed and mismanaged plastic waste, into the environment are of growing concern. In this study, we gauged, via an online questionnaire, expert knowledge on the use, characteristics, monitoring and risks of plastic additives to the marine environment. We analysed the survey results against actual data to identify and prioritise risks and gaps. Participants also highlighted key factors for future consideration, including gaining a deeper understanding of the use and types of plastic additives, how they leach throughout the entire lifecycle, their toxicity, and the safety of alternative options. More extensive chemical regulation and an evaluation of the essentiality of their use should also be considered.

3.21.P-We266 Low toxicity of environmental plastic from aquatic and terrestrial habitats

*Ricardo Beiras[1], **Begoña Espina**[2], Christian Scherer[3], Luís André Mendes[1], I Pinheiro[4], Laura Rodriguez-Lorenzo[5] and Kathrin Voges[6], (1)University of Vigo, Spain, (2)International Iberian Nanotechnology Laboratory, Portugal, (3)Department of Biochemistry and Ecotoxicology, Federal Institute of Hydrology (BfG), Germany, (4)Iberian Nanotechnology Laboratory (INL), (5)Water Quality Group, International Iberian Nanotechnology Laboratory (INL), Portugal, (6)Department of Biochemistry and Ecotoxicology,, Federal Institute of Hydrology (BfG), Germany*
The LABPLAS H2020 developed a Plastic Toxicity Testing Scheme for assessing the impact of plastics and associated chemicals on the environment. With that aim, we adapted internationally accepted ecotoxicological methods to assess plastic toxicity using a battery of bioassays representative of aquatic (both freshwater and marine) and terrestrial habitats. The scheme is based in recent consensus on environmental fate and effects of plastics: i. plastic litter fragments in the environment as a consequence of weathering producing secondary microplastics. ii. the smaller the particles the higher impact on environmental health. iii. chemicals intentionally or unintentionally added to polymers are the main toxicological concern. Field plastic liter sampling was conducted in 2022 and 2023 in the North Sea, Thames and Elbe river basins, Baltic coast, and a river basin in NW Iberian Peninsula that includes a drinking water reservoir and agriculture land. Plastics were ground down to <250µm particles. Leachates were obtained according to a standard methods (Almeda et al. 2023), using a 10 g/L solid-to-liquid ratio, and organisms were exposed to serial dilutions of the leachates (Tier I) and plastic particles of ingestible size range (Tier II).

This methodology is suitable to test the environmental toxicity of any plastic disregarding size or origin, either environmental samples or samples of commercial plastic materials. When this scheme was applied to monitor ecotoxicity of plastic litter across Europe, moderate to nule toxicity was observed in aquatic tests, and in those cases where toxicity was reported individual items were identified as responsible for the negative effects. These include cigarrete butts and electric cables. Otherwise, weathered plastic litter does not seem to pose a relevant environmental risk to microfauna or flora in aquatic ecosystems. In contrast, plastic litter of terrestrial origin inhibited earthworm reproduction according to a dose:response pattern, pointing at potential ecologically relevant effects on these key organisms in soil communities.

3.21.P-We267 Comparison of Species Sensitivity Distribution Methods for Risk Assessment of Microplastics

***Sara J Hutton**, Kenia Whitehead and Philip E Goodrum, GSI Environmental, Inc.*
Most papers published on ecological risks of microplastics (MP) are based on laboratory studies with limited exposure profiles or field studies that focus on the occurrence of MPs in aquatic organisms. However, the current scientific literature and knowledge regarding MP toxicity is sparse and often challenging to interpret, which can introduce uncertainty when conducting risk assessments (RAs). Most MP RAs currently published use a species sensitivity distributions (SSDs) approach. SSDs are a commonly used method that compare toxicity across species by taking a single point (e.g., NOEC or EC50) from a dose response analysis, however this approach can also underscore the variability and uncertainty in the data. In the past decade, there has been an increase in research and regulatory activity directed at supporting MP RAs that utilize the SSD approach. For example, in 2018 the state of California passed legislation requiring a comprehensive literature review to determine if a RA could be conducted for both human health (via drinking water) and aquatic organisms. California concluded there was insufficient data to conduct a formal RA for human health, but sufficient data were available to generate SSDs based on no observed effect concentrations (NOECs) or lowest observed effect concentrations (LOECs). The SSDs were used to define a 5 percent hazard concentration of 5 particles/liter which is cited in the draft 2024 California Integrated Report: Surface Water Quality Assessments as the threshold used to determine listings waterbodies based on MPs. A refinement to the SSD approach is to use the full dose-response curve (DRC) from each study and integrate these curves into one composite DRC. This approach was first developed by USEPA's Office of Pesticide Programs to support ecological RAs of pesticides, and subsequently applied to site assessments of legacy contaminants (e.g., PCBs). This method produces a composite DRC and confidence interval that reflects the variability and uncertainty in the DRC for each study. Here we compare the threshold values for MPs when SSDs are constructed using the NOEC/LOEC approach and the DRC approach applied to the same dataset. We find that when all study treatments are incorporated into the composite DRC the resulting confidence intervals span many magnitudes more than the SSD approach, this highlights the extent to which the methods used in RA reflect uncertainty which needs to be considered when conducing RAs.

3.21.P-We268 Bioassay-based hazard assessment of chemical mixtures released from plastics: PlastChemTox evidence map

***Ksenia J Groh, PhD**[1], Hans Peter Arp[2], Kiki Dethmers[3], Emera Forni[4], Molly McPartland[5], Laura Monclus[6], Sarah Stevens[7],* *Zhanyun Wang[8], Lisa Zimmermann[9], Jane Muncke[10] and Martin Wagner[6], (1)Eawag - Swiss Federal Institute of Aquatic Science and Technology, Switzerland, (2)Norwegian Geotechnical Institute (NGI), Norway, (3)Independent Consultant in Marine Ecology and Environmental Science, Netherlands, (4)Environmental Toxicology, Eawag - Swiss Federal Institute of Aquatic Science and Technology, Switzerland, (5)Biology, Norwegian University of Science & Technology (NTNU), Norway, (6)Norwegian University of Science & Technology (NTNU), Norway, (7)Norwegian University of Science and Technology (NTNU), Trondheim, Norway, (8)Technology and Society Laboratory, Empa – Swiss Federal Laboratories for Material Science and Technology, Switzerland, (9)Food Packaging Forum (FPF), Switzerland, (10)Food Packaging Forum Foundation, Switzerland*

Throughout their life cycle, plastic materials and products can release diverse chemicals, many of which are known to be hazardous for human health and/or the environment, while others remain to be characterized for their hazards or even identity, as both can often be unknown. Inventories of plastic chemicals are being constantly extended, the most recent being the PlastChem database, where we compiled over 16’000 known plastic chemicals. Despite the growing knowledge, chemical analytics-based individual asessment of all substances released from plastics remains unfeasible. Instead, assessment by means of bioassays, also referred to as effect-based testing, could provide an alternative approach for initial hazard assessment of chemicals in plastic leachates. To review the state-of-the-science in this growing field, we performed systematic evidence mapping of the scientific literature, focused on the question “Which types of toxicities or bioactivities have been measured for chemical mixtures released from which types of plastic materials or products?” A literature search done in March 2023 identified 5874 records, for which the title/abstract were then screened using the following criteria: Population – plastic materials or products; Intervention – release of chemicals from plastic materials or products in any type of medium; Outcome – toxicity or bioactivity testing of thus obtained chemical mixtures, regardless of the results obtained. For the 288 records that remained after the first screening, full texts were searched. Relevant data could be extracted from ca. 200 records. Preliminary results show that bioassay-based testing could offer a rapid and efficient assessment of potential hazards. However, currently available studies were found to be highly diverse, spanning a large range of arbitrary choices in terms of the types of polymers tested and bioassays applied. Future research should seek to (i) establish a guidance for rational selection of test samples that ensures a more systematic representation of various polymers and product types; (ii) develop more standardized methods for obtaining relevant chemical mixtures; (iii) establish a panel of relevant bioassays covering typical hazards that can be expected, taking into account the potential use and the likely exposure routes; and (iv) agree on the approaches to interpreting the bioassay results and performing follow-up testing or initiating risk management actions for positive cases identified.

3.21.P-We269 Towards risk assessment strategies for nano and microplastic particles

***Dana Kühnel**[1], Anita Jemec Kokalj[2], Damjana Drobne[2], Sebastian Purker[3], Christina Hipfinger[3] and Bernd Moritz Giese[3], (1)Helmholtz Centre for Environmental Research (UFZ), Germany, (2)University of Ljubljana, Biotechnical Faculty, Slovenia, (3)BOKU - University of Natural Resources and Life Sciences, Austria*

The risk assessment of nano and microplastic particles is challenging, due to high uncertainties on release, exposure as well as hazard. The field is characterised by many data gaps, and is quite diverse in the sense that nano and microplastic encompass a huge variety in different polymer materials, size fractions, as well as properties that are tailored by the addition of various additive chemicals.

To facilitate risk assessment, within the Horizon 2020 project PlasticsFatE two different approaches are developed with different scopes, namely decision trees to support Integrated Approaches to Testing and Assessment (IATAs) as well as a Prospective Multi Criteria Decision Support System (PMCDS).

IATAs provide a structured and hypothesis-driven approach to the toxicity testing of nano and microplastic particles including plastic-associated chemicals. It basically gathers all available information on impact and interaction of a substance with organisms, and for this purpose all science-based data, information and knowledge is integrated (e.g. phys.-chem. properties of NMP, appropriate test methods, in vitro, in in vivo …). The current focus of our work is on oral exposure via food contact materials, and to support the development of IATAs, decision trees are generated that consider all available knowledge for that specific route of exposure.

PMCDS, on the other hand, is a tool for early risk assessment of plastics for specific applications and is applicable in early developmental stages. It considers polymers, their basic phys.-chem properties, additives, material fate and adsorbed contaminants. Based on these prospective risk indicators and their uncertainties it allows the identification of risk minimized materials. PMCDS is designed to deal with data gaps and uncertainties. If not enough data is available, the PMCDS falls back on a set of already implemented typical values obtained from modeling, databases and published previous results of experiments. In addition to quantitative input by the user, the processing of qualitative information is also supported.

Here we aim to present our achievements and developments in the PlasticsFatE project. The two approaches will be compared according to scope, specificity and applicability for various interest groups, as well as data needs.

3.21.P-We270 Towards safe circular economy by assessing chemical risks of plastic recycling
